The presence of family during resuscitation is somewhat controversial. Traditionally, family members were excluded from the resuscitation area. More recent data have challenged this practice. Families believe they have a right to be present and that they should be asked. Most of those present at a resuscitation feel that the process helped them adapt to the death and that their presence benefited the deceased.¹² Postresuscitation psychological testing of family members present at a resuscitation found no harm and a trend toward benefit for the survivors.¹³ Out-of-hospital resuscitations have occurred for years in the presence of family members. The American Heart Association in its 2000 guidelines has recommended offering the option of viewing resuscitation to families.¹⁴

Conversely, health care providers remain opposed to this practice. Concerns listed include interference in the resuscitation, offering false hope to the family while cardiopulmonary resuscitation continues, fainting or other medical deterioration of witnesses, discomfort or anxiety of team members, and medicolegal conflicts.^{13,16} Despite such anecdotal reports, the overwhelming body of evidence suggests a reasoned policy of allowing the family to view resuscitation.

Deaths of Children

Regardless of the etiology of the child's death, survivors are at increased risk of pathologic grief. Divorce is common after the death of a child. Parents of deceased children display a wide range of emotional responses, but anger and guilt with associated despair predominate. These emotions may be related to a sense of failure of the parent's protective role. Both parents are equally devastated and unable to support each other adequately. The need to care for surviving children may not allow time for proper grieving to occur. In particular, a perinatal death with a surviving twin or subsequent pregnancy within months places families at higher risk for pathologic grief responses.

Surviving children are also deeply affected by the death of a sibling. Feelings of abandonment, fear of death, and guilt predominate. If the child wished the sibling dead at a time near the death, the child may believe that the "magical" thinking was causative. Parents, unable to deal with their own grief, may explain the death in misleading or vague terms.

Managing a pediatric death in the ED is the most stressful professional situation most physicians will encounter. Most emergency physicians feel a sense of guilt or inadequacy after a pediatric death, and many will feel impaired for the duration of their shift.¹⁷ The American Academy of Pediatrics and the American College of Emergency Physicians have developed a joint policy on the death of a child in the ED. They recommend a "family-centered and team-oriented approach" to the death of a child.¹⁸

The autopsy is particularly helpful in cases of pediatric death. It provides an organic, identifiable cause of death, helping to alleviate guilt. It can offer a source of comfort to the family that the knowledge gained may be useful in helping other children. Organ donation is also useful in this fashion.¹⁹ A memory box, containing a lock of the child's hair and impressions of hands and feet, can be of comfort to the grieving parents.¹⁶

Intervention, and Referral

ALCOHOLISM AND ALCOHOL ABUSE: MEDICAL ASPECTS

Alcoholism is a ubiquitous medical and social problem that crosses social and economic boundaries. Ethanol dependence, defined as regular use resulting in tolerance to the drug and the likelihood of withdrawal symptoms if intake is suspended, is experienced by 4.4 percent of Americans. Ethanol abuse, affecting another 3 percent of the population, is a separate problem marked by social or medical problems that result from inappropriate use of ethanol but without the presence of dependence.^{1,2} The lifetime risk for alcohol dependence was recently calculated at 13.3 percent.³ Examples of ethanol abuse include intermittent bouts of drinking resulting in aggressive or antisocial behavior or driving while intoxicated. Although alcoholism is less common in women than in men, affected women are no less susceptible to medical and traumatic complications.⁴

Although alcoholism by itself does not constitute a medical emergency, alcohol abuse and dependence were found to be important in the presentation of 2.6 million patients to ED visits, or 2.7 percent of all visits.⁵ These presentations included trauma, infections, and various entities involving the gastrointestinal tract and central nervous system. Acute alcohol intoxication and other complications of alcohol use, such as hepatitis, pancreatitis, and alcohol withdrawal, frequently result in ED visits. Alcohol is often used with other drugs. Emergency physicians should be able to recognize alcoholism as a contributor to a patient's presenting problems and as an underlying problem requiring care.

Etiology

The pathogenesis of alcoholism is multifactorial, with genetic and environmental inputs. Studies of isolated twins and adopted children and

of families in general have confirmed a heritable component to alcoholism that seems greater in men than in women and is greater in identical twins than in fraternal twins. Close relatives of alcoholics have a fourfold risk of alcoholism over controls, even when they are adopted children raised away from their genetic family from birth.

Alcoholism has been defined as a "primary, chronic disease with genetic, psychosocial, and environmental factors influencing its development and manifestations . . . [and] is characterized by impaired control over drinking, preoccupation with the drug ethanol, use of ethanol despite adverse consequences, and distortions in thinking, most notably denial. Each of these symptoms may be continuous or periodic." Male sex, age between 25 and 34 years, poor education, pre-existent psychiatric disorder, and homelessness are common associations; nevertheless, alcoholism is a disorder that crosses all socioeconomic boundaries and involves all age groups. Among the homeless, estimated at 250,000 on any given night and 3 million people per year, 20 to 45 percent are alcoholics. Secondary psychiatric diagnoses, including antisocial personality, mania, and schizophrenia, are more common in alcoholics than in the general population. Suicide attempts and problems with drugs other than ethanol are also common among alcoholics.

The fact that 10 percent of the population have ethanol-related problems means that alcoholism touches most Americans' lives at some time, whether at home, on the road, or in the workplace.

Effects of Alcohol on Health

Ethanol abuse and its association with trauma represent a major public health issue. Forty percent of Americans will be involved in an ethanol-related motor vehicle collision in their lifetimes, and more than 40 percent of fatal motor vehicle accidents are associated with use of ethanol. Those who drink are also at increased risk for accidents within the home and for injuries from assault.

Alcoholics have been estimated on average to have a life span 10 to 15 years shorter than that for moderate drinkers or abstainers.⁶ Increased mortality results chiefly from heart and liver disease, cancer, and trauma. Although the occurrence of coronary artery disease is decreased among alcoholics, heavy ethanol use increases the likelihood of hypertension and, hence, hypertensive disease, and itself is a common cause of cardiomyopathy. Ethanol is the most common cause of liver failure in the United States and worldwide. Fatty liver is present in virtually all alcoholics, and 10 to 35 percent develop alcoholic hepatitis. Heavy ethanol use also is associated with increased risk of cancer of the esophagus, stomach, pancreas, liver, and breast.

Chronic toxicity from ethanol abuse may affect nearly every major organ system with serious health consequences (Table 295-1). A detailed discussion of these complications is beyond the scope of this chapter.

There is good evidence that moderate ethanol use may actually promote health (in contrast to tobacco, which is legal but for which there is no safe level of consumption). A large population-based study found that subjects who consumed between one drink a month and one drink a day had a lower mortality rate than did those who drank more or less. This observation is the basis for so-called U-shaped or J-shaped curves of mortality in relation to alcohol consumption, with mortality lowest with moderate rates of consumption, greater with abstinence, and greatest at the highest levels of consumption. Decreased mortality may result from diminished coronary risk among users of ethanol, apparently mediated through increased blood levels of high-density lipoprotein and an antithrombotic effect. Although these effects persist at higher levels of ethanol use, the other deleterious effects of chronic use of the drug outweigh those.

Trauma and the Ethanol-Intoxicated Patient

Alcohol is an important predisposing factor for trauma of all types. The drinker and those in the vicinity of the drinker are at risk: of the

TABLE 295-1 Some Adverse Health Effects Associated with Ethanol Abuse and Dependence

Central nervous system
Acute intoxication
Ethanol withdrawal
Seizures
Hallucinations
Wernicke encephalopathy
Korsakoff psychosis

Anemia secondary to marrow suppression, folate deficiency, gastrointestinal bleeding, splenic sequestration
Leukopenia secondary to marrow suppression, splenic sequestration
Immune
Bacterial pneumonia
Tuberculosis
Hepatitis C
Other
Fetal alcohol syndrome
Breast cancer in women

more than 11 million victims of interpersonal trauma seen annually, 25 percent report alcohol use by their assailant,⁷ and alcohol abuse as reported by the injured woman is the strongest predictor for acute injury related to domestic violence.⁸ The proportion of fatal collisions involving a driver with a blood alcohol level higher than 10 mg/dL dropped from 51 to 41 percent between 1987 and 1996, but then increased by 4.1 percent from 1999 to 2000, when alcohol-related fatalities totaled 16,199. Alcohol-related trauma clearly represents a significant public health problem, with a large impact on emergency medicine practice. In addition, it has been argued that injured alcoholic patients require more observation, testing, and/or treatment than do other trauma patients, because they may be more severely traumatized, they are at higher risk of complications, and intoxication may mask serious injuries. A study of more than 1 million motor vehicle crashes, which attempted to control for safety belt use, vehicle deformation, vehicle speed, and other factors, found that drivers who drank were more likely to suffer a serious injury or death. However, when severity of injury was controlled, chronic alcoholism, but not acute intoxication, was found to be an independent predictor of poor outcome. These findings most likely reflect the comorbidity of underlying organ system dysfunction. Although there is good evidence that stable intox-

icated trauma victims, for example, with a Glasgow Coma Score of 15 and nontender abdomens, may be managed conservatively,⁹ severely injured and/or severely intoxicated patients can be expected to require more diagnostic and treatment resources than other patients.

Evaluation of intoxicated patients with head injuries is particularly problematic. Serious head injuries are easily overlooked in intoxicated patients, some of whom, especially in inner-city locales, may arrive at the ED with no definite history of trauma and no external signs of head trauma. In our experience, the most common serious error made in management of intoxicated patients is to assume for too long that a depressed or abnormal mental status is secondary to intoxication. Intoxicated patients should undergo computed tomographic (CT) evaluation, if there is a history of head injury and the Glasgow Coma Score is less than 15; for any worsening of mental status while under observation; or if there is no improvement in mental status by 3 h after admission. Once the decision to perform CT has been made, no delay should be allowed due to lack of cooperation by the patient, which may be due to ethanol or concomitant drug use or the effects of head injury. Sedation may be required, with careful attention to airway protection and paralysis and intubation, if necessary.

Hypothermia and Ethanol Intoxication

Many cases of hypothermia during the winter months in urban settings are associated with ethanol use. Many homeless persons are heavy users of ethanol and, on cold nights, may use ethanol to inure themselves to the effects of low temperature. Although the sedative effects of ethanol may result in exposure predisposing to hypothermia, ethanol also directly contributes to body cooling. It depresses central thermoregulatory mechanisms, decreases shivering, and enhances heat loss through vasodilatation. Management of the hypothermic intoxicated patient is similar to that of hypothermia in other patients. Prognosis is related to severity of hypothermia and the presence of underlying diseases, but does not appear to be adversely affected by ethanol intoxication.

Ethanol Withdrawal

Some alcoholics exhibit one or more symptoms of withdrawal upon discontinuation of ethanol intake. Symptoms and signs include tremor, anxiety, agitation, and signs of autonomic hyperactivity, including cardiac dysrhythmias, and, most frequently, sinus tachycardia or atrial fibrillation. Seizures may occur, and hallucinations, usually visual, reflect moderate to severe withdrawal. Signs and symptoms of withdrawal are most likely to reach peak intensity at 48 h after the patient's last drink. There is wide variation in the timing of onset and peak severity of alcohol withdrawal, which reflects differences in patterns of ethanol intake, individual susceptibility to withdrawal, and concomitant illness. For example, significant withdrawal may occur while alcoholics still have detectable blood ethanol or within a short time after the last drink. These situations likely reflect a recent pattern of decreased but continued intake of ethanol, or alcoholics' common practice of self-treatment with ethanol when symptoms first appear, followed by presentation for seeking medical care if those symptoms fail to resolve.

Because ethanol withdrawal is a syndrome complex, more than one sign is present in most cases. When alcoholic patients present with one sign typical of ethanol withdrawal, other causes should be considered. Seizures in particular are frequently secondary to other causes, most notably recent or remote head trauma, and whether the patient recounts a history. Hallucinations may be secondary to a psychiatric disorder (although these are more likely to be auditory, not visual) or concomitant drug use.

MANAGEMENT After the diagnosis of alcohol withdrawal is established, an examination for complicating medical conditions or injury should be performed. Patients with alcohol withdrawal are frequently volume depleted and may require crystalloid infusion. If possible, patients should be placed in a quiet area with a minimum of stimulation. For patients who have experienced seizures, **CT examination is indicated when focal seizures have occurred, when a focal neurologic finding is elicited if there has been head trauma, or when the patient has a persistent postictal defect in consciousness.**

The use of benzodiazepines to treat alcohol withdrawal has been validated by many studies.¹⁰ A recent randomized controlled trial found that treatment of patients who have experienced one withdrawal seizure with a small dose of lorazepam is effective in preventing seizure recurrence,¹¹ adding further evidence for benzodiazepines as the primary treatment of choice for alcohol withdrawal. 7-Aminobutyric acid, carbamazepine, valproic acid, β -blockers, and other agents have been advocated for treatment of alcohol withdrawal,¹⁰ but none has the support of clinical evidence. Phenobarbital is effective, but has no advantage over benzodiazepines, and due to its risk profile, particularly respiratory depression and hypotension, has fallen out of favor. It is still used for control of status epilepticus (see Chap. 225).

The initial dose of lorazepam is 2 to 4 mg intravenously, followed by doses of 2 to 4 mg every 15 to 30 min until a condition of light sedation is attained (Table 295-2). Clinicians should approach treatment of alcohol withdrawal prepared to administer lorazepam repeatedly and in cumulatively large doses. At the same time as primary therapy is initiated for alcohol withdrawal, 1 L of D5NS with 100 mg of thiamine and 4 g of magnesium sulfate is given over 1 to 2 h. Although magnesium has not been shown to be effective against ethanol withdrawal in general, hypomagnesemia has been closely associated with tremor in alcoholics and may play a role in the genesis of seizures.

DISPOSITION Patients with alcohol withdrawal and complicating medical problems, such as infections or congestive heart failure, should be admitted to the hospital. Patients who fail to respond to one or two doses of sedative medications also should be admitted. **Administration of lorazepam, more than 8 mg, is in most cases an indication for admission** to a nursing unit, where the patient can receive close observation by nursing and physician staffs, and in many hospitals, an intensive care unit. Patients with mild alcohol withdrawal that responds to treatment may be discharged. If they have received phenobarbital, no outpatient prescription is necessary. In any case, the benefit of prescribing outpatient benzodiazepines is doubtful if a patient is likely to resume drinking after discharge from the ED.

The Elderly Patient and Alcohol

Fewer older people drink regularly, and intake among older drinkers is less than that among younger people. Nevertheless, alcohol is a significant problem among the elderly, and alcohol is by far the most common drug-related problem in this age group, as other (illegal) drugs are rarely abused. Moreover, because many physicians are even less likely to consider the possibility of alcohol abuse or alcoholism in older than in younger patients, the diagnosis is often missed. The

TABLE 295-2 Treatment of Alcohol Withdrawal

1. Fluid resuscitation, D5NS or D5LR with 100 mg thiamine/L
2. Lorazepam 2-4 mg *IV*, followed by 2-4 mg *IV* q15-30 min until light sedation
3. Magnesium sulfate, 4 gm *IV* over 1-2 h

significance of the impact that alcohol has on the health of the elderly is made clear by the following: the prevalence of alcohol-related hospitalizations during a recent year for people older than 65 years was 54.7 per 10,000 population for men and 14.8 per 10,000 for women. Alcohol plays a significant role in motor vehicle collisions and other trauma involving the elderly¹² and has a greater impact on health than in younger persons, because mortality and morbidity from all types of trauma is greater among older patients.

Women and Alcohol

Women are less likely than men to abuse alcohol¹⁴ and yet are more prone to alcohol-associated health problems, especially cirrhosis. A population-based study found that, among those averaging six or more drinks per day, the relative risk for mortality for women was five times that of men. The reason for this observation is unclear but may be related to the fact that women have virtually no first-pass metabolism of alcohol by gastric alcohol dehydrogenase and a smaller volume of distribution than men, resulting in considerably higher blood alcohol levels after ingestion of a given dose of alcohol.

Women who drink during pregnancy predispose their children to growth retardation in utero, fetal alcohol syndrome, characterized by facial dysmorphism, and mental and growth retardation after birth. Even women who report intake of less than one drink a day are at increased risk to have a child in the bottom decile for weight at birth. Because emergency physicians frequently diagnose pregnancy and patients with alcohol problems are often seen in EDs, emergency physicians are more likely than many physicians to have the opportunity to advise pregnant patients about the risks inherent in using alcohol during pregnancy.

ALCOHOL AND DRUG ABUSE: EMERGENCY DEPARTMENT IDENTIFICATION, INTERVENTION, AND REFERRAL

Emergency Department Recognition of Alcohol and Substance Abuse

Clinical medicine until recently has lacked the social mandate, resources, will, and training necessary to treat alcohol and drug addiction adequately, despite the proven effectiveness of treatment in breaking the cycle of addiction and reducing recidivism, and instead often has deferred to the criminal justice system.¹³ Emergency physicians are experts in the stabilization, diagnosis, and treatment of *acute* alcohol and drug emergencies and their secondary complications, but often fail to detect and refer patients for treatment of addiction. Referral rates as low as 13 and 23 percent¹⁴ have been reported among ED patients with documented substance abuse problems. As a result, many ED patients who could be assisted in breaking the cycle of addiction continue to visit the ED with trauma and medical problems. Studies in trauma centers have shown that, although up to 44 percent of patients screen positive for chronic alcohol abuse, fewer than 15 percent of the nation's trauma centers do such screening, and even fewer provide alcohol counseling.¹⁵

Barriers to detection and referral include insufficient evidence-based knowledge, time constraints, inadequate treatment resources, and a belief that substance abuse is not an appropriate emergency room concern. Emergency physicians have an opportunity to use the ED visit, the "teachable moment," to link patients presenting to the ED with the substance abuse treatment system. Brief educational sessions with emergency medicine residents have resulted in a significant difference in their willingness to discuss substance abuse. After a 4-h didactic training session in screening and brief intervention, use of these skills increased from 17 percent before training to 58 percent compared with a control group in which performance remained the same overtime.¹⁶

Emergency medicine physicians' attitudes also may be based on the incorrect assumption that substance abuse is significantly different from other medical conditions and that it defies treatment. In reality, drug dependence shares many of the same characteristics as those of chronic illnesses. McLellan and colleagues found that the etiology, pathophysiology, and response to treatment (including relapse and adherence rates) in patients with drug and alcohol dependence are similar to those in patients with diseases such as asthma, type II diabetes, and hypertension.¹⁷ Further, treatment works and is associated with reduced health care costs. When substance-abusing patients receive adequate evaluation, medication management, and monitoring, they receive lasting benefits,¹⁷ and a gain of \$7 is reported for every dollar invested in treatment; overall, the \$200 million spent on treatment resulted in a \$1.5 billion savings for California taxpayers.¹⁸

Effectiveness of Brief Intervention

Chafetz established the effectiveness of screening, detection, and brief intervention four decades ago at Massachusetts General Hospital.¹⁹ A randomized controlled trial among a population consisting primarily of homeless men demonstrated that it was possible to enhance care, even in a hard-to-reach group, by "establishing emotionally meaningful communication with these patients." As a result of this intervention performed by a social worker and psychiatric resident, 65 percent completed a referral to an alcohol clinic as opposed to 1 percent of the control group. Forty percent completed five or more voluntary visits compared with 0 percent of the control subjects who were managed by the ED staff in the routine manner.

Many models for brief intervention have been tested in case controlled or randomized control trials. In 32 of 39 studies reviewed by D'Onofrio and Degutis on the effectiveness of brief counseling for alcohol problems, patients were helped by these interventions.²⁰ Positive effects included reduced alcohol consumption, lower blood pressure, and fewer sick days.²⁰ A 48 percent reduction in injuries requiring hospital admission on 3-year follow-up was reported by Gentilello and colleagues in a randomized controlled trial of brief motivational interviewing among alcohol-impaired patients in a trauma center.¹⁵ The elements common to successful trials included feedback, responsibility, advice, menu or choice, empathy, and self-efficacy (FRAMES). A World Health Organization study evaluating heavy problem drinkers across 12 nations with very different cultural orientations and social circumstances reinforced the strength of this counseling method.²¹

In some EDs, social workers, psychologists, addiction specialists, volunteers from Alcoholics Anonymous or Narcotics Anonymous, or health promotion advocates (peer educators) have joined the traditional ED team to assist in screening, using brief intervention techniques, and referring patients to the treatment system, primary health care, and other needed services (e.g., housing, food, clothing, and jobs).

One of the first of these models to report ED data was Project ASSERT at Boston Medical Center,²² which used trained community outreach workers from cultural backgrounds similar to those of the patients. They interview patients in the ED examining rooms by using a health-needs history to screen for substance abuse and other preventable conditions, and they offer health education and referrals for smoking cessation, domestic violence counseling, and other services. If substance abuse is identified, outreach workers assess readiness to change, negotiate the pros and cons of change, explore treatment options with patients, discuss potential treatment sites, secure placement, and provide taxicab vouchers (if needed) for transportation to a treatment facility.

Use of such a model among 7118 adult ED patients screened for alcohol and drug problems during the first study year resulted in 2931 problem situations detected. Among 245 enrollees who participated in a 90-day follow-up, there was a significant reduction in self-report of problems related to substance abuse, a 45 percent decrease in drug-abuse severity scores, a 67 percent reduction in the number of enrollees using cocaine or crack, a 62 percent reduction in the number

using marijuana, a 56 percent reduction in alcohol use, and a 64 percent reduction in binge drinking. More than 50 percent reported that they followed up on a treatment referral. Project ASSERT also has been implemented successfully at Yale New Haven Hospital. During the first year 5812 patients were screened and more than 1500 Brief Negotiated Interviews (BNIs) were performed. Of the 712 patients who were referred to a specialized alcohol and drug treatment center, 41 percent were contacted and 78 percent enrolled in the program.²³

Diagnostic Criteria

Alcohol use disorders include a spectrum of problems ranging from at-risk drinking to dependence. It is important to identify where patients fall along this continuum, because the intervention may differ. *At-risk drinking* is defined as drinking above certain limits that increases risk for injury and/or illness. Currently the drinker is not experiencing any problems, medical, legal or social. Another term is *hazardous drinking*. If the patient drinks over the recommended limits and is currently experiencing medical, social, or legal issues, that patient is drinking at harmful levels. The National Institute of Alcohol Abuse and Alcoholism (NIAAA) defines at-risk drinking for men no older than 65 years of age to be more than 14 drinks per week or more 4 drinks per occasion. For women or anyone older than 65 years, at-risk drinking is defined as more than 7 drinks per week or more than 3 drinks per occasion. A standard drink is defined as 12 g of pure alcohol, which is equal to one 12-oz bottle of beer or wine cooler, one 5-oz glass of wine, or 1.5 oz of distilled spirits.²⁴

According to the American Psychiatric Association criteria (*Diagnostic and Statistical Manual of Mental Disorders*, 4th ed.), the diagnosis of alcohol or substance dependence requires that at least three of the following criteria be present during a 12-month period:

1. Tolerance: manifested by the need for markedly increased amounts of substance for intoxication or by a diminished effect with continued use of the same amount.
2. Withdrawal: manifested by withdrawal symptoms or taking a substance (or closely related substitute) to avoid withdrawal.
3. Consuming larger amounts of substance than intended.
4. Persistent or unsuccessful attempts to cut down use.
5. Spending a great deal of time obtaining or consuming the substance or recovering from its effects.
6. Giving up or reducing important social, occupational, or recreational activities.
7. Continuing substance use, despite knowing it caused or will exacerbate a psychological or physical problem.

Screening Methods

Universal screening in the ED for substance abuse requires practitioners to first ask questions that reflect their concern for the patients' overall health and safety. Substance abuse questions should be imbedded among other preventive health issues to reduce stigma. Questions should be asked in a nonjudgmental, matter-of-fact fashion. Questions can be prefaced with a statement such as:

I am going to ask you some very personal questions that I ask all my patients that I hope improve the care I give. You do not have to answer them if you are uncomfortable.

1. Do you wear seat belts every time you are in a car?
2. Do you smoke?
3. Do you drink beer, wine, liquor, or distilled spirits?
4. Do you feel safe in your current relationship?
5. Do you use drugs not prescribed by a physician now and then?

Ask current drinkers:

1. On average, how many days per week do you drink alcohol?
2. On a typical day when you drink, how many drinks do you have?

3. What is the maximum number of drinks you had on any given occasion during the last month?

The NIAAA guidelines also recommend that practitioners proceed with the CAGE questions to assess for severity.²⁴ The CAGE (Table 295-3), a mnemonic for the questions in the table, has been studied extensively and is easy to remember and use.

A score of 1 or higher requires further assessment. A score of 2 or higher is highly specific for alcohol dependence. Although the CAGE test is designed for assessing lifetime dependency, the questions should be prefaced with the phrase "in the last 12 months" to detect current problems. If the patient presents with alcohol intoxication and clinical evidence of an alcohol-related health problem, it may be better to start with CAGE to prevent resistance or argument on the part of the patient to attempts to quantify alcohol consumption. If patients state that they use illegal drugs or misuse prescription drugs, "use of drugs" can be substituted for "drinking" in the CAGE questions.

Standardized tests, such as the CAGE, have been found to have a higher sensitivity for screening for substance-abusing patients than other diagnostic tools, including saliva tests, breath alcohol testing, breath smell, patient self-report, or presenting complaint. Brief screening instruments are easy to administer, assist in identifying dependent drinkers, and may facilitate the process of matching an individual to the most appropriate treatment resource. In one study, 31 percent of patients presenting to an urban ED had positive results on the CAGE screening test, whereas only 13 percent were biochemically positive for alcohol with a saliva alcohol test.¹⁴

The CAGE test has been specifically studied for its applicability to the ED.²⁵ The sensitivity was reported as 75 percent for at-risk drinkers and 76 percent for dependent drinkers. The specificity was 88 percent for at-risk drinkers and 90 percent for dependent drinkers.

If concerns about drugs and alcohol arise based on the screening questions or the presenting problems, a brief intervention should be performed and a referral made once the acute medical issues are addressed.

Intervention Methods

The first principle of intervention is that it comes *to* people, instead of people having to seek it out. The second is that it is timely. The best time for early intervention is the crisis (the teachable moment) that brings the person with an alcohol or drug problem into the system for a medical, social, or criminal justice problem. The entire interaction often can be accomplished in less than 10 to 15 min, and the dialogue can take place at discharge or, ideally, while suturing or casting.

The BNI is a dialogue format that was developed in a busy urban ED for negotiating change in substance-related behaviors.²² In this method, the practitioner, a nonaddiction specialist, is the facilitator rather than the agent of change. The BNI may result in behavior change for the individual who is at risk and facilitate contact with the treatment system for the individual who is dependent. Through negotiation, patients' needs are tailored to solutions, and patients are matched with treatment modalities they are able to accept.

The BNI is based on the principles of brief motivational interviewing developed by Miller and Rollnick,²⁶ which are encapsulated in the FRAMES acronym (feedback, responsibility, advice, menu or choice, empathy, and self-efficacy). This intervention is based on a stages-of-change model in which five stages of change with highly predictable

TABLE 295-3 CAGE Questionnaire

C: Have you ever felt that you should *cut* down on your drinking? A: Have people ever *annoyed* you by criticizing your drinking? G: Have you ever felt bad or *guilty* about your drinking? E: Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover (*eye opener*)?

patterns are identified: precontemplation, contemplation, preparation, action, and maintenance, with the possibility of setbacks or relapse. Substance abusers are thought to cycle through these five stages in the course of changing their addiction behavior. Intervention techniques have been developed to suit each of these stages and explore with individuals the pros and cons of their behavior. In this process, the interventionist assists the person abusing or dependent on alcohol or drugs to (1) define the problem, (2) identify the abuser's present stage of readiness to change, and (3) move through the stages of change toward recovery.²⁷

The BNI consists of the following steps:²⁸

1. *Establish rapport and ask the patient's permission to discuss their use of alcohol and drugs.* Establish an atmosphere of positive regard in which the patient is not a problem but a person who has a problem.
2. *Explore the pros and cons of their current use.* Use open-ended questions such as: "Help me to understand what you like about your use of alcohol?" Listen carefully and reflect back what you hear so the patient knows you have understood what is being said. Then inquire what the patient likes less about their use. Explore the importance to the patient of the issues that emerge. Establish which of the pros and cons has the greatest salience to concentrate on those with the highest priority. Explore the patient's level of confidence in making a change.
3. *Use reflective listening* to summarize what you think the patient said to verify your interpretation. "On the one hand, you like the taste, how it helps you to loosen up and forget your problems, and it is something to do when you're bored. On the other hand, you said you don't like how you feel the next day, and wrecking your cars in the crash and ending up in the ED is no fun. You also told me you are spending a lot of money on drinking and are concerned about not meeting some responsibilities. So then in the balance, where does that leave you?"
4. *Assess readiness to change on a readiness ruler.* The patient is asked to mark on a drawing of a ruler, with a scale of 1 to 10, how ready they are to change the way they drink.
5. *Negotiate a workable plan* with the patient based on the readiness score (not ready, unsure, or ready) and inner strength and support system. If the patient is ready for change (a score of 8 to 10), then solicit previous experience in trying to quit and brainstorm a menu of options and available resources. If the patient scores in the unsure range (5 to 7), inquire, "Why didn't you mark 4?" This allows the patient to state in their own words why they are less ready and the provider an opportunity to offer positive encouragement. Some patients are unsure about making a change, because they do not feel confident or able. They may lack resources, such as childcare, or fear losing their apartment or job. A list of social services and other resources and referral for further assessment may be more appropriate. If the score is in the not-ready range (1 to 4), ask why they didn't mark 1 and explore what it will take to get more ready. If they are not interested in further discussion, then express concern, offer information about the effects of drugs and alcohol, provide reassurance, and hope and indicate that, if they change their mind, they can call a number on the resource list.
6. *Provide verbal or written feedback and advice* to patients to follow NIAAA guidelines, to avoid alcohol with certain medications, to cut back or stop drinking to address certain health conditions, not to drink or drive, and, if not successful, to seek further assessment.
7. *Document* the negotiated plan in the chart and in the discharge instructions.

The Referral Process

If a patient is ready to accept referral, a staff member familiar with treatment resources can assist the patient with placement. Each ED should post a resource list and provide a handout for patients with the

names, addresses, and phone numbers of treatment programs. The U.S. Department of Health and Human Services' Center for Substance Abuse Treatment has an online resource locator (<http://findtreatment.samhsa.gov/facilitylocator/doc.htm>). The resource list may include specialized facilities for patients with mental illness, inpatient and outpatient detoxification, acupuncture, and methadone maintenance programs, outpatient individual and group counseling, residential communities, Alcoholics and Narcotics Anonymous (ALANON), and programs focused on the needs of women, culture-specific programs, and programs designed for gay, lesbian, and transgendered clients. The American College of Emergency Physicians online tool kit also offers suggestions for setting up such a resource list (www.Acep.org/1,4688,0.html).

If a patient who is injecting drugs is not ready to accept a treatment referral, it may be possible to negotiate contact with a needle exchange program. Such programs have documented effectiveness in reducing the spread of the human immunodeficiency virus²⁹ and hepatitis B and C and facilitating entry into the drug treatment system.

extreme form are characterized by physical depletion and chronic fatigue, feelings of helplessness and hopelessness, and the development of negative attitudes toward self, work, life, and others. Among physicians, symptoms of burnout are thought to be potential precursors of more severe manifestations of impairment, including alcoholism, drug abuse, and suicidal ideation.

Emergency physicians practice in an environment that can foster burnout. Critical decisions must be made with incomplete information. Noises, smells, crowding, children, families, terminal illnesses, substance abusers, psychiatric patients, police, and criminals are part of the everyday clinical work. The ED, the historical safety net for unmet needs, faces unrelenting demands for an ever-widening range of services. It is easy to become overwhelmed.

The American Medical Association defines an impaired physician as "one who is unable to practice medicine with reasonable skill and safety because of physical or mental illness, including deterioration though the aging process, loss of motor skill, or excessive use . . . of drugs, including alcohol." Various estimates of impairment range from 7 to 13 percent. Well before attrition occurs, there are warning signs that, with awareness, can be identified and remedied before a patient's care and a physician's status are threatened.

Suicide, the ultimate manifestation of impairment, accounts for one-third of the premature deaths among physicians. The percentage is higher for women, in particular young women. Annually, more than 100 physicians complete suicide.

BURNOUT

Burnout is a condition born of good intentions. Doctors who fall prey to it are, for the most part, individuals who have striven for perfection.² It grows from unrealistic goal setting. Burnout is fostered by common personality characteristics of those who choose and succeed in emergency medicine. Near-compulsive overachievement,^{3,4} denial of one's limits, a low level of trust, distant interpersonal relationships, and independent self-sufficiency are common. An effect is that the processing of deep feelings is repressed. Instead of addressing their own symptoms of personal stress, *physicians tend to project feelings* of irritability, anger, and frustration on others: patients, nurses, and their families.

The ability to dissociate one's feelings from one's work is an adaptive coping mechanism for working with contagious disease and dangerous situations, but it can help physicians ignore their own vulnerabilities. They may not recognize the toll that a lifestyle of little sleep, poor diet, and little time for recreation or reflection may be having on them and their families. Dissociation becomes deadly when the "it can't happen to me" philosophy is used to justify increasing alcohol and drug consumption or other self-destructive behaviors.⁵

Fear of incompetence is nearly universal among physicians and is the source of many of the stressors related to medical decision making. When dealing with other people's lives, mistakes can have life-threatening ramifications. If one cannot accept his or her limits and the possibility of making a mistake, one must (at least hope to) be perfect and all-knowing, a situation that promotes arrogance and a strong need to defend against perceived criticism. Even symbolic challenges, perhaps by someone asking a question about care or interjecting a different opinion, can strike deep at defense mechanisms, frequently resulting in inappropriate physician behavior.

PROFESSIONAL ENVIRONMENTAL STRESSORS

Stressors arising from nonmedical issues within the professional environment and from a physician's personal environment can compound the difficulties in providing quality emergency care. Career satisfaction has been found to correlate with the following issues: (1) control over working conditions, (2) hospital administrative support, (3) having time for family and personal life, and (4) departmental security.

PHYSICIAN WELL-BEING

Sanford H. Koltonow

Physician well-being is an important personal and professional issue.¹ When distracted by unmet needs, one may lose the edge necessary to manage multiple patients, bring forth one's skills and knowledge, and be decisive. The practice of medicine is a sacred privilege that also contains risks to the equanimity of the provider that often are not apparent.

The practice of emergency medicine requires a large knowledge base and advanced cognitive and interpersonal skills. Not quite as obvious is the need for excellent *intrapersonal* skills. Situations arise that conflict with one's personal values and produce intense feelings of uneasiness. To remain effective, coping methods need to be used that are adaptive and resolve conflict. The thought that one can meet *all* of a patient's needs ignores one's own needs for supports and limits. Physicians who understand their attitudes toward work and their profession can make reasonable choices about structuring their work. Those who understand their needs and abilities in relation to others can function more effectively as members of health care teams and as members of families.

Stress is necessary as a force that motivates. When excess stress becomes detrimental, it is more appropriately called *distress*. Much like Starling's law, each individual has his or her own curve with a point beyond which further stress causes less, rather than more, output.

Burnout is a state of physical, emotional, and mental exhaustion that occurs as a result of intense involvement with people over long periods in emotionally demanding situations. Physicians suffering from burnout often refer to a sense of lack of accomplishment in their work. As the stress syndrome progresses, providers attempt to decrease their contact with patients and staff, become less respectful listeners, and order more tests and referrals. They may behave rudely and be quick to anger, argue, and blame. Burnout within a department or organization usually is experienced as increased turnover, absenteeism, poor morale, and patient dissatisfaction. Burnout symptoms in their

Death and Dying

Death and dying involve physicians in sharing one of a family's most personal and powerful events. Emergency physicians need to become comfortable exploring patient's wishes and informing families of unexpected death and morbidity, because they will be called on to do so often. Empathy requires emotional energy. Speaking with a grieving family forces a physician to face system and personal conflicts.

The need of the patient and family for compassion is a difficult process to rush. There are questions from loved ones about the events leading up to a death that must be dealt with empathically to facilitate the grieving process. Offering understanding, comfort, compassion, and solace can be an important source of satisfaction for physicians. Often, deaths resurrect powerful feelings in physicians, based on prior personal experiences.

Some difficulties of physicians may stem from the belief that a physician's career represents the battle against death and disease. Facing a surviving family or counseling a dying patient may symbolize "failure" in that battle. In addition, a physician can become a target for misplaced anger and denial.

Malpractice Litigation

Universally, physicians feel the need to expend significant resources to prevent malpractice litigation (as opposed to the resources used to prevent malpractice). For those unfamiliar with the process, a medical malpractice lawsuit can be frightening.⁶ It seems to strike at one's very being and self-worth. Many physicians will respond with disbelief, then anger, and finally depression. The process of meetings, testimony, and eventually the trial can be dehumanizing. The single factor most predictive of a dysfunctional response is the experience of isolation. Embarrassment and self-doubt can cause avoidance of one's very sources of support. Colleagues' responses may reinforce a physician's feeling of shame. Knowing the physician is busy preparing a defense, colleagues may change their referral and social patterns, which can be interpreted as judgment about the facts of the case.

Self-doubt frequently carries over to one's personal life. For reasons of not wanting to bring home the pain or from feelings of shame for getting named in a lawsuit, many physicians withdraw from their spouses and families, furthering their isolation.

PERSONAL ENVIRONMENTAL STRESSORS

Sleep Deprivation

Shift work and scheduling difficulties are the most common sources of stress, career dissatisfaction, and attrition in emergency medicine. Circadian principles acknowledge the body's natural rhythms and can help in integrating one's work schedule with one's personal life and promote quality sleep and, thus, health.⁷

SLEEP PHYSIOLOGY Sleep occurs in discrete stages. The bulk of delta sleep or *slow wave sleep* (SWS) occurs early in the sleep period. There is an increase in SWS in subjects who perform challenging intellectual tasks. Slow wave sleep is thought to be vital for *physical* recuperation. Those deprived of SWS often complain of fatigue and muscle aches.

Rapid eye movement (REM) *sleep* is characterized by rapid conjugate eye movements, a change in the electroencephalogram to a pattern similar to wakefulness, and the occurrence of dreams. Those with shorter sleep periods will have REM deprivation, which is difficult to make up. Rapid eye movement sleep is thought to be vital for *psychological* well-being. Those deprived of it complain of irritability and moodiness. They also score higher on testing of aggressive behavior. Rapid eye movement sleep also may be important in the consolidation of complex learning. Experimental subjects deprived only of REM

sleep but allowed the other phases begin displaying a thought disorder reminiscent of psychosis within 3 to 4 days.

Humans have a 25-h circadian clock. Many physiologic functions follow circadian patterns that can be transposed by keeping experimental subjects awake at night and sleeping during the day. This process is known as *entrainment* of the circadian rhythm. Many circadian patterns have been demonstrated to be sensitive to entrainment, including alertness. The duration of the sleep period depends more on the phase of the circadian rhythm than on the prior period of wakefulness. This partly explains why those working short stretches of nights sleep fewer hours during the daytime than those working night shifts regularly, leading to REM sleep deprivation.

Many physicians attempt to use Pharmaceuticals to assist them in falling asleep. Essentially all decrease the proportion of REM sleep. Stimulants, including nicotine and caffeine, impede onset of sleep and normal sleep stage progression.

Studies on sleep deprivation show that the ability to perform challenging intellectual tasks is slowed but otherwise relatively unchanged; however, motivation to perform routine tasks is diminished. Because the quality of emergency medical practice often depends on properly performing routine tasks that may follow prolonged periods of intellectual exertion, physicians who work different shifts need to schedule themselves in ways that minimize risk to patients.

SUPPORTIVE STRATEGIES When planning shift rotations, it is healthier to rotate forward (from days to afternoons to early mornings), because the human circadian rhythm is 25 h long. Many physicians favor 12-h shifts to increase the number of days off. **When rotating shifts, however, it takes longer to reset the biologic clock across a 12-h change than across an 8-h change** (Table 296-1).

The circadian "gold standard" is not to change shifts at all, but those working only night shifts must maintain a daytime sleep pattern, even during days off, to avoid re-entrainment to a daytime pattern. Working nights for long periods is difficult due to pressures to participate in daytime family and social activities or to be involved regularly in administrative activities.

There is a compromise known as *anchor sleep*, which minimizes circadian disruption. **By sleeping a block of at least 4 h at the same time every day, one tends to anchor the circadian rhythm.** It can be

TABLE 296-1 Strategies and Recommendations to Assist in the Health of Shift Workers

Given the right set of circumstances, the best strategy is to work the same shift all of the time and keep the same sleep pattern.
For those unable to maintain consistent sleep patterns, use compromise strategies such as anchor sleep and napping to mitigate circadian disruptions. Rotate all shifts in a clockwise direction, with at least 1-month minimum time per rotation.
One or two night shifts in a row causes minimal circadian disruption. Sleep in a quiet, darkened room, minimizing disruptions. When working nights, give the work schedule to likely daytime callers. Start the awake period with a high-protein meal and switch to complex carbohydrates toward bedtime. Avoid caffeine and high-calorie, high-fat snack food before sleep. Eat meals regularly. Use bright light (more than 10,000 lux) for 2 h after rising, as an adjunct for entraining to new shifts. Get regular exercise. Vigorous aerobic exercise after rising may diminish the time needed to adjust to new shifts. Avoid heavy exertion before attempting to sleep.
Work with family and friends to plan regular quality time together. Do not try to live a day-shift lifestyle while working night shifts. Hold administrative meetings early in the morning or late in the afternoon when working night shifts. Respect the circadian rights of those working nights by excusing them from meetings held during the day.

Source: Adapted with permission from Whitehead DC, Thomas HR, Slapper DM: A rational approach to shift work in emergency medicine. *Ann Emerg Med* 21:1250, 1992.

useful for permanent nightshift workers during their days off or during short periods of irregular shift work, making it easier to return to "normal" sleep patterns.

Social life is important for shift workers. Maintaining close ties with family and friends helps to relieve stress and mitigates the sense of temporal isolation that shift workers face. Planning for quality social time is as vital as planning for work.

Family

It has long been known that supportive, intimate relationships can improve stress management, improve mood, and encourage healthy living. Good relationships also are associated with a decrease in somatic symptoms, less depression, increased life span, and greater job satisfaction. The personality characteristics chosen by and supported in medicine often conflict with intimacy, family, and self-care priorities. With the increasing complexity of a physician's clinical and administrative schedule, social and community obligations, and the spouse's and children's interests, it is the family as a unit that is most likely to suffer.

Specific hardships are associated with being in a relationship with a physician.⁸ Two-physician families are becoming more common, with their own specific pressures. Living with the persistent demands of medicine, most physician couples live for the future, convinced that eventually there will be time to spend together. The couple unconsciously assumes that the delay will not endanger the quality of the relationship and that the relationship will remain as fresh and intense as the day it was postponed.

Complex defense mechanisms, learned in the milieu of the emotional and physical fatigue of training and practice, frequently lead to a blunting of one's ability to respond to deep personal feelings. The most common complaint from physicians' families entering counseling is that the physician member is emotionally unreachable, if not physically absent.

Physicians become professionally comfortable being decisive and responsible. Rarely are the feelings or opinions of others welcomed; physicians merely give "orders." As experts, they know what is best for patients. This behavior is commonly carried over to the home. The physician is tired, communication falters, and compromise is one sided as the family member decides to "let it go; at least he's [or she's] finally home." Arrogance is enabled. Conflict is postponed until crisis develops.

Spouses can benefit from a support organization. The aim is to assist in understanding medical stress, share coping mechanisms, reduce isolation, and understand their own role in the patterns that shape their intimate relationships.

If a physician provides medical treatment to his or her family, the care given can be unsuitable, either excessive or inadequate. A physician cannot remain objective in assessing loved ones, and it is most often inappropriate to try. The physician and his or her family deserve as complete and thorough an evaluation as would be provided to patients arriving at their ED.

Aging

Aging sometimes makes it physically difficult to do all that is required. Changes in the shift rotations are more difficult. Visual and hearing acuity may suffer. It may be difficult to accommodate medical problems or medication schedules.

Career transitions are available in many specialties, but, as a new specialty, emergency medicine does not have as much experience in tailoring the practice to accommodate older physicians.

STRATEGIES FOR WELL-BEING

Table 296-2 lists the author's principles for promoting personal well-being. The overriding tenets are self-awareness and self-responsibility.

TABLE 296-2 Principles for Promotion of Physician Well-Being

Commit to being aware of your stresses and anxieties. Relate to stress as a challenge to overcome, not as something intolerable with power over your life. Maintain perspective. Don't take yourself too seriously. Develop a separate
identity, one not dependent on your role as a physician. Allow yourself space to be human. Realize medicine is not the cause of your problems or unhappiness—you are free to choose the lifestyle and work environment. Confront the options. Be here now. If your family, religion, community, or other activity is actually
a priority, spend time with it. Your family deserves planned blocks of time that are sacrosanct. Focus on the intrinsic rewards of medicine: altruism, interest in the science,
the challenge of the patients who need your skills, and stimulation by the broad range of people with whom you work. There are rewards in medicine you find motivating. If these are not apparent, then this is an area in need of exploration.
Develop networks with your peers. Don't allow yourself to become isolated. Support systems need to be acceptable to all concerned and not threaten professional status. You must have personal and professional confidants and accurate feedback. Learn to recognize maladaptive coping mechanisms in yourself and colleagues. Expose students and residents to
psychotherapists, who can establish
scientific and interpersonal credibility. This exposure can facilitate their personal use during times of crisis. Be certain there is adequate staffing provided to afford relief, time-off, and
backup in times of crisis. Care for yourself by
attending to your physical health:
Make necessary provisions to assure adequate, quality sleep.
Get regular exercise, control your weight, and pay attention to your diet.
Provide for your relaxation. This is different from leisure.
See your doctor(s) and follow <i>their</i> instructions.

No individual or institution created your conflicts or can resolve them. However, one can mold the environment until it best suits one's needs. Choices and alternatives always exist.⁹

Self-Assessment

During a particularly difficult period, most people know they feel stressed and may not be functioning as efficiently as usual. Frequently, this is attributed to a difficult patient, a busy shift, or a particular personal stressor outside of one's control. Self-awareness enables individuals to begin to appreciate their patterns of response from a wider perspective. Paradoxically, some physicians, when faced with the disillusionment of a lifestyle not realized, use denial and cling harder to their original motives.

Table 296-3 lists some questions to be used as a starting point to assess one's own emotional fatigue. If several of the answers are affirmative, perhaps this is evidence of divergence between personal values and career activities. This divergence may motivate you to seek feedback from a trusted source.

TABLE 296-3 Questions for Self-Assessment

Do you find the old ways of coping are not as reliable as they once were? Do you find yourself becoming cynical about your colleagues or the "system"?
Do you waste time at work, dreading to see patients or slowed by indecision?
Are you drinking, eating, or smoking more than is normal for you? Is your self-esteem unduly affected by criticism? Have you lost the intrigue with medicine? Do you feel helpless over the loss of control in the direction that medicine
is taking?
Do you have continuous problems with insomnia, fatigue, or depression? Do you feel lonely or isolated? Do you avoid others so they don't see how unhappy you are?

Principles of Management

Common methods for overcoming professional fatigue use time management, support systems, debriefing and relaxation, administrative training, and physical self-care. Regardless of the validity of the need, one cannot say *yes* to one commitment without saying *no* to something else. A process of *value clarification* helps identify those obligations one is willing to commit to and provides a starting point for determining personal priorities. One then should set life's major goals in all areas—physical, mental, financial, spiritual, and social—according to the individual's most meaningful objectives.

Develop relationships with peers that go beyond the immediate clinical issues. Listen and provide emotional support and challenge. Be the one to take the risk of talking about the things that are felt but ignored. Share the social reality of what living and practicing in current society is like by sharing thoughts, feelings, and strategies. The fear that someone may discover one's vulnerabilities needs to be resisted. Such a fear encourages low levels of trust in peers and tends to isolate one from the social supports needed in times of crisis.

Concern for the well-being of medical trainees must be constantly modeled in training. Many trainees do not have the advantage of *mentors* who share with them their mistakes, let down their guard, and demonstrate that a lack of perfection does not mean incompetence. Such mentors demonstrate that a mistake is compatible with excellence and compassionate care. Errors in problem solving can be used to improve learned behavior. A faculty that can mentor on personal and professional humility is the best prevention against medical arrogance.

Well-being committees within hospital or medical societies can provide education and referral to other resources. Lines of communication are opened as physicians learn coping techniques that others have found effective. Topics to present to the medical staff include value clarification, goal setting, time management, grieving, and reframing. A well-being committee is different from professional assistance programs for impaired, disabled, or "troubled" physicians, although these programs should complement one another.

The *critical incident stress debriefing* team is an approach that attempts to reduce the severity of poststress disorders by intervention at the time of occurrence. Personnel who have experienced a critical or anxiety-provoking situation are debriefed as a group. The process is facilitated by experienced group leaders of similar professional background in conjunction with mental health professionals. The goal is to intercede before unhealthy reactions have time to be fully incorporated. Each individual is asked to describe what he or she saw, heard, and felt. The debriefing becomes a setting to share experiences and counter isolation. Participants are given the message that the discomfort they are encountering is a normal reaction to an abnormal experience. It also allows the opportunity to identify those individuals who may need further assistance.

Rapport

In emergency situations, one often does not have the benefit of an ongoing doctor-patient relationship. There are some easy things that emergency physicians can do to build rapport and trust. Most revolve around communicating the perception of listening and caring. Physicians should greet patients by name and introduce themselves, shaking hands when appropriate. Emergency physicians should sit down whenever possible; regardless of how long physicians actually remain in the room, patients perceive it as much longer. When touching patients, do so gently with an air of caring. Respect a patient's privacy by closing curtains and exposing only that which is necessary. When clinically appropriate, listen to a patient's overall agenda, because it may save time. Do not use complex language. If a patient is lying down, sit or bend down and put your eyes at the patient's level. Set expectations for a patient with the first encounter, for examples, "results will be back in 2 h, and I'll be back to discuss them then," or "I have a criti-

cal patient to care for but you'll be next." Finding a small need that you can fulfill (e.g., a glass of water, a pillow, a phone call) will help establish rapport.

Conflict Resolution

Conflict resolution skills are important in emergency medicine for interactions with patients, peers, physicians in other specialties, and other hospital staff. The issues of conflict differ, but the dynamics are similar.

Demanding patients or families are best handled by acknowledging their expectations and attempting compromise. Sometimes, it is effective to acknowledge that the patient has been heard and his or her perspective considered, and the physician has a different perspective and position. Although firmness may be necessary, rarely will anything be gained by hostility or by confrontation.

Administrators, nurses, and consultants may be other sources of conflict; often, ongoing personality conflicts exist, provoked by the intensity of the work environment. One needs to focus on finding the "common ground," which is the patient's needs.

Not every conflict is a battle that must be won. Healthy conflict resolution requires physicians to know when to stand up and when to negotiate or retreat.

Malpractice Litigation Support

More than 95 percent of physicians react to being sued with periods of emotional distress. Malpractice litigation stress support groups can be developed or may exist in state medical societies. The groups consist of risk management professionals who describe what to expect at each step and clarify the meaning of legal terms and physicians with prior experience who share their experiences. Family members also may participate and can provide insight into the process their family is experiencing and their emotional responses.

Physical Health

Most physicians do not get regular preventive health care, likely due to the tremendous time constraints of practice and a denial of one's vulnerability to illness. Either way, a physician can wind up caring less for self than for the patients.

Exercise and proper diet help maintain physical health and relieve emotional tension. In addition, setting aside the time for one's own health, within one's busy schedule and conflicting priorities, confirms with action the belief that caring for oneself is an important use of time.

Relaxation Techniques

Relaxation is quiet time that allows for personal reflection, integration, and planning.

Relaxation is different from leisure, although leisure activity is an important way to achieve balance. The stressors of leisure activity, such as sports, outdoor activities, hobbies, or special skills, are enjoyable in part because they are so different from the common stressors of professional life. Leisure activity will also often involve family and friends.

Relaxation is also different from doing nothing. Relaxation increases awareness and focuses the mind while resting the body. It is a time to be present, to reflect, and to process experiences and feelings. Systematic relaxation requires concentration and deliberate mental activity. It will lead to lower arousal and release of strain. Many techniques are available for relaxation, including meditation, progressive muscle relaxation, selective awareness, self-hypnosis, somatics, yoga, breath control, and biofeedback. Audiotapes are available to help guide one conveniently through the learning process. For some, religious thought and introspection may fulfill the need for relaxation.

IDENTIFICATION OF IMPAIRMENT

Emergency physicians frequently feel temporarily emotionally overwhelmed. These feelings become maladaptive when they become established behaviors (Table 296-4).

Detecting impairment in others is difficult.⁵ Psychologically and chemically impaired professionals are often able to delay notice by protecting their job performance at the expense of every other dimension of their lives. The common signs of uncharacteristic behavior are frequently ignored. Family, neighbors, friends, and coworkers may become involved in *enabling* impaired behaviors. Physicians feel that they are experts capable of treating their own problems, because they have received training in pharmacology and psychiatry.

Intervention is almost always required with impaired physicians, because of the massive denial and other defense mechanisms they employ. Shame, embarrassment, fear, and guilt keep many health care workers from consciously accepting that they are not in control until confronted by trusted colleagues or, more commonly, authorities. Intervention requires referral to individuals with *specialized training*.

The seriousness of the emotional impact of confrontation on the sick physician must be appreciated; it is critical to anticipate and prevent the possibility of a suicide¹⁰ or bodily harm by accident or trauma. These possibilities are not uncommon, particularly among impaired health professionals.

RESOURCES

1. The Institute for the Study of Health and Illness is a nonprofit educational and research foundation focused on, among other things, the professional development of physicians who serve people with life-threatening illnesses. Directed by Rachel Remen, M.D., it offers books, tapes, and category I CME credit at small retreats that focus on topics such as loss, grief, personal limitation, impotence, isolation, and the examination of goals, values, and meanings. (Contact: ISHI, P.O. Box 316, Bolinas, CA 94924.)

2. The Society and Center for Professional Well-Being of Durham, North Carolina, is a professional educational and consultative organization offering programs in value clarification, practice assessment, mediation, conflict resolution, and support group development. (Contact: Dr. John-Henry Pfifferling, telephone 1-919-489-9167.)
3. The Talbot-Marsh recovery program for substance abuse and psychiatric disabilities in Atlanta, Georgia, specializes in treating health care professionals and is nationally recognized as a model for extended outpatient treatment of substance-abusing physicians. (Telephone 1-800-445-4232.)
4. The Menninger Clinic of Topeka, Kansas, provides individual, marital, and family therapy and is a major psychoanalytic training program. It also sponsors educational workshops in a retreat setting in Estes Park, Colorado, for one week each July. Designed specifically for physician couples, it focuses on the problem of balancing the demands of medical practice with the needs for self and family. (Contact: P.O. Box 829, Topeka, KS 66601; telephone 1-800-288-7377.)
5. The American College of Emergency Physicians, Society for Academic Emergency Medicine (SAEM), and other medical societies provide state-of-the-art educational resources. Most of the topics in this chapter have been included in their presentations. The American College of Emergency Physicians has a membership section on well-being, which one may join for the informational newsletters of articles by other members and to become active in supporting such issues with the college. (Contact: Well-Being Section, American College of Emergency Physicians, P.O. Box 619911, Dallas, TX 75261-9911.)
6. The American Medical Association's Department of Mental Health has established the Physician's Health Foundation. Its purpose is to provide financial assistance for physicians disabled from any cause, including psychological or chemical impairment and human immunodeficiency virus. The foundation also supports research, focused education and retraining programs, job placement, and the International Conference on Physician Health. (Contact: Elaine Tejeck, telephone 1-312-464-5073.)

TABLE 296-4 Possible Signs and Symptoms of Burnout

Using home time only as time to rest, with withdrawal from family activities
"Acting out" behavior on spouse, family members, nurses, and staff
Chronic complaining, cynicism, blaming others
Dreading to see patients
Writing short, ambiguous charts; quality assurance or utilization review notice of inappropriate or unintelligible comments
Request frequent consultations
Inappropriate anger toward medicine, patients, staff, authority
Overprescribing to a patient's symptoms
Sharing personal problems with patients, blurring of boundaries
Degrading of peers, backbiting, questioning motives of others
Frequent illness, unexplained absence, and patterns of late arrival or early departures
Frequent job changes
Excessive "toys" that become time-consuming obsessions, such as computers, boats, and planes
Spending nonwork time at the practice without apparent reason
Unusual number of patient complaints
Passive-aggressive response to change

Section Twenty-Six

ABUSE AND ASSAULT

CHILD ABUSE AND NEGLECT

Carol D. Berkowitz

SPECTRUM OF CHILD ABUSE AND NEGLECT

The concept of child maltreatment, defined as harm to a child because of abnormal child-rearing practices, is a broadening of the initial description of the battered child syndrome. *Child maltreatment* is an all-inclusive term covering physical abuse; sexual abuse; emotional abuse; parental substance abuse; physical, nutritional, and emotional neglect; supervisory neglect; and Munchausen syndrome by proxy.¹ The ease with which physicians are able to recognize these disorders in part depends on their knowledge of normal children and normal development. The physical stigmata of maltreatment are characteristic, although the findings of neglect and sexual abuse are more subtle than those of gross physical trauma.

CHILD NEGLECT

Child neglect includes physical and emotional neglect. Neglect results from failure of the child's caregiver to provide adequate clothing, shelter, food, health care, and/or schooling. Children who are the victims of neglect may appear in the ED dirty, improperly clothed, and unimmunized. Their medical problems may not have been attended to in a timely manner. They may have suffered from burns or fractures because of inadequate supervision. Child neglect from early infancy also can result in the syndrome of failure to thrive (FTT). This syndrome usually affects children younger than 3 years, although older children who remain in a non-nurturing environment show similar manifestations.

The FTT patient is often brought to the emergency department because of other medical problems, such as intercurrent infections; skin rashes, in particular severe monilial diaper dermatitis; or acute gastroenteritis.

The history of the acute illness may not alert the physician to the chronic nature of the underlying problem. The physical examination provides the clue to the diagnosis of longstanding malnutrition. Overall physical care and hygiene are frequently poor. Infants have very little subcutaneous tissue. The ribs protrude prominently through the skin, and the skin of the buttocks hangs in loose folds. There may be alopecia over a flattened occiput, reflecting that the baby has been allowed to lie on its back all day. Muscle tone is usually increased (although sometimes these babies are hypotonic). This increased tone is most notable in the lower extremities, and infants may manifest scissoring, similar to infants with cerebral palsy.²

Infants with FTT also show distinct behavioral characteristics. They are wide-eyed and wary. If brought in close proximity to the examiner's face, they may purposely turn away to avoid eye contact. They become irritable if interpersonal interaction is pursued. They are difficult to console and are not cuddly. They prefer inanimate over animate objects and spend much time with their hands in their mouths. When left alone, they assume a "straphanger's position," with their arms flexed at the elbows and extended over their shoulders.

Weights and lengths should be plotted on the appropriate growth curves. In general, weight is more adversely affected than length, although this depends on the duration of the neglect. This may be reflected in a body mass index [weight (kg)/height (m²)] below the fifth percentile. Likewise, longstanding neglect results in a diminution in the rate of the growth of the head.

In addition to observing for these physical signs, physicians should obtain certain historical information, including the birth weight (to assess the rate of growth); any maternal use of cigarettes, alcohol, and/or drugs during pregnancy; previous hospitalizations; and the parental stature. A full social service assessment also should be obtained, although this is usually done by a medical social worker.

Infants suspected of suffering from significant environmental FTT should be admitted to the hospital. Weight gain in the hospital is felt to be the sine qua non of environmental FTT. Most infants gain weight within 1 to 2 weeks after admission; in addition, the hospitalization enables a more extensive social service assessment while the infant is in a protected environment. A skeletal survey of the long bones should be carried out to detect any evidence of physical abuse.³

Children older than 2 to 3 years with environmental neglect are termed *psychosocial dwarfs*. Their short stature is a more prominent finding than their low weight. These children manifest a classic triad of short stature, bizarre voracious appetite (eating from trash cans), and a disturbed home situation. They are frequently hyperactive and have delayed or unintelligible speech. Psychosocial dwarfs have been studied endocrinologically and have been found to have low to normal levels of growth hormone that fail to increase with stimulation of insulin or arginine. These children also should be admitted for evaluation and initiation of appropriate social intervention. The endocrinologic disturbances rapidly reverse after hospitalization or placement in a foster home.

MUNCHAUSEN SYNDROME BY PROXY

Munchausen syndrome by proxy (MSBP) is a relatively uncommon form of child abuse in which a parent induces or fabricates an illness in a child to secure for himself or herself prolonged contact with health care providers. Children with MSBP may arrive at the emergency department with reported symptoms such as bleeding, seizures, altered mental status, apnea, diarrhea, vomiting, fever, rash, or multiple organ system involvement. These symptoms may result from administration of agents such as warfarin or ipecac.^{4,5} Often the cases are medically perplexing, and families frequently move from hospital to hospital, seemingly in search of diagnosis. Children with MSBP are often subject to multiple unnecessary tests as physicians seek to uncover the etiology of the disorder. The parent (the biologic mother in 98 percent of cases) encourages the staff to do more diagnostic procedures and often seems uncharacteristically happy if a test is positive.

Social service and psychological evaluation is mandatory in the evaluation and management of these children, who should be admitted to the hospital to ensure their safety and to institute needed therapy. Covert video surveillance has been used in some centers to document a parent's invasive actions.

SEXUAL ABUSE

Victims of prior child sexual abuse are frequently difficult for inexperienced physicians to assess, because of an unfamiliarity with the normal prepubertal genital examination. Children who have been sexually abused are brought to the ED because of a disclosure about the abuse or because of other symptoms such as those referable to the genitourinary tract, including vaginal discharge, vaginal bleeding, dysuria, urinary tract infections, or urethral discharge; behavior disturbances, including excessive masturbation, genital fondling, or other sexually oriented or provocative behavior; encopresis; regression; nightmares; and unrelated complaints.⁶ Approximately 15 percent of

children diagnosed in an ED as victims of sexual abuse in one report had unrelated complaints such as abdominal pain, asthma, and sore throat.

Children who are sexually abused rarely disclose their abuse until time has elapsed from the acute episode. Children who are seen immediately after an assault should be evaluated for evidence of acute injuries and for the presence of forensic material, such as semen or other bodily secretions that may provide DNA evidence.⁷

More often, several years have elapsed since the abuse was initiated, although it may be ongoing. Children 8 to 11 years of age frequently disclose that they have been victims of sexual abuse for a significant period. The assailant is known to the child in more than 90 percent of cases.

A medical history should be obtained from all children being evaluated for sexual abuse. Because evidence of the abuse may not be apparent until the child is examined, the physician may have to obtain additional medical history information after the physical assessment. The record of the medical history should include pertinent statements about whether the child has any underlying condition or has undergone any previous procedures that might cause changes in the anogenital area. Genitourinary surgery or trauma would be particularly important to note.

The child should be questioned directly about what happened. The child's name for genitalia and other body parts should be recorded, and all statements that the child makes concerning the abuse should be recorded verbatim. The demands of a busy ED may make it difficult for physicians to conduct a detailed and sensitive interview. In such cases, a hospital social worker should be consulted.

Examining physicians must maintain a high index of suspicion of sexual abuse when evaluating children who have anogenital or behavioral complaints. The physical assessment should include an evaluation of the child's overall well-being and a general physical examination. The skin should be examined for bruises. Nongenital physical injuries are unusual, even after acute abuse. Rarely, there may be grip marks on the forearms or puncture wounds on the inner aspects of the lips caused by a slap to the face. The age of the child and the degree of sexual development should be noted.

The genital examination should be confined to a careful inspection of the genitalia and perianal area. In general, there is no need for a speculum examination unless the victim is an older adolescent or unless perforating vaginal trauma is suspected. Likewise, sedation is rarely needed, and most children can be reassured verbally if they are at all apprehensive. Careful inspection of the external genitalia is sufficient to establish physical evidence of genital injury. The examination is sometimes augmented by the use of a colposcope to enable detection of subtle changes in the hymen. The colposcope also facilitates photographing the external genital area. However, most EDs are not equipped with a colposcope, and this instrument is, in fact, not critical to an adequate assessment of the anogenital area. Magnification can easily be achieved with the use of handheld lenses. Toluidine blue dye applied to the genital area also may detect subtle acute injuries. The use of digital cameras, which may be available in the emergency department, may permit photographs, which can then be reviewed by more experienced examiners.

Many different positions have been used to facilitate the examination. Infants may be seated on their parents' laps. Children are easily examined supine on the examining table with their legs in a frog-leg position. Some physicians also place all children in a prone knee-to-chest position to help fully assess the contour and homogeneity of the hymen. Placing a child in "stirrups" is usually unnecessary unless she is obese or has achieved adult stature.⁸

The normal prepubescent girl has full labia majora and small thin labia minora. The vaginal opening is covered by the hymen, a fine reddish-orange, thin-edged membrane. The thickness and color of the hymen varies as a function of age. It is normally thick during infancy and again with the onset of puberty. In between, it is thinner, most of-

ten annular or crescentic, and smooth edged. The hymenal orifice can be measured, although there is a range of variation depending on the child's age, size, position, and degree of relaxation. The significance of the diameter of the hymenal orifice as an indication of prior vaginal penetration is questioned by most experts. Trauma may result in changes such as hymenal notches, also referred to as *concavities* or *clefts*. Concavities at the 6-o'clock position are associated with prior penetrating trauma. Attenuation or reduction in the amount of hymenal tissue may lead to a gaping opening. Irregularities in the contour, in particular deep notches, are also associated with prior injury. Scarring, as demonstrated by marked alteration in the vascular pattern (white areas or swirling vascularity), is another sign of healed injury. In contrast, erythema may be secondary to irritation, inflammation, and/or chronic manipulation and is not specific for abuse.⁹

Physical findings indicative of a sexually transmitted disease should also be noted, including a vaginal discharge, warts consistent with condylomata acuminata or condylomata lata, and vesicles or ulcers consistent with herpes genitalia.

It is critically important for emergency physicians to be aware that the absence of physical findings does not preclude abuse. There are many sexually abusive activities (such as oral-to-genital contact) that would not be expected to produce scarring trauma. In addition, as is true elsewhere in the body, injuries can heal without residual scarring.

The genital examination in the sexually victimized young boy is less revealing. Rarely, there may be bite marks on the penis or scrotum. There may be a urethral discharge; the penis may become erect without tactile stimulation and remain erect.

The perianal examination is often more revealing, although it too may be completely normal in the case of acute or chronic sodomy. Acute penetration may produce no changes or may be associated with fissures, abrasions, hematomas, and changes in tone, including both dilatation and anal spasm. In the young female patient, anal penetration is easier than vaginal penetration, and changes in this area may be seen. Anal fissures or tags may be noted. The perianal folds, or rugae, may be thickened in some areas, thinned out in others, and distorted. The perianal skin may be lichenified and thickened secondary to frictional rubbing. Anal tone may be reduced when there has been repeated prior anal penetration. However, stool in the rectal ampulla may lead to similar dilatation, and one should be careful to note the presence or absence of stool.¹⁰

The laboratory evaluation of sexually abused children should include cultures of the throat, vagina (or urethra), and rectum for gonorrhea and a culture from the vagina (or urethra) for *Chlamydia*. Rapid antigen assays are not considered reliable forensic evidence in prepubescent children. A serologic test for syphilis is indicated if there is clinical evidence of syphilis, a history of syphilis in the assailant, or the presence of another sexually transmitted disease. Testing for the human immunodeficiency virus should be done only after appropriate counseling and if there is reason to suspect infection.

A suspicion of child sexual abuse mandates that a report be filed with child protective services or law enforcement agencies. These agencies will pursue an investigation and attempt to ensure that the child is placed in a protected environment.

Although there is the likelihood that the child may be removed from the home, a return appointment for follow-up of cultures for sexually transmitted diseases and a referral for psychologic counseling should be given.

PHYSICAL ABUSE

The spectrum of injuries and presenting complaints in children who have been intentionally traumatized is wide. Familiarity with this spectrum enables physicians in the ED to arrive at the correct diagnosis in a timely manner. Two-thirds of the victims of physical abuse are younger than 3 years, and one-third are younger than 6 months. The physical vulnerability of such small children is easy to understand.

A report published in 1999 noted that nearly one-third of infants and young children presenting to the ED with abusive head trauma had been previously evaluated (mean time, 7 days) and the diagnosis had been missed.¹¹

Historical data may raise suspicions of inflicted trauma. A history that is inconsistent with the nature or the extent of the injuries (e.g., a fractured femur in an infant from a fall off a bed), a history that keeps changing as to the circumstances surrounding the injury, a discrepancy between the story the child gives and the story the caretaker gives, a history of previous trauma in the patient or siblings, or a delay in seeking medical attention should raise one's index of suspicion of physical abuse. Knowledge of normal motor development assists physicians in determining the likelihood that an injury happened in the stated manner. Children younger than 6 months are incapable of inducing accidents or accidentally ingesting any drugs or poisons. The evaluating physician should record the developmental milestones the child has achieved, e.g., the age of sitting unsupported, walking. A recent study showed that developmental milestones were recorded in none of the emergency department visits in which physical abuse was suspected.¹² Parental behavior in the ED should be observed, and it should be noted if the parents appear intoxicated or under the influence of drugs. The level of parental concern about the injury also should be noted.

Toddlers and older children should be questioned about the circumstances of the injury, and the comments should be recorded verbatim on the record. These statements are frequently admissible in court under exceptions to the hearsay rule and may help establish the diagnosis of child abuse.

The physical examination should note the child's overall hygiene and well-being. Normal children, especially toddlers who are just learning how to walk, may have multiple ecchymoses over the anterior shins, the forehead, and other bony prominences. Most falls result in bruises on only one body surface. Bruises over multiple areas, especially the low back, buttocks, thighs, cheeks, ear pinnae, neck, ankles, wrists, corners of the mouth, and lips, suggest physical abuse. Hand prints may be observed, or there may be uniform but bizarre bruises caused by belts, buckles, cords, or blunt instruments.¹³ Bites produce bruising in a characteristic oval pattern, with teeth indentations along the periphery. Bites with an intercanine diameter larger than 3 cm have been inflicted by an adult. Bites should be photographed and swabbed for forensic evidence (saliva). Lacerations of the frenulum or oral mucosa may be present, especially in infants who have been force-fed. Lacerations and abrasions in the genital area are seen in toddlers who are "punished" because of toilet-training accidents.

Estimating the duration of a bruise by the color of the lesion is imprecise. Often, no discoloration is noted initially, although the bruised area may be swollen and tender. Within a day or two, the lesion may become reddish-blue, and this may last for about 5 days. The color changes to green, then to yellow, and finally to brown before resolving. Variability in the appearance of color changes does exist and depends on the size and depth of the hematoma.¹⁴

Children with multiple bruises should be evaluated with a complete blood cell count, a differential blood count, and coagulation studies, including a platelet count, a prothrombin time, and a partial thromboplastin time. Occasionally, a child with leukemia, aplastic anemia, hemophilia, or thrombocytopenia is brought for evaluation because of multiple bruises.

Burns constitute another form of inflicted injuries. These may be scald burns caused by immersion in hot water. Such burns do not conform to a splash configuration; rather, an entire hand or foot ("glove-and-stocking" pattern) may be involved. There is sharp demarcation of the burn margin. The buttocks may be burned during toilet-training "punishment" by immersion in a bathtub filled with hot water. Knees, anterior thighs, feet, and portions of the abdomen are spared, and the buttocks and genitalia are scalded. Cigarette burns leave small (approximately 5 mm) circumferential scab-covered injuries. These le-

sions may resemble impetigo, as do scald injuries, which may resemble bullous impetigo. A culture of material from these lesions differentiates the burn from the infection. Other inflicted burns can result from forced contact with metal objects, such as an iron, curling iron, or heater grid.

Skeletal injuries may be detected when a child presents with unexplained swelling of an extremity or refusal to walk or to use an extremity. Fractures may take any form, but spiral fractures, caused by torsion (twisting) of a long bone, and metaphyseal chip fractures suggest inflicted injury, especially when present in infants younger than 6 months. Skeletal surveys, referred to as a *trauma series* (or *trauma x*), should be obtained. These include films of all long bones, the ribs, the clavicles, the fingers, the toes, the pelvis, and the skull. They may reveal periosteal elevation secondary to new bone formation at sites of previous microfractures or periosteal injury; multiple fractures at different stages of healing; fractures at unusual sites such as the ribs, the lateral clavicle, the sternum, or the scapula; or repeated fractures to the same site. Such x-ray findings support the diagnosis of child abuse. Sometimes, bone scans will reveal fractures not readily apparent on x-rays.¹⁵

Head injuries are a serious and potentially lethal form of child abuse.¹⁶ Infants with significant intracranial hemorrhage may have no apparent external injuries and may present with vomiting, irritability, apnea, or seizures. Intracranial hemorrhages may result from vigorous shaking of the infant or from thrusting the infant down onto a surface, such as a mattress. This is referred to as *shaken baby* or *shaken impact syndrome*. Older children may have been beaten about the head or face. Changes in mental status should therefore be evaluated by head computed tomography if there is any suspicion of abuse. Bruises around the ears, eyes, and cheeks and swelling of the scalp secondary to subgaleal hematomas or underlying skull fractures may be noted. Funduscopic examination may reveal retinal hemorrhages, which are usually associated with subdural hematomas. Retin Cam, a wide-field digital ophthalmic camera, allows for photodocumentation of the fundus. Such equipment is not readily available in most emergency departments but may be found in some hospitals with a neonatal intensive care unit. Ophthalmologic consultation is appropriate in cases of suspected abusive head trauma.^{17,18} Intracranial hemorrhages may result from direct trauma to the skull or severe shaking of the child. These children should be evaluated with computed tomography, and coagulation studies should be performed to rule out underlying coagulopathies. Magnetic resonance imaging studies are also being used to help differentiate recent from older intracranial bleeding episodes and are the preferred imaging modality in children without symptoms of acute head injury. Additional eye injuries caused by trauma may include hyphema, lens dislocation, and retinal detachment.

Injuries to the abdomen are equally serious and are a common cause of death from child abuse. Symptoms include recurrent vomiting, abdominal pain and tenderness, diminished bowel sounds, and/or abdominal distention. A history of injury and bruising of the overlying skin may be absent. Abdominal x-ray films may reveal a distended stomach with a "double-bubble sign" secondary to a duodenal hematoma. Diffuse distention also may be noted. Laboratory studies may reveal anemia, an elevated amylase level from traumatic pancreatitis, or hematuria from kidney trauma. Other abdominal injuries caused by trauma may include hepatic or splenic rupture, intestinal perforation, or rupture of intra-abdominal blood vessels.

Any serious injury in a child younger than 5 years, especially in the absence of a witnessed event, should be viewed with suspicion. Other injuries that may suggest child abuse include those the child states were inflicted by another, were self-inflicted, or were inflicted by an unknown assailant.

The behavioral interaction between the child, the parent, and the physician may provide supportive evidence of the diagnosis of abuse. These children are often very compliant and submissive. They do not resist the medical examiner and readily submit to painful procedures

such as blood drawing. They are overly affectionate to the medical staff, frequently preferring the nurse or the physician to the parent. Sometimes, they are protective of the abusing parent, try to foster to his or her needs, and lie to cover up the true nature of the injury.

Parental behavior is less uniform, but certain distinct characteristics may be noted. The parents may not interact with the child in a comforting or supportive manner during the examination. They may become angry at the physician early in the course of the evaluation and may refuse diagnostic studies. They may appear to be intoxicated or under the influence of drugs. They may have brought the child in for seemingly minor complaints and ignored the major injuries or lesions. They may insist on hospital admission of the child for these minor problems and may readily confess they can no longer cope with the child. They may express fear of losing control.

The social service assessment may reveal an unstable home situation, with frequent moves, poor parental support systems, low parental self-esteem (often caused by battering during their own childhood), parental substance abuse, and/or domestic violence. This adds further supportive evidence of a high-risk situation.

MANAGEMENT

Once the medical assessment has been completed, the physician must initiate the appropriate treatment. The medical management should be guided by the physical findings. Frequently, hospitalization is needed.

Although the specifics of the laws surrounding child abuse and neglect differ from state to state, every state does require that suspected cases be reported.¹⁹ A verbal report is made initially to the police department and/or the child protection agency of the locality in which the abuse has occurred. Law enforcement officers often appear in the ED, especially if the child does not require hospitalization. The child may be removed from the home and placed in protective custody, taken to a juvenile facility, placed temporarily with other relatives, or placed in a foster shelter home. The final disposition is dependent on a court hearing. The physician is also required to complete an official report detailing the specifics of the evaluation and giving his or her diagnostic opinion as to the reasons the injuries or neglect are nonaccidental. The report should use nontechnical terms, e.g., *bruise* instead of *ecchymosis*, so the law enforcement and social service workers can understand the extent of the injuries.

Physicians are sometimes hesitant to report suspected cases. They are not "100 percent" certain. They are fearful of the parental response to the report. They are concerned about removing a child from the natural home. It is important to remember that physicians are required by law to report all suspected cases of abuse and neglect. Failure to report suspected cases can result in misdemeanor charges and lead to a fine or imprisonment. In addition, physicians are protected by the law from legal retaliation by the parents.

Parental anger is a natural response to the filing of a report of suspected child abuse. The physician should refrain from being accusatory. Instead, the physician should note his or her concern about the child's well-being and advise the family that a physician is required by law to report any suspicions. The physician should verbally acknowledge the anger but persist in the role of child advocate. This job is facilitated in hospitals that have child abuse teams available to assist physicians in the ED.

FEMALE AND MALE SEXUAL ASSAULT Kim M. Feldhaus

EPIDEMIOLOGY

Sexual assault accounts for nearly 1 percent of all violent crimes reported in the 2001 U.S. Uniform Crimes Report.¹ Authorities believe that as few as one in three cases are reported to law enforcement.² Most sexual assaults are committed by a person known to the victim, whether a current or former partner, relative, friend, or first-time acquaintance.^{3,4} The vast majority of information and statistics available relate to female rape victims. Only recently has male sexual assault been recognized and reported; the estimated incidence of male sexual assault is approximately 10 percent of all sexual assaults.²

Rape is a violent crime motivated by the need for power and control or by anger. Of victims who seek medical care following the sexual assault, general body trauma is present in 45 to 67 percent.^{3,6,7} Rates of documented genital injury in sexual assault patients range from 9 to 45 percent; higher rates are documented if staining techniques or colposcopic magnification is used.^{8,9} However, genital injuries are not an inevitable consequence of rape, and lack of genital injuries does not imply consensual intercourse. Evidence of semen or sperm has been documented in up to 45 percent of victims without evidence of injury on examination.³

The physician's responsibility is to provide for the patient's physical and psychological well-being first and then, if the patient consents, to provide police with corroborative forensic evidence. Victims should be encouraged to undergo an evidentiary examination as soon as possible because critical evidence may be lost if this examination is delayed. The victim may later choose not to proceed through the criminal justice system, but collection of forensic evidence does not commit him or her to seek prosecution.

CLINICAL FEATURES

The Female Rape Examination

HISTORY The purpose of the history is to obtain data tactfully about the assault, along with a pertinent past medical history, in order to provide proper medical care. The victims should not have to relive every detail of the assault, and in fact, an extensive detailed history may hinder subsequent prosecution.^{10,12} A professional, caring manner should be conveyed, and the history should be obtained in private.

Assault History

1. *Who?* Did the victim know the assailant? Was it a single assailant or multiple? Ask about their identity and race, and document in the medical records.
2. *What happened?* Was the victim physically assaulted? With what (e.g., gun, bat, or fist), and where? Delineate actual or attempted vaginal, anal, or oral penetration. Did ejaculation occur? If so, where? Was a foreign object used? Was a condom used? This information will direct the physical examination to areas of potential injury.
2. *When?* When did the assault occur? Most authorities caution that the chances of finding forensic evidence greater than 72 h after the assault are slim, and therefore, a forensic examination should not be performed. Emergency contraception is most effective when started within 72 h of the assault.
4. *Where?* Where did the assault occur? Corroborating evidence may be found based on the location of the assault.
5. *Suspicion of drug-facilitated rape?*¹³ Was there a period of amnesia? A history of being out drinking and then suddenly feeling very intoxicated? A history of waking up naked? Of waking up with genital or pelvic soreness?
6. *Douche, shower, or change of clothing?* Any of these activities performed prior to seeking medical attention may decrease the probability of sperm or acid phosphatase recovery, as well as other bits of trace evidence.

Medical History

1. *Last menstrual period? Birth control method?* This will help to determine pregnancy risk.
2. *Last consensual intercourse?* If the patient has had consensual intercourse within the last 3 to 4 days, it may confuse laboratory analysis of sperm, acid phosphatase, and genetic typing.
3. *Allergies and prior medical history?* This information is necessary before prescribing antibiotics or pregnancy prophylaxis.
4. *Prior sexual assault?* Has this ever happened to the victim before?

PHYSICAL EXAMINATION The physical examination should be performed thoroughly and compassionately. Document a general medical examination, including vital signs and level of consciousness. Bruises, lacerations, or other signs of trauma should be described in detail using a body map. Carefully inspect the victim's face, oral cavity, neck, breasts, wrist, thighs, and buttocks. Areas of tenderness should be recorded. Inspect the perineum for bruising, abrasions, and lacerations. A speculum examination should be performed, noting any vaginal discharge, vaginal abrasions, cervical abrasions, and cervical lacerations. Examine the rectum for abrasions or lacerations. The routine use of anoscopy following anal assault increases the detection of trauma.¹⁴ If blood is present on rectal examination, anoscopy or sigmoidoscopy should be performed to look for the bleeding source.¹⁴

Toluidine blue can be used to detect small vulvar lacerations, since lacerations expose the deeper dermis, containing nuclei that absorb this stain.^{8,10,12} Prior to inserting the speculum, the dye is applied to the perineum with gauze and wiped away with lubricating jelly. Lac-

erations are demonstrated by a linear blue stain. The magnification provided by a colposcope also has increased the documentation of genital injuries, especially injuries to the posterior fourchette.⁹

EVIDENTIARY EXAMINATION Forensic evidence collection is performed within 72 h of the assault and serves legal purposes only. If more than 72 h have elapsed, the patient should still receive a full history, physical examination, documentation of injuries, and treatment for pregnancy and sexually transmitted disease (STD) prophylaxis.

Informed consent is required prior to evidence collection, and a system to maintain "chain of evidence" is essential. Most hospitals have a prepackaged rape kit (Table 298-1) with equipment and directions. Not every piece of the forensic evidence kit needs to be used every time; the collection of evidence should be tailored to the specifics of the assault. Follow the directions carefully to avoid evidence being declared inadmissible in court due to irregularities. The least invasive procedures should be performed first, and unnecessary duplication of procedures should be avoided.

Clothing worn during the assault or since the assault should be collected because it often reveals signs of a struggle (torn collar, missing buttons, etc.) Examining the skin with a Wood's lamp will reveal semen stains on a patient's body. These areas should be swabbed with a moistened cotton-tipped applicator. Microscopic examination of wet mounts (from vaginal, oral, or anal samples) for the presence of sperm should be left to forensic scientists.^{4,10,15} If there is a concern for drug-facilitated sexual assault, urine should be obtained for drug testing. This testing should be done by law enforcement to preserve chain of evidence, and victims should be informed that any previous volitional, recreational drug use (such as cocaine or marijuana) also may be revealed in the toxicologic screening.^{12,13} The urine sample should be refrigerated after receipt by law enforcement in order to preserve the detection of drugs of abuse.

The Male Rape Examination

History taking is similar to that in the female rape examination. The physical examination must be tailored to the particulars of the assault. Victims of oral penetration require a careful examination of the oral cavity; pharyngeal edema or mucosal lacerations may be found. Swabs should be taken of buccal and gingival areas if an oral assault occurred. In cases of anal assault, inspect the anus externally for signs of trauma, and perform anoscopy.¹⁴ Up to two-thirds of victims will have minor genital injuries such as perineal contusions, anal fissures, or rectal mucosal tears.¹⁴ Obtain a rectal swab or a rectal aspirate in cases

of anal assault for evidentiary purposes. Sterile saline can be injected into the rectum, allowed to equilibrate, and then aspirated.¹¹ Swabs from the victim's penis should be collected and examined for saliva if there is a history of oral copulation.

FORENSIC LABORATORY EVALUATION

The definition of rape is legal, not medical, and contains three elements: (1) any degree of carnal knowledge, (2) nonconsent—unless the victim is a minor, intoxicated, or mentally incompetent, in which case they are deemed unable to give consent, and (3) compulsion or fear of great harm.^{10,12}

Proof of recent sexual contact includes the presence of sperm on wet mounts and the identification of acid phosphatase or other seminal products in any oral, anal, or vaginal cavity swabbing. Proof of force can be substantiated by documentation of injuries or a struggle (i.e., clothing evidence) or by the victim's statements regarding threats or coercion. Evidence that can help identify the assailant includes trace evidence (such as foreign hair) and DNA analysis or ABO secretor status typing of blood, saliva, or semen.¹⁵

Evidence of Semen

Historically, the courts and legal professions have placed a high significance on sperm or seminal fluid detection as confirmatory evidence for rape.¹⁵ The detection of sperm depends on several factors, including time lapse between the assault and the physical examination, whether the assailant is azoospermic or has had a vasectomy, whether the assailant ejaculated, whether the victim douched prior to examination, and whether she has had consensual intercourse in the previous 72 h.^{10,12,15} Previous studies suggest that one-quarter to one-third of sexual assault victims will have sperm detected as part of the evidentiary examination.¹³ Evidence of seminal fluid (presence of spermatozoa or high levels of acid phosphatase or presence of p30 prostate specific antigen) is found in 38 to 48 percent of cases.^{3,7}

Genetic Typing and DNA Analysis

Genetic typing helps to narrow the field of suspects but cannot specify an individual. Forensic analysis of evidence is used to determine genetic markers for the victim, the evidence, and the possible assailants. Determining blood type and secretor status can be used to exclude a potential assailant if his genetic typing does not match that of the evidence. DNA typing can be used to characterize an individual's unique genetic material and distinguish two individuals statistically. This typing can be performed on very small samples of evidence, as well as on old or decomposing samples.

All evidence collected from a victim should be labeled carefully with the victim's name, the type and source of the evidence, the date and time of collection, and the name of the person who collected the evidence. Following instructions for proper collection and storage of evidence is critical to producing optimal laboratory results.^{11,12}

CORRELATES WITH PROSECUTION

Several studies have examined the relationship between victim characteristics, assault characteristics, and forensic evidence and the legal outcome of an individual case.^{6,7,16} Successful prosecution has been associated with younger victims, victims who had evidence of trauma on examination, and cases where a weapon was used.⁶ The presence of a known assailant, a history of multiple assailants, or evidence of trauma can increase the odds that charges will be filed by law enforcement.⁷ Charges were filed three times more often in cases where forensic evidence was collected as compared with cases where a forensic evaluation was not performed, regardless of the results of the evidence collection.⁷ There is a gradient association between the severity

of overall trauma (both genital and general body trauma) found on examination and the odds of charges being filed by law enforcement, as well as the odds of a conviction being secured.⁷ A recent Canadian study reported no statistically significant relationships between legal evidence collected and the filing of charges in cases of sexual assault. However, many nonmedical variables such as the victim's age, use of alcohol, and relationship between victim and assailant were statistically associated with the filing charges.¹⁶

TREATMENT

Treatment of the rape victim includes, first and foremost, management of any physical injuries and psychological needs according to standards of care. This is followed by pregnancy prophylaxis and STD and human immunodeficiency virus (HIV) prophylaxis. Recent research suggests that many sexual assault victims are not receiving the full complement of treatment for pregnancy prevention and for STDs.¹⁷ Drug or alcohol screens should be obtained only if medically indicated and if the results will influence treatment.

Pregnancy Prophylaxis

A pregnancy test should be obtained on all female rape victims of childbearing age in order to identify any preexisting pregnancy, and a negative pregnancy test should be documented before providing postcoital contraception. Contraceptives are pregnancy category X, and although a postcoital dose in very early pregnancy is not anticipated to have teratogenic effects, all women who receive postcoital contraception should have gynecologic follow-up in case pregnancy occurs. Although the risk of pregnancy after an isolated sexual encounter during nonfertile periods of the menstrual cycle is thought to be less than 1 percent, it is significantly higher at midcycle. Approximately 5 percent of all sexual assault victims become pregnant as a result of the assault.^{5,18} As of this writing, there are several oral medication options for postcoital emergency contraception¹⁹ (Table 298-2). The pooled failure rate of postcoital contraception is 3 percent or less. It should be given within 72 h.

The exact mechanism of action of emergency postcoital contraception is unclear, but it is thought that the agents act primarily to inhibit or disrupt ovulation or possibly to inhibit fertilization or implantation. Emergency contraception is not effective once implantation has occurred, and it will not disrupt an existing pregnancy. Common side effects include nausea and vomiting. Rates of nausea and vomiting for progestin-only medications are reported to be less than with combination pills.

Sexually Transmitted Disease Prophylaxis

Most of the literature demonstrates poor compliance of sexual assault patients with follow-up.²⁰ Therefore, prophylaxis for STDs should be given to all.^{12,21} The current guidelines from the Centers for Disease Control and Prevention (CDC) recommend prophylaxis against gonorrhea, *Chlamydia*, *Trichomonas*, and bacterial vaginosis.²¹ The CDC also recommends postexposure vaccination for hepatitis B, with the first dose administered at the time of the initial examination.²¹ A negative pregnancy test should be documented prior to administering antibiotics because a positive pregnancy test will alter the choice of antibiotics. See Chap. 141 for further information on treatment of STDs. Table 298-3 presents the current CDC guidelines for antibiotic choices

TABLE 298-2 Postcoital Contraception*

Plan B (levonorgestrel) 1 tab initially then 1 in 12 h
Preven (ethinyl estradiol and levonorgestrel) 2 tabs initially then 2 in 12 h
Ovral (ethinyl estradiol and norgestrel) 2 tabs initially then 2 in 12 h

*Medication for nausea also should be prescribed.

TABLE 298-3 Treatment of Sexually Transmitted Diseases Following Sexual Assault**1. Recommended regimens for gonorrhea prophylaxis:****Ceftriaxone** (125 mg IM in a single dose)*Alternative regimens:*

Cefixime 400 mg PO in a single dose

or

Ciprofloxacin 500 mg PO in a single dose

*or*Ofloxacin 400 mg PO in a single dose *If**pregnant:*

Ceftriaxone 125 mg IM in a single dose (avoid fluoroquinolones and tetracyclines)

*plus***2. Recommended regimens for Chlamydia prophylaxis:****Azithromycin** 1 g PO in a single dose*or***Doxycycline** 100 mg PO twice a day for 7 days*Alternative regimens:* Ofloxacin 300 mg PO

twice a day for 7 days

or Erythromycin base

500 mg PO four times a day for 7 days

*or*Erythromycin ethylsuccinate 800 mg PO four times a day for 7 days *If**pregnant:* Erythromycin base 500 mg PO four times a day for 7 days*or*

Amoxicillin 500 mg PO three times a day for 7 days (avoid

fluoroquinolones and tetracyclines) *plus***3. Recommended regimens for trichomoniasis and bacterial vaginosis prophylaxis:****Metronidazole** 2 g PO in a single dose*If pregnant with symptomatic bacterial vaginosis:*

Metronidazole 250 mg PO three times a day for 7 days

or

Clindamycin 300 mg PO two times a day for 7 days (avoid topical metronidazole gel or clindamycin cream)

If pregnant with symptomatic trichomoniasis:

Metronidazole 2 g PO in a single dose

If pregnant and asymptomatic:

Controversy exists regarding use of oral metronidazole in first trimester.

Untreated BV and trichomoniasis have been associated with adverse

pregnancy outcomes. Consult with patient's primary obstetrician

regarding close follow-up or prophylactic treatment with metronidazole

*plus***4. Recommended regimens for hepatitis B prophylaxis:****Hepatitis B vaccine** at time of initial examination

Follow-up doses of vaccine at 1-2 months and 4-6 months

Hepatitis B immunoglobulin not routinely administered.

and hepatitis B vaccination. Administration of hepatitis B immunoglobulin (HBIG) generally is not recommended but may be considered in a high-risk situation (assailant with known hepatitis B positivity or in a high-risk group). For those in a high-risk situation who have been vaccinated, a booster and HBIG should be given only if antibody titers are inadequate.²¹

Counseling and Testing for HIV

The true risk of contracting HIV from a single sexual encounter is unknown but believed to be low.

highest with receptive, unprotected anal intercourse (0.008-0.032 infections per episode with an HIV-positive partner); the risk with receptive vaginal intercourse is 0.005 to 0.0015 infections per episode.^{22,24} Circumstances of a specific assault may change the probability of HIV transmission: type of assault, presence of trauma,

viral load in the ejaculate, preexisting presence of a genital lesion or sexually transmitted infection in the assailant or victim, ejaculation on mucous membranes, and a history of multiple assaults.^{21,23} Besides the uncertainty of HIV transmission after sexual assault, other factors complicate decision making about postexposure prophylaxis (PEP): potential inability to identify or test the assailant for HIV expense of PEP, side effects of medication (e.g., nausea, vomiting, and anorexia in up to 50 percent of patients), the need for repetitive laboratory testing, the usual time delay between assault and initiation of PEP, and the need to provide follow-up with physicians familiar with PEP for HIV.^{23,24} Extrapolating from the CDC guidelines for occupational PEP and from data regarding the benefits of PEP, PEP for HIV can be "recommended" for victims with the highest-risk exposures and should be "considered" for victims with moderate-risk exposures. Routine PEP following sexual assault by an assailant whose HIV status is unknown is not recommended^{23,24} (Table 298-4).

If PEP is offered, the victim should be aware of the unknown efficacy and known toxicities of antiretroviral agents as well as the need for close follow-up and strict compliance with the regimen. The guidelines for occupational mucous membrane exposure should be followed, and treatment should be begun within 72 h.^{23,24} Consultation with an HIV or infectious disease specialist is encouraged. See Chap. 154 regarding occupational exposure guidelines.

FOLLOW-UP CARE

Ideally, counseling for sexual assault patients should be available 24 h a day in the emergency department. Often, a rape counselor will precede the physician in assessing a victim, preparing him or her for the examination, and provide moral support. Multidisciplinary *sexual assault response teams* are common in some areas of the country and work to provide coordinated, sensitive care of the sexual assault victim, including addressing medical, legal, and psychological needs.^{12-25,28} If no social worker or rape counselor is available when a sexual assault victim arrives, the physician should provide information on local rape counseling centers where the patient may seek further care.

Follow-up medical care is needed to ensure that any injuries have healed properly and to ensure the effectiveness of the pregnancy prophylaxis and STD treatment. A male rape victim should be referred to

TABLE 298-4 Probability of HIV Transmission Based on Type of Sexual Assault**High:** Recommend PEP

Unprotected receptive anal intercourse with known HIV+ assailant

Unprotected receptive anal intercourse with an assailant of unknown HIV status from a high-risk population (estimated to have a 30% or greater risk of HIV infection) **Moderate:** Consider PEPUnprotected vaginal intercourse with a known HIV+ assailant Unprotected receptive anal intercourse with an assailant of unknown HIV status from an intermediate-risk population (estimated to have a 10-30% risk of HIV infection) **Low:** Inform patient of PEP

Unprotected vaginal intercourse with an assailant of unknown HIV status from a low-risk population Unprotected receptive anal intercourse with an assailant of unknown HIV

status from a low-risk population Oral sex without ejaculation (risk of transmission from oral sex with

ejaculation is unknown) **Recommended PEP:** Inform patient that

expected benefits of PEP outweigh

risks and that PEP is advisable. **Consider PEP:** Inform patient and tailor decision to clinical situation andpatient desires. **Inform patient:** Explain benefits and risks of PEP but advise patient that risk of infection is low and probably outweighed by toxicity and cost of PEP.*Source:* From Moran²³ and Lurie et al.²⁴

a urologist or a proctologist. Young children should be referred to a pediatrician for evaluation. These follow-up instructions should be explained clearly in a written aftercare information sheet because victims often recall very little of their emergency department encounter.^{12,25}

INTIMATE PARTNER VIOLENCE AND ABUSE Patricia R. Salber

Intimate partner violence is defined as a pattern of assaultive, coercive behaviors that may include inflicted physical injury, psychological abuse, sexual assault, progressive social isolation, stalking, deprivation, intimidation, and threats. These behaviors are perpetrated by someone who is, was, or wishes to be involved in an intimate or dating relationship with an adult or adolescent victim and are aimed at establishing control by one partner over the other.¹

The term *intimate partner violence and abuse* (IPVA) should be used instead of older terms such as *spousal abuse*, *wife battering*, or *domestic violence*, because IPVA more accurately reflects the fact that this type of abuse occurs not only in adult heterosexual married relationships but also in cohabiting, separated, gay and lesbian relationships, and adolescent dating relationships.

Intimate partner violence and abuse occurs in every race, ethnicity, culture, geographic area, and religious group, and it affects individuals from all socioeconomic and educational backgrounds.^{2,6} Male victimization also occurs.

Effects extend beyond the victim. Children who grow up in violent homes may be physically or emotionally abused or neglected, and witnessing violence can have short- and long-term adverse health consequences.^{5,6} About 30 to 60 percent of reported cases of spousal abuse also report child abuse.⁷ Children also can be incidentally injured or injured when they try to intervene in the struggle.⁸ Children exposed to violence in the home may develop significant behavioral difficulties, including depression, abusive behaviors, or drug abuse. Perpetrators of violence, in particular severe violence, may be at risk for suicide, committing murder or suicide, or being murdered by a family member.⁹

Unless a history of IPVA is specifically sought and responded to during health care encounters, IPVA may go unrecognized and untreated. The consequences may be further intimate partner violence and abuse-related injury, illness or death.

EPIDEMIOLOGY

In 1999, a reported 671,110 women and girls older than 12 years experienced murder, rape, sexual assault, robbery, aggravated assault, and simple assault at the hands of an intimate. This figure is substantially lower than the 875,340 reported in 1998 and more than 40 percent lower than the 1.1 million reported in 1993. In addition, 120,100 men were reported as victimized by intimates in 1999, down from 157,330 in 1998.¹⁰

Risk factors for IPVA include female sex, age between 16 and 24 years, low income household, relationship status of separated rather than divorced or married, and children younger than 3 years in the home.^{6,10} Women aged 16 to 24 years experienced violence by intimates at a rate of approximately 16 in 1000, compared with an overall rate of about 6 in 1000. Ninety-six percent of female intimate partner violence victimization occurs between the ages of 16 to 49 years, especially in low income households, although IPVA rates are still significant in households earning \$50,000 or more.

Black and white females experience intimate partner violence at similar rates for every age group except 20 to 24 years, in which rates

in black women are higher than those in white women. Rates for Hispanic women are lower than those for black and white women; however, rates of victimization follow a similar age distribution.¹⁰

Of the 1642 people murdered by intimates in 1999, 1218, or 74 percent, were women.¹¹ An intimate was responsible for 32 percent of all murders of women compared with 4 percent of male homicides. The rate of IPVA murders has been declining since 1976, with the rate of decline substantially greater for males. Approximately 60 percent of IPVA homicides are committed with a gun.¹² Between 1993 and 1998, about two-thirds of reported female and male victims of IPVA were physically attacked. Those in the remaining third were victims of threats or attempted violence. Fifty percent of female victims of IPVA were injured by their attackers compared with 32 percent of male victims.³

EMERGENCY DEPARTMENT DIAGNOSIS

Overall, an estimated 5 million visits each year to the ED are made because of IPVA.¹³ Between 4 and 15 percent of women seen in EDs are there because of symptoms related to IPVA, with 2 to 4 percent presenting with acute IPVA trauma.^{14,16} In addition, more than 50 percent of women seen in EDs have experienced IPVA at some point in their lives.¹⁴

The responsibilities of the ED team include:¹⁷

1. Identification of IPVA
2. Validation of the victim's experience
3. Assessment of immediate risk and safety planning
4. Referral to IPVA experts
5. Medical record documentation

IDENTIFICATION

There are myriad presentations of IPVA, including injuries; chronic pain syndromes; obstetric and gynecologic manifestations, including rape, sexually transmitted diseases, and complications of pregnancy; mental health presentations, including anxiety, hyperventilation, panic disorders, posttraumatic stress disorder, dissociation, phobias, suicide attempts,¹⁸ and complications of alcohol and other substance abuse. There are no "typical" presentations of IPVA in the ED, but there are important historical and examination features that suggest IPVA.

Certain Characteristic Injuries Characteristic injuries include fingernail scratches, bite marks, cigarette burns, bruises suggesting strangulation, and rope burns.

Injuries Suggesting a Defensive Posture Forearm bruises or fractures may be sustained when women try to fend off blows to the face or chest.

Central Pattern of Injury Examples of central patterns are injuries to the head, neck, face, and thorax and abdominal injuries in pregnant

An Extent or Type of Injury Inconsistent with the Patient's Explanation Such injuries include multiple abrasions and contusions to different anatomic sites inconsistent with the mechanism of injury.

Multiple Injuries in Various Stages of Healing These may be reported as "accidents" or "clumsiness."

Substantial Delay Between the Time of Injury and the Presentation for Treatment Victims may wait several days before seeking medical care for injuries. They may seek care for minor or resolving injuries.

Visits for Vague or Minor Complaints Without Evidence of Physiologic Abnormality This pattern may include frequent ED visits for a variety of injuries or illnesses, including chronic pelvic pain and other chronic pain syndromes.

Suicide Attempts Women who attempt or commit suicide often have a history of IPVA.¹⁸

Obstetric and Gynecologic Presentations Sexual coercion and rape occur in some IPVA relationships. The result may be unwanted pregnancies and sexually transmitted diseases, including human immunodeficiency virus.¹⁹ Complications related to pregnancy, including complications of abdominal trauma, smoking or alcohol and drug use, low maternal weight gain, and neglect of prenatal care, are other features associated with IPVA.²⁰

Partner's Behavior Partners accompanying victims of IPVA may provide clues to the diagnosis by exhibiting controlling or abusive behavior. Further, the victim may appear frightened of her partner or refuse to answer questions and instead defer all responses to the partner.

SCREENING FOR IPVA

Because the features of IPVA are so varied, many experts recommend routine screening for IPVA for all adolescent and adult women who present to the ED.^{16,21,22} National screening consensus guidelines have been published and are available online at <http://www.fvvpf.org>.²³ At a minimum, the ED staff should screen all non-critically ill adolescent and adult patients and mothers of children seen in the ED for current exposure to IPVA. Because of the known adverse long-term impacts of IPVA on health, when time permits, screening for lifetime exposure should be considered.

Screening should be conducted by providers educated about the dynamics of IPVA and the safety and autonomy of abused patients. Screening should be conducted in a safe and private environment with direct and nonjudgmental language. If translators are required, it is best to use individuals who have no connection to the patient and, if possible, who have had education about the dynamics of abuse. Documentation of screening, its results, safety assessment, and any interventions, including referrals and required reporting, should be clearly charted.

Screening guidelines for adolescent and adult patients are summarized in Table 299-1. Sample verbal screening questions are listed in Table 299-2.

TREATMENT GOALS

If ED staff feel that the immediate goal is to "place the victim in a shelter" or "have the attacker arrested," they are bound to become frustrated. Ensuring the safety of the woman and her children is the foremost goal. It is the woman, however, who must make the ultimate determination of whether it is safe to return home. By providing women with information about IPVA, risks, and options, the physician will help the woman decide what is best for her and her family.

Validation: Providing Confirmation and Support

Patients must be told that violence, abuse, and intimidation are not a part of normal, healthy relationships. The victim's reports and experiences should be acknowledged and believed. Let victims know that you take the situation seriously and that you are concerned about the health and safety of her and her children. Victims also should be told explicitly that they have done nothing that warrants the violence and abuse. It is the perpetrator whose behavior is unacceptable. Finally, make it clear that ED personnel can help victims contact IPVA experts (trained social workers or IPVA advocates) who can help them develop

TABLE 299-1 Summary of National Consensus Guidelines for Screening for Intimate Partner Violence and Abuse in the Emergency Department

Screening	Assessment	Intervention	Documentation	Referral and Follow-Up
Routinely screen at every visit	Assess immediate safety	Careful listening and support	Legible, full signature, maintain confidentiality of records	Check if patient has a PCP to follow up with or refer to PCP, mental health provider, social worker, or DV advocate
Screen for current abuse and if time allows, screen for past history of abuse	Assess health impact of abuse	"I'm concerned for your health and safety"	Abuse history:	Obtain permission to notify provider
Privately (one on one) or with nonrelated trained interpreter	Danger and lethality assessment	"You are not alone"	Subjective information: patient states...	Know current phone numbers for:
Ask: What happened? When did it happen? Where did it happen? Who did this?	If the danger assessment is positive, assess for suicide and homicide	"Help is available"	Objective information: detailed description of patient's appearance, behavioral indicators, injuries and health complaints	DV programs
Respect patient decision to disclose or not		"It is not your fault"	Use of rape kits where appropriate	Legal services
Discuss any required reporting		"You don't deserve it"	Results of physical examination	Children's programs
Include screening questions on intake forms		"What happened to you can affect your health"	Use of body maps	Mental health services
		Provide DV information and materials	Photography (with patient's consent)	Law enforcement
		"What can I do for you?"	Radiology, laboratory findings, collection of forensic evidence: clothes, debris, etc.	Substance abuse
		Provide a safety plan	Any materials and referrals offered	Transportation
		Offer services to DV advocate, social work, police, shelter, etc.	Results of health and safety assessments	Local clergy or other community organizations

Abbreviations: DV = domestic violence; PCP = primary care physician.

Source: National Consensus Guidelines on Identifying and Responding to Domestic Violence Victimization in Health Care Settings. San Francisco, Family Violence Prevention Fund, 2002.

the logistics of leaving the relationship or assist with other safety strategies, if the victim chooses to stay in the relationship.

The validation process, in and of itself, has been documented to be a turning point for victims by helping them to begin to plan for a life without IPVA. Therefore, validation should be considered a treatment goal for each IPVA encounter.^{24,25}

Safety Assessment

High risk indicators of a potentially lethal situation include escalation in the frequency or severity of violence; the threat or actual use of weapons, in particular firearms; obsession with the victim; hostage taking; stalking; and homicide or suicide threats or attempts and evidence of violent behavior outside the home. Other risk factors for serious injury or death include substance abuse, especially with drugs, such as crack cocaine or amphetamines, that are associated with an increase in violent behaviors.²⁶

The most dangerous periods for victims of IPVA are during the time of abuse disclosure and during attempts to leave the relationship. Some victims feel safer remaining in the violent relationship rather than leaving without adequate planning for safe departure.²⁶ If lethality risk is high, it is important that victims have an opportunity to speak with IPVA experts, such as hospital-based social workers or community-based advocates, before discharge from the ED. Hospital admission of the victim or children is another option in high-risk situations in which there is no other way to ensure safety.

Referral to IPVA Experts

Victims of IPVA should be referred to IPVA experts, such as hospital social workers or community-based IPVA advocates, who can help the victim assess the situation, understand options, plan for safety, and arrange safe shelter. Community advocates are typically on-call or

available by telephone. If it is not possible or necessary that a personal contact be made before discharge from the ED, the victims should be given up-to-date information about IPVA services in the community, so that follow-up can be arranged later at the patient's discretion. The IPVA advocates should not be asked to call the patient directly unless the patient agrees, because calls to the home could jeopardize the patient's safety.

Resources for health care providers to prepare their practices for optimal response to IPVA are available from the following organizations:

1. Physicians for a Violence-free Society: www.pvs.org
2. Family Violence Prevention Fund's National Health Resources Center on Domestic Violence: www.endabuse.org/health
3. National Domestic Violence Hotline: 1-800-799-SAFE (7233)

ED Record Documentation

Documentation should include whether IPVA was identified by routine screening or by voluntary patient statements. With voluntary statements, it is better to record a description of the abuse in the victim's own words (e.g., "the patient states her boyfriend, Jim Smith, struck her in the eye with his closed fist"). Avoid using legalistic jargon, such as "the patient alleges her husband hit her," because it can be interpreted during legal proceedings that the recorder doubted the veracity of the statement.

Record episodes of past and current abuse. Include dates, times, locations, details of incidents, and the names of any witnesses, if possible. Describe the patient's appearance and demeanor and any visible injuries. Use a body map and photographs to supplement the written description, particularly for documentation of injuries, such as scalp hematoma hidden by hair and soft tissue injuries that are not yet discolored. Collect relevant forensic evidence, such as saliva from bite wounds and semen (using a rape kit), if sexual assault has occurred.

TABLE 299-2 Sample Oral Questions to Screen for Intimate Partner Violence and Abuse

<p>Framing questions: Sometimes it feels awkward to suddenly introduce the subject of abuse, particularly if there are no obvious indications a woman is being abused. The following questions are examples of ways providers can introduce the issue. We now know intimate partner violence and abuse is a very common problem. It is harmful to your health and the health of your family members. Are you in a relationship where your partner threatens to harm you, insults you, belittles you, or hits, kicks, or slaps you? Because partner violence is common in women's lives, I now ask every woman I see in the emergency department if she has been physically, sexually, or emotionally abused.</p> <p>I don't know if this is a problem for you, but many of the women I see as patients are dealing with abusive relationships. Some are too afraid or uncomfortable to bring it up themselves, so I ask about it routinely. Some women think they deserve abuse because they have not lived up to their partners' expectations, but no matter what someone has or hasn't done, no one deserves to be beaten or emotionally abused. Because so many women I see in my practice are involved with someone who hits them, threatens them, continually puts them down, or tries to control them,</p> <p>I routinely ask all of my patients about abuse.</p> <p>Many of the lesbian and gay men we see here are hurt by their partners. Does your partner ever try to hurt you?</p> <p>Direct questions: However one initially raises the issue of intimate partner violence and abuse, it is important to include direct and specific questions.</p> <p>Did someone hit you? Who was it? Was it your partner or husband?</p> <p>Has your partner or ex-partner ever hit you or physically hurt you? Has he ever threatened to hurt you or someone close to you?</p> <p>I'm concerned that your symptoms may have been caused by someone hurting you. Has someone been hurting you? Does your partner ever try to control you by threatening to hurt you or your family?</p> <p>Has your partner ever forced you to have sex when you didn't want to? Has he ever refused to practice safe sex? Has your freedom been restricted or are you kept from doing things that are important to you (like going to school, working, or seeing your friends or family)?</p> <p>Does your partner frequently belittle you, insult you, and blame you?</p> <p>Do you feel controlled or isolated by your partner?</p> <p>Do you ever feel afraid of your partner? Do you feel you are in danger? Is it safe for you to go home? Is your partner jealous? Does he frequently accuse you of infidelity?</p> <p>Indirect questions: In some clinical settings, it may be appropriate to start the inquiry with an indirect question before proceeding to more direct questions. The following questions are examples of this approach. Have you been under any stress lately? Are you having any problems with your partner? Do you ever argue or fight? Do the fights ever become physical?</p> <p>Are you ever afraid? Have you ever gotten hurt?</p> <p>You seem to be concerned about your partner. Can you tell me more about that? Does he ever act in ways that frighten you? You mentioned that your partner loses his temper with the children. Can you tell me more about that? Has he ever hit or threatened to physically harm you or the children?</p> <p>How are things going in your relationship or marriage? All couples argue sometimes. Are you having fights? Do you fight physically? You mentioned that your partner drinks alcohol (or uses drugs). How does he act when he is intoxicated? Does his behavior ever frighten you? Does he ever become violent? Like all other couples, gay couples have various ways of resolving their conflicts. How do you and your partner deal with conflicts? What happens when you disagree? What happens when your partner doesn't get his (her) way?</p>

LEGAL CONSIDERATIONS

Reporting to Law Enforcement

Most states have laws that require health care providers to report injuries resulting from firearms, knives, or other weapons. Twenty-three states have reporting requirements for injuries resulting from crimes (IPVA is a crime in all 50 states); seven states have statutes that specifically require health providers to report injuries resulting from IPVA. The specifics of the reporting requirements vary from state to state, and the adequacy of response by the police to reporting varies by jurisdiction. Inadequate or inappropriate response to the reports (e.g., informing the perpetrator of the report without provision for safety of the victim) can increase the risk of harm to victims. ED personnel should be aware of reporting requirements and police response in their area. In addition, victims of IPVA must be apprised not only of the requirement to make a police report but also of possible ramifications.

Medicolegal Liability

DUTY TO CARE As routine IPVA screening, intervention, documentation, and referral become widely recognized in the medical literature and in the medical community as the standard of care, the risk

that health care providers who fail to meet this standard may be found liable increases. A recent ED case, although settled out of court, has heightened awareness of the issue in the legal community.²⁷

DUTY TO WARN Victims of IPVA should be asked routinely whether they have suicidal or homicidal ideation. Such ideation, particularly if accompanied by a concrete plan of action, should trigger immediate consultation with a mental health provider. All physicians have a duty to warn potential victims if they become aware of a patient's intent to harm a third party. If commitment to a psychiatric facility is planned, the third party is protected and does not have to be warned.²⁸

PREPARING THE ED FOR OPTIMAL RESPONSE TO IPVA

EDs should take the following steps to prepare for optimal IPVA response:

1. Place multicultural, multilingual brochures and posters in examination rooms and other areas of the hospital that provide information about IPVA and its impact on victims and other family members and provide information about community-based programs that provide services to victims.
2. Implement a routine screening protocol that addresses training of ED personnel, confidential interviewing, and appropriate interventions, including validation and referral.
3. Establish an IPVA continuous quality improvement program that assesses adherence to recommended screening and intervention strategies.

4. Form close relationships with hospital- and/or community-based IPV experts to ensure appropriate referral practices.
5. Establish a program in the ED and other hospital facilities that addresses IPV.

ABUSE IN THE ELDERLY AND IMPAIRED

Ellen H. Taliaferro

Abuse continues to be an underrecognized and underreported cause of morbidity and mortality in the elderly. Historical information often remains undetected during medical evaluation, and social stigmata surround the problem. About 3 percent of the elderly population experiences abuse or neglect.¹ This number is significant, because the number of elderly in the United States is growing. By the year 2020, about 20 percent of the U.S. population will be 65 years or older. Detection of elder abuse and neglect is contingent on physicians' awareness of the problem and the ability to recognize risk factors. Community emergency medical services² and emergency departments³ also should play a role in the identification of elder abuse.

The American College of Emergency Physicians adopted a policy statement on the management of elder abuse and neglect.⁴ This statement contains the following recommendations:

1. Emergency departments should have written protocols on the recognition and treatment of elder abuse.
2. Hospitals should have appropriate ancillary staff and other resources readily available to help in the assessment and disposition of those individuals who may be abused or neglected. The hospital staff should be educated in local laws governing the reporting of such incidents and in defusing potentially hostile situations.
3. Hospitals and emergency departments should establish relationships with agencies that oversee the management and investigation of elder abuse.
4. In jurisdictions that have mandatory reporting requirements, persons reporting in good faith should be immune from liability for compliance.
5. Further research should be conducted in epidemiology, detection, prevention, and management of elder abuse and neglect; standardized definitions of elder abuse developed by the National Center on Elder Abuse should facilitate research in this area.

The National Center on Elder Abuse⁵ has defined seven types of elder abuse (Table 300-1). In addition, there are three basic categories of elder abuse: (1) domestic elder abuse that occurs in the home, (2) institutional elder abuse, and (3) self-neglect or self-abuse. In most states, statutes provide the definitions of these different categories of elder abuse. Neglect can be intentional or unintentional. Unintentional neglect may occur through ignorance or inability to provide care.

SOCIAL AND ENVIRONMENTAL RISKS FOR ELDER ABUSE

In general, elderly victims are socially isolated from family and friends, but many live with their abuser. When abuse occurs, the abuser is often dependent on the victim for housing and financial, social, and emotional support. Caretakers usually attempt to provide ac-

TABLE 300-1 Elder Abuse Definitions (Category 1A)

Types of Abuse	Definitions	Examples
Physical	Injury or harm intending to cause suffering, pain, or impairment	Slapping, biting, burning, pushing, improper or use of restraint
Sexual	Nonconsensual sexual involvement of any kind	Rape; sexual threats or innuendoes
Emotional or psychological	Inflicting anguish, pain, or distress, verbally or nonverbally	Threats to institutionalize or withhold medicine, food, or water
Financial or material exploitation	Illegal or improper use of funds, property, or assets	Stealing, forgery, financial coercion, or blackmail
Neglect	Refusal or failure of caregiver to fulfill obligations or duties	Not providing food, clothing, medicine, shelter, supervision, or social support
Abandonment	Desertion by custodian or caregiver who has assumed responsibility for care	
Self-neglect	Failure of the older person to provide for own mental and medical care	

Source: National Center on Elder Abuse. Available at: <http://www.elderabusecenter.org>.

ceptable and appropriate care. However, when the caregiver is overwhelmed, frustrated, or resentful of the responsibilities involved in the task of caring for a less than fully independent elder, abuse or neglect may occur.

Certain conditions tend to set the stage for abuse or neglect. Functional disability and worsening cognitive impairment of the aging individual, especially an acute decline, are risk factors associated with elder mistreatment.⁶

Abuse is associated more with personality problems of the caregiver than with situational stress.⁷ In general, abusers are heavily dependent individuals. Caretakers who are disabled, alcohol- or drug-dependent, cognitively impaired, or mentally ill are also at risk for abusive or neglectful behavior.

CLINICAL FEATURES

Mistreatment or neglect of elderly patients may be difficult to recognize. It occurs most commonly in residential settings. The problem is complicated by the fact that, when abuse is suspected, it may be difficult to secure confirmation from the patient. The patient may welcome and be relieved by the physician's concern and identification. However, embarrassment, fear of abandonment, fear of retaliation, and fear of nursing home placement can prompt the patient to deny the physician's concerns. The history and physical examination are excellent tools to identify elder abuse.⁸

History taking should focus on: (1) detecting the presence of caretaker mental illness, mental retardation, dementia, or drug or alcohol abuse; (2) family history of violence; (3) caretaker dependence on the elder patient for housing, finances, or emotional support; (4) patient isolation, as reflected by the fact that the patient does not have the opportunity to relate with people or to pursue activities and interests in a manner that the patient chooses; (5) whether the patient and suspected abuser are living together; and (6) recent occurrence of stressful life events, such as loss of job, moving, or death of a loved one for the caretaker.⁹

Important historical information concerning the patient should include dependency needs. Problems such as mental confusion, immobility, and need for assistance with hygiene can be associated with neglect. Eliciting a history of cognitive impairment is essential, because abused victims have been found to have significantly greater cognitive impairment than nonabused elderly patients. Abused patients also have a traumatic history of problematic behavior such as incontinence, nocturnal shouting, wandering, or paranoia.¹

An important direct question to put to the patient is, "Are you happy at home, or have you experienced any recent changes in mood or sleeping or eating patterns?" Look also for the sudden onset of be-

havioral signs and symptoms that suggest victimization: depression, fear, withdrawal, confusion, anxiety, low self-esteem, or helplessness.

Other historical indicators of abuse or neglect include a pattern of "physician shopping," unexplained delay in seeking treatment, lack of medical care, a series of missed medical appointments, previous unexplained injuries, explanation of past injuries inconsistent with medical findings, and previous reports of similar injuries.

The **physical examination** begins with an observation of the interaction between the patient and accompanying caretakers. The following findings suggest abuse:

1. The patient appears fearful of his or her companion.
2. There are conflicting accounts of the injury or illness between the patient and caretaker.
3. There is an absence of assistance from the caretaker.
4. The caretaker displays an attitude of indifference or anger toward the patient.
5. The caretaker is overly concerned with the costs of treatment needed by the patient.
6. The caretaker denies the patient the chance to interact privately with the physician.

The mental status examination should try to elicit signs and symptoms of confusion or disorientation. If such signs are present, it is important to seek an underlying cause, especially if they are new, because they may represent underlying medical disorders or may be reflective of intentional or unintentional medication abuse or misuse resulting from abuse or neglect.

The general physical examination should focus on detecting signs and symptoms of poor personal hygiene, inappropriate or soiled clothing, dehydration, malnutrition, and worsening decubiti. Specific injuries suggestive of abuse are unexplained fractures or dislocations, unexplained lacerations or abrasions, burns in unusual locations or of unusual shapes, unexplained injuries to the head or face, the presence of sexually transmitted diseases, and unexplained bruises.

Detection and diagnosis of elder abuse depends on being open to what is reported by the patient or others. Without such openness, reported abuse may be dismissed as paranoia, dementia, or patient non-compliance. A high index of suspicion is necessary. Otherwise, signs of abuse and neglect may be erroneously ascribed to frequent falls, accidental medication errors, failure to thrive, or the normal decline with aging.

There is no substitute for direct questioning when inquiring about abuse. In one report,¹⁰ 33 percent of abused victims stated on initial presentation to the emergency department that they were involved in an abusive relationship. Another 6 percent of abuse cases were detected by eliciting information from other informants. The remaining

cases were elicited by physical examination (43 percent) or by social service evaluation during hospitalization (19 percent).

TREATMENT

Elder abuse treatment is twofold. First, ED treatment of the injuries and illnesses resulting from abuse or neglect must be specific for the injuries and illnesses detected. Second, detection of elder abuse or neglect must be aimed at intervention. Therefore, all treatment, whether delivered in the emergency department or the hospital, for the victim and the victim's caregiver, should be on the basis of multidisciplinary assessment and may result in admission of the elderly patient to an extended-care facility.

Intervention includes the resolution of disposition problems brought about through caregiver exhaustion, the inability of patients to care for themselves in the community, and abandonment by individuals and institutions. Intervention requires a complex array of skills. For example, the serious problem of drug and alcohol abuse among the elderly must be recognized and addressed by emergency department staff. Physical problems often disguise the existence of a problem of substance abuse.

In cases of proven or strongly suspected elder abuse or neglect, intervention must include the involvement of adult protective services.^{5,11,12} All 50 states have passed legislation aimed at protecting elderly victims of domestic abuse and neglect and establishing adult protective services programs. Forty-two states have mandatory reporting laws directed toward health care and social service professionals. The National Center on Elder Abuse provides a listing of telephone numbers for elder abuse reporting in the 50 states and Puerto Rico.⁵ They also provide a nationwide reporting hotline called Eldercare Locator (1-800-677-1116, verified November 2002). Overall, about 20 percent of reports are from health professionals, 15 percent from service providers, 16 percent from family or relatives, and the remaining 50 percent from friends, neighbors, clergy, bankers, and others. In addition, since 1975, the Older American Act has required each state to have a long-term care ombudsman program to investigate nursing home care complaints.

DISPOSITION

Elderly patients with problems requiring hospital admission should be admitted to the appropriate medical service, and the department of social services should be consulted for evaluation. Patients who do not medically require admission may need to be admitted for protective placement if they cannot be safely discharged to their caretakers or returned to their institutional setting. Clinical strategies to stop abuse include hospitalization, close monitoring through office visits, and home nursing. Patients must not be returned to their living situations if there is any doubt about their safety. A formal safety assessment can be requested from professionals, such as a hospital-based social worker or an on-call community-based elder abuse counselor. It is important to remember that abuse or neglect may occur when a caregiver is overwhelmed, frustrated, or resentful of the responsibilities involved in taking care of the patient. Caregivers should be provided with intervention options, such as arranging for home care, respite, or counseling and should be given advice as to the appropriate care for their family members.

The serious problem of drug and alcohol abuse among the elderly must be recognized by ED staff and addressed through appropriate referrals. Communities with geriatric treatment centers provide a valuable resource for patients identified through emergency department visits.

Referrals also should include specific available services, such as "Meals on Wheels," home health aides, visiting nurses, transportation, emergency shelter, legal aid, and medical and mental health services.

VIOLENCE IN THE EMERGENCY DEPARTMENT

Marshall C. McCoy

Violence once threatened only law enforcement personnel among those dealing with the public. Now it has spread into the health care arena. No health care providers are more at risk for violence than those involved with the first-line care of patients. Prehospital care providers have shown an increasing fear of violent calls and admit that violent encounters contribute to high levels of burnout.¹ Mock and coworkers found that violence occurs in 5 percent of emergency medical services runs, and an additional 14 percent of calls are precipitated by violence.² Recent surveys of ED residents have shown that one of their primary concerns is for their safety while working in the ED.³ Although comprehensive data addressing the problem are still being collected from ED personnel, urban and rural hospitals are reporting a higher incidence of potential and actual violent episodes in their EDs.⁴

By its nature, the ED has an atmosphere of controlled chaos. EDs provide unlimited and unrestricted access and have readily available drugs. They are frequented by those who are fatigued or hungry, and they accommodate family and friends of critically ill patients who have heightened levels of frustration and anxiety. Furthermore, EDs are frequented by substance abusers who are often violent. Other factors that may predispose the ED to violence are increasing waiting times, staff shortages, overcrowding, patient financial problems, and the high expectations of the patients.

About 50 percent of all health services providers will be involved in a violent episode in their career. In a 1988 survey of 127 teaching hospitals, 32 percent of respondents had at least one verbal threat daily, 25 percent reported using restraints at least once daily, and 18 percent had at least one threat from a weapon monthly. Unfortunately, 7 percent reported a death related to ED violence in the past 5 years. Of the institutions responding, 35 percent lacked 24-h ED security, and of the 9 respondents who reported a death, 55 percent lacked 24-h security.³

Close to 5 percent of all emergency psychiatric patients have weapons on their person. One study using metal detectors to screen all ED patients over a 6-month period found 33 hand guns, 1324 knives,

97 mace-type canisters, and various other items considered dangerous to the patient and staff.⁶ The presence of metal detectors in an ED appears to improve feelings of safety and protection.⁷ Preventive measures often are not employed until after a violent event occurs.

RECOGNIZING THE VIOLENT PATIENT

Most perpetrators of violence are males with a history of substance abuse. Education, ethnicity, marital status, and diagnosis are not reliable predictors. However, these factors may lead to frustration and anxiety for both the staff and the patient, increasing the likelihood of a violent encounter.

The most obvious predictor of potential violence is the patient's history. Any patient with a past history of violent behavior must be handled cautiously. Trivializing a patient's threat, no matter how subtle, may be the cause of unrecognized violence escalation in its early stages. Every patient exhibiting violent or threatening behavior should have a thorough physical and mental status examination. This may require some form of control (restraints or sedation) before an examination can be completed.⁸ Using family members, friends, therapists, and/or medical records as a source of history may be valuable. The examining physician needs to differentiate between an organic and a functional cause of the disordered behavior. The treatment of an underlying disorder may completely remove any threat, such as the administration of intravenous glucose to a disoriented, aggressive hypoglycemic patient. The organic diseases most likely involved in a violent episode are those related to drugs and withdrawal syndrome(s), especially delirium tremors. According to the American Psychiatric Association, the presence of any one of the following indicators should prompt a search for an organic etiology: a patient older than 40 years of age with no previous psychiatric history; disorientation, lethargy, or stupor; abnormal vital signs; visual hallucinations; or illusions. A thorough evaluation should include laboratory work, toxicology screening, electrocardiograms, and in some cases, computed tomographic (CT) scans and lumbar puncture.

The most common functional disorder related to violent behavior is schizophrenia, especially in patients in paranoid subgroups or with personality disorders.

PRODROMES OF VIOLENCE

In most cases, violent behavior does not erupt suddenly. Therefore, recognition of the prodromes of violence and the phases of escalation is necessary. The first is the anxiety phase, followed by defensiveness, and then physical aggression.⁹ Each phase should evoke a professional response that is proportionate to the patient's behavior. There may be overlap of phases.

Phase 1: Anxiety

The first level of behavior seen in a potentially violent patient is anxiety. Patients, but also their family and visitors who have been waiting for long periods, exhibit anxiety. In general, the signs of increasing anxiety are indicated by body language. Movements that seem to have no purpose other than to expend energy may be the first clue. These may include pacing, wringing of hands, clenching of fists, unwillingness to stay in the treatment area, or a disheveled appearance. Speech may be pressured and loud. Questions such as "Why am I here?" or "How long is this going to take?" may be asked. It is not necessarily what is said but the manner of speech that suggests anxiety. One of the most common reasons for escalation of behavior beyond anxiety is that the staff ignores these signals rather than acknowledging and responding to them in a constructive way. The appropriate response to the anxiety phase is the development of some type of rapport. Time (a precious commodity to emergency staff and physicians) is usually all that is needed. Listening to the patient's concerns and addressing them

appropriately may be all that is required to diffuse the situation. Dismissing or ignoring the patient, family, or visitors will only cause more anxiety. Most patients are fearful of a loss of control and usually welcome the opportunity to politely vent their feelings. The patient must be treated honestly and with respect and empathy. Simple courtesy will go a long way toward establishing rapport and preventing future problems. Be supportive with responses that acknowledge the patient's feelings, such as "I understand why you are angry." A peace offering of food or drink also may help. Do not be judgmental. Concentrate on what the patient is saying, and do not feign attention. Restating what the patient has just said may help clarify the patient's complaints and allow the patient to continue venting. Remain on the topic and, above all, remain calm. This will help the patient feel more in control.

Phase 2: Defensiveness

The next level in the continuum of violent behavior is defensiveness. A patient may present to the emergency department in this stage, having passed the anxiety stage outside the hospital. At this point, the patient's behavior is volatile and becomes verbally abusive and profane, often with associated body posturing. Verbal attacks may be directed to staff members or others in the department and may include statements about age, gender, weight, or heritage. The patient's behaviors are irrational and often have nothing to do with why the patient presented to the ED. The patient is losing control and may feel helpless. If the patient is restrained, feelings of helplessness may be further magnified.

The goal is to prevent total loss of control by the patient. This goal is achieved by setting reasonable limits and by offering the patient a choice. One must be firm in tone and action but professional and calm. Do not overreact or make false promises. The patient must have reasonable limits set and be made aware of the consequences of continued aggression. Limits must be simple, clear, enforceable, and consistent. No consequence should be stated if it is not enforceable. Giving the patient reasonable choices helps diffuse the situation and makes the patient feel rewarded for good behavior. If the situation continues to deteriorate, the patient should be isolated. A show of force by uniformed security personnel may then be in order. Although this may cause further deterioration of behavior, this is the exception, not the rule.

Phase 3: Physical Aggression

The third level is physical aggression. The patient is totally out of control, and no amount of verbal intervention is effective. The physically aggressive patient must be confronted and controlled physically, for the safety of the violent patient, other patients, visitors, and staff. When all other interventions have failed, no further negotiation is warranted. Physical control of a patient requires personnel skilled in the technique and should never be attempted single-handedly. Using appropriate restraint enables the staff to provide necessary care for a violent patient. Physical control is implemented not for punitive reasons but in the interest of patient care and safety for others.

RESTRAINT AND SECLUSION

The philosophy of any institution should be to limit the use of restraints or seclusion to situations where less restrictive interventions have failed and the clinical appropriateness is clearly justified. A *restraint* is defined as any device, including manual holds, that is attached or adjacent to the patient's body that cannot be removed easily and restricts freedom of movement or normal access to one's body. *Seclusion* is the involuntary confinement of a person in a room or area so that the person is physically prevented from leaving. The purpose of restraints or seclusion is to ensure the safety of patients and others or prevent damage to property, never for punitive reasons, convenience, or when a patient may be medically compromised by their use.

Health care providers and administrative personnel should familiarize themselves with the Acute Medical and Surgical Care Restraint Standards and the Behavioral Health Care Restraint and Seclusion Standards¹⁰ as set forth by the Joint Commission on Accreditation of Health Care Organizations (JCAHO) and the Center for Medicare/Medicaid Services (CMS). These standards and their interpretations are ever-changing, so periodic review is necessary.

In general, the Acute Medical and Surgical Care Restraint Standards are used to promote healing, e.g., patients who will compromise their medical care by self-removal of an endotracheal or intravenous tube. Essentially all other clinical justifications for restraint will fall under the standards used for behavioral health care. It is important to note that these standards are invoked regardless of the patient's location within an institution.

In the case of physical restraint, each institution should have policies and procedures that document when restraints can be used, who can order restraints, how patients are monitored in restraints, and mechanisms for the review of their use. Any documents should begin with the clinical indications for restraint and the alternatives that were attempted and deemed to be ineffective.

According to the JCAHO, only licensed independent practitioners (LIPs) can order restraints. However, often the LIP is not present when the need for restraint is determined. Therefore, trained caregivers may institute the restraint, and an LIP must perform a face-to-face evaluation within 1 h of restraint use. A written order must be obtained that includes the type of restraint, reason for restraint, and time limit of the order.¹⁰ Any written or verbal order is limited to 1 h for children younger than age 9, 2 h for individuals aged 9 to 17 years, and 4 h for individuals aged 18 and older.¹¹

Early release from the restraint before the time-limited order has expired may be initiated by trained providers if the patient demonstrates a reduction in the condition that led to the restraint. For patients in restraints or seclusion, continuous monitoring is required. Those in restraints require evaluation every 15 min, and this should include examination for signs of injury associated with the restraints, nutrition, hydration, circulation and range of motion in the extremities, vital signs, hygiene and elimination, physical comfort, psychologic status, and readiness for discontinuation of the restraints. Since approaching or awakening a restrained patient every 15 min may cause further agitation, evaluation may not necessarily include all the former parameters, but as many as practical should be performed. Patients in seclusion must be observed continuously for the first hour, after which audio or video equipment may be used, but it must be monitored continuously.

Seclusion generally has been considered a better alternative to restraints because it allows some freedom of movement and is medically safer. In adolescents and robust adults, however, free use of the extremities, combined with their strength, may be dangerous, and the isolation and sense of rejection may be psychologically harmful.¹² Seclusion rooms require walls that cannot be damaged by combative patients, safety windows for continuous monitoring, appropriate lighting, and calming colors.

Once the decision to restrain a patient is made, appropriate personnel must be assembled. A trained security person or hospital staff member should act as the team leader because untrained personnel may cause undue harm to the patient or staff. Soft restraints should never be used on a truly violent patient. One should explain the reason for restraint to the patient, and once restrained, the patient should never be abandoned. No patient for whom restraints were necessary should be allowed to leave the ED against medical advice. If necessary, contacting hospital legal authorities may be helpful. In general, if a patient is brought to the ED in handcuffs, he or she should remain in handcuffs until the threat of violence and medical condition are assessed. Remember that many an escape has taken place in a hospital setting.

MEDICATIONS

Some patients are too violent, even when restrained, to perform an adequate evaluation. In these patients, the use of medications can be a safe and effective means to manage violent behavior. Rapid tranquilization is the delivery of medications in a titrated fashion to gain control of aggressive patients. Antipsychotic agents and benzodiazepines, alone or in combination, are the most frequently used medications. Each can be given IM, IV, or PO, giving the physician alternatives in delivery methods depending on the patient's condition. Intramuscular injection is usually the route of choice because these medications are absorbed rapidly. Moreover, attempting intravenous access on a violent patient can be dangerous.

Haloperidol (Haldol) is currently the antipsychotic of choice. In an adult, a 5-mg IM injection has rapid onset and can be repeated as needed to obtain the desired effect. In the elderly, the starting dosage should be lowered to 1 or 2 mg. Few patients will have extrapyramidal side effects, but if they occur, they are easily treated with benztropine or diphenhydramine. Haloperidol also has fewer side effects than older antipsychotics such as chlorpromazine (Thorazine) or thioridazine (Mellaril), which are more sedating and can cause hypotension and anticholinergic effects.

Benzodiazepines are more sedating than the antipsychotics but have no extrapyramidal side effects. Lorazepam is an excellent choice due to its rapid onset. Doses of lorazepam 2 to 4 mg IM or IV are effective in most patients, but additional doses may be needed in withdrawal syndromes or extremely agitated patients. The use of benzodiazepines in combination with haloperidol is also effective and has a more rapid onset of effect and reduces the number of subsequent injections needed.

Droperidol, a sedative-hypnotic with antiemetic properties, also has been used for violent patients. Doses of 2.5 mg IM or IV are absorbed rapidly but can be heavily sedating. Rare cases of QT-interval prolongation with resulting torsades de pointes have been reported in patients receiving droperidol.¹³ However, the causal relationship between QT prolongation and droperidol is questioned.¹⁴ Therefore, droperidol could be used in patients in whom benefits outweigh the potential risks.

VIOLENCE PREVENTION

The single best way to handle a violent patient or curtail the potential for violence in the ED is by prevention. Careful planning of the work area, cooperation with hospital security personnel, and training of all ED personnel to recognize violent patients are critical.

Interviews of the potentially violent patient should be conducted in a safe, calm environment. Seclusion rooms for interviewing patients should be safe for both the patient and the interviewer. Solid walls with sturdy, heavy furniture that cannot be lifted should be used. Lighting should be able to be dimmed or brightened, depending on the circumstance. No free-standing objects, such as ashtrays, pictures, or pencils, should be allowed because they all could become potential weapons. The room exit should be clear of obstruction and readily available to the interviewer. Panic buttons may be installed or signals developed to be used in the event of threatening behavior on the part of the patient. If violent aggression does develop, the room should be large enough for a team of security personnel to safely overcome the patient without undue harm.

Deterrence is also a preventive technique. Signs outside the ED should clearly state that weapons of any type are not permitted, and trained hospital security personnel should be visible to everyone entering the emergency department. The use of metal detectors and x-ray machines for personal articles, such as handbags, may allow for easy screening of those entering the treatment area. Carefully placed monitors and alarm buttons also may be warranted. However, metal detec-

tors, monitors, and alarms are only a part of an overall security system and complement personnel training in the management of potential and actual violent situations.^{15,16}

The education of ED personnel is the most important factor in curbing violence in the ED.¹⁷ Several national programs, such as that offered by the National Crisis Prevention Institute (<http://www.crisisprevention.com/program/nci.html>), are invaluable in teaching a basic understanding of violent behavior, its recognition and management, and basic self-defense against violent patients. Educational seminars conducted by security personnel and law enforcement officials also may be of benefit.

PRINCIPLES OF IMAGING

CONTRAST STUDIES

John Eng

Iodinated intravascular contrast agents significantly improve the visualization of structures in many radiologic examinations, and millions of doses are administered each year in the United States for this purpose. While it is always advisable to discuss the need for iodinated contrast agents with a radiologist on a case-by-case basis, some general indications are offered here. Throughout this chapter, *contrast agent* refers to iodinated intravascular contrast material unless otherwise indicated.

IODINATED INTRAVASCULAR CONTRAST AGENTS

Mechanism of Action

Iodinated intravascular contrast agents are water-soluble molecules that contain several radiodense iodine atoms per molecule. Following injection, contrast agents remain in the vascular space for only a short time (initial-pass $t_{1/2}$ 1-3 min) and are distributed rapidly into the extracellular space. With normal renal function, the $t_{1/2}$ of elimination is approximately 2 h. Contrast agents do not enter the intracellular space or cross an intact blood-brain barrier. They are excreted rapidly by the kidney via glomerular filtration without tubular resorption.

Since the radiodense iodine atoms absorb more x-rays than do biologic tissues, contrast agents appear white (like the bones, which are also radiodense) if they are present in high enough concentration during examinations made with x-rays (radiographs). Contrast agents are visible on arteriography during the short time they are in high concentration in the vascular space. They are visible in the urinary tract during intravenous urography (IVU), after excretion by the kidney. Because of its ability to discriminate subtle differences in radiodensity, computed tomography (CT) shows the presence of contrast agents in all tissue compartments even though they may be present in relatively low concentration (compared with arteriography or radiography).

Types of Agents

Contrast agents are classified according to osmolality (Table 302-1). High-osmolality agents have been in clinical use since the 1950s, and they are often called *ionic* contrast agents because they are all organic salts (Figure 302-1). Low-osmolality agents have been in use since 1986, and they are commonly called *nonionic* agents because all but one are organic molecules without electronic charge (Figure 302-2). A number of studies have demonstrated that low-osmolality contrast agents are associated with at least a 50 percent reduction in the incidence of both minor and severe reactions (see Table 302-1). Fatal reactions are rare.¹ Anecdotally, injection of low-osmolality agents is associated with less subjective effects, such as flushing, heat, chemical taste, and osmotic diuresis. Currently in the United States, low-osmolality contrast agents cost on average five to six times more than an equivalent dose of a high-osmolality agent. The use of low-osmolality contrast agents is surrounded by some controversy due to the significant cost differential for a relatively modest difference in the incidence of severe reactions, which are rare. The controversy has subsided somewhat as the price of low-osmolality agents has slowly decreased since their introduction.

Types of Contrast Reactions

Contrast reactions can be divided into three categories: anaphylactoid, chemotoxic, and vasovagal (Table 302-2). Anaphylactoid reactions occur idiosyncratically, and they mimic allergic or anaphylactic reactions and shock. Anaphylactoid contrast reactions have no known consistent pathophysiologic mechanism. They may involve one or more of the following mechanisms: histamine release, complement activation, hapten formation, contact sensitivity, endovascular reactions, and central nervous system factors. However, unlike true immunoallergic or anaphylactic reactions, they do not involve IgE mediation. An increased risk of anaphylactoid contrast reaction is associated with a history of asthma, food or drug allergy, or a previous contrast reaction. Low-osmolality agents are associated with a lower risk of anaphylactoid contrast reaction.

Chemotoxic reactions are related to osmotoxic and other chemical effects of contrast agents. The pathophysiologic mechanisms for chemotoxicity are not well understood, but its occurrence is less idiosyncratic. Since many of the chemotoxic cardiovascular reactions, such as dysrhythmia and pulmonary edema, occur primarily with coronary artery injections, their occurrence in the emergency department setting is probably of less concern than in the cardiac catheterization suite.

Contrast agents also can cause vasovagal reactions, a result of increased vagal tone of the heart and blood vessels of unknown etiology but thought to be related to the central nervous system. In addition to being caused by contrast agents, vasovagal reactions also may be caused by the circumstances surrounding their administration, such as fear, anxiety, or discomfort from needle puncture.

RISK ASSESSMENT AND PATIENT PREPARATION

There are no absolute contraindications for receiving intravascular contrast agents. Certain clinical conditions either increase the risk of developing a contrast reaction or increase the severity of the reaction should one develop. Risk assessment and, in some cases, preventive measures should be performed prior to contrast agent administration. Considerations for patient preparation are summarized in Table 302-3, and additional comments are offered below.

History of Allergy

A history of asthma or severe allergy (e.g., anaphylaxis) to one or more allergens is associated with an increased risk of a contrast reaction. Patients with a history of asthma may have a fivefold greater risk of an adverse reaction than the general population, and a history of allergy may double the risk.² A history of reaction during a previous contrast agent administration is associated with a three- to eightfold greater risk of a subsequent adverse reaction than in the general population.²

Renal Disease

Classically, the risk factors for developing renal insufficiency from contrast agents are preexisting renal insufficiency (creatinine level > 1.5 mg/mL), diabetes mellitus, volume depletion, use of diuretics in cardiovascular disease, advanced age (> 70 years), multiple myeloma, hypertension, and hyperuricemia.³ More recent studies have shown that the most significant risk is associated with the coexistence of diabetes and renal insufficiency.⁴

TABLE 302-1 Comparison of High- and Low-Osmolality Contrast Agents

Characteristic	High-Osmolality Agent (Ionic)	Low-Osmolality Agent (Nonionic)
Approximate osmolality relative to serum	5	2*
Overall incidence of adverse reaction	5–8%	1–2%
Incidence of severe reaction	1–2 per 1000	1–2 per 10,000
Incidence of fatal reaction	1/40,000–1/250,000	1/200,000–1/500,000
Relative cost	1	5–6

*One nonionic agent, iodixanol (Visipaque), is isosmolar.

As a preventive measure, patients with preexisting renal insufficiency, diabetes, or volume depletion should receive hydration in the form of NS at 100 mL/h beginning 12 h before and continuing 12 h after contrast agent administration. In patients with end-stage renal failure receiving chronic dialysis, the contrast agent and extra fluid must be removed by dialysis, but the dialysis does not need to be performed emergently⁵ unless there is significant underlying cardiac dysfunction (and thus increased risk of direct cardiac chemotoxicity). In patients with chronic renal failure, there is some evidence that acetylcysteine given orally beginning the day before contrast agent administration can reduce the risk of developing acute contrast-agent-induced renal failure,^{6,7} but this is not currently considered standard practice.

Cardiac Disease

Patients with significant cardiac disease appear to be at increased risk for contrast reactions. Significant cardiac disease includes severe angina pectoris, congestive heart failure, severe valvular disease, primary pulmonary hypertension, and cardiomyopathy.

Metformin Therapy

Metformin (Glucophage) is an oral antihyperglycemic agent used to treat non-insulin-dependent diabetes mellitus. Development of potentially fatal lactic acidosis is a rare adverse effect of metformin and may occur if contrast-induced renal insufficiency (itself a rare event) develops. Therefore, metformin should be discontinued at the time of contrast agent administration and withheld for 48 h afterward. The drug may be restarted after the patient's renal function is rechecked and found to be normal.⁸

Anxiety

There is some evidence that severe contrast reactions may be partially mediated by anxiety. Therefore, an anxious patient should be reassured and calmed prior to contrast injection.

FIG. 302-1. The general chemical structure of the anion of a high-osmolality contrast agent. The R groups are either diatrizoate or

iothalamate, depending on the manufacturer. The corresponding cation is either sodium or meglumine.

FIG. 302-2. The basic chemical structure of a nonionic, low-osmolality contrast agent. There are five such agents currently on the market, each with a different R group: iohexol (Omnipaque), iopamidol (Isovue), iopromide (Ultravist), ioversol (Optiray), and ioxilan (Oxilan). All the R groups contain multiple hydroxyl groups for solubility. A sixth low-osmolality agent, iodixanol (Visipaque), chemically links two of the basic structures to further reduce osmolality. A seventh agent, ioxaglate (Hexabrix), has a different chemical structure (not shown) that is unique because it is both ionic and low osmolality.

Other Diseases

In patients with pheochromocytoma, pretreatment with phentolamine, an α -adrenergic antagonist, is recommended prior to contrast agent administration. In a nonstabilized patient with recent seizures, pretreatment with diazepam may be advisable.² Convulsions or seizures following contrast agent administration may be due to a lowering of the seizure threshold, or they may be a final result of a severe hypotensive or vasovagal reaction.⁴

As mentioned earlier, hyperuricemia and dysproteinemias, such as multiple myeloma, are associated with an increased risk of contrast-induced renal insufficiency, but there is conflicting evidence regarding the strength of this relationship. Similarly, some studies suggest that sickle cell trait and disease are also associated with an increased risk of contrast reaction, but the significance of the relationship is unclear.

Premedication

Premedication with a steroid regimen has been shown in some studies to reduce the overall incidence of contrast reactions to both high- and low-osmolality agents. However, no controlled studies have been performed to determine whether premedication reduces the incidence of severe reactions. Most institutions prescribe premedication if there is a history of a significant (more than nausea, vomiting, or a few hives) reaction to a previous contrast agent injection.⁹ Some institutions also premedicate if there is a history of severe allergy to any substance. There are no standard indications or protocols for premedication. Two commonly prescribed premedication regimens are listed in Table 302-4.^{10,11}

TABLE 302-2 Classification of Contrast Reactions

Reaction Type	Signs and Symptoms
Anaphylactoid	
Generalized urticaria	Hives (generalized)
Laryngeal or facial edema	Stridor, facial swelling
Bronchospasm	Wheezing, dyspnea
Cardiovascular collapse (shock)	Hypotension, sinus tachycardia
Chemotoxic	
Renal tubular injury	Rising creatinine
Cardiac dysrhythmia	Electrocardiographic changes
Cardiac impairment	Pulmonary edema
Neurotoxicity	Seizure
Mild reactions	Nausea, emesis, warmth, dizziness, headache, pallor, flushing, shaking, chills, diaphoresis, hives (localized), altered taste, pruritus
Vasovagal	Hypotension, sinus bradycardia

TABLE 302-3 Summary of Patient Preparation Prior to Intravascular Administration of Iodinated Contrast Agents

Item for Consideration	Action
Clinical history	Elicit any history of allergy, asthma, previous use of contrast material, renal insufficiency, diabetes, cardiac disease, seizures, metformin therapy
Creatinine level	Obtain in patients with suspected renal dysfunction only (see Table 302-5)
Hydration	Consider in patients with renal insufficiency, diabetes, volume depletion
Premedication	Prescribe for patients with history of contrast allergy and possibly patients with history of severe allergy to a substance other than contrast material (see Table 302-4)
Selection of low-osmolality agent	Refer to American College of Radiology guidelines (see Table 302-6)

Serum Creatinine

A baseline serum creatinine level should be determined prior to contrast agent injection for patients with suspected renal dysfunction or considered at increased risk for contrast-induced nephrotoxicity⁴ (Table 302-5). **Determination of the serum creatinine level is not necessary in patients without suspected renal dysfunction.** Furthermore, in cases of suspected renal dysfunction, clinical judgment may determine that an urgently needed contrast-enhanced examination should not be delayed by determination of the serum creatinine level.

Selective Use of Low-Osmolality Agents

Because of their lower incidence of reactions, low-osmolality agents are used by many institutions with selected patients at higher risk for developing a contrast reaction. The American College of Radiology has suggested guidelines for the selective use of low-osmolality agents⁴ (Table 302-6). These guidelines are the result of a consensus and are not evidence-based because it is difficult to study severe contrast reactions due to their rarity. Some practices have elected to use low-osmolality agents exclusively, especially since they are generally better tolerated by patients (e.g., less nausea, vomiting, flushing, and heat sensation).

INDICATIONS FOR INTRAVASCULAR CONTRAST AGENTS

An intravascular contrast agent is required to visualize vascular structures in arteriography, venography, and vascular CT (e.g., aorta and pulmonary arteries). An intravascular contrast agent is also required to visualize the urinary tract in an IVU. In such cases, decisions regarding the use of intravascular contrast agents are linked to the decision to perform the examination. Aside from these indications, decisions

TABLE 302-4 Commonly Prescribed Regimens for Premedication Prior to Contrast Administration

Regimen	Dosage
1	Methylprednisolone (Medrol) 32 mg PO 12 h and 2 h before contrast injection
2	Prednisone 50 mg PO 13 h, 7 h, and 1 h before contrast injection, <i>and</i> Diphenhydramine (Benadryl) 50 mg PO 1 h before contrast injection

Source: Regimen 1 from Lasser et al¹⁰ and regimen 2 from Greenberger and Patterson,¹¹ with permission.

TABLE 302-5 Recommendations for Obtaining Serum Creatinine Level Prior to Administration of Intravascular Iodinated Contrast Agents

History of "kidney disease" as an adult, including tumor and transplant Family history of kidney failure
Insulin-dependent diabetes mellitus of 2 years' duration or greater Non-insulin-dependent diabetes mellitus of over 5 years' duration (if on diabetic medication for that period) Paraproteinemia syndromes or diseases (e.g., myeloma) Collagen vascular disease Patients taking certain medications: metformin (Glucophage), nonsteroidal anti-inflammatory drugs, or nephrotoxic antibiotics (e.g., aminoglycosides)

Source: American College of Radiology,⁴ with permission.

regarding the use of contrast agents usually arise in the context of non-vascular CT. Although highly desirable in many situations, contrast enhancement is not *absolutely* required for nonvascular CT and may not add much to the emergency department evaluation in many situations. While the potential imaging benefits versus the risks of contrast-enhanced CT always should be discussed with a radiologist on a case-by-case basis, some general guidelines are offered below (Table 302-7).

Vascular Computed Tomography

As with conventional angiography, an intravascular contrast agent is required for CT evaluation of vascular structures. In the emergency department, such an examination is done most commonly to evaluate the aorta for trauma, dissection, or aneurysm. If the clinical suspicion is high, initial evaluation with conventional aortography should be considered instead of CT because, in such cases, aortography (requiring additional doses of a contrast agent) probably would be performed whether or not the CT findings are positive.

Helical CT (a high-speed form of CT) has been used in conjunction with rapid contrast injection to perform CT pulmonary arteriography as an alternative to conventional arteriography for the detection of pulmonary embolism. A scintigraphic ventilation-perfusion scan may be performed as a screening study prior to either type of pulmonary arteriography (usually prior to conventional arteriography). If results of the ventilation-perfusion scan are normal or near normal and the a priori probability is also low, pulmonary embolism is excluded, and in most cases, further evaluation with a contrast study is unnecessary (see Chap. 56).

TABLE 302-6 American College of Radiology Suggested Guidelines for the Selective Use of Iodinated Intravascular Low-Osmolality Contrast Agents

Patients with a history of any previous adverse reaction to intravascular iodinated contrast material, with the exception of a sensation of heat, flushing, or a single episode of nausea or vomiting
Patients with asthma
Patients with a previous serious allergic reaction to materials other than contrast agents
Patients with known cardiac dysfunction, including recent or potentially imminent cardiac decompensation, severe dysrhythmias, unstable angina pectoris, recent myocardial infarction, and pulmonary hypertension
Patients with renal insufficiency (particularly those with diabetes)
Patients with generalized severe debilitation, as determined by a physician
Patients at high risk for contrast extravasation
Any other circumstances where, after due consideration, the radiologist believes there is a specific indication for the use of low-osmolality contrast material, examples of which include but are not restricted to
(1) sickle cell disease,
(2) patients at increased risk for aspiration,
(3) patients who are very anxious about the contrast procedure or who request or demand the use of low-osmolality contrast material, and
(4) patients in whom the risk factors cannot be satisfactorily established

TABLE 302-7 Indications for Iodinated Intravascular Contrast Agents

Required
Arteriography
Venography
Intravenous urography
Vascular CT (CT aortography for injury, dissection, aneurysm; CT pulmonary arteriography for embolism)
Highly desirable but <i>not absolutely</i> required
CT for trauma to abdominal or pelvic organs
CT for abdominal or pelvic abscess
CT for appendicitis or diverticulitis
CT for bowel obstruction
CT for orbital infection
Not indicated
Musculoskeletal CT for trauma (e.g., face, spine, pelvis)
Cranial CT for trauma or acute neurologic symptoms
Abdominal CT for urolithiasis

Intravenous Urography and Urolithiasis

The intravenous urography (IVU), or intravenous pyelogram, is the classic study for the evaluation of ureteral obstruction due to urolithiasis. During an IVU, contrast material excreted by the kidney visibly flows in the urinary tract up to the level of obstruction. If the obstruction is partial, its severity may be estimated. However, the obstructing calculus is not always visualized. More recently, non-contrast-enhanced helical CT has been applied to detect ureteral calculi directly in the setting of suspected obstruction.^{12,13} The size and location of the calculus, which indicate the likelihood of spontaneous passage, can be determined accurately. However, the degree of functional obstruction cannot be evaluated without contrast agent administration. Therefore, non-contrast-enhanced CT is less helpful in evaluating a patient with known calculi who presents with new symptoms.

Renal ultrasound is often requested in the evaluation of suspected acute ureteral obstruction. In such a setting, ultrasound is usually *not* helpful because (1) hydronephrosis may be absent in early acute ureteral obstruction, (2) a dilated renal collecting system may be due to causes other than acute ureteral obstruction, and (3) the detection of calculi within the kidney does not necessarily imply obstruction by a more distal calculus.

Abdominal Trauma

Intravenous contrast agents are indicated in all CT examinations performed to detect intra-abdominal injuries from blunt trauma, including liver laceration, splenic laceration, renal trauma, bowel hematoma, pancreatic fracture, ureteral injury, and bladder perforation. Intravenous contrast agents differentiate normal organ parenchyma from hematoma within an area of injury. In patients for whom the risk of administering intravenous contrast agents is thought to be too great, non-contrast-enhanced CT is probably still of benefit, but small to moderate intra-abdominal injuries may be missed, especially if there is no associated intraperitoneal fluid from hemorrhage. Because of the importance of intravenous contrast, some institutions proceed with contrast agent injection (using a low-osmolality agent) in all patients undergoing emergent abdominal CT regardless of past medical history. With such a policy, it is felt that the imaging benefits of contrast enhancement combined with an emergency situation outweigh any possible risk of adverse reaction.

In the setting of penetrating trauma to the back or flank, an intravenous contrast agent is administered as part of the triple-contrast CT, the other two types of contrast being orally and rectally administered. Triple-contrast CT should be reserved for patients who have a wound that penetrates the muscular fascia, are clinically stable, and have no obvious signs of intraperitoneal or other internal injury.¹⁴ In such patients, intravascular contrast imaging is required to detect renal and vascular injuries, and rectal administration of contrast material is particularly important for detecting subtle colonic injury.

Acute Abdomen

Intravenous contrast enhancement is indicated for all CT examinations performed for the evaluation of acute abdomen. Acute abdominal conditions for which CT is commonly performed include appendicitis, diverticulitis, intra-abdominal abscess, and bowel obstruction. While intravenous contrast material enhances the visualization of all these conditions, its role is not as great as in CT for abdominal trauma. For example, mesenteric inflammation is detectable in the absence of intravenous contrast enhancement in the case of appendicitis or diverticulitis. Furthermore, intravenous contrast enhancement is not involved directly in detection of the complications of acute gastrointestinal inflammation, such as bowel obstruction, abscess formation, and bowel perforation. One cause of an acute abdomen, bowel ischemia, is an exception, in that intravenous contrast enhancement plays a major role in its detection, especially when strangulation is present.

The role of intravenous contrast enhancement in the detection of intra-abdominal abscess is somewhat controversial. Thorough filling and opacification of bowel loops by an oral contrast agent is arguably more important than the use of intravenous contrast agents in optimal CT evaluation for the presence of intra-abdominal abscess. As in other pathologic processes in the female pelvis, radiologic evaluation of intrapelvic abscess in a female usually should begin with transabdominal and endovaginal ultrasound rather than CT. The uterus and ovaries are almost always better visualized by endovaginal ultrasound.

For the diagnosis of appendicitis in children, ultrasound with graded compression is an accurate alternative to contrast-enhanced CT.¹⁵ The technique is rapid and requires no intravascular contrast material. Its main disadvantage is the requirement of a sonographer skilled in the specific technique of examining the appendix.

Focused helical CT of the appendix without intravenous contrast enhancement has been shown to be a cost-effective method of evaluating patients with clinically suspected appendicitis.¹⁶ This examination is performed with both oral and rectal contrast material but without intravenous contrast agents, and images of only the axial levels surrounding the appendix are obtained.¹⁷ A focused CT examination of the appendix should be considered only if the primary clinical question is the presence or absence of appendicitis. Evaluation for other intra-abdominal pathologic conditions may be limited in this type of focused CT examination.

Cranial Computed Tomography

Contrast-enhanced cranial CT is not often utilized in the emergency setting. Abnormalities detected only by contrast-enhanced cranial CT, such as meningitis, some subacute infarcts, and small metastases, rarely change the immediate diagnostic workup and treatment and are more appropriately evaluated with magnetic resonance imaging (MRI). In the case of infarction, administration of a contrast agent may exacerbate the patient's clinical condition. However, CT cranial angiography sometimes has a role in stroke diagnosis and treatment. Intravenous contrast material may obscure intracranial hemorrhage, especially in the subarachnoid space.

Skeletal Trauma

Since bone appears much denser on CT than does even intravascular contrast material, imaging of the skeletal system does not require contrast agent injection. Emergent skeletal CT is performed most often to evaluate fracture of the axial skeleton. Intravenous contrast enhancement may be necessary to detect concomitant injury of the abdominal or pelvic organs.

CT of the spine, particularly of the lumbar spine, following administration of *intrathecal* contrast material is performed occasionally for the evaluation of back pain. This procedure, CT myelography, essentially has been replaced by MRI, which provides significantly better visualization of the spinal cord, nerve roots, and intervertebral disks. CT myelography should be performed only in special cases, such as preoperative evaluation and planning.

IODINATED GASTROINTESTINAL CONTRAST AGENTS

In most nonemergent fluoroscopic studies of the gastrointestinal tract, oral or rectal barium sulfate contrast material is preferred over iodinated contrast material (e.g., Gastrografin, Gastroview, Hypaque) because barium demonstrates the mucosa in greater detail and is less susceptible to dilution. However, iodinated contrast agents are indicated in many emergent situations in which barium contrast material is contraindicated: (1) suspected or potential bowel perforation (including trauma or abscess), (2) administration before gastrointestinal surgery or endoscopy, and (3) evaluation of the position of percutaneously placed bowel catheters. Iodinated contrast agents are appropriate in these situations because they are reabsorbed rapidly from the peritoneal and interstitial spaces.⁴ If a fluoroscopic study with iodinated contrast material does not demonstrate a suspected perforation, many radiologists repeat the study using barium to look for small leaks, which are often more apparent with barium than with iodinated contrast agents.

For gastrointestinal studies involving iodinated contrast material, low-osmolality agents are indicated in the following situations: (1) oral administration in patients who are at risk for aspiration because contrast-induced pulmonary edema is less with low-osmolality agents and (2) patients with fluid or electrolyte imbalances because low-osmolality agents cause less dilution and fluid shifts into the bowel lumen.⁴

Following oral or rectal administration, a small amount of iodinated contrast agent (approximately 1-2 percent) is absorbed by the bowel and excreted into the urine.⁴ Therefore, the risk of developing an anaphylactoid contrast reaction is theoretically the same as it is for intravascular administration, and the same preprocedural evaluation and precautions apply. However, moderate or severe contrast reactions are reported only very rarely following oral or rectal administration of iodinated contrast agents. Therefore, the actual risk may be lower than that for intravascular administration. These comments are also applicable to administration of iodinated contrast material into the bladder

or male urethra for the evaluation of trauma. In such examinations, it is likely that absorption of the contrast agent is even less than in the gastrointestinal tract.

The administration of oral or rectal contrast material is important in a number of indications for abdominal CT, particularly those involving the detection of fluid collections, such as abscesses, that may be confused with a fluid-filled bowel loop. Unlike fluoroscopic studies, gastrointestinal CT studies entail no significant difference in diagnostic quality between barium and iodinated contrast agents because only very dilute gastrointestinal contrast material is required. Therefore, high-osmolality iodinated contrast agents may be used routinely for emergent CT evaluation of the gastrointestinal tract.

DIAGNOSIS AND TREATMENT OF CONTRAST REACTIONS

The great majority of adverse effects from contrast agents are mild or moderate events that are not life-threatening and require only observation, reassurance, and general supportive measures. However, vigilance must be maintained because most severe contrast reactions begin with mild to moderate symptoms and signs. The vigilance need not be prolonged because essentially all life-threatening contrast reactions occur immediately or within 15 min of injection.

From a clinical perspective, acute reactions to contrast agents can be classified in the following types: (1) nausea and/or vomiting, (2) urticaria (hives) without respiratory symptoms, (3) bronchospasm (wheezing) without cutaneous or cardiovascular manifestations, (4) isolated hypotension, (5) vagal reaction, (6) isolated laryngeal edema, and (7) generalized anaphylactoid reaction.^{2,4} Clinically, an anaphylactoid reaction is characterized by a severe or rapidly accelerating combination of one or more of the following: bronchospasm, generalized urticaria, angioedema, laryngeal spasm or edema, and hypotension with tachycardia (shock). Table 302-8 presents one

TABLE 302-8 Guidelines for the Diagnosis and Treatment of Contrast Reactions

Signs and Symptoms	Treatment	Treatment Interval	Treatment Precautions
Nausea and/or vomiting			
Transient	Supportive observation		
Severe, protracted	Prochlorperazine 5-10 mg IV or IM	Every 3 ^h	Give slowly; drowsiness
Urticaria			
Scattered, transient	Supportive observation		
Scattered, protracted	Diphenhydramine 25-50 mg PO/IV/IM	Every 2-3 h	Drowsiness, hypotension
Severe	Cimetidine 300 mg IV <i>or</i> Ranitidine 50 mg IV	Every 6-8 h	Give slowly; drowsiness
Profound, diffuse edema	See anaphylactoid reaction		
Bronchospasm (wheezing)	O ₂ 6 L/min by mask; pulse oximeter		
Isolated wheezing	Albuterol inhaler 2 puffs or nebulized treatment	Every 4-6 h	Proper inhalation technique (use of spacer)
Moderate or severe	See anaphylactoid reaction (below)		
Hypotension, isolated	O ₂ 6 L/min by mask		
Sinus tachycardia (shock)	NS 1-2 L IV bolus <i>or</i> LR 1-2 L IV bolus <i>and</i> If poorly responsive, see anaphylactoid reaction (below)	Per blood pressure and urine output	Fluid overload
Sinus bradycardia (vagal)	Atropine 0.6-1.0 mg IV <i>and</i> IV fluids as for sinus tachycardia	Every 3—5 min up to 3 mg total	Monitor pulse rate; fluid overload
Laryngeal or facial edema (stridor)	See anaphylactoid reaction (below)		
Anaphylactoid reaction			
Moderate	O ₂ 6 L/min by mask; pulse oximeter Epinephrine 1:1000 0.1-0.3 mL SC (0.1-0.3 mg)	Every 10-15 min up to 1 mL	Patients on f3-blockers, may experience hypotension due to unopposed a-adrenergic stimulation
Accelerating or severe	Epinephrine 1:10,000 1 mL IV (0.1 mg) over 5-10 min	Every 5-10 min up to 10 mL

approach to the treatment of acute contrast reactions. Contrast reactions also may have nonspecific manifestations, such as pulmonary edema, angina, seizure, or hypertensive urgency. Such reactions should be treated with standard therapies and protocols (see Chap. 34).

first four of these are life-threatening, time-sensitive conditions for which the bedside ultrasonographic examination provides rapid, easily interpreted information that is often unavailable in a timely manner by any other means. The other two applications, for suspected obstructive renal disease and acute gallbladder pathology, are ordinarily not acutely life-threatening but are so common and so amenable to ultrasonography studies that they have gained widespread acceptance as primary indications. Other potential applications (not reviewed in detail) include determination of urinary bladder postvoid residual volume, soft tissue foreign body detection, deep venous thrombosis (DVT) evaluation, soft tissue abscess evaluation, and vascular access.

FUNDAMENTALS

The ultrasonographic image is created electronically from high-frequency sound waves generated by the transducer (or probe), which also receives the reflected waves. The time required for the reflection of each structure determines its depth on the image, and the intensity of the reflection determines its shade on a black-to-white scale. A perfect reflector of ultrasound waves appears white and is referred to as *hyperechoic*. A perfect transmitter of ultrasound waves has no reflection and appears black, or *anechoic*. A great advantage of ultrasonography is that most structures, particularly those not well visualized by standard radiography, have intermediate echogenicity that is quite characteristic and allows for identification of normal and abnormal organs and tissues.

An important factor in determining the quality of the image is the frequency of the transducer employed: the lower the frequency, the greater the depth of penetration but the lower the resolution. For all the primary ED indications (except endovaginal ultrasound), a general-purpose probe of approximately 3.5 MHz is appropriate and will allow visualization even in obese patients. A 5-MHz probe can be used in thin adults or pediatric patients, providing better resolution. Some of the specialized applications, including many vascular and procedural uses (Table 303-2), require higher-frequency probes for adequate sonographic examination.

Color Doppler technology provides information on blood-flow characteristics of vascular structures by superimposing colors over the normal grayscale image. The displayed colors, which range from red to blue, indicate the direction and velocity of blood flow relative to the transducer. While this technology is helpful in identifying vascular structures, it is not necessary for any of the primary ED applications of ultrasonography.

An important limitation of ultrasonography is that even small amounts of air (e.g., in bowel loops and pneumoperitoneum) preclude effective visualization distal to the gas. Bone, too, is poorly imaged by ultrasound (compared to plain x-ray), and finding appropriate acoustic windows that avoid these problems is one of the skills required of the emergency sonologist.

PRINCIPLES OF EMERGENCY DEPARTMENT SONOGRAPHY Scott W. Melanson Michael B. Heller

Emergency ultrasonography examinations should usually be restricted to those areas that are amenable to the type of limited, goal-directed examinations described in this chapter and in textbooks on emergency ultrasonography. Any abnormality noted on a bedside examination that the examiner cannot explain should be further evaluated with formal ultrasonography or another imaging modality.

At this time, only a half-dozen ED applications are firmly established as a major contribution to daily practice (see Table 303-1). The

Suprapubic aspiration
Vascular access

Orientation

Certain arbitrary but generally accepted conventions are used for creating and displaying ultrasonographic images. The skin-transducer interface is placed at the top of the image. Each transducer has a mark of some sort, which is used for left-right orientation. The *marker always points to the left side of the screen, as viewed from in front*. When scanning in the transverse plane, the physician points the marker groove to the patient's right side, and the image is displayed as a cross section from the patient's feet (Figure 303-1). For longitudinal or sagittal views, the *marker points to the patient's head*. The image then appears with the most cephalad portion on the left (Figure 303-2).

The transmission of ultrasound waves is blocked by highly echogenic structures (e.g., gallstones), resulting in a relatively anechoic area distal to the echogenic structure. This effect is known as *acoustic shadowing*. *Acoustic enhancement* occurs distal to an anechoic, fluid-filled structure, such as the gallbladder. The area distal to the anechoic structure has increased echogenicity because of the greater number of ultrasound waves reaching this area through the anechoic structure. Examples of these phenomena are present in almost every ultrasonographic image. However, the many other technical factors that influence the creation of ultrasonographic images and artifacts are beyond the scope of this discussion. Two of the most common and useful are illustrated in Figure 303-3.

FIG. 303-1. Transverse ultrasonographic image. This is obtained by directing the marker dot on the probe toward the patient's right side. [Reproduced with permission from Heller M, Jehle D (eds): *Ultrasound in Emergency Medicine*. Philadelphia, Saunders, 1995.]

2. Longitudinal ultrasonographic image. The marker dot on the probe is directed toward the patient's head. [Reproduced with permission from Heller M, Jehle D (eds): *Ultrasound in Emergency Medicine*. Philadelphia, Saunders, 1995.]

Characteristics of the Emergency Department Ultrasonography Examination

The ED ultrasonography examination is significantly different from the formal sonography that is performed in the radiology suite. The most important distinction is that the ED examination is very focused. Five of the six examinations seek only one primary finding: a yes-or-no answer (see Table 303-1). This generally allows the examination to be performed in a single position (supine) and within only a few minutes. Also, the ED examination can be more interactive. The physician can use the patient's response and clinical findings together with the ultrasound image to aid in interpretation.

FIG. 303-3. Acoustic shadow created by solitary gallstone. Acoustic enhancement increased echogenicity distal to the gallbladder is also well documented.

The ED applications described are usually performed with relatively modest, very portable, non-Doppler units. The addition of Doppler technology, which allows for evaluation of function (flow) as well as form (anatomy), can be expected to significantly expand the utility of bedside emergency ultrasound during the next decade.

PRIMARY INDICATIONS

Primary applications are those examinations that are critically time-dependent and/or of such nature that the information gained is likely to be of major benefit to the patient and physician (see Table 303-1). These examinations each involve looking for only a few easily recognized findings. The straightforward, limited nature of these examinations allows emergency physicians to perform them with less-formal training than the imaging specialist, occasionally under severe time constraints.

Abdominal Aortic Aneurysm

Ultrasonography is as accurate as computed tomography (CT) and more accurate than angiography in measuring aneurysmal diameter.¹ Specific indications for ultrasonographic evaluation of the aorta include abdominal pain in hypotensive patients and elderly patients with unexplained back, flank, or abdominal pain.

SONOGRAPHIC CONSIDERATIONS The aorta is located in the midline of the abdomen, to the left of the inferior vena cava (IVC), just anterior to the spine and posterior to all other abdominal contents (Figure 303-4). The aorta normally tapers as it progresses distally, and any diameter greater than 3 cm is abnormal. An ultrasonographic examination that images the aorta from the diaphragm to its distal bifurcation is extremely accurate at confirming or refuting the diagnosis of abdominal aortic aneurysm (AAA). Although pressure on the transducer usually displaces intervening bowel gas, complete visualization is sometimes impossible. Such examinations are considered indeterminate.

With experience, it is generally not difficult to differentiate the aorta from the IVC (see Figure 303-4). The IVC, usually to the right of the aorta, has thinner walls and changes remarkably in size with probe pressure and the Valsalva maneuver. Both the aorta and the IVC

are pulsatile, although the gentle, undulating pulsation of the IVC can, with experience, be differentiated from the forceful, centripetal aortic pulsation.

The primary sonographic finding of AAA is an aortic diameter greater than 3 cm. When AAA is suspected, the aorta should be imaged in the transverse and sagittal planes from the diaphragm to its bifurcation at the level of the umbilicus. Transverse images measured horizontally from outside wall to outside wall are the most reliable in accurately determining true aortic size. Echogenic thrombus within the outer margins of AAAs is very common, and care must be taken to identify the outer limits of the aortic wall (Figure 303-5). While ultrasonography is very accurate in measuring AAA size, it is often impossible to determine sonographically whether the AAA has ruptured, because rupture most often occurs into the retroperitoneal space. A hypoechoic retroperitoneal hematoma may be seen but is often very difficult to identify. AAA rupture into the peritoneal space is usually fatal.

Renal Colic

Intravenous pyelogram (IVP), spiral CT, and ultrasonography are all used in evaluating patients thought to have renal colic (see Chap. 96). Bedside ultrasonography often allows a much more rapid diagnosis and disposition of ED patients than either IVP or spiral CT, and there are situations where the use of contrast material or ionizing radiation is unwise (e.g., pregnancy, renal insufficiency, and volume depletion). False-negative sonographic results occur, but the sonographic appearance of hydronephrosis in the appropriate clinical setting aids in diagnosis, and negative findings on examination should lead to an alternative diagnosis. Renal colic without hydronephrosis remains in the differential diagnosis.

SONOGRAPHIC CONSIDERATIONS A standard 3.5-MHz probe is generally used for renal scanning, but a 5-MHz transducer can be used with better resolution in thin adults and children. The right kidney is best visualized in the anterior to midaxillary line over the lower ribs, but a subcostal approach can sometimes be successful in imaging the kidneys, avoiding the distraction of rib shadows. The left kidney is more difficult to see because of overlying bowel and stomach and the

FIG. 303-4. Transverse view of a normal abdominal aorta and inferior vena cava (IVC). The vertebral body is represented by the large hypoechoic area in the far field.

FIG. 303-5. Abdominal aortic aneurysm with intraluminal thrombus.

absence of the liver, which acts as an acoustic window, but is perfectly amenable to ED visualization as well. The best initial approach to the left kidney is somewhat more dorsally, in the posterior axillary line over the lower ribs. Occasionally, a posterior thoracic approach is necessary to adequately visualize the kidneys. Deep inspiration lowers the diaphragm and may move the kidneys caudally into a more easily visualized location. To fully evaluate the kidneys for hydronephrosis, both longitudinal and transverse images should be obtained, and both kidneys should be scanned with each examination.

The kidneys are retroperitoneal organs measuring approximately 12 cm in length and 5 cm in width, and are divided into two sonographically distinct areas: the renal cortex and the renal sinus. The renal cortex occupies the periphery of the kidney and has an echogenicity similar to that of the liver or spleen. The renal sinus appears as a central echogenic stripe within the kidney and includes the collecting system as well as major vessels of the hilum (Figure 303-6). Renal medullary pyramids appear hypoechoic relative to the cortex and are triangular in shape, occurring at the junction of the cortex and the more echogenic renal sinus. When the urine produced in a kidney flows freely into the bladder, there is no appreciable urine within the renal sinus, and therefore no significant anechoic space within the hilum. Obstruction of urine outflow from a calculus results in the development of hydronephrosis, which appears as an anechoic fluid collection within the echogenic renal sinus (Figure 303-7). Hydronephrosis can be graded from mild, with minimal separation of the sinus echoes, to severe, manifested by extensive separation of the central echoes, with renal parenchymal thinning.

Renal cysts occur commonly and can be confused with hydronephrosis. Renal cysts are thin-walled, round, anechoic structures with distal acoustic enhancement that typically occur in the periphery of the kidney and lack the more echogenic border typical of the collecting system, as seen with hydronephrosis.

The urolith (calculus) causing the obstruction most often lodges at the ureterovesicular junction, the ureteropelvic junction, or the pelvic brim. While stones at the ureterovesicular junction can occasionally be seen sonographically through the bladder window, **calculi are usually not identified by sonographic examinations.** One study found that the ureteral calculi were identified by ultrasonography in only 19 percent of patients with documented stones, whereas spiral CT and IVP were able to identify 94 and 52 percent, respectively. Hydronephrosis was identified sonographically in 73 percent of the patients with

FIG. 303-7. Hydronephrosis of the right kidney with distended renal collecting system (*).

ureteral calculi.² In another study, emergency physicians performed bedside renal ultrasonography after a 500-mL bolus of NS in 108 patients suspected of having renal colic. When used in conjunction with the history and a kidney-ureter-bladder film, the emergency physicians were able to diagnose renal colic with a sensitivity of 97 percent. The specificity and accuracy were 59 and 83 percent, respectively. It is possible that the fluid loading the patients received prior to the ultrasonographic studies resulted in a number of the false-positive results that contributed to the low specificity.

Hydronephrosis occurs in more than 65 percent of pregnant women, peaking between 24 and 28 weeks of gestation. This is believed to be caused by mechanical pressure of the enlarged uterus on the ureters and is usually more pronounced in the right kidney. This condition resolves within several weeks of delivery. False-positive scan results are also seen with overly vigorous hydration or a very full bladder. Peripelvic cysts and extrarenal pelvis are two fairly common conditions that may also cause confusion.

Gallbladder Disease

Ultrasonography is generally accepted to be the modality of choice in the evaluation of biliary disease.⁴ Greater than 90 percent of biliary disease is calculous in origin, and, regardless of composition, even the smallest of gallstones are visible sonographically. Conversely, only 15 percent of gallstones are visible with standard radiographs.

SONOGRAPHIC CONSIDERATIONS The gallbladder is an ideal organ for sonographic evaluation. This cystic structure is typically filled with anechoic bile and can be imaged through the liver, an excellent acoustic window. The gallbladder can be imaged in the right upper quadrant over the lower ribs or just below the costal margin. Deep inspiration moves the gallbladder caudally, often facilitating its visualization. The gallbladder varies in size, being smallest after fatty meals and largest after fasting, but it is typically 7 to 10 cm in length and 2 to 3 cm in width. The absence of reflective surfaces within the gallbladder results in distal acoustic enhancement. With experience and high-quality equipment, it is possible to visualize the common bile duct, especially when dilated, and this finding may be of considerable clinical import.

The primary sonographic finding in biliary disease is gallstones. Gallstones appear as bright, echogenic foci within the gallbladder and

FIG. 303-6. Normal appearance of the right kidney.

move with changes in position unless impacted (Figure 303-8). A minority of gallstones float within the bile. Symptomatic gallstones may be very small in relation to the volume of the gallbladder, and a thorough search of the organ is mandatory. To ensure this, the patient should be instructed to halt inspiration when the gallbladder is well visualized. During this breath holding, the entire gallbladder should be visualized in one axis, sweeping from one side of the gallbladder to the other. This should be repeated with scanning done 90 degrees to the axis of the first scanning plane, thus obtaining both sagittal and transverse images. *Acoustic shadows* appear as anechoic lines distal to the echogenic stones. These shadows are caused by the blockage of ultrasound wave transmission distal to the stone and are helpful in identifying stones, often being more readily identified than the gallstone itself. Gallbladder polyps can mimic the appearance of gallstones, but do not change position upon moving the patient and do not create acoustic shadows.

A second extremely important sonographic finding of biliary disease is a positive sonographic Murphy sign. **The sonographic Murphy sign is considered positive when the point of maximal tenderness to transducer pressure is directly over the sonographically located gallbladder.** A positive sonographic Murphy sign in the presence of cholelithiasis is reported to have a 92 percent positive predictive value for symptomatic gallbladder disease. Gallbladder wall thickening, defined as proximal gallbladder wall thickness greater than 3 mm, occurs in 50 to 75 percent of patients with acute cholecystitis, but this finding is not specific for cholecystitis. Edematous states, as well as such conditions as liver disease, AIDS, ascites, renal disease, and the postprandial state, can also result in gallbladder wall thickening. Gallbladder sludge is nearly always abnormal in the ambulatory patient, suggesting biliary disease. Sludge is composed of calcium bilirubinate and cholesterol granules, and generally form a bile-sludge layer within the gallbladder and does not create acoustic shadows (Figure 303-9). Finally, a fluid collection around the gallbladder, or pericholecystic fluid, is evidence of marked inflammation and often of perforation. This is usually seen in patients with other clinical and sonographic evidence of cholecystitis.

In summary, the sonographic signs of biliary disease are gallstones, sonographic Murphy sign, gallbladder wall thickening, gallbladder sludge, and pericholecystic fluid. The combination of a positive sonographic Murphy sign and any of the other sonographic findings described is highly reliable in diagnosing acute gallbladder disease. In

FIG. 303-8. Multiple dependent gallstones with acoustic shadowing.

FIG. 303-9. Gallbladder sludge. The sludge is seen to layer out in the gallbladder. Multiple gallstones are also present. [Reproduced with permission from Heller M, Jehle D (eds): *Ultrasound in Emergency Medicine*. Philadelphia, Saunders, 1995.]

fact, the presence of any two of the sonographic signs in the appropriate clinical setting is highly suggestive of the disease. Completely normal examination findings, including a negative sonographic Murphy sign, are reliable in excluding symptomatic gallbladder disease.

Focused Abdominal Sonography for Trauma (FAST)

Abdominal CT scanning remains an important tool in evaluating trauma, with an accuracy of more than 90 percent in detecting presence of intra-abdominal injuries. However, CT is expensive and requires a hemodynamically stable, cooperative patient. It also involves contrast-medium administration and ionizing radiation. Diagnostic peritoneal lavage (DPL) has sensitivities greater than 90 percent for hemoperitoneum. However, up to one-third of laparotomies performed on the basis of positive DPL findings are unnecessary. As little as 20 mL of blood mixed with the standard liter of peritoneal lavage fluid will result in a positive DPL (100,000 red blood cells per cubic millimeter). In addition, this invasive procedure requires significant time and causes complications in up to 5 percent of patients.

Focused abdominal sonography for trauma (FAST) has proven to be a valuable tool in the evaluation of trauma victims. More than two dozen studies in European and North American centers have demonstrated that ED sonography has an accuracy similar to that of DPL for the detection of hemoperitoneum but has several advantages: it is more rapid (generally completed in under 5 min), requires no preparations (e.g., nasogastric tube and urinary drainage catheter), has no contraindications, and is noninvasive. While ultrasonography cannot reliably identify intraabdominal organ injuries (as can CT), it is accurate in predicting the need for laparotomy in trauma patients. Large studies have found the sensitivity of ultrasonography to be 86 percent or higher with specificities of 98 percent or higher,⁵ depending on the gold standards employed. Some studies have used the need for a therapeutic laparotomy as the gold standard, whereas others have used the presence of any intra-abdominal injury or blood on CT as the gold standard, regardless of need for laparotomy (see Chap. 259 for further discussion). Subcutaneous emphysema and marked obesity can impair the ability of ultrasonography to image the abdomen, but it is uncommon that they prevent an adequate FAST examination. Training for as little as 2 to 8 h has been sufficient for emergency physicians and surgeons to learn the FAST examination,⁶ and it has completely replaced DPL in many centers.

SONOGRAPHIC CONSIDERATIONS The primary finding in the FAST examination is anechoic fluid collections (blood) within the peritoneal cavity. Figure 303-10 shows the four standard views of the trauma ultrasonographic examination. The right upper quadrant view, the easiest of the FAST examination views to visualize, is obtained by imaging over the lower rib cage in the area of the anterior to midaxillary line with the marker dot pointed cephalad. The liver, kidney, and Morison pouch are examined (Figure 303-11). The Morison pouch is a potential space between the Gerota fascia of the kidney and the Glisson capsule of the liver, and is usually devoid of fluid. Because the Morison pouch is one of the most posterior compartments of the supine abdomen, blood tends to accumulate in this space, creating an easily identified anechoic stripe (Figure 303-12). Organ lesions, while not reliably identified by ultrasonography, may appear as anechoic areas within the organ or as echogenic foci. The left upper quadrant view examines the potential space between the spleen and the kidney, the splenorenal space (Figure 303-13). This view is obtained by placing the transducer in the mid to posterior axillary line over the lower left costal margin. Again, blood will appear as an anechoic stripe between the spleen and kidney. While not routine, placing the patient into a Trendelenburg position may increase the amount of blood in the upper abdomen, facilitating sonographic identification of blood in both the right and left upper quadrant. Both upper abdominal views are also capable of identifying hemothorax, where the anechoic fluid collection appears above the diaphragm. Studies have found ultrasound to be at least as accurate as chest x-ray in identifying hemothorax.^{7,8} The pelvis is the most dependent location within the intraperitoneal cavity in a supine patient, explaining why hemoperitoneum commonly collects in this location. The pelvic view seeks to identify intraperitoneal blood in the potential space between the rectum and uterus (pouch of Douglas) or its homologue in the male, the rectovesicular space. As with the other views, blood here appears as a fluid collection between two adjacent soft tissue structures (Figure 303-14). Unclothed intraperitoneal blood is anechoic, with sharp borders against the peritoneal confines. The pelvic view is facilitated by a full bladder, which can be produced by instilling 250 mL of NS via a urinary drainage catheter. The full bladder acts as an acoustic window, optimizing the view of the pelvic structures. As little as 250 mL of intraperitoneal

FIG. 303-11. Normal ultrasonographic image of the right upper quadrant demonstrating an absence of fluid in Morison pouch (mp).

blood should be routinely noted with ultrasound; even smaller collections can often be identified.

The last view, that of the subcostal area, examines the heart for evidence of pericardial fluid collections, which would suggest cardiac injury (Figure 303-15). Rapid ultrasonographic evaluation of the heart has resulted in faster times to diagnosis and to surgical intervention, as well as improved survival rates and neurologic outcomes in patients with penetrating cardiac injuries.⁹ It is occasionally necessary to differentiate pleural from pericardial fluid. Any fluid collection that follows the contours of the heart and is surrounded by the echogenic pericardium is pericardial fluid. There is no pleural reflection between the liver and heart; the subcostal view will therefore demonstrate pericardial, but not

FIG. 303-10. Standard four views of the FAST examination. (Reproduced with permission from Sisley AC, Rozycki GS, Ballard RB, et al: Rapid detection of traumatic effusion using surgeon-performed ultrasonography. *JTrauma* 44:291, 1998.)

pleural, fluid. Blood within the pericardial space can appear anechoic but may be partially echogenic, depending on the degree of clotting and defibrination that occurs.

First-Trimester Pregnancy Evaluation

No set of historical factors, signs, or symptoms can accurately identify patients with ectopic pregnancy, and no laboratory tests are diagnostic of this condition. Sonographically identifying an intrauterine pregnancy can markedly reduce the possibility of ectopic pregnancy because heterotopic pregnancies (concurrent intrauterine and ectopic pregnancies) occur with an incidence of less than 1:30,000 pregnan-

cies, except for infertility or in vitro fertilization patients, who must be managed in concert with their obstetrician.

When ultrasonography is used only in selected first-trimester ED patients (rather than all patients), 40 to 50 percent of the ectopic pregnancies are not identified. Approximately one-half of these ectopic pregnancies are ruptured at the time of diagnosis, which increases the risk of morbidity and mortality while decreasing the likelihood of subsequent normal pregnancy.¹⁰ Ultrasonographic evaluation of *all* first-trimester pregnant patients presenting to the ED with any abdominal or pelvic pain, vaginal bleeding, or risk factors for ectopic pregnancy has been recommended. Such an approach markedly decreases the frequency of delayed diagnoses and ectopic rupture at the time of diagnosis.¹¹ Emergency physicians have been proven capable of performing pelvic sonography in the evaluation of women at risk for ectopic pregnancy with an accuracy similar to that of obstetrics-gynecology consultants. Furthermore, when an emergency physician performed the sonography, the patients were dispositioned much more quickly than when the ultrasonogram was performed by an obstetrics-gynecology consultant (60 vs. 180 min).¹²

SONOGRAPHIC CONSIDERATIONS
detail in Chap. 103.

Cardiac Ultrasonography

Two-dimensional echocardiography has become an invaluable tool in the evaluation of cardiac anatomy and function. Echocardiography is capable of evaluating myocardial wall motion, valve function, the great vessels, and pericardial fluid collections. The examination of these structures can be technically demanding, requiring specialized transducers and specialized training. Applications of bedside ultrasonography by emergency physicians is therefore limited to critically time-dependent diagnoses that can be recognized by emergency physicians with a modicum of training and the standard ultrasonography equipment available in the ED. The evaluation of cardiac trauma, pulseless electrical activity (PEA), and pericardial tamponade are such applications. The sonographic findings of interest in such settings are pericardial fluid collections and myocardial wall activity. 303 °
PRINCIPLES OF EMERGENCY DEPARTMENT SONOGRAPHY

FIG. 303-14. Positive pelvic FAST examination findings. An anechoic fluid collection is seen distal to the large fluid-filled bladder.

The use of ultrasonography in the evaluation of potential cardiac trauma was discussed earlier in the section on the FAST examination. Both blunt and penetrating trauma can result in hemopericardium, which can be rapidly diagnosed with ultrasound (see Figure 303-15). Electromechanical dissociation is a cause of PEA that has an extremely poor prognosis. An echocardiogram demonstrating a flaccid, inactive heart in a patient with PEA suggests very little chance of survival. In contrast, a hyperdynamic heart with small right-heart dimensions suggests hypovolemia, a readily treatable condition. Cardiac tamponade can be very difficult to diagnose at the bedside without the assistance of ultrasonography. Echocardiography provides a means of rapidly determining whether a pericardial fluid collection is present, without which there can be no tamponade.

A number of windows used to sonographically evaluate the cardiac structures have been described. The *subcostal view* is the most useful to emergency physicians. This view can be obtained while other procedures are being performed with a 3.5-MHz transducer. Other views are best obtained using specialized transducer heads with small footprints (the surface area of the portion of the transducer that comes into contact with the patient) in order to image between the ribs. The subcostal view, obtained by placing the transducer in the area of the xiphoid process aiming toward the left shoulder, provides visualization of all four cardiac chambers. As always, structures that are closest to the transducer appear at the top of the image monitor; the liver, therefore, appears uppermost on the monitor, with the right atrium adjacent to it. The left atrium and ventricle appear closest to the bottom of the screen.

Other views used to evaluate cardiac structure include the left parasternal short-axis (LPSA), the left parasternal long-axis (LPLA), and the apical views. The *parasternal window* is obtained by placing the transducer between the second and fourth intercostal spaces adjacent to the sternum. In the LPLA, the ultrasound beam is directed in a plane parallel to a line drawn from the right shoulder to the left hip. This view images the aortic valve, proximal ascending aorta, and left ventricle well. The LPSA view is obtained by rotating the transducer 90 degrees, so that the beam is parallel to a line drawn from the left shoulder to the right hip. Here the left ventricle appears as a round, thick-walled chamber, and the right ventricle appears more anteriorly in a crescent shape. The LPSA view is best used to image the mitral valve, papillary muscles, and aortic valve. The *apical view* is obtained by placing the transducer over the point of maximal cardiac impulse on the precordium (the apex) with the beam directed to the right shoulder. This view allows for the assessment of chamber size and the identification of aneurysms and intracardiac masses. The emergency physician can generally obtain the information necessary for the bedside indications mentioned above by using only the subcostal view. The other views described may provide added information if the examiner has the appropriate equipment and training.

SONOGRAPHIC CONSIDERATIONS The echocardiographic evaluation of cardiac tamponade requires little training and can be rapidly performed at the bedside. The subcostal view should visualize any pericardial fluid collection large enough to result in tamponade. The pericardium is a dense, fibrous, echogenic sac that surrounds the heart. The pericardial space contains less than 50 mL of pericardial fluid under normal circumstances. Pericardial effusions appear as echo-free areas within the pericardial space. Small pericardial effusions (<100 mL) usually occupy a dependent position in the pericardial sac, while large effusions (>300 mL) are present both anteriorly and posteriorly. Whether a pericardial fluid collection affects cardiac function depends on such variables as the amount of fluid present, the rate of formation, and the underlying condition of the pericardium (diseased or not). Intrapericardial pressure rises abruptly after 80 to 200 mL of fluid has collected rapidly in the previously normal pericardial space. Early sonographic signs of increased intrapericardial pressure include right atrial and right ventricular collapse in diastole,

but these findings are not always appreciable during the ED sonographic examination.

The interpretation of an echocardiographic finding of pericardial fluid collection must incorporate the clinical status of the patient. While the absence of a pericardial fluid collection excludes the diagnosis of cardiac tamponade, the mere presence of a pericardial fluid collection in an unstable patient is not diagnostic of pericardial tamponade. When pericardiocentesis is deemed necessary, sonographic localization of the heart will assist in determining the best approach for the procedure.

The patient with PEA (i.e., electrical cardiac activity without a palpable pulse) can be suffering from a wide variety of conditions, some fatal, some easily treated. Ultrasonography greatly assists in the rapid diagnosis and treatment of such patients. The sonographic examination is straightforward. Cardiopulmonary resuscitation should be stopped briefly during the ultrasound examination. Any of the standard cardiac windows can be used, but the subcostal view has the advantages of easy imaging with standard ultrasonographic transducers and lack of interference with other procedures. Once visualized, the ventricles and valves are examined for evidence of activity. A patient in true electromechanical dissociation has no demonstrable cardiac activity. Several treatable causes of PEA can be diagnosed with a sonogram and appropriate treatment instituted. The ventricles of a hypovolemic patient contract vigorously, while the right-heart dimensions are diminished. Cardiac tamponade, another treatable cause of PEA, can also be easily diagnosed with echocardiography, as discussed above.

OTHER EMERGENCY DEPARTMENT APPLICATIONS

Formal radiology department ultrasonography studies have been helpful in a great number of conditions beyond those already discussed. Emergency physicians, given the appropriate time, training, and equipment could technically perform any of these examinations at the bedside. This section discusses some applications that have been used by emergency physicians but are not now considered primary indications.

Deep Venous Thrombosis

Compression ultrasonography has been performed by emergency physicians to evaluate ED patients suspected of having lower-extremity DVT.¹³ Such studies detect venous thrombosis based on the fact that a vein filled with thrombus is not compressible, whereas normal veins can be easily compressed. An examination of the lower extremity for DVTs, therefore, consists of sonographically identifying the common femoral vein and artery and proceeding distally to the trifurcation of the popliteal vein, imaging the veins at 3- to 5-cm intervals. The inability to compress a vein by transducer pressure is diagnostic of DVT in the portion of the vein being imaged. Echogenic thrombus is occasionally visualized within the vein, but slow-flowing blood may have a similar appearance, making this finding nonspecific. Compression ultrasonography has both a sensitivity and a specificity of approximately 95 percent in venographically proven proximal leg DVTs, but the test is not accurate for identifying calf DVTs. Because approximately 20 percent of calf DVTs propagate to the proximal leg, repeat studies of the lower extremity are recommended in patients suspected of having a DVT found to have negative findings on compression ultrasound study. (See Chap. 56 for a detailed discussion.)

Visualization of Bladder and Fluid Collections

Ultrasonography excels at identifying fluid collections, and a number of possible ED applications use this property. Unless devoid of urine, the bladder is very easy to identify by ultrasonography, and most ultrasonography machines have the capability to estimate bladder volume

based on easily performed measurements. The invasive and painful procedure of catheterizing the bladder to determine postvoid residual volume can often be obviated by ultrasonography. Furthermore, suprapubic bladder catheterizations and aspirations are easier and more likely to be successful when guided by ultrasonography. Identifying abscesses is another area where ultrasonography can be of assistance. With the use of high-frequency transducers (7.5 to 10 MHz), the presence or absence of fluid collections within subcutaneous masses can be determined. If an abscess is present, the depth of the abscess and surrounding structures (e.g., vessels) can be identified. The fluid within the abscess appears anechoic or has scattered echoes within a hypoechoic collection, representing necrotic debris. Just as ultrasonography can identify hemothoraces, it can identify even small pleural effusions and guide aspiration attempts.

Procedural Uses

In addition to the bladder aspiration, mentioned above, there are several other procedural applications for ultrasonography in the ED. While plain-film radiography or fluoroscopy is very accurate at identifying radiopaque foreign bodies, other objects, such as wood, can be very difficult to identify in a wound. Ultrasonography is capable of identifying wooden objects as small as 2.5 by 1.0 mm in soft tissue and is also capable of identifying metal, plastic, glass, and vegetable matter.^{14,15} With high-frequency probes (7.5 to 10 MHz), foreign bodies appear echogenic, often with acoustic shadowing. With a small wound that is not amenable to exploration, it is acceptable to image directly over the potential entry site with the transducer and gel.

Sonography may also be used to assist in the percutaneous placement of central venous catheters.¹⁶ Studies have found that the use of ultrasonography to guide this procedure results in a decreased failure rate and lowers the overall incidence of complications.¹⁷ Here, a 7.5-to 10-MHz probe identifies the location of the vein to be cannulated (e.g., internal jugular vein), and then the percutaneous puncture can be performed with accurate knowledge of the location of the vein. The vein is seen to compress considerably before puncture occurs.

Appendicitis

The sonographic evaluation of patients suspected of harboring acute appendicitis is mentioned here primarily as a cautionary note. The finding of a noncompressible appendix greater than 6 mm in diameter has been found to be helpful in making the diagnosis of appendicitis in the appropriate clinical setting.¹⁸ However, several aspects of this examination make it particularly unsuited for performance by emergency physicians. This examination is generally quite time-consuming, requires specialized training and experience, and can be very difficult technically. The diagnosis of appendicitis is also not as critically time dependent, as are such entities as ruptured AAA or hemoperitoneum in a trauma patient, and generally is best left in the hands of sonologists trained in this technique. Other potential uses for bedside ultrasonography in the ED can be found in standard emergency sonography texts.^{19,20}

PRINCIPLES OF EMERGENCY DEPARTMENT USE OF COMPUTED TOMOGRAPHY Stephanie B. Abbuhl

BASIC PHYSICS AND TERMINOLOGY

Computed tomography (CT) is a technique that creates cross-sectional images with the use of x-rays and computerized image reconstruction. The patient passes through a gantry that contains an x-ray tube on one side and a set of detectors on the other. The gantry rotates around the patient, obtaining information from the detectors that is then analyzed by computer and displayed as an image. The image information can be manipulated by the computer to display a greater spectrum of densities than can be displayed on conventional x-ray film.

Image Formation and CT Numbers

The various shades of gray that make up a CT image are determined by the density of a structure and the amount of x-ray energy that passes through it. This phenomenon is referred to as the *attenuation* of the x-ray. The degree of beam attenuation on a CT image is quantified and expressed in Hounsfield units (HU), which are also referred to as CT numbers. Attenuation values span a range of 4000 CT numbers, from air at -1000 HU to cortical bone at +3000 HU, and water is assigned the density of approximately 0 HU.

In conventional CT, each cross-sectional slice through a patient's body has a thickness, referred to as its *z axis*. The data are divided fur-

ther into tiny cubes of equal volume called *voxels* (volume elements). Each voxel is assigned a CT number that is determined by the degree to which the material in that voxel absorbed the x-ray beam. The two-dimensional CT image is formed by displaying the front face of each voxel, termed a *pixel* (picture element), in a composite matrix. The most common matrix size of CT scanners is 512 rows of pixels by 512 columns, or a total of 262,144 pixels¹ (Figure 304-1).

Volume Averaging

Certain factors affect the accuracy of the Hounsfield units and the accuracy of the image. The degree of linear attenuation and the resultant CT number are determined by the average density of the material within that voxel. Therefore, when a voxel is filled with several structures (or the structure of interest is smaller than the voxel), the voxel is assigned a CT number or Hounsfield unit that is subject to the *volume averaging* artifact. If the resolution of a very small structure is important, decreasing the scan thickness will improve accuracy. However, the benefits of thinner sections must be considered with the risk of a higher radiation dose to the patient with the increased number of slices. Scanning protocols are designed to balance image resolution with acceptable radiation dose.

Image Noise

Although thinner sections increase image resolution, some of the advantages are lost due to increased image *noise*, also known as *quantum mottle*. Image noise is due to an insufficient number of x-ray photons reaching the detectors, resulting in a grainy image. Image noise can be reduced by increasing the radiation dose, but a compromise between radiation exposure and image noise determines the quantitative x-ray dose.

Window and Level

Window width and *window level* are display settings that can be manipulated to optimize the appearance of the image. Selecting a window

width determines the range of CT numbers that will be represented on a specific image. The computer assigns different shades of gray to CT numbers that fall within the selected range. Computed tomography numbers that are above the chosen range will appear white, and numbers below the chosen range will appear black. By increasing the window width, a greater range of CT numbers is assigned to a shade of gray. This technique is used when it is desirable to view a variety of tissues that vary greatly in density (e.g., lung). The disadvantage to wider windows (400 to 2000 HU) is that subtle differences in density will not be visualized.¹

When the goal is to visualize a section of anatomy with minor discrepancies in tissue density, narrow window width is chosen (50 to 400 HU). A good example of the use of narrow window width is in the brain, where there is little difference in tissue densities; nevertheless, with the higher contrast achieved with a narrow window, white and gray matter can be differentiated.

Window level determines the CT number that will be the center of the gray scale. The window level is generally set at the same value as the average attenuation number of the tissue of interest.

The image from a single data set can be displayed at different window widths and levels to highlight various tissues of interest. For example, in chest CT, settings that optimize the image of the soft tissue mediastinal structures use a moderate window width (e.g., 350 HU) centered at a level just above water (e.g., +30 HU). However, this setting does not allow visualization of the details of the lungs (Figure 304-2A). In contrast, lung settings use a wide window (e.g., 1400 HU) and a low level (e.g., -600 HU) to center the gray scale so it includes air densities (see Figure 304-2B). To optimize the image of a bony structure, a wide window (e.g., 1500 HU) and a higher level (e.g., +305 HU) would be used to center the gray scale toward higher-density tissues (Figure 304-3).

SCANNER GENERATION

The terms *first-generation through fourth-generation scanners* are used to represent the developments in technology that relate the configuration of the x-ray tube to the detectors. The first-generation scanners, which are no longer in use, had a thin x-ray beam pass linearly over the patient in a 180-degree arc, followed by a single detector on the opposite side.² Scanning time was very lengthy. Second-generation scanners used multiple detectors and a fan-shaped x-ray beam that continued to pass linearly across the patient before rotating. Scan times improved but were still very long.

Third-generation scanners represented a significant advance in technology, and scan times were greatly reduced. This design incorporates a fan-shaped beam and a detector array, and both move in a circle within the gantry. With the use of a rotating detector, all the readings that make up a view can be recorded at the same time.¹

Fourth-generation scanners have a detector array that is fixed and positioned in a complete circle within the gantry. The x-ray tube produces a fan-shaped beam that rotates around the patient. Scan times are theoretically shorter than with third-generation scanners, but as of this writing, few fourth-generation scanners have been installed.²

SPIRAL COMPUTED TOMOGRAPHY

The greatest technologic advance came with the advent of spiral or helical scanning. Rather than scanning with the traditional axial method, where the slices lie parallel to one another, spiral scanning obtains data continually in a spiral fashion. There is a continually rotating x-ray gantry and continuous table movement. This continual movement was achieved by a critical advance in hardware technology with the introduction of slip-ring interfaces in gantry construction, allowing for continuous rotation of the source detector assembly.³ With conventional CT, a patient is required to hold the breath for each additional slice. When a patient breathes to different depths with each

FIG. 304-1. The gray disc represents a cross-sectional slice corresponding to the patient. To create an image, the patient's data are segmented. A pixel is a two-dimensional square. A voxel incorporates the thickness of the slice and is a three-dimensional cube. (Reproduced from Romans: *Introduction to Computed Tomography*, p. 4, 25, 29. Philadelphia, Lippincott, Williams & Wilkins, 1995).

FIG. 304-2. Computed tomography windows. A. Mediastinal window. The mediastinal anatomy is well shown; no lung detail can be seen. A = aorta; P = pulmonary artery; S = superior vena cava. B. Lung window. The vascular anatomy of the lungs is now well seen. (Reprinted by permission from Lisle D: *Imaging for Students*, p 82. London, Hodder Arnold, 1997).

slice, lesions as large as 1 cm can be missed as a result of slice *misregistration* (Figure 304-4). In a typical spiral scanner, 60 images can be acquired in 1 min or less. There is less breath holding (often just once) and thus less likelihood of slice misregistration.

Because spiral scans are acquired at a slight slant, computer software must adjust for the angle by averaging the data. This statistical method of processing the data is referred to as *interpolation* (linear and nonlinear). The evolution of mathematical software processes enabling missing data to be estimated in helical data sets also has been critical to the advancement and success of spiral CT.³ There is, however, a small decrease in resolution inherent to interpolation (Figure 304-5).

The term *pitch* refers to the relation of table speed to slice thickness. If pitch is set at 1:1, the table will move at a speed that allows the gantry to rotate once for every slice thickness chosen. For example, with slice thickness at 5 mm, the table moves at a speed that allows the gantry to rotate once every 5 mm of table travel. If the pitch is adjusted to 2:1 and the slice thickness is maintained at 5 mm, the tube rotates only once for every 10 mm of table motion. Pitch sometimes is adjusted toward 2:1, which, in essence, "stretches the spring" and fewer data are acquired.¹ Pitch usually is set at close to 1:1 but may be increased when it is important to cover a long anatomic area in a very short time, as with CT angiography.

Spiral CT scanning has optimized the delivery of IV contrast. The rapid speed of the scanning technique allows for much finer control over which phase of IV contrast enhancement is imaged and allows for the possibility of obtaining more information from a single bolus of contrast. For example, in the abdomen, images can be obtained during the hepatic arterial, portal venous, and equilibrium phases. Delayed images are also easily and rapidly obtained when enhancement characteristics of certain lesions need to be visualized or when the urinary excretory phase must be imaged. This capability is used widely in trauma, where major organ lacerations and active bleeding sites are best visualized during early phases of contrast enhancement, whereas bladder perforation may be better imaged on delayed contrast imaging.

The major advantages of helical scanning over conventional scanning are:

Volumetric data acquisition is obtained rapidly. Less contrast material is needed because of increased scanning speed. Images can be retrospectively reconstructed at any desired interval or thickness or may be overlapping without rescanning the patient.

Respiratory, cardiac, and other motion artifacts are reduced. The continuous nature of the data allows high-quality three-dimensional and multiplanar reconstruction.

Although the advantages of spiral CT predominate, there are some disadvantages:

If pitch (relation of table speed to slice thickness) is increased from 1:1 toward 2:1, image resolution can be lost.

When scanning very large patients, there will be increased image noise if the milliamperage setting cannot be maintained. Scanners differ with regard to weight limitations, although the average maximum patient weight is approximately 140 to 160 kg (300 to 350 lb).

Some image resolution may be lost due to the interpolation required to process spiral data.

Contrast material injection must be timed precisely, although this problem has been minimized with the use of established contrast protocols and power injectors.

Children and uncooperative adults need sedation and thus close monitoring.

Spiral CT scanners continue to have the capability of acquiring axial images. For example, at some institutions, CT protocols for cervical spine trauma use a spiral CT scanner to obtain axial images, because of the potential improvement in image resolution in this anatomic area. An important issue raised by the advent of spiral CT is what constitutes an appropriate examination archive. At this point, because of the enormous space required to store all the information, most CT scanners delete the raw data soon after the scan is acquired. Thus, it is important to select the reconstruction interval quickly and appropriately so that the opportunity is not lost to request additional reformatted images before the raw data are deleted.

Multidetector Spiral CT

Within the past decade, there have been major advances in spiral CT technology, including the incorporation of multidetector arrays to replace the single-slice systems. Multidetector CT (MDCT) scanners provide up to 4 to 16 simultaneous channels of data acquisition, allowing imaging over long distances using thin collimation, faster than with standard spiral CT. When combined with quicker gantry rotation times (0.5 s for one 360-degree rotation), a MDCT can scan an entire

B

FIG. 304-3. Computed tomography at window and level settings different from those shown in Figure 304-2. A posterior wall fracture of the left acetabulum is shown at settings for bone (A) and for soft tissue (B). The wider window and higher level of the bone settings enable better visualization of bone detail but make all soft tissue structures nearly the same shade of gray. Soft tissue settings allow examination for hemarthrosis and adjacent soft tissue hematoma. (Courtesy of Jeremy I Hollerman, MD).

abdomen and pelvis, using 1-mm collimation, in a single breath hold of 30 to 35 s.⁴

The faster data acquisition capability of MDCT has enabled even more specialized contrast examinations, including early and late arterial phases, parenchymal phase, and delayed phase, after a bolus administration of IV contrast. The use of MDCT for imaging the thoracic aorta, for example, typically will result in superior image quality, because the scans are usually acquired with a narrower section thickness and in a shorter period. In addition, the shorter scan time results in a substantial reduction in the amount of contrast required.⁵ Multidetector CT technology and the sophisticated software for data visualization and analysis also have led to multiplanar and three-dimensional reconstruction capability, surface and volume renderings, and perspective internal renderings (virtual endoscopy).⁶

Multidetector CT scans do not fundamentally alter the radiation dose when compared with spiral CT. However, when thinner slices are acquired, the radiation dose must be increased to maintain a favorable signal-to-noise ratio.⁶ Radiation burden always should be considered when deliberating the risks and benefits of the various imaging modalities.

Electron Beam Tomography

Electron beam tomography, or ultrafast CT, is available in only a few centers in the country and relies on a beam of electrons hitting a large stationary anode with the patient situated at the center. The images have a high resolution and the data acquisition time is extremely short (e.g., 50 to 100 ms).⁶ Ultrafast CT has been used most for cardiovascular applications, including the demonstration of coronary artery calcification and stenosis,⁷ pericardial problems, and aortic dissection.⁶

GENERAL USES AND LIMITATIONS

As CT technology has advanced, the role of CT in the ED has increased enormously. A CT scanner is in, or adjacent to, many EDs today, in recognition of its fundamental utility and to minimize patient transport. The only real disadvantages of CT are its relatively high cost and the use of ionizing radiation. However, in some situations, the radiation dose received is less than that for plain films, as may be the case for lumbar sacral spine plain film versus CT. Standard charges for conventional and spiral CT are the same. Head CT continues to be the primary imaging study for screening ED patients acutely, in particular for detection of acute hemorrhage, trauma, and cerebrovascular accident. Magnetic resonance imaging, however, may have a role, when posterior fossa pathology or subtle parenchymal abnormalities are suspected. In general, CT is the imaging study of choice for the examination of the retroperitoneum and for many disorders of the abdomen and pelvis. At many

FIG. 304-4. Slice misregistration caused by a patient's breathing. Each consecutive slice was 10 mm or more inferior, but the second image appears as the most superior. Lesions as large as 1 cm can be missed as a result of slice misregistration. (Reproduced from Romans: *Introduction to Computed Tomography*, p. 4, 25, 29. Philadelphia, Lippincott, Williams & Wilkins, 1995).

FIG. 304-5. Spiral scans are acquired at a slight slant, because of the continuous motion of the x-ray tube and table. By interpolating the data, the computer creates an image that is not slanted. This process increases the effective slice thickness and causes some loss of image resolution. The more pronounced the slant, the more interpolation is required. The slant is affected by selected slice thickness and pitch. (Reproduced from Romans: *Introduction to Computed Tomography*, p. 4, 25, 29. Philadelphia, Lippincott, Williams & Wilkins, 1995).

institutions, spiral CT has become the primary imaging modality for detection of acute appendicitis⁸ and ureteral calculi. It is also the modality of choice for many disorders of the mediastinum and lungs. Fractures and other bone pathologies are often best visualized with CT, and it is excellent for detecting cervical spine, pelvic, and facial bone fractures.

Only a few areas of the body are poorly imaged with CT. The pituitary fossa and the posterior intracranial fossa can be difficult to visualize, because the adjacent bony structures cause significant streak artifact, particularly with older scanners. Magnetic resonance imaging is the preferred study in these anatomic areas. Computed tomography is not sensitive in differentiating spinal cord or nerve roots from cerebrospinal fluid unless contrast has been injected into the cerebrospinal fluid space (CT myelogram). Magnetic resonance imaging is the imaging study of choice to evaluate the spinal cord.

Although spiral scanning data can be reformatted into high-quality sagittal and coronal plane images, conventional CT usually is limited to the axial (transverse) plane. There are anatomic areas (such as the head and ankles) that can be positioned in the gantry of conventional CT scanners to obtain direct coronal images.

The role of CT in the evaluation of all potential ED presentations is beyond the scope of this chapter. The reader is referred to specific chapters of chief complaints or diagnoses for a discussion of the potential value of CT for each topic.

THE USE OF CONTRAST

Contrast materials for CT examinations can be administered via oral, rectal, intravenous, intraarterial, intraarticular, or intrathecal routes, and usage changes according to the examination desired. In general, contrast usage in the ED is limited to the oral and/or IV routes.

Oral Contrast

Oral contrast agents are used for most CT examinations of the abdomen and pelvis to ensure adequate contrast opacification and dis-

tention of the bowel, which are necessary to enhance the appearance of the bowel wall to detect hematoma, edema, mass, or laceration. Enhancement usually is achieved with *positive* contrast agents, such as iodine-based and barium-based agents. At times, however, *negative* contrast is optimal in the upper gastrointestinal tract and is achieved by using an oral water preparation. Water is helpful, for example, when the indication for abdominal CT is to evaluate the pancreas in a patient with jaundice. Occasionally, distention of the upper gastrointestinal tract also can be achieved by the additional administration of effervescent granules that cause gas formation within the bowel lumen. It is important that the radiologist and/or technician know the purpose of the study so that the correct oral preparation is ordered. It is much more common to administer water-soluble iodinated oral agents to ED and trauma patients to avoid complications from extravasation of barium agents.

The iodine-based oral contrast used for CT is very dilute compared with the full-strength iodine-based contrast used for conventional radiography (upper gastrointestinal and barium enema series). Full-strength solutions may cause artifacts on CT, because of their high density. Whereas full-strength iodine-based contrast aspiration may cause life-threatening pneumonitis, the dilute contrast used for CT poses much less risk. Nonetheless, use of this agent should be avoided, or it should be used with caution in patients at risk for aspiration. If oral contrast is necessary in a patient with a known iodine allergy and a known gastrointestinal tract disorder, a dilute barium sulfate suspension should be administered instead.

Administering oral contrast takes approximately 2 h in a patient with a normal transit time if the entire bowel needs to be opacified. For example, intraluminal contrast must be present in the right colon to evaluate a patient adequately for possible appendicitis. For evaluating certain upper abdominal conditions, an additional 200 mL of oral contrast should be given just before scanning, to opacify the stomach and proximal small bowel. Not infrequently, an ED patient has nausea and vomiting, and a nasogastric tube and antiemetics are required to facilitate the oral contrast administration. Some contrast protocols use recently administered contrast. The terms *double contrast* and *triple contrast* usually refer to the possible combined routes (oral, rectal, or vascular), but in some situations may refer to the concentration.

Intravenous Contrast

Intravenous contrast is used frequently for emergency CT studies, because it creates a more detailed image of many structures, in particular the abdominal, pelvic, and retroperitoneal organs. The contrast material causes beam attenuation that is directly related to the iodine concentration achieved by the vascular supply to that tissue. Abnormal tissue, whether due to a malignant, inflammatory, or infectious etiology, has contrast enhancement patterns different from normal tissue and may appear avascular, hypovascular, isodense, or hypervascular. Images can be obtained at various phases after contrast administration. Depending on the diagnosis in question, the study should be tailored to acquire data at the appropriate time (Figure 304-6).

In certain circumstances, it may be necessary to perform noncontrast and contrast CT scans. Scans to evaluate patients with potential urinary tract calculi must be performed initially without IV contrast, because the presence of contrast can easily obscure any renal stones present. In addition, an obstructing ureteral calculus is usually detected on an unenhanced CT study. However, IV contrast can be useful to determine the exact level of ureteral obstruction or to determine whether a pelvic calcification lies within the ureter. It also may provide information on the function of the kidneys and other potential diagnoses. In general, the best way to optimize any study is to discuss the purpose of the CT adequately with the radiologist and/or technician performing the study.

B

FIG. 304-6. Scans of a 16-year-old boy after a skiing accident. A. Scan before intravenous (IV) contrast bolus enhancement is displayed at standard abdominal soft tissue settings; the intrahepatic clot and laceration are difficult to see. B. After bolus IV contrast administration during dynamic scanning, a scan at the same level as shown in A shows the hepatic laceration well. The laceration extends immediately behind but apparently does not involve the right hepatic vein. The clot appeared hyperdense relative to the liver before IV contrast administration and appears hypodense relative to the enhanced liver after bolus contrast. The clot did not change density. The liver increased in density, because of the circulating IV contrast. C. The upper abdominal component of this patient's relatively small hemoperitoneum is seen as blood in Morison's pouch (the right posterior subhepatic space between the liver and kidney). (Courtesy of Jeremy I Hollerman, MD).

MAGNETIC RESONANCE IMAGING: PRINCIPLES AND SOME APPLICATIONS Irwin D. Weisman

The significant advances in imaging technology of recent years have dramatically expedited diagnosis and improved outcomes in emergency department patients, and magnetic resonance imaging (MRI) has been at the forefront. In just a short time, it has become a major adjunct for neurologic and musculoskeletal evaluation.

Magnetic resonance imaging has the following major advantages:

1. Like ultrasound, it does not use ionizing radiation and no short-term or long-term side effects have been demonstrated. This is in contrast to the high-energy ionizing radiation of computed tomography (CT) and other x-ray methods, which produce small but finite biologic damage that may have long-term carcinogenic implications. Because of this consideration, where applicable, MRI should be preferred over CT and tomography in the pediatric and childbearing female populations.

2. It produces variable-thickness, two-dimensional slices in any orientation through the body part of interest, thus optimizing visualization of tissues and their interfaces. With few exceptions, CT is restricted to a scan plane¹ that is transverse to the long axis of the body.
3. Because of the different physical principles underlying magnetic resonance (as opposed to x-rays), it provides better contrast resolution and tissue discrimination in many areas compared with x-rays or ultrasound. For example, spinal cord, bone marrow, muscles, and tendons are better visualized with MRI than with CT. As a result, MRI is replacing invasive methods such as myelography, arthrography, and increasingly, catheter angiography.

MRI is a specific application of nuclear magnetic resonance to medical imaging.^{1,2} Nuclear magnetic resonance was discovered simultaneously in 1946 by Bloch and colleagues at Stanford University³ and by Purcell and colleagues at Harvard University.⁴ Bloch and Purcell shared the Nobel Prize in 1952 for their outstanding contribution to the physical sciences.

PHYSICAL BASIS

The nuclei of hydrogen in water and fat molecules behave like small spinning bar magnets. When placed in a strong uniform magnetic field (greater than 0.01 tesla or 100 gauss), they execute a circular motion, or precession, weakly aligning to form a net nuclear polarization nearly parallel to the external magnetic field. If a short pulse of radio frequency (rf) energy (radio wave) is applied that is precisely tuned to the precession frequency of the water and fat proton nuclear magnets, the nuclei absorb a small amount of energy, change their alignment, and then gradually return to their previous equilibrium positions. In responding to the radio wave, the net nuclear magnetization generates a small voltage: the nuclear magnetic resonance signal. This can be detected and recorded electronically.

Two parameters, T1 and T2, also known as longitudinal and transverse relaxation times respectively, govern the behavior of the electronic signal detected. The relaxation times are a function of the immediate environment of the resonating protons and vary in the different biologic tissues. For example, free water exhibits long T1 and T2 values and fat exhibits short T1 and relatively short T2 values. Image generation requires a large number of repetitions of the sequence that produces the nuclear resonance signal. The time between repetitions is called TR. For technical reasons, a two-pulse sequence is used to generate a particular type of signal called a spin echo. The spacing between pulses is labeled TE/2, and an echo occurs at a time TE. There are important relationships between the intensity of the nuclear magnetic resonance echo and TR, T1, TE, and T2. Based on the effects of the different relaxation times (T1 and T2), two types of imaging are carried out. Short repetition times (TR) between successive cycles of rf excitation pulses and short echo times (TE) produce stronger signals from tissues with relatively short T1 times, such as fat, especially bone marrow. Hence, weighting favoring short T1 results from pulse sequences using short TR and short TE. On the other hand, longer TRs eliminate much of the T1 signal difference between fat and water, so that further manipulation of the rf pulse spacing (longer TE) will enhance signals from tissues with long T2 times, such as edema fluid. Long TR, TE pulse sequences preferentially weight long T2 tissues. Thus, the two basic methods of MRI scanning are labeled T1-weighted and T2-weighted imaging.

To construct an image from the tissue-specific signals of an object (for example, a patient), it is necessary to apply small, spatially inhomogeneous, three-dimensional magnetic fields called gradients. They modify the signal decay of the nuclear magnetization and spatially tag the hydrogen nuclear magnets in the object for mapping the image. The actual reconstruction of an image is complex, just as in CT scanning, and requires a relatively fast computer with a large memory.

The ultimate result is a two-dimensional, medically diagnostic, cross-sectional body image that is displayed on a video monitor and recorded on film or digitally stored on a hard disk or magnetic tape as a permanent record. In most gray-scale imaging formats, the strongest signal corresponds to maximum brightness on the black-and-white monitor. Therefore, in heavily T2-weighted images, water appears bright, whereas fat appears intermediate gray. On the other hand, on T1-weighted images, fat appears bright and water appears dark (Figure 305-1). Another commonly used basic imaging mode is proton density weighting, crudely described as a balance between T1 and T2 weighting. Table 305-1 lists the expected signal intensities for several biologic tissues in these three cases. Many newer and more sophisticated imaging pulse sequences have evolved from this imaging framework, such as chemical fat suppression, inversion recovery, short T1 inversion recovery (STIR), fluid attenuation inversion recovery (FLAIR), gradient echo recall, magnetization transfer, rapid acquisition with relaxation enhancement (RARE), echo planar, and diffusion gradient. For a more complete discussion of the technical aspects and clinical applications of MRI, readers are referred to more specialized texts.^{3,6}

The physical basis of image formation using MRI is quite different from CT, which is based on differential x-ray absorption coefficients. Even though both are tomographic imaging techniques, the meaning of bright and dark signals in MRI is relative to the pulse sequence eliciting them and has very little resemblance to the contrast in CT.

The core of an MRI system is the large magnet needed to generate the strong, constant, and uniform magnetic field, as well as the magnetic gradients. The magnet is composed of coils of a special superconducting wire that loses all resistance to electrical current when submerged in liquid helium. At this temperature, -269°C (-450°F), the coils can handle the relatively large currents of electricity required to produce the magnetic field. A specially designed, thermally insulated container encloses the magnet coils and the liquid helium. The liquid slowly boils away and must be replaced at regular intervals. The magnet is housed in a special room containing steel sheets and copper screen, which shield the system against interference by steel and radio waves on the outside and vice versa. The other components of the system, consisting of a radio transmitter, a sophisticated rf receiver, and a high-speed large-memory computer, are located near the operator's console just outside the room.

SAFETY

The only hazard associated with diagnostic x-rays is the effect on biological tissue of ionizing radiation, but this is well known and documented. Although no definite long-term harmful effects have been attributed to MRI, there are known potential safety concerns that need to be addressed (Table 305-2). In a few cases, the large static magnetic field could be a health hazard to the patient,^{7,9} necessitating the use of alternative diagnostic methods such as ultrasound or CT. Internal cardiac pacemakers may be converted to an abnormal asynchronous mode by the magnetic field. Certain types of steel cerebral aneurysm clips (ferromagnetic as opposed to nonmagnetic stainless steel) may be subject to strong forces, with the potential of harming the brain. Small steel slivers embedded in the eye (occasionally seen in asymptomatic sheet metal workers or welders) could injure the retina and cause blindness. Life-support equipment containing magnetic steel will be strongly attracted into the magnetic field, threatening both the patient and the system. Injuries from unsecured apparatus have been known to occur.

Cochlear implants may be damaged or cause unacceptable injury due to eddy current heating effects. Patients in any of the aforementioned categories cannot be scanned with MRI. There are other devices, such as implantable cardiac defibrillators, neurostimulators, and bone growth stimulators that may malfunction in the presence of high magnetic fields. Certain prosthetic heart valves contain nearly magnetic stainless steel components that are subject to strong forces when placed in powerful magnetic fields. However, it has been pointed out

FIG. 305-1. Examples of T1-weighted and T2-weighted magnetic resonance images. A. T1-weighted axial image: note that the cerebrospinal fluid in the lateral ventricles of the brain (*white arrows*), which is essentially water with a long T1, appears dark, whereas the subcutaneous fat around the calvarium with a short T1 appears bright (*white arrowhead*). B. T2-weighted axial image of the same brain as in A. Note that the CSF, which has a long T2, now appears bright, whereas the surrounding subcutaneous fat with its shorter T2 is intermediate in brightness.

that the stress placed on the valve by the heart itself exceeds that generated by even high-field magnets, and hence this is only a relative contraindication to MRI scanning.

The pulsed radio waves and time-varying magnetic field gradients induce electric currents, which are a source of heat energy that is deposited within the body. Software programs built into the computers restrict the frequency of pulsing so that the maximum allowable power deposition averaged over the whole patient is never exceeded. Occasionally, superficial burns have been reported when a patient's skin has come into direct contact with uninsulated wire leads near the transmitter coils, but taking proper precautions prevent this from happening.

The complete examination takes from 30 to 60 min, is painless, and is well tolerated by most patients. It does require suspension of all motion (except for breathing) for periods ranging from a few seconds to 15 min at a time, depending on the particular pulse sequence. Some patients are claustrophobic and have difficulty with the examination. Most problems of this nature are satisfactorily treated with minor tranquilizers administered orally. Some of these patients may need to be

referred to open architecture, less confining low-field MR scanners with possible reduced diagnostic sensitivity. Patients heavier than 140 kg (300 lb) may be over the weight limit for most high field scanners (>0.5 T). However, they can usually be accommodated in the low-field magnets because of the less restrictive environment. Infants, younger pediatric patients, and agitated adults need to be sedated as in CT, because any motion degrades the MRI scan. Development of MR-compatible pulsed oximeters has made sedation more routine.

Some minor precautions are necessary. Magnetically encoded plastic cards, such as credit, cash, and parking cards, may be damaged when they come within a certain distance of the magnetic field. Some watches with steel parts and hearing aids (and their batteries) are vulnerable to damage. Any ferromagnetic steel objects are potentially lethal missiles if carried into the magnet room. Patients need to leave such objects outside the scanning room. Deaths and at least one case of blindness have been reported in connection with the above-mentioned hazards.⁷ Another minor hazard is the loud noise produced by the gradient coils, which has the potential to produce long-tear

TABLE 305-1 Tissue Appearance in Magnetic Resonance Imaging

Weight	TR (ms)	TE (ms)	Fat	Water	Muscle	Ligament	Bone Cortex
T1	300-600	20-30	Bright	Dark	Intermediate	Dark	Dark
Proton density	2000-6000	10-40	Intermediate	Intermediate	Intermediate	Dark	Dark
T2	2000-6000	60-120	Intermediate	Bright	Intermediate	Dark	Dark

Note: Above values for TR and TE are relative and not absolute.

TABLE 305-2 Emergency Department Patients in the Magnetic Resonance Environment

Device/Equipment	Action/Substitute
Pulse monitoring	MR-compatible pulse monitor*
Blood oxygenation	MR-compatible blood oxygen monitor*
Blood pressure	MR-compatible blood pressure device*
Oxygen therapy	Wall O ₂ in the MR suite, or aluminum MR oxygen cylinders
Medication infusion pumps	Multiple high-pressure extension tubings, to place the infusion pump outside of the high-gauss magnetic field
Anesthesia pump	MR-compatible anesthesia pump*
Swan-Ganz catheters	Not MR compatible
External fixation devices, halo devices	Some compatible; consult with MR personnel and provide type/manufacturer
Electrocardiogram monitoring	Diagnostic waveforms are not available in the MR environment; low-level capability for identifying prominent arrhythmias is available

*Available from MR department personnel.

Abbreviation: MR = magnetic resonance.

hearing loss. This can be addressed by offering the patients earplugs or other noise-attenuating devices.

In summary, patients with implanted cardiac pacemakers, defibrillators, ferromagnetic cerebral aneurysm clips, or cochlear electronic devices, should not have MRI examinations. It is difficult to compose a complete list of preclusion to MRI as the arena of MR safety continues to expand and become more complex with proliferation of more sophisticated implant and monitoring devices. These issues have been addressed recently with further updates.^{7,9} The list is constantly being

modified (extended or contracted) as technology changes and as clinicians gain more experience with implantable systems.^{7,9}

APPLICATIONS

MRI has been widely applied to the brain and spinal cord,¹⁰ where it provides images that are superior in diagnostic quality to those obtained with CT. Furthermore, this information can be obtained with less risk to patients because CT myelography requires intrathecal contrast agents for a specific diagnosis. Although special intravenous contrast agents are frequently required to improve the sensitivity of MRI, they have been associated with much less toxicity (including decreased incidence of renal failure) and reactions as compared with the intravenous CT contrast agents. However, some precautions are advised, especially in cases of established asthma and early pregnancy.^{7,9} Recent developments in echo planar and diffusion imaging make it possible to diagnose cytotoxic cerebral edema almost immediately after an acute ischemic event, even earlier than with CT or conventional MRI. This has obvious implications with the advent of more aggressive fibrinolytic therapy aimed at early salvage of brain tissue after strokes. Figure 305-2 demonstrates an acute pontine infarct shown by MRI that takes advantage of diffusion imaging. CT is notoriously insensitive in this area of the brain.

Except in the cases of acute intracerebral hemorrhage, skull fracture, and some calcified brain lesions, MRI may completely replace CT of the head. The exact role of MRI versus CT in trauma and degenerative disease of the spine is still evolving.

CT visualizes fracture fragment relationships and bone detail more optimally, but MRI visualizes the soft tissues with better resolution. Because of its sensitivity to marrow and trabecular bone changes, MRI is more accurate in detecting acute fractures, especially in the hips and knees where CT and plain film findings may sometimes be equivocal.

MRI has been useful in examining the chest and abdomen (especially the chest wall, mediastinum, liver, spleen, adrenals, pulmonary arteries, and aorta), but has played a lesser role compared with CT because of respiratory motion and heart pulsation artifacts that degrade anatomic delineation of critical structures. They can be compensated for to some degree

A

B

FIG. 305-2. Acute pontine infarct. A. FLAIR (fluid attenuated inversion recovery) axial image of the brainstem demonstrates a questionable area of increased signal in the left pons (white arrowhead). B. Diffusion axial image through the same region as the image in A delineates a hyperintense signal (white arrowhead) indicating a focus of restricted diffusion most consistent with an acute pontine infarct.

with electrocardiograph and respiratory gating and associated electronic manipulation, but the methods are cumbersome and difficult to implement with an acutely ill patient. A recent innovation is the introduction of breath-hold MR cholangiography for the noninvasive evaluation of the biliary and pancreatic ducts.¹¹ It has had limited application to cooperative patients with biliary or pancreatic disease not amenable to ultrasound, CT, or other conventional methods. There has also been progress in cardiac MRI,^{5,12} but introduction of these methods into the emergency practice are currently limited due to cost, availability, and reproducibility.

MRI has a major role in other areas of the musculoskeletal system,⁶ especially the knee, shoulder, hip, and temporomandibular joints. Although MRI is not indicated for most acute fractures, it may be preferred in the diagnosis of rotator cuff tear of the shoulder, internal derangement of the knee (meniscus, tendon, and ligament tears), tendon or soft tissue injury to any of the small joints, soft tissue injury in the spine, and posttraumatic avascular necrosis of any bone. In addition, carpal tunnel syndrome has been evaluated using MRI. Figure 305-3 demonstrates a meniscus tear in the knee. Before MRI, arthrography,

FIG. 305-3. Bucket-handle meniscal tear. A. Normal medial and lateral menisci and B. normal posterior cruciate ligament in the intercondylar notch as demonstrated on magnetic resonance proton-density (partial T2 weighting) coronal and sagittal images. The menisci are the dark triangular structures in A marked with arrowheads. The normal posterior cruciate ligament is shown as a small black arrow in A and B. C. Proton-density coronal scan showing a large complex tear involving the posterior horn of the medial meniscus (black arrowhead) with most of the fragment displaced into the intercondylar notch (the "bucket-handle," long black arrow) inferior to the normal posterior cruciate ligament. D. Sagittal proton-density image showing the meniscal fragment (long black arrow) displaced under the posterior cruciate ligament (short black arrow) and having a similar appearance ("double PCL sign"). Not shown is the "bucket" part of the meniscus, which stays attached to the medial tibia.

FIG. 305-4. Cervical spinal cord compression. T1-weighted sagittal magnetic resonance imaging demonstrates moderate spinal cord compression by an acute traumatically herniated disk at the C2-3 level (*arrow*). The patient was in a motor vehicle accident and also suffered associated bilateral C2 pedicle fractures.

FIG. 305-5. Thoracic spinal cord compression due to osteomyelitis/discitis and epidural abscess. T1-weighted fat suppressed and intravenous gadolinium contrast-enhanced sagittal image of the thoracic spine demonstrates abnormal signal in the vertebral bodies of T10 and T11 with associated disk space and end plate destruction (*white arrows*) consistent with discitis and osteomyelitis. There is an epidural abscess with an enhancing capsule (*white arrowhead*) posterior to the vertebral bodies of T6-T9, which compresses the thoracic spinal cord anterior to the abscess.

which involves injection of contrast agents into the joint, was used to detect cartilage injuries. This type of examination is not only painful but carries a small but measurable risk of infection and contrast reaction. MRI of these joints is painless and only requires that the patient be able to hold still for a moderate length of time. The information obtained in the knee and hips exceeds what can be obtained using other methods. In the hips, MRI has proven to be the most reliable method for detecting avascular necrosis.

In problematic cases, MRI has detected stress fractures and occult fractures in the small bones of the hand. Even though it does not visualize cortex, any break in the medullary cancellous bone can be readily detected.

The sequelae of soft tissue musculoskeletal trauma, such as complete muscular or tendon tears, hemorrhage, and edema, are very easily diagnosed with MRI. Even injuries to the medium-sized nerves and brachial plexus can be demonstrated.^{13,14}

MRI has also been used to study infection in bone and soft tissues, where in many cases it has been superior to modalities such as nuclear medicine and CT.¹⁵⁻¹⁶ However, if the patient has a metallic prosthesis in the region of the abnormality, rf currents or magnetic field inhomogeneities due to the metal induce artifacts in the MRI scan reduce the sensitivity. This is even more of a problem in CT, where x-ray scattering from the prosthesis may completely obliterate the scan. In such cases only nuclear medicine studies may be useful, in particular indium¹¹¹ tagged to white blood cells.

MRI is extremely sensitive and specific in detecting metastatic disease in bone when questions arise after a positive bone scan. MRI is neither practical nor cost effective to use for whole body surveys, but when applied to specific lesions, the anatomic information expedites diagnosis.

CT continues to be the modality of choice for suspected head, spine, and abdominal injuries, because it is quick, more widely available, and more compatible with life-support equipment. Although MRI-compatible respirators and pulsed oximeters are now available, most standard life-support equipment either contains magnetic steel components or sensitive electronics that will not operate properly in the presence of rf or large static or dynamic magnetic fields. MRI is used in an elective setting after a patient has been stabilized and there is time to address the less acute problems.

MRI IN THE EMERGENT SETTING

At present there are two areas where MRI is the procedure of choice in the acute setting: (1) evaluation of suspected spinal cord compression from any cause, and (2) radiographically occult femoral intertrochanteric and neck fractures. In both cases, the unique ability to form images in axial, coronal, or sagittal planes gives MRI a distinct advantage. Another major factor is the superb contrast resolution of MRI that facilitates detection of spinal cord injury or fracture through cancellous bone of the hip. Figure 305-4 demonstrates an example of cervical cord compression resulting from a traumatically herniated disk. Thoracic cord compression due to infection is shown in Figure 305-5. Figure 305-6 is an example of an occult femoral intertrochanteric fracture best demonstrated on MRI. Small studies^{17,18} have confirmed higher sensitivity and specificity for MRI as compared with radionuclide bone scanning, tomography, and CT in the detection of occult fractures, especially in the femoral head and neck.

Another potential area for MRI evaluation in the acute setting is aortic dissection. MRI is superior to contrast-enhanced CT and possibly transesophageal ultrasound in delineating the aortic intimal flap. Unfortunately, many of these patients are unstable hemodynamically and are agitated, requiring life support and sedation. Thus few, if any, are good candidates for MRI. As more MRI-compatible life-support and monitoring equipment becomes available, this situation will change.

Finally, a second potential application is in pediatric fractures¹⁹ when there may be significant injury to unossified cartilage around open growth plates. Fractures through cartilage are not seen on plain films but are easily identified on MRI.

One innovation—the development of low and very low magnetic field imaging systems—may have some impact on emergency depart-

ments. Most of the hazards previously delineated apply to high-field systems. In low-field systems, in which the magnetic flux density is less in magnitude and more restricted in spatial extent, it is easier to accommodate life-support equipment. The design of these units allows more access to the patient and reduces the chances of interference with the proper operation of the life-support electronics. Thus installation of a low-field MRI scanner in the emergency department becomes more feasible. However, because of theoretical considerations, signal to noise is much less (i.e., less signal) at low field. Therefore there may be trade-off in diagnostic quality of the scans. Some signal can be recovered with optimal design of the software and hardware, but this remains a controversial area. There may be a place for low-field MRI in the emergent setting in the evaluation of subacute intracerebral hemorrhage and brain edema.

MR angiography, which (except for innocuous intravenous contrast) is noninvasive, has been evolving slowly and improving steadily.⁵ It may eventually be the method of choice in the emergent evaluation of suspected subarachnoid hemorrhage or in leaking aortic aneurysms. An example of an intravenous contrast MR angiogram delineating a subclavian "steal" syndrome is shown in Figure 305-7.

MRI continues to evolve with more potential applications to emergency medicine in addition to its role in spinal cord compression, radiographically occult fractures, and acute aortic dissection. The new areas are diffusion imaging (to detect early strokes), noninvasive cerebral and body MRI angiography, and in the future cardiac and pulmonary MRI angiography. Taking advantage of its compatibility with life-support equipment, further development of a low magnetic field system with improved signal to noise might accelerate introduction of the above applications into emergency medicine practice.

FIG. 305-6. Occult hip fracture. A. Anteroposterior radiograph of a 55-year-old patient on steroids who had right hip pain after a fall. No fracture is evident. B. T1-weighted coronal magnetic resonance scan of the same hip clearly demonstrates a nondisplaced intertrochanteric femoral shaft fracture (arrows).

FIG. 305-7. Intravenous contrast-enhanced magnetic resonance angiogram of the aorta and great vessels delineates the major lesion of a subclavian "steal" syndrome. Image of the aortic arch and great vessels reconstructed from computer generated maximum-intensity projection data after a three-dimensional volume acquisition following an injected intravenous bolus of a gadolinium chelate. A long segmental subtotal occlusion of the proximal left subclavian (solid white arrow-head) predisposes the patient to a subclavian steal situation. In that case, blood needed to supply the left arm is "stolen" from the brain via reversed flow in the left vertebral artery (short white arrow). There is a second major lesion, a significant stenosis in the right internal carotid artery (long white arrow).

Section Twenty-Eight

SPECIAL SITUATIONS

INJECTION DRUG USERS

Brigitte M. Baumann Suzanne

M. Shepherd

The practice of injection drug use and the lifestyle of the injection drug user (IDU), place the individual at risk for a wide variety of infectious and noninfectious complications.¹ In addition to an increased risk of the human immunodeficiency virus (HIV), hepatitis, and sexually transmitted diseases, the IDU's lifestyle is also associated with an increased risk of trauma. The high incidence of homelessness, nutritional deficiencies, smoking and alcohol use, and mental illness further compromise this population's health.

Approximately 2.4 million individuals in the United States have used heroin at some point in their lives, with nearly 130,000 having used it within the past 30 days.² The ED is a common point of entry to health care for many IDUs, with an estimated 14 percent of all drug-related ED episodes involving heroin. Between 1991 and 1996, heroin-related ED episodes more than doubled (from 35,898 to 73,846) and in youths aged 12 to 17 years, heroin-related episodes nearly quadrupled.² To adequately evaluate IDUs, health care providers should be aware of the drugs used in their catchment area as well as their street names. Patients should be asked about drug type(s) and amount, preparation of materials for injection (e.g., licking needles or use of saliva or tap/toilet water for drug reconstitution), reuse of needles, needle sharing, use of antibiotics, and coincident illness. Socioeconomic issues such as the IDU's ability to purchase medications and return for follow-up should also be addressed when making dispositions. The IDU should receive nonjudgmental instruction in measures to reduce the risk of complications and infections. Finally, drug rehabilitation (even as a referral) should always be offered.

PATHOPHYSIOLOGY

In addition to placing patients at greater risk for immunocompromising infections such as HIV and hepatitis, IDU itself has been associated with immune dysfunction. Exaggerated and atypical lymphocytosis, diminished lymphocyte responsiveness to mitogenic stimulation, hypergammaglobulinemia, increased opsonin production, high levels of circulating immune complexes, and reticuloendothelial abnormalities, have been found. Because of this immune stimulation, false-positive syphilis serology, positive Coombs tests, and thrombotic thrombocytopenic purpura have all been described in this population. Given immune dysfunction, febrile IDUs should be suspected of having infections, even when the fever is low grade and with normal/near-normal white blood counts and erythrocyte sedimentation rates.³

CLINICAL FEATURES

Complications of the IDU may be obvious, such as a painful mass caused by a skin abscess. However, constitutional symptoms such as weakness, anorexia, body pains, weight loss, and fever are common and may be the only subtle sign(s) of serious underlying disease (Table 306-1).

Fever

Fever is part of the presenting complaint in the majority of ED visits by IDUs and is associated with infection in more than two-thirds of patients.⁴ Prospective studies of febrile IDUs have found bacteremia in up to 42 percent, pneumonia in 26 to 38 percent, and endocarditis in

up to 13 percent of patients.⁴ Neither clinical judgment nor derived predictive rules were reliable in identifying those with serious underlying causes of fever.⁴

Noninfectious causes of fever include acute toxic reactions to substances of abuse, reactions to injected adulterants, and withdrawal syndromes. Cocaine and amphetamines can cause fevers acutely, occasionally in excess of 40°C (104°F). Adulterants used to dilute active substances may also cause dramatic febrile reactions accompanied by alteration in mental status and leukocytosis. One syndrome known as "cotton fever" is associated with the use of cotton balls as filters for drug suspensions. Patients with cotton fever develop a flulike syndrome within hours after injection. Physical findings may include tachypnea, tachycardia, abdominal pain, and inflammatory retinal nodules. Chest radiographs are typically normal, but may demonstrate inflammatory pulmonary granulomata. This syndrome spontaneously resolves within 24 h. While the cause remains unclear, it has been proposed that the acute symptoms are caused by either endotoxin from gram-negative rods introduced by injection or by the pyrogenic effect of injected cotton particulate matter. Patients withdrawing from barbiturates or heroin also may appear acutely ill, with chest and abdominal pain, diaphoresis, tachycardia, and fever.

Because no reliable markers are available to exclude serious illness in the febrile IDU, common practice has been to obtain blood cultures and admit such patients for observation, awaiting culture results. In clinically well patients for whom follow-up can be ensured, outpatient evaluation is reasonable as long as an adequate cultures are obtained.

Dyspnea

A wide range of both infectious and noninfectious causes may produce dyspnea and cough in IDUs. Pneumonia in IDUs is typically community-acquired. However, other infectious causes for dyspnea include opportunistic infections and septic pulmonary emboli from right-sided endocarditis. The febrile IDU presenting with dyspnea, cough, or an abnormal chest radiograph should be placed in respiratory isolation until tuberculosis has been excluded and/or an alternative diagnosis is found.⁵

Noninfectious causes of dyspnea include pneumothorax, hemothorax, toxic reactions to injected substances, and hypersensitivity reaction. Pneumo- and hemothorax are seen most commonly with the practice of "pocket shooting," when drug users inject into veins in the supraclavicular fossa to access the subclavian, jugular, or brachiocephalic vein. Talc lung is a syndrome of progressive respiratory distress and diffuse interstitial infiltrates caused by the injection of the adulterant talc.⁵ Hypersensitivity reactions, associated with both heroin and cocaine injection, present with cough and wheezing and typically respond to inhaled (3-agonist therapy. Noncardiogenic pulmonary edema is associated with both heroin and cocaine use. Patients may complain of dyspnea or have a low pulse oximetry reading, with the chest radiograph revealing diffuse alveolar infiltrates; treatment is supportive. Finally, septic, air, or needle fragment emboli can produce dyspnea.⁷

Altered Mental Status

Drug intoxication or withdrawal, stroke syndromes, hypoxia, delayed leukoencephalopathy, infectious diseases, mycotic aneurysms, and secondary trauma from either loss of consciousness and fall or drug-related violence may all cause altered mental status in the IDU. Central nervous system (CNS) infections may be a result of embolic complications of distant infections (e.g., endocarditis) or of extensions of local infections (e.g., vertebral osteomyelitis). Infections commonly

TABLE 306-1 Evaluation of Injection Drug Users in the Emergency Department

Presenting Symptom	Other Findings	Possible Diagnoses	Ancillary Tests
Fever alone	Needle and track marks Heart murmur Rales and rhonchi Hypoxia	Pneumonia Endocarditis Occult bacteremia	Chest radiograph Blood cultures Urinalysis Erythrocyte sedimentation rate Echocardiogram
Fever and nausea/vomiting Rigors Abdominal pain	Diaphoresis Recent injection	Drug withdrawal "Cotton fever"	CBC Blood cultures
Fever and dyspnea/cough	Rales/rhonchi Purulent sputum Hypoxia	Bacterial pneumonia Atypical pneumonia Opportunistic pneumonia	Chest radiograph Blood cultures Sputum culture and Gram stain
Fever and weakness Weight loss Anorexia Night sweats Diarrhea	Cachexia Oral thrush	HIV infection Tuberculosis Hepatitis B and C	HIV serology Blood cultures Chest radiograph Sputum for AFB stain and culture Hepatitis serology
Fever and back pain	Heart murmur Focal neurologic signs Flank tenderness	Osteomyelitis Epidural abscess Endocarditis Renal abscess	Blood cultures Erythrocyte sedimentation rate Bone radiographs CT or MRI Urinalysis
Dyspnea/cough	Expiratory wheezes Rales/rhonchi Fever Pleuritic chest pain	Hypersensitivity reaction Noncardiogenic pulmonary edema Pneumonia Septic pulmonary emboli Talc reaction	Chest radiograph Spirometry Echocardiogram Consider blood cultures
Painful limb	Localized erythema Tenderness Localized bruit Muscle pain/swelling Fever	Cellulitis Abscess Pseudoaneurysm Myositis Fasciitis Retained foreign body	Wound cultures Soft tissue radiographs CT Doppler ultrasonography Consider blood cultures
Altered mental status	Obtundation Focal neurologic signs Meningismus Seizure	Drug overdose/intoxication Drug withdrawal CNS lesion Meningitis Tetanus	CT scan Drug screen Lumbar puncture Consider blood cultures
Eye pain/vision loss	Periorbital vesicles Subconjunctival lesions Keratitis Iridocyclitis Retinitis	Herpes zoster Kaposi's sarcoma Keratoconjunctivitis sicca Herpes simplex CMV Varicella zoster Toxoplasmosis Syphilis Fungal infection	

Abbreviations: AFB = acid-fast bacillus; CBC = complete blood cell count; CMV = cytomegalovirus; CNS = central nervous system; CT = computed tomography; MRI = magnetic resonance imaging.

seen in this population include epidural abscess, bacterial and fungal meningitis, and brain abscess. Meningococcus, pneumococcus, and *Staphylococcus aureus* spreading from a primary endocarditis are the common causes for bacterial meningitis. Opportunistic organisms are common in the patient with coincident HIV infection.

Stroke syndromes may be secondary to low-flow states during heroin intoxication, hypertensive hemorrhage from amphetamines, phencyclidine, or cocaine, and embolized vegetations from infectious endocarditis. Delayed leukoencephalopathies, both hypoxic and non-hypoxic, have been reported in IDUs, but are rare.

Back Pain

Back pain may be the result of an epidural abscess, vertebral osteomyelitis, or complications from trauma. In patients with coincident

HIV, opportunistic infections may present with a more indolent course. Nontraumatic focal back pain usually requires imaging studies such as computed tomography (CT) and magnetic resonance imaging (MRI) to evaluate for possible infection.

SPECIFIC INFECTIONS

HIV

The use of intravenous drugs plays a major role in the acquisition and transmission of HIV.⁸ In the United States, the proportion of HIV cases directly attributable to intravenous drug use is estimated at 50 percent, and HIV seroprevalence rates in IDUs range from 10 to 65 percent. The proportion of HIV cases caused by intravenous drug use increased from 17 to 27 percent from the 1980s to the early 1990s,

thought to be largely a result of increasing use of intravenous cocaine. In addition to widespread needle sharing, cocaine's highly addictive properties and short duration of effect encourage frequent injections. The prevalence of HIV in IDUs has expanded the spectrum of diseases associated with intravenous drug use to include those typically associated with HIV infection. While AIDS-defining illnesses in intravenous drug users are similar in spectrum to those in nonintravenous drug users, the distribution of such diseases appears to be different. IDUs have proportionately more cryptococcal disease, *Pneumocystis carinii* pneumonia, tuberculosis, and wasting syndrome, and significantly less cytomegalovirus (CMV) infection, non-Hodgkin lymphoma, and Kaposi sarcoma.⁸ Overall, IDUs generally have a less complicated course than do homosexual HIV patients. However, this advantage is lost by unnecessary complications caused by their psychiatric disorders, noncompliance, and concealment of signs of disease, all of which lead to worse outcomes from infections.

Endocarditis

The incidence of endocarditis in the IDU is estimated to be 40 times that of the general population, or approximately 1 case in 500 IDUs. Unlike the general population, endocarditis in IDUs is typically right-sided (50 to 76 percent), with 40 to 69 percent of cases involving the tricuspid valve, 20 to 30 percent involving the mitral and aortic valves, and 5 to 42 percent involving multiple valves.^{3,9} The pathogenesis of right-sided endocarditis in IDUs is thought to be dependent on four factors: (1) endothelial damage; (2) specific interactions between microorganisms and valvular location; (3) degree of bacterial load; and (4) host immune status.⁴

Patients with IDU-related endocarditis usually have no evidence of prior valve damage, a common risk factor for endocarditis in non-IDUs. It is thought that the IDU contributes to endocardial damage via mechanical and ischemic mechanisms. Mechanical damage is caused by both direct bombardment with particulate matter (talc or other diluents) and by increased right-sided pressure gradients and turbulence as a consequence of drug-induced pulmonary hypertension. The tricuspid valve is particularly susceptible to mechanical damage because it is the first valve exposed to these substances. Additional endothelial damage may be caused by chronic valvular inflammation due to frequent antigenic exposure. An increased risk of endocarditis in intravenous cocaine users is attributed to a the greater frequency of injections (increased mechanical damage), less chance of needle sterilization because cocaine does not need to be heated in order to go into solution, and the greater likelihood of needle sharing. An alternative explanation is that the vasoconstrictive properties of cocaine may cause interstitial or endothelial damage which predisposes to infection.

Specific interactions between valvular location and infecting organisms may account for the prevalence of right-sided *Staphylococcus aureus* and *Pseudomonas aeruginosa* endocarditis. *S. aureus* is the most common pathogen in isolated tricuspid valve endocarditis, accounting for 50 to 60 percent of cases among IDUs. *S. aureus* possesses unique surface proteins that enable it to adhere to host tissue. In addition, IDUs are postulated to have a greater expression of matrix molecules that bind to the microbial surface components recognizing adhesive matrix molecules found on injected particulate matter. This increased affinity as well as *S. aureus'* protective fibrin coat enhances vegetation formation and prevents host clearance. *Pseudomonas* endocarditis is more prevalent in IDUs because of the frequent use of tap or toilet water in the preparation of the street drugs pentazocine and tripeleminamine.³

Bacterial load is related to the risk of endocarditis in a "dose-response" fashion. The fact that cocaine, which has a shorter half-life than heroin and requires more frequent dosing, is associated with more cases of endocarditis may be related to increased mechanical damage and greater frequencies of bacteremia. Immunologic dysregulation with hypergammaglobulinemia, high levels of circulating immune complexes, exaggerated lymphocytosis as well as atypical

lymphocytosis is thought to play a role in the increased risk of endocarditis. In IDUs with HIV low CD4⁺ T-cell counts increase the risk for endocarditis sixfold.³

Presenting signs and symptoms in IDUs with endocarditis include fever, cardiac murmur (>50% of patients), cough, pleuritic chest pain, and hemoptysis. Right-sided murmurs, which vary with respiration, are typically pathologic and more specific for the diagnosis.⁹ In those with right-sided endocarditis and septic pulmonary emboli, pulmonary complaints, infiltrates on chest radiographs, and moderate hypoxia have been described in more than one-third of patients, and may mislead the physician to identify the lung as the primary source of infection. Pyuria and hematuria are ascribed to glomerulonephritis, embolic renal infarction, and perinephric abscess.

Blood cultures will be positive in more than 98 percent of IDU-related endocarditis patients if three to five sets are obtained. True culture-negative endocarditis in the setting of high clinical suspicion and careful laboratory procedure is rare. *S. aureus* has been isolated from blood cultures in more than 50 percent, and up to one-third of these isolates, particularly those from large urban areas, are methicillin resistant.¹⁰ *Streptococcus* is the second most frequently reported isolate, particularly *S. viridans*. Unlike *S. aureus*, streptococci are more likely to involve left-sided structures.

Other less-commonly isolated organisms include enterococci and gram-negative bacteria, particularly *P. aeruginosa*, *Serratia marcescens*, and *Klebsiella pneumoniae*. Atypical organisms usually reflect local environmental pathogens or drug-injecting habits. For example, licking needles prior to injection has been implicated in *Eikenella corrodens*, *Haemophilus parainfluenzae*, *Bacteroides* sp., and *Neisseria* sp. infections. Up to 20 percent of IDU-related endocarditis is polymicrobial in nature. Although rare, fungal endocarditis has been reported, with *Candida parapsilosis* accounting for over half of all isolates.

Diagnosis generally requires microbial isolation from a blood culture and/or the ability to demonstrate typical lesions on echocardiography.⁹ The classic findings of embolic phenomena, Janeway lesions and Roth spots, are usually not observed unless the infection is advanced. A complete blood count (CBC), chest radiograph, and urinalysis will usually demonstrate abnormalities, although no single result is specific for endocarditis. Typical radiographic findings include infiltrates consistent with septic emboli, pneumonia, or congestive heart failure.

Transthoracic echocardiography (TEE) is the most sensitive imaging modality for demonstrating vegetations, myocardial and ring abscesses, and tricuspid valve involvement in IDU-related endocarditis and will reveal diagnostic cardiac lesions in up to 80 percent of patients. While the accuracy of TEE is clear, the timing of the study is not. Some authors advocate early imaging to confirm the diagnosis, while others advocate reserving imaging on those with positive blood cultures, to determine response to therapy and plan treatment.

Attempts to develop criteria that prospectively identify endocarditis in the IDU with reasonable certainty have failed.⁴ At least two sets of blood cultures should be obtained in patients with suspected endocarditis, followed by hospital admission. The need for empirical antibiotic therapy should be determined by the patient's clinical stability and ability to wait for initial blood culture results. Initial treatment should be directed against *S. aureus* and *Streptococcus* spp., with consideration of local sensitivities and pathogens. Vancomycin or nafcillin and gentamicin are often initial therapy. The addition of an aminoglycoside has been shown to shorten the duration of bacteremia and duration of treatment in patients with *S. aureus* infections. Although 4 to 6 weeks of antibiotic therapy is standard, excellent cure rates have been achieved with only 2 weeks of an isoxazolyl-penicillin (e.g., cloxacillin) and an aminoglycoside in patients with right-sided endocarditis caused by sensitive *S. aureus*.¹

Complications of endocarditis include pump failure, dysrhythmias, and pulmonary and systemic emboli. Mortality is related to vegetation location and size, response to antibiotics, and therapeutic compliance.

Left-sided endocarditis is more likely to be complicated by left-sided heart failure, septic cerebral and systemic emboli, and the need for surgery. Overall mortality for IDU-related left-sided endocarditis is 14 to 21 percent. In patients with right-sided endocarditis, the noteworthy complication is septic pulmonary emboli in 30 to 60 percent. Most complications related to right-sided endocarditis may be managed medically, and the prognosis is excellent with overall mortality rates 2 to 7 percent.

Pulmonary Infections

Community-acquired pneumonia caused by *S. pneumoniae* and *H. influenzae* is the most common pulmonary infection in the IDU.¹² However, patients are at high risk for aspiration pneumonia, tuberculosis, and, in HIV-positive patients, opportunistic infections from *P. carinii*, cytomegalovirus, and atypical mycobacteria.¹² Extrapulmonary tuberculosis affecting the cervical lymph nodes, CNS, bone, abdomen, genitourinary system, pericardium, skin, and the eyes, as well as drug resistance, are also more common in the IDU. In those IDUs with septic emboli or endocarditis, *S. aureus* must be considered. Aspiration pneumonia should be considered in those with a history of depressed level of consciousness and/or radiographic infiltrate in the posterior or basal lung segments. Because of the risk of atypical infection, coincident bacteremia, and endocarditis, admission to the hospital is recommended, and respiratory isolation should be maintained until tuberculosis is excluded.

Skin and Soft Tissue Infections

Unique features of skin infections in the IDU include a high rate of skin and pharyngeal colonization with *S. aureus* and streptococcal species, and the high frequency with which cutaneous abscesses are caused by oral flora.^{13,14} Conflicting evidence exists as to whether HIV seropositivity confers additional risk for the development of skin abscesses.¹⁴ The IDU will self-inject, often multiple times a day, with nonsterile needles, which may be licked prior to injection. Tap water, toilet water, or saliva often are used to dissolve narcotics, and each has been implicated in harboring causative organisms in both skin and blood-borne infections. Female gender is associated with an increased incidence of skin infections because of a relatively high rate of skin injection (skin popping).

Local infections of the skin and soft tissue include cellulitis, subcutaneous abscesses, septic phlebitis, necrotizing fasciitis, Fournier's gangrene, gas gangrene, and pyomyositis. Cellulitis is typically caused by *S. aureus* and *Streptococcus* spp. Cultures from cutaneous abscesses are often polymicrobial, with aerobic gram-negative rods, anaerobic cocci, and bacilli.¹³ Quinine, used to "cut" heroin, may increase the risk of abscess formation. The extensive interconnected abscesses produced by skin-popping provide ideal growth conditions for *Clostridium botulinum* and *C. tetani*. Broken needles lodged in the skin are foreign bodies that potentiate infection. Groin injection has been associated with local gangrene, as well as with the development of rapidly progressive and fatal Fournier gangrene. Cutaneous abscesses in the neck may involve the carotid triangle and produce airway obstruction, vocal cord paralysis, and laryngeal edema.

Presenting signs and symptoms of cutaneous infections, including pyomyositis, are fever, pain, localized erythema, and edema. The painful area should be carefully inspected for fluctuance, crepitance, and lymphangitis. Infections over venipuncture sites suggest infected pseudoaneurysms. Pulsatile masses must be imaged with ultrasonography prior to incision and drainage, as attempts to aspirate or incise and drain an infected pseudoaneurysm can result in significant hemorrhage. Angiography may be required to identify vasospasm, thrombosis, emboli, mycotic aneurysms, or septic hematomas. Plain radiographs can demonstrate air in the soft tissues. Computed tomography delineates the involvement of other structures and the extent of deep abscesses, especially in complex areas such as the neck. Whenever

crepitus or subcutaneous air is detected or deep tissue or muscle involvement is suspected clinically, a surgical consultation for possible exploration or debridement is appropriate. Wound botulism and tetanus have been reported in IDUs, and tetanus immunization status should be updated appropriately.^{15,16}

IDUs with superficial cellulitis without evidence of systemic involvement can be managed as outpatients with oral antibiotics to cover streptococci and staphylococci. Febrile or toxic-appearing patients, or those not responding to outpatient treatment, require hospital admission. Blood and wound cultures should be obtained, and broad-spectrum intravenous antibiotics initiated pending culture results. Coverage should include penicillinase-resistant synthetic penicillin or vancomycin plus an antipseudomonal aminoglycoside, antipseudomonal penicillin, or cephalosporin. Surgical consultation is indicated for deep tissue and necrotizing soft tissue infections.

Vascular Infections

Vascular injury associated with IDU includes inadvertent arterial injection with resultant vasospasm or thrombosis, septic thrombophlebitis, venous and arterial pseudoaneurysms, and infected hematomas. Arterial injection rarely results in major vessel occlusion; instead, pain, edema, and patchy mottling of the affected limb caused by ischemia occur. Tissue necrosis and gangrene are the consequence of persistent focal ischemia, the etiology of which is thought to be a combination of vasospasm, embolization of particulate matter, and endothelial injury leading to thrombosis and vasculitis.¹⁷

When limb ischemia is suspected, a vascular surgeon should determine if either surgical intervention or intraarterial thrombolysis is indicated. However, the majority of cases involve distal vessels, and treatment is limited to heparin and supportive care. Limb edema can progress to compartment syndrome, which may require fasciotomy, or rhabdomyolysis.

Infected pseudoaneurysm is a commonly reported vascular complication in IDUs and is most often reported in the femoral, followed by the radial and brachial arteries.^{17,18} Venous pseudoaneurysms are relatively rare and are usually secondary to septic phlebitis, with the femoral vein most often involved. Patients typically present with fever and a painful mass. Although similar in gross appearance to an abscess, the presence of pulsations and a bruit suggest this diagnosis. Because of the disastrous hemorrhagic consequences of attempted incision and drainage or medical management with a course of antibiotics, all painful masses, particularly in the groin, should be imaged. Treatment for infected pseudoaneurysm usually involves resection of the infected vessel. Appropriate broad-spectrum antibiotics should be initiated in the ED. Revascularization at the time of resection of the pseudoaneurysm may be necessary.¹⁸

Bone and Joint Infections

Bone and joint infections usually occur from either contiguous spread from an overlying skin or soft tissue infection, or secondary to hematogenous spread from a distant site. In contrast to the general population in which *S. aureus* predominates, infecting microorganisms in the IDU tend to be unusual, with *Candida* and gram-negative organisms the most common. In IDUs, osteomyelitis is seen more frequently in the axial skeleton than in the extremities.

Pyogenic infections predominate in bones and joints. Earlier studies in IDU-related osteomyelitis or septic arthritis found a high likelihood of polymicrobial or uncommon organisms; however, recent studies demonstrate an increasing frequency of *S. aureus* and *Streptococcus* groups A and G bone infections in IDUs. Because of the high incidence sexually transmitted diseases in this population, gonococcal arthritis and tenosynovitis should also be considered. *E. corrodens* osteomyelitis has been reported in IDUs who lick their needles prior to injection.

Nonpyogenic organisms may cause osteomyelitis and septic arthritis in IDUs. Mycobacterial infections usually involve the ribs and vertebral column (Pott disease). These infections present with night sweats, fevers, weight loss, and localized pain. *Candida* spp. has been reported in as high as 20 percent of IDU-related osteomyelitis patients. Candidal infections are postulated to be hematogenous in origin. Some patients report an initial flulike syndrome lasting 3 to 4 days, followed by the appearance of metastatic lesions involving the skin, eye (chorioretinitis and endophthalmitis), and the bones and joints several days to weeks later. Rarely, *Aspergillus* spp. may cause osteomyelitis of the sternum in IDUs.

IDU-related osteomyelitis involves the vertebral column in approximately 50 percent of cases, particularly the lumbar segments, followed by the sternoclavicular joint in approximately 18 percent of cases, and the extremities, particularly around the hip and knee joints, in 17 percent of cases. Vertebral osteomyelitis usually presents with localized pain and tenderness to palpation over the involved bone and a soft tissue mass may be palpable. Symptoms may be present for days in the case of bacterial infections to weeks in the case of fungal or mycobacterial infections. Many patients both fever and leukocytosis and an elevated erythrocyte sedimentation rate (ESR) and C-reactive protein are helpful, if present, but their absence does not exclude these infections. Drainage from contiguous abscesses should be cultured. Biopsy or needle aspiration of joint space and bony infections may be necessary, especially in the case of unusual or fastidious organisms, such as *Mycobacterium*, *Candida*, or *Eikenella*. Appropriate imaging for osteomyelitis will vary by institution; however, MRI, CT, and radionuclide bone scans are used. Patients with osteomyelitis warrant admission. Unless the patient appears septic or coincident endocarditis is a concern, antibiotic administration should be based on culture results and is typically required for 4 to 6 weeks.

Septic arthritis in the IDU usually involves the knee or hip. Sternoclavicular infectious arthritis, well described in this population, strongly suggests IDU. Patients often will note a recent history of trauma to the area, but causality has yet to be proven. Patients will describe pain, localized tenderness, and swelling at the sites. The ESR is usually elevated, and fever and leukocytosis may be present. Up to 80 percent of patients will have normal plain radiographs; however, joint space widening, articular surface erosion, and surrounding soft tissue infection may be noted. Bone scans are often positive early in the process, and these infections also may be delineated with CT or MRI. The most sensitive but nonspecific finding on synovial fluid analysis is a white blood cell count greater than 20,000/ \times L, with a neutrophil predominance. Synovial fluid Gram stain may aid in antibiotic selection. Immobilization, physical therapy, therapeutic arthrocentesis, and occasionally open drainage may be warranted.

Hepatic Disease

The IDU can develop liver disease, including cirrhosis, from both parenterally and sexually transmitted hepatitis A, B, C, G, and non A-G viruses, as well as the delta virus.¹⁹ More than 80 percent of IDUs are estimated to have had hepatitis, with the majority of cases caused by hepatitis B and C. These patients frequently progress to chronic active hepatitis. When an IDU patient presents with a clinical syndrome suggestive of acute hepatitis, appropriate laboratory testing includes serum transaminases, bilirubin levels, alkaline phosphatase, prothrombin time, and serologic testing. If other significant disease can be excluded, most can be managed as outpatients. Admission criteria include inability to tolerate oral intake, toxicity, and prolonged prothrombin time. Patients should be counseled on both sexual contact and needle exposure and should be encouraged to inform all sexual and needle partners and household contacts of exposure. Seronegative patients should receive hepatitis B and A immunization.

Ophthalmologic Infections

Ophthalmologic infections in the IDU are usually the result of hematogenous seeding from a primary source of infection, such as endocarditis, or of opportunistic infections associated with HIV disease.²⁰ Bacterial endophthalmitis often presents acutely, with pain, redness, lid swelling, and decrease in visual acuity. Inflammation is usually present in both anterior and posterior chambers. White-centered, flame-shaped hemorrhages (Roth spots), cotton wool exudates, and macular holes may be present. *S. aureus* is the most commonly isolated organism, followed by *Streptococcus* sp. Treatment involves subconjunctival and systemic antibiotic therapy; surgical intervention may be needed.

Fungal endophthalmitis, usually caused by *Candida*, is more common than bacterial endophthalmitis. Symptoms include blurred vision, pain, and decreased visual acuity and can progress over days to weeks. White cotton-like lesions are seen on the choroid retina, with vitreous haziness. Uveitis, papillitis, and vitritis also have been reported. Since 1980, a marked increase in *Candida* sp. infections has been reported in IDUs who use brown heroin. *Candida* chorioretinitis or endophthalmitis is characterized by the appearance of a high fever, followed in 3 to 4 days by ocular symptoms, cutaneous lesions, and costochondral involvement. Aspergillosis is the second most common fungal cause of endophthalmitis in IDUs, producing ocular symptoms and signs without cutaneous or musculoskeletal involvement. The prognosis for fungal endophthalmitis depends on prompt diagnosis and treatment. Fungal endophthalmitis secondary to *Torulopsis*, *Helminthosporium*, and *Penicillium* spp. also has been reported in IDUs. In IDUs with HIV, cytomegalovirus, toxoplasmosis retinitis, and choroidal *Cryptococcus* and *Mycobacterium avium intracellulare* infections have been reported.

THE ELDER PATIENT

Arthur B. Sanders

Older patients represent a special population for emergency medicine. The approach that focuses on one chief complaint and develops a differential diagnosis based on life-threatening and common diseases may miss significant conditions in older persons. Older patients are more time-consuming, more difficult to evaluate, and use more resources than do younger adult patients. The complexity of their presentations and dispositions, as well as communication problems with the patients, their families, and primary care providers, all make the ED evaluation of elderly persons more difficult as compared with younger adult patients.¹ The physiology of aging results in altered disease presentations, altered pharmacodynamics, and decreased functional reserve, as well as social problems, which must be dealt with in the setting of a busy ED.

EPIDEMIOLOGY

The elderly population in the United States is growing rapidly, with projected increases from 200 percent for the 65- to 74-year-old segment, 300 percent for the 75- to 84-year-old segment, and more than 500 percent for those older than age 85 years by the year 2050. Approximately 12 percent of the population was 65 years of age or older in 1990, whereas 20 percent of the population (or 55 million persons) will be 65 years of age or older by the year 2030. As noted, the oldest elderly, those age 85 years and older, are the most rapidly increasing segment of the elderly population. This is also the population with the most health problems and in greatest need for health care. There is great variability in the physiologic age of individual patients. A 55-year-old with multiple chronic diseases and poor physiologic reserve may have a physiologic age much older than a healthy 80-year-old.

In 1995, almost 16 percent of ED visits were made by patients age 65 years and older, and 46 percent were admitted to the hospital.² Older patients spend more time in the ED, require more ancillary tests, and are more likely to be admitted to critical care units as compared to younger patients. The National Center for Health Statistics (NCHS) 2000 survey documents that persons aged 75 years and older had 64.8 ED visits per 100 persons per year, twice the rate for younger persons.³ The rate of ambulance use increased with age, with 43 percent of persons age 75 and older taking ambulance transport to the ED.³

PATHOPHYSIOLOGY

The basic principles of geriatric emergency medicine have been defined (Table 307-1). Older patients often present with ambiguous complaints, such as not feeling right, feeling weak, or not doing usual

TABLE 307-1 Principles of Geriatric Emergency Medicine

1. The patient's presentation is frequently complex.
2. Common diseases present atypically in this age group.
3. The confounding effects of comorbid diseases must be considered.
4. Polypharmacy is common and may be a factor in presentation, diagnosis, and management.
5. Recognition of the possibility for cognitive impairment is important.
6. Some diagnostic tests may have different normal values.
7. The likelihood of decreased functional reserve must be anticipated.
8. Social support systems may not be adequate, and patients may need to rely on caregivers.
9. A knowledge of baseline functional status is essential for evaluating new complaints.
10. Health problems must be evaluated for associated psychosocial adjustment.
11. The emergency department encounter is an opportunity to assess important conditions in a patient's personal life.

Source: Reproduced with permission from Sanders AB, Witzke DB, Jones JS, et al: Principles of care and application of geriatric emergency care model, in Sanders AB (ed): *Emergency Care of the Elder Person*. St. Louis, Beverly Cram Publications, 1996, p 59.

activities. Vague complaints, such as general weakness or functional decline, may indicate important diseases, such as sepsis, subdural hematoma, or myocardial infarction. Assessment of functional status can be used for classifying and evaluating these complaints.

Common diseases often present atypically in older persons, resulting in missed diagnoses unless physicians understand and suspect the atypical presentations in this population. For example, consider two common presenting complaints—chest pain and abdominal pain—and common diagnoses for each—myocardial infarction and acute appendicitis. Fewer than half of patients 85 years of age and older will present with chest pain as a symptom of acute myocardial infarction.⁴ Instead, patients present atypically with dyspnea, syncope, weakness, or dizziness.⁴ Older patients with acute appendicitis are often diagnosed late and have a high perforation rate.⁵ A large percent of patients with appendicitis are diagnosed more than 48 h after the onset of symptoms, with up to 20 percent diagnosed after 3 days. The abdominal pain is vague, and the symptoms may be poorly localized. Classic patterns of pain and accompanying symptoms, such as nausea and vomiting, are present in only a minority of older patients with acute appendicitis. Older patients with acute abdominal conditions commonly lack physical findings of guarding or rebound.⁶

Older patients frequently will have confounding comorbid diseases, and emergency physicians should evaluate whether the presenting complaint reflects an exacerbation of one of the comorbid diseases or a new disease process. Comorbid diseases, especially those treated with multiple medications, may also affect the management and disposition of patients.

Older adults take an average of more than four prescription drugs and more than two over-the-counter drugs each day. Approximately 30 percent of older persons will develop adverse medication effects, and they are twice as likely as younger adults to have adverse effects. Adverse medication effects account for approximately 5 percent of hospital admissions. The number of medications that a patient takes is directly related to the chance of adverse drug effects. Normal aging results in a loss of cardiac, pulmonary, hepatic, and renal functional reserve.⁷ Thus, the margin of error decreases for many medications, such as nonsteroidal anti-inflammatory drugs. The distribution of drugs changes with age; as lean body mass decreases, the larger proportion of adipose tissue increases the volume of distribution of drugs, such as benzodiazepines, phenytoin, barbiturates, and phenothiazines, and prolongs their duration of action. Drug clearance depends primarily on hepatic and renal function. The decreased renal function with age may affect drugs such as digoxin and the aminoglycoside antibiotics. Drug receptor interactions also play a role in pharmacody-

namics. Older persons have an increased sensitivity to warfarin and benzodiazepines. Common complications of medications or drug interactions include delirium, depression, functional decline, worsening dementia, orthostatic hypotension, weakness, dizziness, falls, and incontinence. The impact of new medications prescribed in emergency departments, such as anticholinergics, sedatives, and diuretics, as well as adverse interactions with current medicines, should be anticipated.⁸

Older persons frequently have cognitive impairment that may not be recognized by health care providers.⁹ Cognitive impairment includes both acute confusional states (delirium) and dementia. Abnormal cognitive states in older patients affect the reliability of the history and impact disposition planning. Acute cognitive impairment can be an important symptom of sepsis, congestive heart failure, metabolic abnormality, adverse drug effect, or subdural hematoma. When older ED patients are screened for cognitive impairment, 30 to 40 percent of those who have no previous history of impairment will have abnormal cognition based on formal mental status exams.⁹ Approximately 10 percent of patients will meet formal criteria for delirium, which should be considered a symptom of a medical emergency. Formal tools for evaluation of cognition are recommended later in this chapter.

Accurate laboratory test interpretation requires a knowledge of which "normal" values are altered with aging. Although many laboratories control for age variations in neonates and children, few list control values for older patients. For example, laboratory parameters such as the sedimentation rate, glucose and creatinine levels, and arterial blood oxygen tension change with physiologic aging.

The likelihood of decreased functional reserve should be anticipated in older persons. Most patients are asymptomatic until they are stressed or reach a critical threshold in which symptoms are manifested. Most organ functions decline with age. Resting cardiac output decreases at approximately 1 percent per year after age 30 years. Pulmonary, renal, neurologic, and immunologic functions also decrease with age. Chronologic and physiologic age, however, may vary considerably, depending on genetics, environment, health behaviors, diet, tobacco use, alcohol use, exercise, and stress. When older persons are stressed, for example, by extreme heat or cold, their regulatory mechanisms are not as effective as when they are not so stressed.

Older persons should be viewed in the context of their home environment and social support network. Simply addressing an injury or illness may not be adequate. More than 20 percent report a change in their ability to care for themselves following their ED visit. An independent-living 80-year-old woman who sprains her ankle may become incapacitated. Enlisting the help of a social service network and of home health providers will ensure that such patients are able to carry on the functions of daily living. In addition, many older persons need to rely on caretakers, so an assessment of the caretaker's ability to help the patient is important. Is the caretaker an elderly spouse who will predictably injure himself or herself in trying to lift a patient who is incapacitated by a new injury? Elder abuse and neglect is a significant issue that should be assessed by questioning the patient and caretaker separately (see Chap. 300).¹⁰

The emergency health care professional can play a key role in screening for such important conditions such as elder abuse, depression, alcoholism, malnutrition, incontinence, falls, and immunizations. In a multicenter study in which patients were screened, almost 80 percent of older patients demonstrated a problem in one or more of these areas."

SPECIFIC ISSUES

Altered Mental Status

Of ED older patients with no prior history of cognitive problems, 30 to 40 percent will meet the criteria for either delirium or cognitive dysfunction, and this is often unsuspected by the physician.⁹ Consequently, older patients should be routinely screened for cognitive dys-

function. The simplest screening tool is evaluation for orientation and three-item recall. If no problem is detected, no further testing need be done. If the screen is failed, further testing can be done. The Confusion Assessment Method (CAM) scale is a useful tool for the emergency physician (Figure 307-1). Using the CAM scale, the patient is evaluated for (1) acute onset, (2) fluctuating course, (3) inattention, (4) disorganized thinking, and (5) altered level of consciousness. These factors are assessed through the ED history and observation, as well as structured questions such as three-item recall, stating the days of the week or months of the year backward. Patients who present with inattention—either acute onset or fluctuating course—and disorganized thinking or altered level of consciousness should be considered to have delirium and evaluated for acute medical problems as the cause. Cognitive function can be further assessed with formal mental status tools such as the Mini-Mental Status Exam (MMSE). These scales are useful because they are widely accepted as indicative of cognitive dysfunction and can be followed by different clinicians over time (Figure 307-2).

Delirium, dementia, or decreased level of consciousness are usually obvious on history and physical examination. The Glasgow Coma Scale is useful for classifying a decreased level of consciousness. Acute mental status changes in older patients represent a medical emergency of presumed organic cause requiring diagnostic tests to determine the etiology.¹² The differential diagnosis includes a large number of disorders such as pneumonia, urosepsis, electrolyte imbalance, medication reaction, or congestive heart failure, which can cause a decrease in mental status.

1. ACUTE ONSET OR FLUCTUATING COURSE		
Is there evidence of an acute change in mental status from the patient's baseline?	No	Yes
or		
Did the (abnormal) behavior fluctuate during the day (i.e., tend to come and go or increase and decrease in severity)?		
II. INATTENTION		
Did the patient have difficulty focusing attention (e.g., being easily distractible or having difficulty keeping track of what was being said)?	No	Yes
III. DISORGANIZED THINKING		
Was the patient's thinking disorganized or incoherent (e.g., rambling or irrelevant conversation, unclear or illogical flow of ideas, or unpredictable switching from subject to subject)?	No	Yes
IV. ALTERED LEVEL OF CONSCIOUSNESS		
Overall, how would you rate the patient's level of consciousness?		
—Alert (normal)		
—Vigilant (hyperalert) —Lethargic (drowsy, easily aroused) —Stupor (difficult to arouse) —Coma (unarousable)		
Do any checks appear on this sheet?	No	Yes

FIG. 307-1. Confusion Assessment Method (CAM) worksheet. The diagnosis of delirium is suggested with the presence of the first two criteria and either the third or fourth criteria. 	Hospital?	_____	1
	Floor?	_____	1
Registration			
3. Name three objects, taking one second to say each. Then ask the patient to repeat all three after you have said them.		_____	3
Give one point for each correct answer. Repeat the answers until patient learns all three.			
Attention and calculation			
4. Serial sevens. Give one point for each correct answer. Stop after five answers. Alternate: Spell WORLD backwards.		_____	5
Recall			
5. Ask for names of three objects learned in question 3. Give one point for each correct answer.		_____	3
Language			
6. Point to a pencil and a watch. Have the patient name them as you point.		_____	2
7. Have the patient repeat "No ifs, ands, or buts."		_____	1
8. Have the patient follow a three-stage command: "Take a paper in your right hand. Fold the paper in half. Put the paper on the floor."		_____	3
9. Have the patient read and obey the following: 'CLOSE YOUR EYES.' (Write it in large letters.)		_____	1
10. Have the patient write a sentence of his or her choice. (The sentence should contain a subject and an object and should make sense. Ignore spelling errors when scoring.)		_____	1
11. Have the patient copy the design. (Give one point if all sides and angles are preserved and if the intersecting sides form a quadrangle.)		_____	1
			
		_____ = Total	30
<p>In validation studies using a cutoff score of 23 or below, the MMSE has a sensitivity of 87%, a specificity of 82%, a false-positive ratio of 39.4%, and a false-negative ratio of 4.7%. These ratios refer to the MMSE's capacity to accurately distinguish patients with clinically diagnosed dementia or delirium from patients without these syndromes.</p>			

FIG. 307-2. Mini-Mental Status Examination (MMSE). (Courtesy of Marshall Folstein. Reproduced with permission from Folstein MF, Folstein S, McHugh PR: Mini-Mental State Examination: A practical method for grading cognitive state of patients for the clinician. *J Psychiatr Res* 12:189, 1975.)

Functional Decline

Functional decline represents a change in a patient's ability to perform tasks of independent living and is not a part of normal aging. This can be assessed with the use of a standard scale for activities of daily living (ADL), which evaluates a patient's ability for bathing, dressing, toileting, transferring (in or out of a bed or chair), continence, and feeding (Table 307-2). The patient is asked whether he or she can perform each of these functions with no assistance, with partial assistance, or cannot perform these functions. If a patient cannot perform these basic activities of daily living, then a caregiver is necessary. Deterioration in ADL generally follows an orderly progressive pattern of bathing, dressing, toileting (including continence), transferring, and feeding. When this pattern is not seen, such as deterioration in feeding before the others, organic disease should be suspected. Another scale, the instrumental activities of daily living (IADL), assesses more sophisticated skills, such as telephone use, walking, shopping, preparing meals, housework, handiwork, laundry, taking medicines, and han-

dling finances (see Table 307-2). It is best to use these formal scales in evaluating older patients and assessing changes over time. Acute functional decline represents an acute medical syndrome that needs appropriate workup and treatment (Figure 307-3). The differential diagnosis for functional decline includes serious diseases such as myocardial infarction, sepsis, and subdural hematoma, as well as adverse drug reactions. Patients will often present with a vague symptom, such as weakness, that on further questioning and use of the scale is noted to be functional decline. A functional assessment in the ED can be used to guide decision making regarding hospitalization, discharge planning, and future health care needs.¹³

Trauma

Trauma is a major cause of morbidity and mortality among older persons. Although fewer than 20 percent of trauma patients are 65 years of age or older, older patients represent 28 percent of trauma deaths.¹⁴

TABLE 307-2 Activities of Daily Living (ADL) and Instrumental Activities of Daily Living (IADL) Scales

Activities of Daily Living (ADL) Scale (Katz et al)	Instrumental Activities of Daily Living (IADL) Scale (Lawton and Brody)
Bathing	Telephone use
Dressing	Walking
Toileting	Shopping
Transfer	Preparing meals
Continence	Housework
Feeding	Handiwork
	Laundry
	Take medicines
	Manage finances

They are more likely to have significant complications and prolonged hospitalizations because of their decreased functional reserve. Falls are the most common mechanism of injury for older persons, followed by motor vehicle crashes and pedestrian accidents. Regardless of injury severity or mechanism of injury, mortality starts to increase for patients at 50 years of age and continues to increase with increasing age. The major challenge for emergency physicians who treat older patients with multisystem trauma is that the standard physiologic indices, such as blood pressure and pulse, often remain within normal limits until the patient deteriorates acutely. Occult shock must be strongly suspected in all older patients who experience significant trauma. Early hemodynamic monitoring of older trauma patients can detect occult shock early in the course and improve the chance of survival (see Chap. 253).^M

Falls

Falls are not a normal part of aging.¹⁵ A fall is a symptom, and emergency physicians need to assess both the cause and the consequences

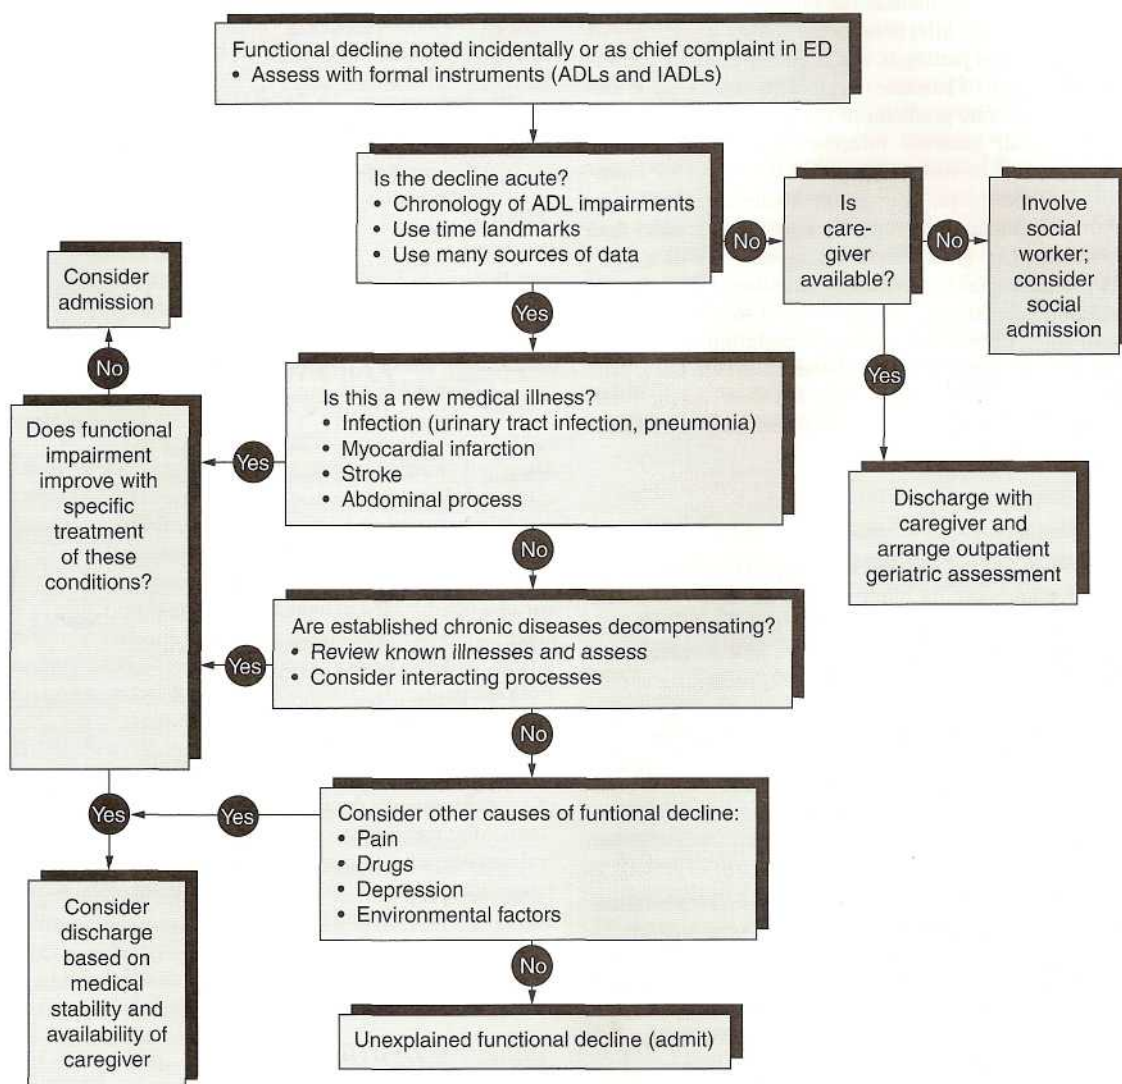

FIG. 307-3. Algorithm for the evaluation and management of functional decline in elderly patients. Abbreviations: ADL = activities of daily living scale; IADL = instrumental activities of daily living scale. [Reproduced with permission from Lachs MS: Functional decline, in Sanders AB (ed): *Emergency Care of the Elder Person*. St. Louis, Beverly Cracom Publications, 1996, pp 143.]

of the fall.¹⁶ The causes of a fall may include acute or chronic diseases, medications, and environmental factors. Consequences of a fall include injury and fear of falling, resulting in a decrease in activities. A fall can represent a sentinel event in an older person's life and result in a downward spiral of decreased activities, leading to death. As many as 50 percent of older patients admitted to the hospital after a fall die within 1 year. An emergency physician should obtain the history of what caused the fall and determine whether further ED screening tests (electrocardiography, computed tomography, laboratory tests, social service consultation, etc.) need to be done to evaluate the cause. The patient should then be informed about fall assessment programs that decrease the incidence and morbidity from falls.

Infections

Multiple factors as well as changes in the immune system with age are responsible for the increased susceptibility to infection in the elderly.¹⁷ In addition, older persons will have atypical disease presentations of sepsis. Focal symptoms or signs of infection may be lacking. Instead, patients may present with isolated fever or nonspecific symptoms of anorexia, weakness, fatigue, and functional decline as the only evidence of infection. Hypothermia may be evident instead of fever. The most common sites of infection include the lungs, urinary tract, abdomen, and skin. Urinary tract infections in the elderly encompass a broader spectrum of potential pathogen, and is complicated by comorbidities, the frequent presence of baseline asymptomatic bacteriuria, and the lack of pyuria as an accurate predictor of urinary infection.¹⁸

Bacteremia and occult bacterial infection are common in the febrile elderly. Mellors and coworkers identified the following multivariate predictors of bacteremia and occult bacterial infection in febrile adults without localizing symptoms or signs: (1) age older than 50 years; (2) diabetes; (3) white blood cell count (WBC) greater than 15,000/ \times L; (4) neutrophil band count greater than 1500/ \times L; and (5) erythrocyte sedimentation rate greater than 30 mm/h.¹⁹ Patients with one or two of these factors had a seven- to eightfold relative risk for bacteremia or focal bacterial infection. Other studies in the febrile elderly have also found that leukocytosis and "left shift" on the WBC differential was also associated with a two- to threefold greater likelihood of bacterial infection.

DISPOSITION

For all the foregoing reasons, elderly patients in the ED are more likely to require hospital admission for their illness or injury than are younger patients. When discharged from an ED, elderly patients may not fully understand the instructions, may not be able to obtain and take prescribed medications, may not be able to access appropriate follow-up, or may not be able to care for their personal needs during the period of illness. An elderly patient's family, friends, and social support system should be informed and involved before the patient leaves the ED.

ADULTS WITH PHYSICAL

DISABILITIES Paul J.W. Tawney

John N. Oh

Many individuals live with significant impairments and disabilities; an estimated 5 to 10 percent of the total population of the United States has major disabilities. Persons with disabilities seeking medical care in an ED may present with problems that are specific to their impairment or with signs and symptoms different from those that would occur in a nondisabled patient. An important principle in evaluating disabled adults is to remember that the individual who is disabled is not unable, and every effort should be made to obtain the history directly from the patient. Do not automatically direct questions to persons with the disabled individual without first finding out whether the patient is capable of giving accurate responses. Sit down to get at eye level with a patient in a wheelchair. Make an effort to use a dysphasic or dysarthric patient's communication system so that they may tell their story. After emergency care is rendered, referral of patients with physical and cognitive impairment to a physiatrist (a physical medicine and rehabilitation physician) is appropriate for comprehensive management of functional deficits.

SPINAL CORD INJURY

Autonomic Dysreflexia

Patients with spinal cord injuries at or above the T6 level are at risk for developing autonomic dysreflexia (also called autonomic hyperreflexia).^{1,2} This reflex is initiated by a noxious stimulus from below the level of the patient's spinal cord lesion. Intact sensory neurons below the level of the lesion transmit a message up the spinothalamic

tract and posterior columns, where interconnections stimulate the intermediolateral gray matter neurons, producing sympathetic outflow from spinal cord levels between T6 and L2, releasing norepinephrine, (3-hydroxylase, and dopamine. This sympathetic reflex is relatively unopposed because the normal inhibitory impulses that would prevent it originate above T6 and are blocked at the level of injury.²

The sympathetic response produces a rise in blood pressure, vasoconstriction, skin pallor, and piloerection below the level of the lesion. Intact carotid and aortic arch baroreceptors detect the hypertension, producing increased parasympathetic activity in the vagus nerve causing bradycardia and, above the level of the lesion, profuse sweating, vasodilation, and skin flushing.^{1,2}

Common signs and symptoms of autonomic dysreflexia are a pounding headache, nasal congestion, a feeling of apprehension or anxiety, visual changes, and most significant, a marked increase in systolic and diastolic blood pressure above baseline.^{1,2} Patients with spinal cord injury at or above the T6 level often have lower baseline systolic blood pressures, in the 90- to 110-mm Hg range. Therefore, blood pressure elevations of 20 to 40 mm Hg or systolic pressures of 130 to 150 mm Hg are significant. Acute elevation in blood pressure is the most worrisome and potentially life-threatening manifestation of this syndrome.

A variety of stimuli can produce an acute episode of autonomic dysreflexia. The most common causes usually involve the urinary system: bladder distention, urinary tract infection, and kidney stones. The second most common reasons involve the colon: fecal impaction or bowel distention. However, any noxious stimulus below the level of injury can lead to autonomic dysreflexia, including peptic ulcers, appendicitis, and gallstones, fractures, deep venous thrombosis (DVT), pressure ulcers, ingrown toenails, tight-fitting clothing, sunburns, blisters, heterotopic ossification, sexual intercourse, pregnancy, and labor and delivery.

Treatment begins with monitoring and controlling the patient's blood pressure. If possible, the patient should sit up to lower blood pressure.^{2,3} All constrictive clothing items should be loosened. If the systolic blood pressure is above 150 mm Hg, an antihypertensive agent with a rapid onset and short duration should be used.³ Nitroprusside and nitrates are the most commonly used agents. More aggressive treatment should be undertaken if these agents do not adequately correct the elevated blood pressure.

After assessment of the blood pressure, the bladder should be checked for distention and infection.^{2,3} If the patient does not already have a urinary catheter, one should be placed. The stimulus of catheterization may add to the autonomic reflex, and lidocaine jelly should be used in the urethra prior to catheter insertion if it is readily available, but its lack should not delay the placement of the catheter. If the patient already has an indwelling urinary or suprapubic catheter, it should be checked for obstruction and proper placement. The bladder can be gently irrigated through the catheter with body-temperature normal saline solution to check for obstruction and improper placement. Urine should be sent for urinalysis and culture.

If symptoms persist, the physician should suspect fecal impaction.^{1,2} Prior to the rectal examination, the patient's blood pressure should be managed, and the anal opening should be anesthetized with lidocaine jelly placed into the rectum for 5 min before beginning the examination.^{1,2} The patient's blood pressure should be monitored to ensure that the hypertension is not aggravated during this procedure, since rectal examination can exacerbate autonomic dysreflexia. If the blood pressure increases, stop the examination, instill more anesthetic agent, and wait additional time. If the bladder or bowel does not appear to be the cause of the patient's symptoms, a search for other causes should be undertaken.

Following relief of an acute episode, patients should be monitored for at least 2 h after resolution to ensure that there is no recurrence.³ Patients with bladder distention do not routinely require discharge with an indwelling urinary catheter. It is best to discuss that option with the patient's physician. If the patient responds poorly or the cause has not been identified, the patient may be admitted for more aggres-

sive pharmacologic control of blood pressure and a more thorough investigation of the cause.^{4,5} The Clinical Practice Guideline for Acute Management of Autonomic Dysreflexia available through the Paralyzed Veterans of America (www.pva.org) is highly recommended.

Urinary Tract Infection

A urinary tract infection should be suspected when a spinal-cord-injured patient presents with fever, discomfort over the kidney or bladder, worsening spasticity, development of urinary incontinence, autonomic dysreflexia, cloudy or foul-smelling urine, a change in energy level, or a feeling of apprehension.⁴ Unless there are confounding factors, the urinalysis shows pyuria and significant bacteriuria. In a patient with the above-mentioned symptoms and signs and pyuria, empiric treatment for urinary tract infection should be initiated. Absence of pyuria makes the diagnosis less likely but does not completely exclude it. Conversely, pyuria in an asymptomatic patient with spinal cord injury does not warrant treatment. Pyuria without infection can occur from irritation of the bladder wall in patients with indwelling catheters and in those who use intermittent catheterization.⁵

Significant bacteriuria for the spinal-cord-injured population is defined according to the method used for bladder emptying. For women who can spontaneously void, significant bacteriuria is defined as greater than 100,000 colony-forming units (CFUs) of bacteria per milliliter. For men who spontaneously void or use condom catheters, greater than 10,000 CFUs/mL is considered significant. For both women and men who use intermittent catheterization, greater than 100 CFUs/mL indicates significant bacteriuria. For patients with indwelling urethral or suprapubic catheters, any detectable level of bacteriuria is significant.⁴

Urinary tract infections in the spinal-cord-injured population are considered complicated urinary tract infections.⁶ Antibiotics with broader-spectrum coverage should be used, since such organisms as *Proteus*, *Klebsiella*, *Pseudomonas*, *Serratia*, *Providencia*, enterococci, and *Staphylococcus* are more common. Because of the higher risk of upper-tract infection, 7 to 14 days of treatment should be considered.^{4,6}

Asymptomatic bacteriuria is very common in patients with a neurogenic bladder and requires periodic or indwelling catheterization. Asymptomatic bacteriuria should not be routinely treated.^{4,5}

Acute Abdomen

Classic signs of the acute abdomen are often missing in patients with spinal cord injury.⁷ The diagnosis of perforated peptic ulcer, intestinal obstruction, appendicitis, peritonitis, cholecystitis, and renal abscess is often delayed because the classic findings of abdominal muscle rigidity, rebound, abdominal tenderness, fever, and leukocytosis may not be present. In patients with spinal cord injury, other signs and symptoms suggestive of an acute abdomen are autonomic dysreflexia, referred scapular tip pain, abdominal distention, change in muscle spasticity, nausea and vomiting, and a sense of apprehension.⁷ A high index of suspicion, along with laboratory and imaging tests, is necessary to avoid missing the diagnosis.⁸ One confounding factor is that urinary tract infections may present with similar signs and symptoms. Thus the finding of pyuria or bacteriuria alone should not be used to exclude the diagnosis of an acute abdomen. While abdominal radiographs are also useful in the diagnosis of intestinal obstruction, many patients with spinal cord injury have chronic dysmotility problems and have baseline increased bowel gas and air-fluid levels that may mimic a mechanical obstruction. Ultrasound, radiologic studies using radiocontrast media, and computed tomography (CT) imaging studies are often required for correct diagnosis in such patients.⁸

Syringomyelia

Posttraumatic syringomyelia may present months to years after a spinal cord injury.^{9,10} This process produces a cystic cavitation of the

central cord that may extend over several levels. Ascending sensory level (i.e., a decrease or loss of sensation above the preexisting sensory level) and pain are the most common presenting symptoms. Motor weakness, a change in spasticity, and a change in deep-tendon reflexes may also be seen. Magnetic resonance imaging is the imaging study of choice for making the diagnosis of syringomyelia. Surgery is indicated in progressive neurologic deterioration.

Immobilization Hypercalcemia

Risk factors for immobilization hypercalcemia include age less than 21 years, complete neurologic injuries, cervical injuries, prolonged immobilization, and dehydration.¹¹ Presenting symptoms include anorexia, nausea, headache, malaise, and depression in mild cases. In more severe cases, patients may have persistent nausea and vomiting, gastric dilatation, fecal impaction, and abdominal pain. Microscopic calcium deposition in the kidney may impair its ability to concentrate urine, leading to polyuria and polydipsia. Patients may also develop cardiac dysrhythmias and seizures.¹²

The pathophysiology of immobilization hypercalcemia is thought to be due to the combination of increased bone resorption and the inability of the kidneys to excrete the excess calcium. Compared to other age groups, adolescents are at higher risk due to a higher-than-normal bone turnover rate and more total bone mineral.^{11,12} Immobilization causes a decrease in osteoblastic activity in the weight-bearing bones and an increased rate of bone resorption. Together, these factors lead to a higher-than-normal serum calcium level during prolonged periods of immobilization. In most cases, the kidneys can usually excrete the calcium, but in some patients this ability breaks down.

Treating immobilization hypercalcemia starts with hydration and diuresis with NS solution 2 to 3 L/d with the addition of furosemide. Calcitonin in doses of 1 to 4 IU/kg SC every 12 h can also effectively reduce the serum calcium level.^{11,12}

Heterotopic Ossification

Heterotopic ossification (HO) is the formation of bone in the soft tissues.¹³ The mechanisms of the formation of heterotopic bone are not precisely known. In spinal-cord-injured patients, it is more common among those with spasticity. Symptoms may present as early as 1 month after injury. Pain is prominent in other patients with HO but is often absent in spinal-cord-injured patients. For spinal-cord-injured patients, the most common symptom of HO is a decreased range of motion. Other findings are a change in spasticity, fever, erythema, joint effusion, and swelling.¹³ The differential diagnosis includes DVT, infection, and tumor. Sometimes HO and DVT are seen together.

The incidence of HO in spinal-cord-injured patients has been reported to be 16 to 53 percent. The most common sites are the hip, knee, femur, and shoulder. Plain radiograph findings are often negative in the early stages of HO. The gold standard for diagnosis is the three-phase bone scan. Serum alkaline phosphatase (ALP) levels have been used as a screening test for HO, since developing bone produces ALP. However, this is a nonspecific test indicating increased bone metabolic activity, which may occur in fractures or tumors.

Treatment for HO is usually disodium etidronate 20 mg/kg per d for 2 weeks followed by 10 mg/kg per day for 10 weeks, along with gentle physical therapy. Referral to a physiatrist (a physician specializing in the care of patients with disabilities) or other spinal-cord-injury specialist is recommended to institute and monitor treatment.

Leg Pain

If a patient with spinal cord injury or a brain injury presents with a swollen and painful leg, the differential diagnosis includes trauma (e.g., contusion, sprain, or fracture), spasticity, DVT, heterotopic ossification, and reflex sympathetic dystrophy.¹ For those individuals who

have impaired sensation, language, or cognition that might hinder the history and physical examination, a high index of suspicion and liberal use of ancillary studies are critical. Plain radiographs are usually adequate for evaluating trauma. For those who have suffered from a recent spinal cord injury (within 8 weeks), the risk of deep vein thrombosis is substantial, most likely from venous stasis. Signs and symptoms include swelling, pain, and warmth. Noninvasive venous studies (duplex Doppler) are usually adequate for evaluating DVT.

Another likely cause of leg pain is spasticity. This condition is often chronic in nature, but certain noxious stimuli may acutely worsen the symptoms. Such causes include infections (UTI, upper respiratory infections, pneumonia, gastroenteritis, etc.), trauma, and stress. Initial treatment is to identify and eliminate these causes. Baclofen is the first line for medicinal treatment and should be started at a dose of 5 mg PO tid, and titrated upward according to symptoms. If the patient does not respond to baclofen, tizanidine, diazepam, and dantrolene may be tried. Once the patient is stabilized, a referral to a physiatrist or other specialist in the care of patients with spinal cord injury should be arranged.

BRAIN INJURY

Posttraumatic Hydrocephalus

Patients with a history of traumatic brain injury may present to the emergency department with the complaint of changing functional status, including psychomotor slowing, cognitive decline, change in gait, and loss of continence.¹⁴ An evaluation for possible infectious or metabolic causes must be undertaken, but a CT scan of the head is critical to evaluate for posttraumatic hydrocephalus.^{14,15} A CT scan revealing periventricular lucency, diminishing sulci, and dilatation of the ventricles suggests posttraumatic hydrocephalus. Consultation with a neurosurgeon for appropriate treatment options, such as shunting, should be undertaken.

THE MENTALLY RETARDED ADULT

Linmarie Sikich

Evaluating a developmentally disabled adult in the ED poses a number of challenges, including accurately assessing the ability of the individual to communicate his or her complaints, the ability to make an accurate diagnosis in the absence of sufficient historical information, and the recognition of unusual presentations of common disorders. In addition, 25 percent of individuals with developmental disabilities appear to have significantly increased pain thresholds that result in reduced responses to illnesses and to physical examinations.¹ Such pain insensitivity may limit recognition of medical problems (e.g., intestinal obstruction) until late in the disease process, with potentially catastrophic consequences. Treatment of developmentally disabled individuals is also complicated by questions about guardianship, decreased ability of the patient to understand the treatment recommendations, and often, inadequate preventative and routine medical care. However, it is essential that health care providers overcome these obstacles to provide care to this special population that has difficulty advocating for itself.

EPIDEMIOLOGY

The primary developmental disability is mental retardation, defined as significant cognitive (IQ less than 70) and functional delays with onset before adulthood. Over 40 percent of individuals with mental retardation have associated medical conditions. Typically, the lower the patient's IQ, the more likely a specific etiology of the mental retardation can be identified. Etiologic factors implicated in mental retardation may be prenatal, perinatal, postnatal, or traumatic. Genetic factors account for 7 to 15 percent of all mental retardation; there are 500 genetic syndromes known to be associated with mental retardation.² Depending on the etiology, some medical problems are associated with specific mental retardation syndromes (Table 309-1).³⁻⁵

About 6 million individuals in the United States and 150 million in the world (2.5 percent of the population) have mental retardation. Two other developmental disorders, autism spectrum disorders and language disabilities, are also important for health care providers to recognize. Many autistic individuals have tactile defensiveness and become very agitated when they are touched, which complicates physical examination. People with either autism or language disorder often have difficulty communicating their symptoms and understanding, appropriately generalizing, and responding to information about suggested medical treatments, regardless of their level of cognitive functioning.

Over the past 20 to 30 years there has been a movement in the United States to remove developmentally disabled individuals from institutional settings and care for them in the community. About 89 percent of American adults with mental retardation currently are in the community. However, adults with mental retardation who were moved from an institutional setting to the community had a 51 percent greater mortality rate than those who remained in the institution,⁶ although this may not be generalizable to all communities.⁷ The caretakers of individuals with developmental disabilities who have recently moved may lack adequate knowledge of the patient's baseline and past medical history.⁸

GENERAL APPROACH

The general approach consists of avoiding overstimulation, gathering specific and collateral information, assessing the patient's ability to communicate, performing a physical examination, and obtaining appropriate ancillary studies.

Individuals with intellectual disabilities should be evaluated in an area with as few distractions as possible by a limited number of health care providers.⁹

TABLE 309-1 Medical Problems Associated with Specific Mental Retardation Syndromes

Syndrome	Incidence	% MR	Common Medical Problems
Down	1/1000	4-12	Atlantoaxial instability; obesity; leukemia; dementia; sleep apnea; hypothyroidism; diabetes; cataracts; hearing loss; congenital heart disease
Fragile X	0.67/1000	1-6	Seizures; mitral valve prolapse; dilated great arteries; otitis
Fetal alcohol	2/1000	10	Seizures; congenital heart disease; eye problems; hearing loss
Prader-Willi	0.1/1000	0.4	Obesity; sleep apnea; hypoventilation; diabetes; inability to vomit; hypertension; ischemic heart disease
Williams	0.1/1000	0.4	Hypertension; supravalvular aortic stenosis; ulcers; renal artery stenosis; urethral stenosis; diverticulitis; vesicoureteral reflux; hypercalcemia
Lesch-Nyhan	0.02/1000	0.08	Severe self-injurious behavior; sudden death; gout; renal calculi; renal failure
Tuberous sclerosis	0.1/1000	0.4	Brain and skin tubers; seizures; rhabdomyomas of heart; angiomyolipomas of kidney; renal failure
Cerebral palsy	3/1000	12-30	Pain; contractures; seizures; respiratory and urinary tract infections

Abbreviation: MR = Mental retardation.

Determine the patient's specific baseline behaviors in the following areas: (1) communication, (2) environmental awareness, (3) motor activity, (4) urinary and bowel habits, (5) sleep pattern, (6) appetite, and (7) use of assistive devices such as glasses or hearing aids. Acute disease processes in individuals with developmental disabilities often present as nonspecific changes in routine activities rather than focal complaints. Obtain a complete past medical history, an accurate list of medications, and history of prior adverse medical reactions. Frequently used medications and associated side effects are shown in Table 309-2. Next, determine the patient's living situation. Even relatively minor changes in routine or caretakers can have a dramatic impact on the functioning of some developmentally disabled individuals. Ask both the patient and caretakers about possible physical or sexual abuse. Rates of sexual assault in girls with developmental disabilities appear to be two- to fivefold higher than in typically developing girls.¹⁰ Also identify resources for appropriate follow-up care within the community. Finally, determine whether the patient has a guardian, or if not, if the patient is capable of making decisions about medical care.

The evaluation of developmentally disabled patients usually requires collateral information from parents, group home staff, or social service agency staff. The extent and importance of such information increases as the developmentally disabled patient's ability to communicate decreases. Ask the collateral source explicitly how much they know or have in writing, and whether there are others with more information who can be contacted by phone. When possible, written collateral information should be reviewed prior to seeing the patient. Such information often clarifies the patient's usual level of cognitive functioning and communication, past medical history, current medications, and longitudinal vital signs.

TABLE 309-2 Frequently Used Medications and Side Effects

Medications	Frequency of Use*	Important Side Effects
Psychotropics	44%	
Antipsychotics		Extrapyramidal symptoms; neuroleptic malignant syndrome; dystonia can affect swallowing and breathing; sedation; orthostatic hypotension; weight gain; constipation
SSRIs		Gastrointestinal distress; agitation; insomnia; sedation
Benzodiazepines		Sedation; disinhibition; agitation; delirium
Anticholinergics		Blurry vision; urinary retention; constipation
Lithium		Hypothyroidism; delirium; cardiac arrhythmias
Anticonvulsants	30–50%	
Carbamazepine		Sedation; delirium; ataxia
Lamotrigine		Blood dyscrasias; rashes; constipation; lowers other drug levels
Cardiovascular	25%	Severe rashes
		Overdosage may lead to cardiotoxicity
Laxatives	20%	
		Vitamin deficiencies
Bronchodilators	14%	
		Agitation; decreased bone mineralization
Analgesics	12%	
		Renal problems; anemia
Histamine blockers	10%	
		Psychosis
Thyroid supplements	8%	
		Psychosis; agitation; hot flashes; odd skin sensations

Abbreviation: SSRI = Selective serotonin reuptake inhibitor.

*Source: Data from Cooper SA: Clinical study of the effects of age on the physical health of adults with mental retardation. *Am J Ment Retard* 102:582,

Assess the Individual's Ability to Communicate

Developmentally disabled individuals have a broad range of cognitive and communicative abilities. Approach patients in a manner consistent with their abilities and be sensitive to and respectful of their thoughts and feelings. About 85 percent of mentally retarded individuals are mildly impaired and typically function at about a fifth-grade level. They can generally provide relevant history and describe many of their symptoms. They are also likely to understand simple written directions. About 10 percent of mentally retarded adults are moderately affected; they function at the level of a preschool child, are likely to be able to follow commands, and may be able to answer simple questions. The remaining 5 percent are likely to have no expressive language, although they sometimes can follow simple commands. Individuals with autism or language disabilities often have significantly more communication impairments than cognitive limitations.

Patients should be directly interviewed in addition to gaining information from collateral sources. If individuals are verbal, attempt open-ended rather than yes/no questions. It is also helpful to ask higher-functioning individuals to repeat back information to make sure they have understood. Many mentally retarded individuals have particular difficulties with time and causality concepts. Nonverbal patients may be able to point in response to simple questions.

A thorough physical examination is needed because sufficient history is often not available to focus the examination. However, examination may be difficult in patients with extreme agitation or tactile defensiveness. The physician should thoroughly explain and (when possible) demonstrate all procedures prior to performing them. If not

medically contraindicated, it may be helpful to offer the patient food or distractions. A familiar person should be present during the examination and for any procedures. If the patient is still too anxious to allow an evaluation, an anxiolytic may be indicated or assistance may be required to briefly hold the patient. During the exam, special attention should be given to all body orifices because objects are often inserted into these areas without the caretakers' knowledge. Vital signs should be obtained when the patient is calm.

Ancillary studies should be obtained as appropriate. If there are no localizing symptoms or physical signs, complete blood cell count, electrolytes, liver function tests, urinalysis, and serum drug levels may be necessary.¹¹

FREQUENTLY ENCOUNTERED PROBLEMS

The incidence of medical problems is greater in individuals with developmental disabilities than in the general population. These differences are most pronounced for individuals with severe to profound mental retardation. For individuals with mild cognitive limitations, the rate of chronic medical problems increases significantly after age 30. Chronic medical problems in the mentally retarded population include seizures; nonischemic heart disease, gastrointestinal problems, and pulmonary disease (in individuals younger than 50); and osteoporosis, arthritis, sensory impairment, and dementia (in the elderly).^{12,16} Emergency department visits are most often precipitated by infections (35 percent), trauma (33 percent), seizures (15 percent), and gastrointestinal concerns (5 percent).¹² In addition, agitation frequently leads to ED evaluations. Most often, mortality is related to respiratory or cardiovascular events, though bowel perforation and seizures are also

Infections

Infections are common in the developmentally disabled population. Aspiration is common in individuals with oral-motor dyspraxias, esophageal reflux, and tube feedings. Urinary tract infections are common, partially due to neurogenic bladder, limited mobility, and poor hygiene. Because individuals may not initially recognize or describe dysuria, they are at greater risk for pyelonephritis. With a history of repeated urinary tract infections, it is important to exclude congenital malformations of the urinary system. Skin infections, dental caries, and periodontal disease are also common.

Injuries

Injuries may be self-inflicted, accidental, or result from assault. Minor trauma can result in fractures because patients are more likely to be osteopenic.¹⁷ The majority of injuries that mentally retarded individuals experience are the result of self-injurious behaviors. Although self-injurious behaviors may be self-stimulating, medical and environmental precipitants are often identified if the self-injurious behaviors are of sudden onset. Bosch and colleagues found that in 28 percent of their patients, treatment of previously undiagnosed, painful medical conditions resulted in significant reductions in self-injurious behaviors.¹⁸ Constipation, gastroesophageal reflux, and peptic ulcer disease were the most common disorders. In these cases, there had often been a cyclic pattern to the self-injurious behaviors or a recent exacerbation. Similarly, increased self-injurious behaviors are often associated with anxiety. If no medical or environmental precipitants for these behaviors can be identified, it may be useful to treat individuals with selective serotonin reuptake inhibitors (SSRIs). Naltrexone or atypical antipsychotics may also be useful. Protective behavioral measures such as a helmet to prevent head-banging may be needed to avoid further injury.

Neurologic Problems

SEIZURES Thirty to 50 percent of all developmentally delayed individuals have seizure disorders. Often, an individual experiences several different types of seizures. The mortality associated with seizures is 2 to 3 times greater among individuals with mental retardation than among those with normal intelligence.¹⁹ The priorities are to ensure adequate oxygenation, stop the seizure, and identify seizure precipitants. Seizures are commonly precipitated by a change in medication. Unintentional medication changes may occur when a person with mental retardation moves to a new living situation, because a medication has been forgotten or given incorrectly. Other common seizure precipitants are addition of new medications that alter the seizure threshold or infection.

DELIRIUM Developmentally disabled individuals appear to be particularly vulnerable to delirium. Typically, caretakers will describe a relatively acute change in mental status. Visual and tactile hallucinations and agitation are not uncommon. Most often, the delirium results from infection or drug toxicity. The latter may occur at low medication doses. Toxicity may also be precipitated by interactions with other medications. For instance, erythromycin and fluoxetine slow the metabolism of several anticonvulsants. Anticonvulsants and anticholinergics frequently cause delirium. Less often, delirium results from metabolic disturbances including hyperglycemia, hypothyroidism, hypoxia, or vitamin or cofactor deficiencies (e.g., carnitine in individuals treated with valproic acid).

SPINAL CORD COMPRESSION DUE TO ATLANTOAXIAL INSTABILITY **Individuals with mental retardation, especially Down syndrome, often have atlantoaxial instability as a result of connective tissue laxity and anomalies of the atlas and axis.** The spinal cord is vulnerable to compression with neck flexion or extension. Intubation, tracheal suctioning, laryngoscopy, bronchoscopy, and dental work are examples of procedures that can result in neck flexion and cord compression. Chronic atlantoaxial instability can also cause more subtle neurologic manifestations, such as easy fatigability, difficulties in walking, neck pain, limited neck mobility, torticollis, clumsiness, sensory deficits, incontinence, and spasticity. These symptoms may progress to paralysis or even death. Most individuals have had symptoms for more than a month prior to their diagnosis. Rarely, sudden subluxation has occurred when there was a sudden change in momentum, as in motor vehicle accidents.²⁰ Treatment of atlantoaxial instability usually involves surgical stabilization.

Gastrointestinal Disorders

Erosive esophagitis and ulcers are common causes of gastrointestinal bleeding in patients with developmental disabilities. About 40 percent of mentally retarded individuals have severe constipation, often with overflow diarrhea and infrequently with rectal tears. Treatment must include both acute and long-term measures. Pica is present in many individuals, about 10 percent of whom will develop bezoars or intestinal obstruction.

Psychiatric Disorders

Psychiatric disorders are estimated to afflict up to 50 percent of the developmentally disabled population. Emergency visits are usually precipitated by aggression or extreme agitation. In such cases, benzodiazepines or low-dose, low-potency antipsychotics, may be acutely helpful in controlling the patient's behavior sufficiently to proceed with an evaluation. Undiagnosed, painful medical problems, including severe constipation, are common causes of behavior problems.¹² Sleep

apnea or anxiety can also be manifest as increased irritability. Anxiety may result from environmental factors, such as change in caretaker or uncorrected sensory deficits, posttraumatic stress disorder, or panic attacks. Akathisia, a dose-related side-effect syndrome caused by both typical and atypical antipsychotics, is manifest as agitation and hyperactivity. Akathisia should be considered if there is a history of worsening agitation with increased antipsychotic medications. This disorder usually responds to propranolol. Finally, agitation may occur in response to psychotic symptoms. Catatonic behavior may reflect delirium, depression, or status epilepticus with absence or partial-complex seizures. Mood disorders typically present with changes in the patient's sleep, appetite, and activity level.

THE HOMELESS PATIENT

Rama B. Rao Lewis R. Goldfrank

Homelessness is a social problem of epidemic proportions worldwide.¹ In the United States alone, estimates of the homeless population range between 3 and 13.5 million, and as much as 7.4 percent of the general population will experience homelessness in their lifetime. Homelessness affects a diverse population of all ethnic groups and includes both urban and rural families, the elderly, children, veterans, migrant farm workers, mentally ill persons, and persons with substance use disorders. Minority groups are overrepresented in this population, most likely due to disparities in economic opportunities. Causes of homelessness are related to divorce or separation, domestic violence, pregnancy, adolescent runaways, substance use, eviction, acute or chronic unemployment, and the deinstitutionalization of persons with mental illness. A disparity between the need for low-income housing and its availability has also contributed to the epidemic of homelessness.

Homelessness has been defined in a variety of ways, including living on the street, in shelters that provide temporary residence, or in single-room occupancy hotels with shared bathrooms. The consequences of homelessness are profound. Homeless adults have an age-adjusted mortality rate nearly four times higher than that of the general population, with a median age of death of 44.² Infant mortality rates among homeless mothers are more than twice those for nonpoor, domiciled mothers, and 50 percent higher than those for poor domiciled mothers. The effects of homelessness on children may be profound, with a higher incidence of acute illnesses and medical treatment.³ Other risks important to homeless populations include communicable diseases, environmental exposures to extreme heat or cold, and traumatic injury due to violent encounters, foraging for food, and seeking shelter.⁴ These factors contribute greatly to acute medical illness among the homeless. Some of the increased risks are associated with poverty, and others are specific to undomiciled patients. Chronic illnesses, such as hypertension and diabetes, are neglected or poorly managed due to desperate living circumstances. Homeless individuals often delay care of minor medical problems until they become severe or unbearable.

The ED is often used as a primary source of medical care for acute and nonacute illnesses of the homeless.^{5,7} Homeless persons have emergency department utilization rates that are 1.5 to 3 times that of the general population, with up to 20 percent reporting that the emergency department was their sole source of medical care.⁷ Outpatient community- and shelter-based clinics provide medical care in a limited fashion and can lead to ED referral for more extensive evaluation and management. In some cities, homeless patients may arrive by police or emergency medical services because of extreme weather emergencies or other health and safety mandates. All of these factors make knowledge of this population important to emergency physicians. The management of the homeless patient is complex, and similarities to the domiciled patient are limited. Decision analysis for this vulnerable population is distinctly different and admission criteria are uniquely dependent on the environment.

CARE AND EVALUATION

Homeless patients may have both specific and nonspecific medical complaints. Once the primary reason for the visit is addressed, a thorough examination of the entire body, including the skin and particularly the feet, should be considered. This is especially necessary for the homeless patient who is disheveled, intoxicated, or has a significant psychosis. A valuable medical history may include the last evaluation for tuberculosis exposure, tetanus immunization status, vaccination status in children, psychiatric history, history of chemical dependence,

and potential for substance withdrawal while receiving care in the ED. A social history may include family support, precipitants of homelessness, and prior contact with a social worker.

SPECIAL MEDICAL CONSIDERATIONS

General Hygiene

Homeless persons have limited access to facilities for maintaining hygiene, and regular bathing and daily dental care may be severely impaired. The emergency physician should closely inspect all of the skin, lower extremities, and perineum as part of the routine evaluation of all homeless patients.

Lower Extremity Diseases

Homeless patients have a variety of lower extremity disorders. Such patients may spend a disproportionate amount of time with their legs in a dependent position while sleeping upright or ambulating for extended periods. The poverty associated with homelessness may prevent some patients from obtaining socks and shoes that are seasonally appropriate and well fitting. Ulcers and wounds from lack of foot protection, blisters from poorly fitting shoes, or bites from rodents or insects may occur.

Some homeless patients may not have an available change of footwear or a place to change and bathe. Socks and shoes may not be removed for days to weeks for reasons such as warmth, fear that footwear may be stolen, embarrassment, or coexisting mental illness. These factors, along with limitations on hygiene, predispose to fungal infections, which can be treated with topical or oral therapy. Also of concern in this population is the condition known as trench foot. Prolonged exposure to moisture around the foot (usually from wet or sweaty socks) leads to absorption of water into the stratum corneum. Over 1 to 2 days, such exposure causes inflammatory changes that result in foot pain and skin breakdown. Bacterial superinfection with *Corynebacterium* species and *Pseudomonas* species can ensue. In the absence of superinfection, analgesia, leg elevation, and drying are adequate to treat the earliest stages of trench foot. In colder climates, frostbite from formation of ice crystals in the tissues is a serious threat to limbs, ears, and nose. Careful in-hospital management is warranted, since the environmental risks persist as long as the patient remains homeless, and compliance with treatment may be difficult if not impossible.

Patients predisposed to peripheral vascular disease can have exacerbation of their illness due to inadequate nutrition, poor protein status, alcoholism and substance use, use of tobacco, and inability to elevate the legs while sleeping upright. The resulting edema can lead to chronic venous stasis ulcers. The ulcers can become infected with common skin flora or even maggots (fly larvae). For uninfected ulcers, the use of venous support garments, such as Unna boots, is a valuable management tool. Unna boots are impregnated with antibiotic ointment and require less frequent changes. Patients with infected ulcers require admission. The erythema associated with cellulitis may be difficult to distinguish from deep venous thrombosis or venous stasis changes. When the diagnosis is unclear, an evaluation of venous flow should be undertaken. For lesions infected with maggots, chloroform is a traditional therapy for deinfestation. Chloroform may not be available due to safety issues of combustibility. Ethyl chloride is an alternative. Ironically, maggots survive by ingesting necrotic tissue, keeping ulcers clean and well debrided. Once deinfestation is completed, close follow-up is mandatory, since natural debridement via fly larvae is terminated. Maggot infestation is a grave sign of serious neglect and suggests the inability to manage a clinical plan outside a supervised setting.

All homeless patients need education to minimize the risk of trench foot and fungal infections. Patients should be told to change or remove

all footwear when environmental conditions allow, examine the feet, and attempt to find a place to rest where their legs may be elevated. Injection drug users should be warned about the risk of skin infection from drug administration into the extremities. Community resources, which can provide clean, dry socks and well-fitting shoes, should be identified. Such preventive measures are especially important for diabetic patients and those who suffer from peripheral neuropathies.

Infections

Homeless patients develop common community-acquired respiratory infections, but tuberculosis is also a threat.⁵ The incidence of tuberculosis increases dramatically when people live under crowded conditions and when patients are immunosuppressed from diseases such as AIDS, malnutrition, or alcoholism. Multiple studies of various homeless populations confirm the high incidence and prevalence of tuberculosis in homeless patients. For homeless patients, compliance with a treatment regimen for an exposure to tuberculosis may be limited. Daily, directly observed therapy programs have been very successful by using incentives to organize therapy and decrease the risk of tuberculosis transmission.

Homeless patients in shelters or other group living arrangements are also at higher risk than are domiciled patients for communicable skin diseases, such as pediculosis (lice), scabies, and impetigo. Defestation of lice and scabies is problematic for patients, since bathing facilities and the ability to wash and change clothing are limited. Patients may return to the environment where infestation originally occurred, and they are at high risk for reinfestation. A dermatologic disease known as bacillary angiomatosis-peliosis has been identified in homeless patients exposed to lice.⁸ The causative organism is *Bartonella quintana*, and the condition can be treated effectively with macrolide antibiotics. *Bartonella quintana* infections may also cause trench fever, endocarditis, and chronic bacteremia in the homeless.⁹

The living conditions of the impoverished can place them at risk for other infections. Diarrheal illness from the ingestion of improperly preserved or discarded food has been poorly studied, but has been described by homeless patients and is particularly problematic when access to toilet facilities is limited. Fecal-oral transmission of illness is also increased.

Sexually transmitted diseases are prevalent in homeless individuals who engage in sexual activity voluntarily or by coercion to obtain food, shelter, cash, or other goods. Money for prophylactic condoms or other forms of contraception is limited, unavailable, or a low priority for survival. These problems, in addition to injection drug use, have led to epidemic rates of HIV among the homeless. Discrimination and disability from HIV disease are also implicated as a cause of homelessness.

The management of HIV disease is complicated for both patients and medical practitioners even under ideal circumstances. Newer drug regimens, which include multiple medications, are expensive and depend on a reliable dosing schedule and follow-up. The use of reverse transcriptase and protease inhibitors may depend on the ability of patients to comply with therapy.¹⁰

Hospital admission of homeless patients with diseases such as varicella or hepatitis may be necessary to avoid infections in shelters or other public areas in which the homeless may congregate.

Compliance

Prioritization of other life-sustaining activities, such as finding food or shelter, may interfere with compliance to medical regimens or follow-up despite the intention to do so.¹¹ Money may be unavailable for prescriptions. Even hospital-dispensed medications may be traded for cash or other items perceived as more essential, depending on the patient's level of despair and how well the patient understands the consequences of forgoing treatment. Some items necessary for treatment, such as insulin syringes or other medications, are valuable for illicit

use and are at risk of theft. Agents such as insulin may lose their efficacy and safety when stored improperly. It may be impossible to refrigerate medications. A regular dosing medication schedule is complicated and nearly impossible in a lifestyle devoid of daily routines.

Lack of medical insurance may limit patient access to primary care for follow-up. Negotiating eligibility for various types of state and federal medical coverage is usually complicated, but may be of tremendous benefit to patients with chronic illnesses, for which poverty potentially thwarts adequate management. Patients should be referred to social workers familiar with eligibility requirements and processing. Unfortunately, even eligible patients may require several visits to social-services agencies to establish medical coverage, and this process alone may be too complex and demeaning to complete.

Other barriers to care include lack of transportation or mental illness. The precarious existence of such patients must be considered with compassion, and they should be treated with a medical regimen that accommodates the limitations of their social situation. For example, patients dependent on soup kitchens should have appointments arranged that would not limit access to mealtimes. Shelter-based drop-in clinic systems may be more realistic than tightly scheduled appointments.

SPECIAL POPULATIONS

Women and Children

Women and children comprise a rapidly increasing proportion of the homeless population. Women may present for routine medical problems or as a result of domestic violence or rape, for which they are at particularly high risk.¹² Some women may resort to prostitution to support themselves or their children. Preventive gynecologic care is often inadequate and extends from inadequate screening for cervical cancer and venereal diseases to insufficient or absent prenatal care. The consequences are devastating. Children born to homeless mothers often have lower birth weights, higher rates of prematurity, and higher rates of infant mortality. Iron-deficiency anemia, malnutrition, elevated blood lead concentrations, and a higher rate of asthma are found in homeless children, as in other impoverished children, compared to the general population.³ Unlike impoverished domiciled children, homeless children are more likely to be inadequately immunized and suffer disproportionately from developmental delay or a lack of progression in school. The long-term psychological, social, and educational consequences of homelessness have yet to be rigorously evaluated.

Homeless adolescents, especially runaways, have high rates of alcoholism, illicit substance use, violent encounters, and psychiatric illness. Engaging in sex for survival has resulted in high rates of unplanned pregnancy, sexually transmitted disease, and HIV infection. Patients should be offered a variety of resources, including education regarding safe-sex practices, counseling, and the location and availability of drop-in centers. Social workers, psychiatrists, and adolescent specialists can cooperatively provide support for homeless runaways regardless of their chief medical complaint.

The Elderly

There are few studies of the homeless elderly. Limited, fixed incomes with progressively increasing housing costs account for the displacement of many elderly people from their homes. Another factor may be gradual changes in cognitive and psychosocial performance, which may not be realized on a brief medical examination. For all people at risk, reassessment for organic disease, dementia, and depression is essential to ensure an appropriate care plan.

Substance Use

Patients who are dependent on alcohol or illicit substances should be identified in order to facilitate appropriate disposition. For homeless

patients who present intoxicated and sedated, close monitoring of body temperature, blood glucose monitoring, and serial evaluations for arousability should be performed in addition to a thorough physical examination. Whenever possible, a specific history of substance use should be obtained. A specific history of withdrawal from any sedative-hypnotic agent or ethanol should alert the clinician to the need for careful observation while primary evaluation of the chief complaint is undertaken. The patient should be asked whether he or she has a past history of participating in detoxification programs and whether that is a current desire.

Mental Illness

Some homeless patients without documented history of chronic psychiatric illness or substance dependence may present to the ED with psychiatric complaints. The stresses of sustaining life without a home are associated with a variety of diagnoses, including adjustment disorders, substance use, and major depression.¹³ Alternatively, some homeless patients have a chronic history of psychiatric illness, including schizophrenia or bipolar disorder, that may be partially responsible for precipitating homelessness.⁵ The psychiatric assessment of homeless patients is important to facilitate adequate disposition of medical problems whose management may be compromised by mental illness. In addition, primary pharmacologic therapy can be evaluated or instituted in patients with chronic psychiatric disorders. All patients should have an assessment for fear and risk of suicide as part of the routine screening.

EMERGENCY DEPARTMENT TREATMENT

ED management includes adjuncts to care, such as use of vitamin supplements and food, dispensing medications, updating immunizations, and reviewing documentation of past medical care. Pregnancy status and potential for sexually transmitted diseases should be investigated in homeless women of childbearing age. Appropriate gynecologic care, prenatal care, or family planning services can thus be arranged. Once a diagnosis and treatment plan is defined, patients should be assessed for language barriers, literacy, and capacity to comply with routine care instructions, medical regimens, or follow-up. An old chart may indicate immunization status, forgotten or disregarded health problems, and the ability of homeless patients to establish continuous care. A lower threshold for hospitalization should be maintained for patients with an impaired ability to manage their own care. This decision is easily acceptable if one appreciates how the patient arrived at the condition in question and how difficult, if not impossible, outpatient care may be under certain circumstances. A public health approach to managing communicable diseases should be incorporated into admission criteria. A multidisciplinary approach to care, including social workers and nursing, medical, and psychiatric staff, may offer the most supportive environment for homeless patients. Such compassionate care in the ED, using trained and motivated individuals, will ensure that patients receive essential care, increase patient satisfaction, and reduce the rate of recidivism among frequent users of the ED.¹⁴

THE MORBIDLY OBESE PATIENT Robert J. Vissers Kathleen A. Raftery

Obesity is the condition of an excessive proportion of adipose tissue to total body weight. It is a major health problem, with the prevalence of obesity in the United States doubling in the past 20 years, such that today over half of all adults are estimated to be overweight.¹ Since body fat is difficult to measure in the clinical setting, body mass index (BMI) is frequently utilized. BMI is calculated by dividing the weight in kilograms by the square of the height in meters. A BMI greater than 28 kg/m² defines obesity in both sexes, and morbid obesity is associated with a BMI of 40 kg/m² or greater.

Morbidly obese patients pose a number of challenges for emergency health care providers. Prehospital care may be delayed due to problems in moving and transporting these patients. Appropriate-sized gurneys may not be readily available. Even providing common amenities, such as hospital gowns or bedpans of adequate size, can be difficult. In addition, the ED staff must anticipate and be prepared for challenges in performing technical procedures. Excess tissue makes access to body fluids and body cavities a formidable task, while performing imaging procedures can be difficult or impossible. Morbidly obese patients may also evince changes in cardiopulmonary physiology and patterns of traumatic injury, which add to the complexity of their care.

PATHOPHYSIOLOGY

The etiology of obesity is heterogeneous, including increased caloric intake, a low level of habitual physical activity, a low resting metabolic rate, and possibly high insulin sensitivity.³ The recent epidemic in developed countries is felt to be more likely due to inactivity than increased caloric intake. The recent discovery of leptin, an antiobesity hormone, has kindled interest in the metabolic pathophysiology of this disease.

Cardiopulmonary Disease

Morbidity and mortality are considerably greater among the obese than in normal-weight patients, and many of the health risks associated

with obesity increase progressively and disproportionately with increasing weight.³ The most significant physiologic disturbances pertain to the cardiopulmonary system.⁴

Coronary artery disease, hypertension, and congestive heart failure are highly correlated with obesity. Both left- and right-sided heart failures are often observed in patients with obesity-hypoventilation syndrome. Obesity has also been linked to depressed left ventricular function even in young, asymptomatic patients.

Obesity is associated with an increased risk of venous thromboembolism, especially after surgery.⁵ This is due to several factors found in the obese patient, including decreased levels of circulating antithrombin III, preexisting venous disease, and increased immobility.³ The obesity-hypoventilation syndrome, also known as the *pickwickian syndrome*, occurs in 5 percent of the morbidly obese. In obese individuals without hypoventilation, disturbances in the ventilation-perfusion relationship are prevalent.⁶ Pulmonary hypertension is a common finding, resulting from chronic hypoxemia, hypoxic pulmonary vasoconstriction, and the added contribution of compromised cardiac function.⁶

The vital capacity, total lung capacity, and functional residual volume are reduced by up to 30 percent in morbidly obese patients. The work of breathing is increased due to higher chest wall and airway resistance and functionally flattened diaphragms. When ventilating obese patients, tidal volume may need to be lowered and adjusted based on inflation pressures and blood gases. Positive end-expiratory pressure may prevent end-expiratory airway closure and atelectasis.³

Recognition of the increased risk of cardiorespiratory compromise in the morbidly obese patient is crucial, even when the patient presents to the ED with a problem unrelated to the cardiovascular system. The morbidly obese patient who states that he or she can only sleep in the upright position should be maintained in an upright position as much as possible, or in a lateral position with the head up while performing procedures. If the patient must remain supine, elevate the head of a patient who is on a backboard by placing towels under the board and utilize continuous pulse oximetry monitoring.

Pregnancy

Obesity will also complicate pregnancy. Body weight before pregnancy and weight gain during pregnancy both influence labor, and obese women are more likely to require cesarean sections and to experience abnormal labor. In addition, these infants tend to be heavier than those born to nonobese women, increasing the potential for difficult labor and delivery. Other complications such as hypertension, diabetes, preeclampsia, and eclampsia occur with increased frequency in pregnant obese women.

Differences in the mechanisms of injury and associated injury patterns have been described, and obesity has been identified as an independent premorbid risk factor in trauma.^{2,3,7}

Excessive weight interferes with activities of daily living, therefore increasing the risk of injury. Moreover, the presence of obesity-related diseases such as diabetes, heart disease, and somnolence secondary to sleep apnea may contribute to accidents. A higher incidence of displaced ankle and elbow fractures has been described in obese patients sustaining minimal trauma (stumbling, low-energy falls).⁸ Obese patients have also been noted to be less likely to wear seat belts because of poor fit or discomfort.

Obesity appears to protect the blunt trauma victim from head injury, but is associated with a significantly higher incidence of injuries to the chest, primarily rib fractures and pulmonary contusions. It is hypothesized that the larger torso serves as a physiologic airbag, and although this offers some protection from head injury, there is an associated increase in thoracic injury. This may partly explain the

dramatically higher mortality rate due to respiratory causes in morbidly obese trauma patients. The impact of morbid obesity on mortality in blunt trauma was seen in a study that found a 42.1 percent mortality rate in severely overweight patients, compared with 5.0 and 8.0 percent in the average and overweight groups.⁷

Despite the logistical difficulties the obese patient presents, the principles of trauma management apply, with necessary spinal precautions and full exposure. The presence of subcutaneous fat obscures physical findings in thoracic and abdominal injuries. The limitations of physical findings are further compounded by poor quality portable chest radiographs in this population. A more aggressive approach to airway management with early intubation and assisted ventilation may be indicated.

The incidence of pelvic fractures is higher in the obese trauma victim. Portable films are often of a poorer quality in the obese patient, therefore clinical suspicion of a pelvic fracture should be pursued by repeat views or computed tomography, despite a negative portable pelvic radiograph.

PROCEDURES

Procedures are more difficult to perform on the obese ED patient (Table 311-1). Landmarks are obscured or nonpalpable, access is often impaired by excessive tissue, and positioning problems are common. Airway management may be difficult, intravenous access delayed, and investigations cumbersome or impossible to obtain in the obese patient. These factors all contribute to inevitable obstructions to rapid assessment and resuscitation. Having alternative approaches readily available is the ideal strategy. The appropriate equipment, such as the right blood pressure cuff, should be easy to access. Extra personnel are often required, and a minimum of six people is usually necessary to transfer the patient, particularly when cervical spine precautions must be maintained.

Airway Management

Obesity may be associated with difficult intubation or bag-valve-mask ventilation, particularly if other predictors of intubation difficulty are present. Obesity alone is not a contraindication to rapid-sequence intubation and this may be the preferred method in most patients. However, in this population it is particularly important to assess and recognize other objective predictors of a difficult intubation (see Chap. 19).

Preoxygenation is critical, since morbidly obese patients will desaturate more quickly than normal-sized adults.⁹ Patients should be kept sitting upright or semirecumbent as long as possible prior to intubation. If bag-mask ventilation is required, the obese patient often has reduced pulmonary compliance, which necessitates higher ventilatory pressures. The pop-off valve on the ventilation bag may have to be occluded in order to provide adequate ventilation.

Once the process of intubation is begun, access to the airway is enhanced by elevating both the head and shoulders with towels or by placing a rolled blanket between the scapulae and under the occiput. Elevation of the shoulders allows displacement of the breasts away from the midline. The greater elevation of the head places it in the sniffing position, and creates more space, as the chest wall of the morbidly obese patient may actually obstruct the handle of the laryngoscope. A shorter-than-average handle for the laryngoscope or an adjustable-angle laryngoscope is useful in this situation.

Alternative techniques of airway management such as awake oral intubation or blind nasotracheal intubation may be utilized if difficulty is predicted. Nasotracheal intubation is technically more difficult than orotracheal intubation, but may be relatively advantageous if performed by an experienced physician to intubate a spontaneously breathing patient with a short thick neck. Transtracheal jet ventilation requires higher ventilatory pressures and therefore may be less useful and cause increased barotrauma in the obese patient with decreased pulmonary compliance. The intubating laryngeal mask airway and the

TABLE 311-1 Procedural Problems and Solutions in the Morbidly Obese

Procedure	Problem	Solution
Bag-mask ventilation	Reduced pulmonary compliance	Occlude pop-off valve
Oral intubation	Potentially difficult airway	Objective predictors of difficulty Adjustable angle laryngoscope Double-lumen esophageal-tracheal tube Surgical airway
Sphygmomanometry	Falsely elevated readings	Use larger cuff size
Pulse oximetry	Poor signal	Earlobe probe
Vascular access	Inability to locate vein/artery	Use 3- to 4-in. catheter Patient positioning Ultrasound-facilitated cannulation
Lumbar puncture	Difficulty in palpating landmarks Difficult to obtain cerebrospinal fluid	Upright patient positioning Increase needle length to 5 in.
Diagnostic peritoneal lavage	Accessing peritoneal cavity	Modified Seldinger technique

esophageal-tracheal double-lumen tube are possible rescue devices, and their utility in the morbidly obese patient has been described.^{10,11} A fiberoptic bronchoscope can also be used to aid intubation, although visualization may be impaired by circumpharyngeal fat.

Finally, a cricothyrotomy may be indicated if other maneuvers fail. Landmarks may not be appreciated by palpation and the cricothyroid membrane is located approximately four fingerbreadths above the sternal notch. Needle cricothyrotomy is difficult given the anatomy of a morbidly obese patient's neck.

Electrocardiogram Analysis

Host factors such as body mass influence the ease of obtaining and interpreting an electrocardiogram (ECG). Landmarks for lead placement may be difficult to determine, and can result in inaccurate lead placement. Variation in fat deposits surrounding the heart and in the chest wall can lead to inconsistent voltage changes, although in general, obese patients demonstrate loss of voltage.¹² Flattening or inversion of the T wave in the inferior or lateral leads is one consistent change. None of these ECG changes is specific for obesity, and such abnormalities should not be attributed to obesity alone.

Sphygmomanometry

Inadequate cuff width and circumference will artificially elevate pressure readings.¹³ However, many morbidly obese patients are hypertensive, and a high pressure reading cannot always be blamed on inappropriate equipment. In order to minimize errors in blood pressure recording, a correct ratio of cuff width to arm circumference, approximately 2:5, should be chosen. The bladder length should be 80 percent of the arm circumference. The ED should stock a variety of sizes of blood pressure cuffs specifically for use in the obese population.

Pulse Oximetry

Tissue thickness can make the transmission of light waves more difficult in the extremely obese, and thus make pulse oximetry readings unreliable. However, pulse oximetry in the moderately obese is generally accurate. In morbidly obese patients, the earlobe could be used instead of the finger for probe placement. Other potential areas of placement include the fifth digit of the hand or foot, the nose, lip, or temporal artery.

Venous Access

Morbidly obese patients are notoriously difficult candidates for intravenous catheterization, venipuncture, or arterial puncture. Anatomy is

distorted by subcutaneous fat, and landmark vessels are often not visible or palpable. This leads to multiple attempts, delay in access, and an increased incidence of central line placement, with delays in changing a line after admission. All these factors contribute to a higher rate of complications, such as wound infection, pneumothorax, phlebitis, and thrombosis. In addition, standard 1.5-in. needles or catheters may not be long enough to penetrate the subcutaneous tissue and reach the target vessel; 3- or 4-in. needles and catheters are preferred. Locating the radial or femoral artery in order to obtain a sample for arterial blood gas analysis can also be extremely difficult. It may be necessary to change needle lengths on the prepackaged arterial blood gas syringes.

Various techniques can be employed to improve access to the vessel. Application of heat, light tapping over the vessel, active or passive pumping of the extremity, and application of topical nitroglycerin can be used to encourage vasodilation. Reactive hyperemia can be created by occluding the circulation for 3 to 4 min, then releasing the sphygmomanometer to 10 to 15 mm Hg below the diastolic pressure.

The medial cubital and basilic veins are the first choice in the morbidly obese, since they are large, the antecubital crease is visible, and the skin and subcutaneous tissues are thinner in this area. Branches of the median and basilic veins on the volar surface of the forearm may be too deep to the adipose tissue to be easily accessed. The cephalic vein on the radial aspect of the wrist is a good second choice if it is not also obscured by fat. Another option is the vessels of the dorsum of the hand. The veins of the fingers may be accessible, especially those over the dorsal aspect of the thumb and forefinger. The veins of the feet are usually not good candidates, since they tend to be obscured by fat or changes from peripheral vascular disease. If peripheral veins are not available, a cutdown at the forearm veins or an attempt at cannulation of the external jugular vein may be considered. Venisection at the saphenous vein, a common alternative in patients of normal weight, will be challenging because of excess adipose tissue.

Central line placement can also be challenging.¹⁴ Femoral catheterization is preferred over saphenous venisection in the obese patient with a palpable femoral pulse, and can be facilitated by placing a towel under the ipsilateral buttock and having an assistant retract the panniculus. Subclavian vein cannulation may be preferable to the internal jugular, since the bony landmarks are more easily palpable. The patient is usually placed in the Trendelenburg position; however, this position may be relatively contraindicated in some cases, such as the patient who cannot sleep supine.³ During subclavian line placement, abduction of the arm (as opposed to the standard recommendation of arm adduction) and retraction of chest tissue away from the clavicle may reduce excessive tissue layers at the site. It is common practice to insert a roll under the shoulders or a pillow lengthwise along the spine to improve access.

Ultrasound can facilitate venous cannulation and arterial puncture, allowing a higher success rate with fewer attempts, because it is performed independent of landmarks.¹⁵

Lumbar Puncture

A lumbar puncture is most successfully performed in the obese patient in the sitting position. With the patient upright, the midline is easier to estimate and both iliac crests are usually palpable. Bone encountered after only a few centimeters usually represents spinous process, and suggests an adjustment in the vertical plane above or below that point. A deeper bony encounter is likely lamina and requires a medial adjustment. Ultrasonography has been described as an aid to locating the vertebra. Despite the excessive tissue, the standard 3-in. needle is adequate for many obese patients, although this may require pushing the needle hub to the point of dimpling the skin. The 5-in. needle is sometimes needed. Tight intervertebral disk spaces are common in this population. The best choice is a 22- or 24-gauge needle, which allows adequate flow and easier passage and decreases the likelihood of post-puncture headache.

Diagnostic Peritoneal Lavage

Diagnostic peritoneal lavage (DPL) is used for the early recognition of intra-abdominal injury requiring exploratory laparotomy. In many centers, the use of DPL has been supplanted by imaging techniques because of increased accessibility to improved computed tomography (CT) and ultrasonography. However, size and weight restrictions and transport difficulties may preclude the use of CT scanning in the obese trauma victim. Abdominal ultrasonography is also less reliable in the morbidly obese patient. Therefore DPL may be the best available diagnostic approach in these patients.

There are three general DPL techniques: the open, semiopen, and closed. In the open technique, a catheter is passed into the abdominal cavity through a large incision that exposes the peritoneum. Because of the larger incision required, the technical difficulties presented by the panniculus, and a potentially higher rate of wound infection and herniation, morbid obesity has been described as a relative contraindication to this procedure.¹⁶

Closed DPL using a blind Seldinger technique with an 18-gauge needle has been shown to be as efficient as the open technique, and may represent the method of choice in the obese patient. In patients whose abdominal wall thickness exceeds the reach of the needle, a modified Seldinger technique has been described, in which a 2- to 4-cm incision is carried down to the midline fascia and an 18-gauge needle is then inserted at that point. This procedure was used successfully in six morbidly obese patients whose weight exceeded the weight limit of the CT scanner, typically 350 pounds.¹⁶

Imaging

Radiographs have limited utility in the morbidly obese. Standard film cassettes are too small to accommodate the entire chest or abdomen, and two or more films may be required. Excessive soft tissue can result in extremely underpenetrated films. Since transport is invariably problematic, morbidly obese patients may need to undergo portable radiography, resulting in lower-quality images.

CT and MRI scans are clearly superior to radiographs, offering better resolution and greater penetration. However, many CT scanners have a weight limit of 300 to 350 lb and a girth limit of 30 in. Most standard MRI scanners have a maximum shoulder-to-shoulder width of 52 in. and a weight limit of 136 to 159 kg (300-350 lb) (Table 311-2). Thus many morbidly obese patients will be excluded from undergoing these studies. There are, however, private companies, veterinary schools, and zoos that have scanners with a larger capacity.

TABLE 311-2 Weight Limits of Standard ED and Imaging Equipment

Wheelchairs (16- to 18-in. width)	118 kg (260 lb)
Wheelchairs (20-in. width)	140 kg (310 lb)
Stretchers	227 kg (500 lb)
Radiology table	136 kg (300 lb)
CT table	136-159 kg (300-350 lb)
MRI table	159 kg (350 lb)

EQUIPMENT PROBLEMS SPECIFIC TO ED CARE

From the time the obese patient enters the waiting area until the time he or she leaves the ED, issues related to the patient's size challenge both personnel and equipment. Waiting-room chairs may be too small. Most wheelchairs also have weight limits and are not designed to safely accommodate patients weighing over 118 kg (260 lb). Gurneys are often too small for the patient if the protective side rails are in place, and without the side rails, the patient is not safe. In addition, collapsible gurneys are not designed to hold the weight of the morbidly obese patient, leading to instability and concomitant patient and staff danger. If they are used, keeping the gurney at a lower height will enhance stability, if the device allows function at this level. Heavy-duty stretchers (one with additional cross-brace supports) and wheelchairs designed to hold patients weighing more than 118 kg (260 lb) are available and should be present in the ED. Metal clamshell transport stretchers are preferable to the standard wooden stretchers for stability, weight-bearing, and unloading of the patient.

The comfort and modesty of morbidly obese patients should be thoughtfully considered during his or her ED stay.¹⁷ The ED should stock oversized hospital gowns. Patients should also be allowed to wear their own night clothing as long as it does not obstruct care.

Any care that requires lifting or turning of the obese patient is difficult, as techniques used for average-sized patients cannot be used. In general, more than two providers should always be utilized to move the patient. Provision of an overhead trapeze will greatly facilitate patient-assisted transfers and should be available in the ED.

PATIENT SAFETY IN EMERGENCY MEDICINE

Cherri Hobgood

Pat Croskerry

Robert L. Wears

Armando Hevia

Error in medicine became a national issue with the publication of the Institute of Medicine report *To Err is Human*.¹ This report suggested that errors in medicine were common, costly, and often disregarded by the medical community. When these error rates were considered in terms of human life and health care dollars, both the public and the medical community took notice. Though the accuracy of these numbers has been the subject of debate, they have stimulated an intense evaluation of the current patient safety standards in U.S. health care.^{2,3} As a result, the medical community is more aware than ever before of the incidence of medical error in their clinical environments. Medicine's unstated objective to provide the highest quality of care for all our patients and continuously improve the care process has now become a mandate. In this chapter, we will discuss error in the ED, examine why error is prevalent in this clinical environment, and identify principles and practices that can make the ED a safer place for all our patients.

Error is defined by the Institute of Medicine (IOM) as the "failure of a planned action to be completed as intended or the use of a wrong plan to achieve an aim."¹ To date, there are no large prospective studies describing the demographics of error in the ED. Three large retrospective inpatient studies on medical error—the Harvard Medical Practice Study, the Colorado-Utah study, and the Quality in Australian Health Care Study—give some indication of the nature of error in the ED, but are clearly limited by the fact that they only considered error associated with patients admitted from the ED.^{4,6} The majority of patients seen in the ED, those that are discharged, are not included. In each of these studies, the ED was responsible for only a small percentage of all adverse events (1.5 to 3 percent), but was consistently identified as the clinical setting with the highest rate of preventable errors with serious consequences. The Harvard Medical Practice Study determined that 3 percent of all injuries due to adverse events in admitted patients occurred in the ED and 25 percent of those resulted in death or disability. Of these serious or fatal injuries, 70 percent were attributed to negligence and 93 percent were deemed preventable.⁴ In the Colorado-Utah study, 53 percent of the ED-related events were considered negligent. Of events attributed to emergency physicians, 95 percent were judged as "negligent."⁵ In the Quality in Australian Health Care Study, the highest proportion of "highly preventable" adverse event injuries, 82 percent, were found in the ED.⁶

These "highly preventable" and "negligent" error estimates, coupled with the IOM report, caused many emergency physicians to feel singled out and defensive about patient safety in the ED. Patient safety in the ED should be an important focus for emergency physicians regardless of the accuracy of the IOM error rates. The impact of medical errors can be visualized by a graph that shows numbers of encounters per death for different activities (Figure 312-1). The points marked UB and LB show the upper and lower bounds of the IOM estimates

FIG. 312-1. Examples of hazardous activities and their death rates. The Y axis represents the total burden of deaths, and the X axis represents the number of encounters required to produce one death. The points marked UB and LB are the upper and lower bounds of the Institute of Medicine estimates, and the points marked M and % are the lower bound divided by 2 and 4, respectively. The lost baggage data point is used as a reference activity of a high-volume process with many opportunities for error to occur. For this reference point the Y axis shows the total number of lost bags per year and the X axis shows the number of bags checked per each bag lost. Bungee J = bungee jumping; Charter Air = charter airline travel; Chemical = chemical industry; Driving = driving an automobile; Eur RR = European rail travel; Lost Baggage = airline industry baggage handling; Mt Climb = mountain climbing; Nucl Pow = nuclear power industry; Sched Air = scheduled commercial airline travel; LB = lower IOM estimate; UB = upper IOM estimate; $1/2$ = half of lower IOM estimate; $1/4$ = one quarter of lower IOM estimate. (Modified from Amalberti R: The paradoxes of almost totally safe transportation systems. *Safety Sci* 37:109, 2002, and reproduced with permission from Wears R: Human error and adverse events in emergency medicine. *EM Pulse* 1:11, 2002.)

(98,000 and 44,000 deaths, respectively). For those who believe that the estimates are inflated, two other points are graphed: the points marked $1/2$ and $1/4$ represent the lower estimate divided by 2 or 4, respectively. It should be clear from this exercise that imprecision in the estimates is not terribly material; health care is in very impressive company, even if we postulate that the lower IOM estimate is off by a factor of 4. Health care is closer in both risk and volume to airline baggage handling than any of the other activities shown. Continued debate over the exact number is a waste of time and viewed as self-serving by the public. A recent comment puts the issue in perspective: "... criticizing the IOM numbers because they are wrong is like criticizing Columbus because he got lost. It may be true but it misses a larger truth."³ Because emergency department volumes continue to grow, patient safety efforts that focus on the emergency department will have a substantial impact on improving the quality of health care in the United States.

MODELS OF COGNITIVE PERFORMANCE

The types of errors that occur in the ED environment are not unique to the ED. Medicine arrived late to error analysis and classification; consequently, most error types had already been described in other areas. One of the most widely accepted error classification schemes is based on a model of cognitive performance originated by Rasmussen and Jensen in 1974, and elaborated upon by Reason.^{7,8} It described three levels: skill-based, rule-based, and knowledge-based.

Skill-Based

Skill-based cognitive performance refers to actions that are automatic due to a previously acquired skill. They usually happen quickly with little conscious input on the part of the clinician. Their clinical action is based on predefined schemata or preprogrammed instructions. For example, getting dressed or driving a car are actions that require little conscious monitoring, i.e., we do not need to explicitly think about them in order to accomplish them. Similarly, for experienced clinicians, prepping a wound, tying a suture, or starting a central line may require relatively little conscious input. Once the decision to proceed with the process is made, the technical performance of the event is virtually automatic. Some decisions can be relegated to a level of automaticity with practice (which arm goes in which sleeve, or which direction the next knot should be tied). Any departure from this kind of skill-based processing requires either a rules-based or knowledge-based approach to perform the task.

Rules-Based

Rules-based processing involves matching the context and clinical symptoms currently facing the clinician with a known rule. These rules are typically of the form "if X then Y," and can be based on past experience, explicit instructions, or clinical guidelines. For example, decision making can be optimized for some conditions by following empirically-derived clinical decision rules. Thus for a patient with an ankle injury, application of the Ottawa ankle rules results in a decision being made about the need for a radiograph.

Knowledge-Based

When faced with novel or unfamiliar situations, or when rules are not useful, we need to use knowledge-based processing. As with rules-based processing, knowledge-based processing is a conscious process. It refers to what we typically think of as analytic thought. Knowledge-based cognitive behavior involves interpreting and understanding novel situations and problems against a background of specific domain knowledge. This type of decision making is most commonly called into play in situations requiring diagnostic reasoning (e.g., integrating the presenting complaint, past medical history, physical examination, and laboratory findings in a patient with syncope) or in management decisions. This is clinical decision making.

As a provider's clinical performance evolves through training and experience, predictable changes occur in cognitive functioning. With increasing experience, clinical problems become more familiar and less novel, and there will be less demand for knowledge-based function. Consequently, the provider is more likely to use rules- or skill-based functions. The relationship between provider proficiency and probability of error varies for different levels of cognitive performance (Fig. 312-2).

ERROR CLASSIFICATION

Classifying clinical errors based on the three-level model of cognition provides insight into how the error may have occurred and offers a possible means of a reduction (Table 312-1). The major types of errors that flow from this model of cognitive performance are skill-based errors, referred to as slips and lapses, and those of rules- and knowledge-based cognition, known as mistakes.⁹ Slips are failures in attention or perception that result in the breakdown of the planned execution of an observable action sequence. These are action errors, often caused by interruptions or a break in the routine of activity performance. Lapses are also skill-based errors however, they are based on a failure of memory that leads to a failure of execution of a plan. Mistakes, on the other hand, usually occur during problem solving.

In rules-based mistakes, the wrong rule is applied. This may occur due either to incorrect rule selection, misapplication of the rule, or in-

FIG. 312-2. The relationship between errors and provider proficiency according to error type. The Y axis represents the probability of error, while the X axis represents the level of provider proficiency. Knowledge-based errors decline with proficiency. Paradoxically, the more skilled the providers, the more likely they will commit an "absent minded" skill-based error, because performance becomes increasingly automatic. Rules-based errors first increase through an acquisition phase of the rule repertoire, then decrease as their use becomes more finely discriminated. [Reproduced with permission from Reason J: Overview of unsafe acts. Presented at the Second Halifax Symposium on Health Care Error, October 2002, Halifax, Nova Scotia, Canada.]

correct identification of the situation and selection of an incorrect rule. Knowledge-based mistakes are more complicated, but the same processes apply. For example, incomplete or incorrect knowledge, and/or flawed analytical processes may lead to mistakes.

Another useful approach to categorizing error in the ED is to break it down into *procedural*, *cognitive*, and *affective* types.¹⁰ Procedural error may occur in any of a variety of procedures typically performed in the ED (e.g., suturing, cast application, insertion of chest tube or central line, diagnostic peritoneal lavage, intubation, and others). Procedural competency first depends on a thorough understanding of the

TABLE 312-1 Commonly Used Definitions of Error

<i>Execution error</i> —Failure of a planned action to be completed as intended ¹
<i>Error of planning</i> —Use of a wrong plan to achieve an aim ¹
<i>Adverse event</i> is an injury caused by medical management rather than by the underlying disease or condition of the patient ¹ <i>Preventable adverse events</i> are attributable to error ¹ <i>Negligent adverse events</i> meet the legal criteria for negligence ¹ <i>Slip</i> —a failure in execution of an action sequence, due to a failure of
attention or perception; the wrong action is observable ^{8,9} <i>Lapse</i> —a failure of execution when the action performed was not the intended action; often related to a failure of memory; the wrong action is not observable ^{8,9} <i>Mistake</i> is a planning failure, where actions go as planned, but the plan was
bad; these are errors of decision making and judgment; these errors stem from cognitive breakdowns and are often influenced by a number of external system factors ^{10,11} <i>Rules-based errors</i> occur when the wrong rule is chosen due to the
misperception of the situation, or the misapplication of rule ⁹ <i>Knowledge-based errors</i> occur from a lack of or misapplication of knowledge or a misinterpretation of the situation ⁹ <i>Active error/failure</i> —unsafe acts or omissions which result in immediate
adverse consequences ^{9,17} <i>Latent error/failure</i> —a decision whose consequences may only become
evident when it combines with other factors to breach the systems defense or that results in unsafe conditions in which unsafe work occurs ^{9,17}

process, followed by numerous repetitions to establish a smooth coordination of visual, motor, and haptic skills, and continuing competency depends on maintenance. Cognitive errors, in contrast, are thinking errors. They may arise anywhere within the large domain of decisions emergency clinicians make in the course of management, diagnosis, and disposition of their patients. Affective error occurs when the emotions or affective state of the physician unduly influence the clinical decision-making process. They typically arise from attribution error, countertransference phenomena, or may originate from the endogenous affective state of the clinician. The properties of these three classes of error differ significantly from each other (Table 312-2).

SYSTEMS CAN ENCOURAGE ERRORS

Students of error and human performance believe that *all humans err*, ergo the title of the Institute of Medicine report *To Err is Human*.¹ Error is to be expected, and although a provider is invariably involved when accidents occur in a professional setting, the causes of the error may be out of the individual's control.¹¹ In fact, the ED's high preventable error rate has been largely attributed to environmental factors such as the complexity inherent in the delivery of emergency care and the variance in work procedures. Therefore, a complete and thorough understanding of the error-prone system will be required to determine the etiology of errors and their correction.

Inevitability and Ubiquity of Error in the ED

It is obvious at even the most casual level of observation that error in the ED is abundant. Unique operating aspects of this microsystem predispose it to a variety of errors (Table 312-3). These are categorized into error-producing conditions (EPCs) and violation-producing behaviors (VPBs).¹² EPCs arise largely from the intrinsic properties of emergency medicine, but also from the design of the system in which it is practiced. Thus intrinsic features include high levels of diagnostic uncertainty associated with an inordinately high decision density, and high cognitive load for ED clinicians. These demands are made more difficult by the clinician's unfamiliarity with most patients, as well as the narrow time windows available for assessing illness. Further diffi-

TABLE 312-3 Operating Characteristics of the ED Which May Compromise Safety

ERROR-PRODUCING CONDITIONS (EPCs)		
Intrinsic	Systemic	Violation-Producing Behaviors (VPBs)
High levels of diagnostic uncertainty	Poor ED design	Gender
High decision density	Poor equipment design	Risk-taking behavior
High cognitive load	Poor maintenance	Normalization of deviance
Narrow time windows	High communication load	Maladaptive group pressures
Multiple transitions of care	Overcrowding	Maladaptive copying behavior
Multiple interruptions/distractions	Holding admitted patients in the ED	Underconfidence
Low signal-to-noise ratio	Production pressures	Overconfidence
Surge phenomena	High noise levels	Maladaptive decision styles
Circadian factors	Inadequate staffing	Authority gradient effects
dysynchronicity/fatigue	Incompatible goals	Likelihood of detection
Novel or infrequently occurring conditions	Poor feedback	Inconvenience
	Inexperience	Safety procedures seen as inconvenient
	Inadequate supervision	

culties arise from frequent interruptions and distractions, surge phenomena (abrupt changes in workload and/or acuity), shift changes and multiple transitions of care, fatigued staff, or staff suffering circadian dysynchronicity due to insufficient recovery time from a shift change. These and other factors may all contribute to uneven, abbreviated, and unsafe care. An especially difficult intrinsic EPC is the low signal-to-noise ratio of some diagnoses that must not be missed [i.e., many serious conditions (signals) that present in the ED such as subarachnoid hemorrhage, aortic dissection, pulmonary embolus, and ectopic pregnancy, are mimicked by a variety of considerably more frequent benign conditions (noise)].

A number of systemic EPCs compromise safety and contribute to error. Insufficient space and beds, suboptimal equipment design and maintenance, and overall inadequacies in ergonomic design of the ED are some common problems. Excessive communication load, noise levels, overcrowding, and production pressures are others. Inexperience and inadequate supervision will compromise performance, as will inadequate staffing levels. The especially poor feedback systems in many EDs compromise good clinical calibration. Occasionally, too, clinicians will be faced with incompatible goals when externally imposed cost-containment conflicts with a patient's therapeutic needs. Ultimately, particular combinations of EPCs may lead to a trade-off (TO) between resource availability (RA) and continuous quality improvement (CQI). The onset of RACQITO signals that a threshold of safety has been crossed.

The other major sources of error are violation-producing behaviors (VPBs), which are mostly due to individual characteristics. Workplace behavior is influenced by gender, personality factors such as the willingness to take risks and deviate from accepted safe operating procedures, underconfidence and overconfidence, responsiveness to authority gradients, and other factors. Impairments in performance may result from personality variables, and maladaptive styles of decision making.⁸ For example, "thematic vagabonding" is characterized by moving quickly from one problem to another, avoiding the pursuit of clinical closure. This indecisiveness in the ED is sometimes accomplished by ordering unnecessary tests or other stalling behavior to avoid making a decision. In contrast to vagabonding, "encysting" is the tendency to focus unduly on minor clinical details of a case at the expense of more significant ones. VPBs may be either intentional or erroneous (e.g., deliberately administering a drug by a route that has not been approved, or ordering a drug to be given without being aware

TABLE 312-2 Comparison of Properties of Procedural, Cognitive, and Affective Errors

Property	ERROR CATEGORY		
	Procedural	Cognitive	Affective
Visibility	High	Low	Moderate
Discreteness*	High	Low	Low
Witnessed	Usually	Not usually	Not usually
Awareness	High	Low	Low
Recorded	Yes	Rarely	No
Temporality	Close	Distant	Distant
Medical nature	High	Low	Very low
Familiarity†	High	Low	Very low
Preventability	High	High but difficult	High but difficult
Root cause analysis	Amenable	Difficult	Very difficult

* *Discreteness* refers to the perceived separateness or isolation of the event from those around it. Procedural errors are often distinct in this fashion, whereas cognitive and affective errors are not.

† *Familiarity* refers to the strength of the clinician's familiarity with the error. Causing a pneumothorax by insertion of a central line is well known to ED physicians, whereas few would be familiar with the etiology of cognitive and affective errors in their decision making.

Source: Reproduced with permission from Croskerry.¹⁰

that it is contraindicated in certain conditions). Importantly, safety violations may be driven by EPCs and, in some EDs, may be seen as convenient or necessary corner-cutting measures in order to meet the work demand ("normalization of deviance"). A quantitative method for assessing the interaction between EPCs and VPBs in the workplace has been developed by Williams using Human Error Assessment and Reduction Technique (HEART) analysis.¹²

Error arising from EPCs and VPBs occur continuously in most EDs. Under current systems of error monitoring, very little of it will show up in data banks or official reports. Some of the error is inconsequential, while most of that which is significant will be corrected continuously. These corrective actions correspond to the series of slices in Reason's swiss cheese model, which provides the defenses, barriers, and safeguards against potential error achieving realization." The holes in the various slices arise from *active failures* (mostly VPBs) combining with *latent conditions* (mostly EPCs). In an ideal system, there would be no holes in the slices, but any ED will fall far short of the ideal. Under certain conditions (e.g., at RACQITO), the holes in successive barriers all line up, allowing the potential accident with a trajectory through the system, resulting in critical incidents or catastrophes. This will often be the first time that particular parts of the system are brought under close scrutiny, and may be the first time that the impact of active and latent failures is revealed.

CLINICAL DECISION-MAKING ERROR

Understanding clinical decision-making error requires some insight into the processes by which decisions are usually made in the ED. Presently, there is no single model of decision making that adequately applies to the complex variety of clinical situations that prevail in most EDs. The normative Bayesian approach that underpins classical decision theory is useful in the development of certain algorithms and clinical decision rules, but has little practical application in urgent or emergent situations, or in "flesh and blood" decision making. Instead, the dynamic, ambient conditions of the ED are more suited to the features and properties of models derived from both Bounded Rationality and Naturalistic Decision Making (NDM).¹³⁻¹⁴

Bounded rationality simply acknowledges the limitations of human cognitive capability and recognizes that fully rational decisions are rarely attainable. In real situations, rationality is bounded by principles that underlie nonoptimizing adaptive behavior. Thus in the bounded rationality of the ED, with its intrinsic and systemic EPCs, clinicians strive not for completely optimal decisions, but for the best decisions possible under the prevailing circumstances. Similarly, NDM accepts that decision making is driven more by situational variables, which may change over time and may be influenced by resource limitations. It avoids quantitative, analytical strategies, emphasizing instead economy of thought and action, and acknowledging the natural variance of cognitive strategies. Both models are more realistic and accepting of human fallibility and the inevitability of error, and are especially applicable in the specific milieu of the ED.

The density and acuity of decision making is exceptional in emergency medicine. The progress of a patient through the ED is driven by multiple decisions underlying the sequence: assessment-management-diagnosis-treatment-disposition. Invariably, the pivotal feature in the sequence is diagnosis, and the clinical decision making that underpins it is therefore critically important for patient safety. Delayed or missed diagnoses are the ED errors that are most likely to lead to disability and death, and account for about half of all litigation brought against emergency physicians.

There are three major sources of diagnostic error (Table 312-4).¹⁵ The first, *no-fault errors*, arises from a variety of factors: silent, subclinical, or atypical presentations; when little is known about a disease; when patients misrepresent their symptoms for psychiatric or other reasons; when the patient is confusing, inaccurate, or uncooperative; when patients are noncompliant; and from other unknowable

TABLE 312-4 Categories of Diagnostic Failures in the ED

ERROR TYPE		
No-Fault	Systemic	Cognitive
Confusing, inaccurate, or misleading information from patient	Error-producing conditions*	Knowledge deficiency
Deliberate misrepresentation of illness (malingering)	Laboratory error (preanalytic, analytic, postanalytic)	Incomplete data gathering
Somatization disorder	Inefficient report follow-up	Test misinterpretation
Factitious disorder	Time delays	Cognitive dispositions to respond†
Insufficient medical information available about a new disease	Unavailability of services	
Patient refusal of critical diagnostic tests/procedure/consultation	Poor patient follow-up	
Silent presentation of comorbid illness		

*See Table 312-3.

†See Table 312-5.

factors. The second, *system errors*, occurs largely as a result of EPCs but also includes laboratory errors, equipment failure, or organizational failures such as inadequate follow-up of abnormal test results, unavailability of expertise or particular resources, delays in testing, missed appointments, backlogs, and other inefficiencies. The third, *cognitive errors*, is probably the most devastating of the diagnostic errors. Some cognitive errors arise from faulty data gathering, test interpretation, or incomplete or incorrect knowledge, but the majority appear to arise through a variety of "cognitive dispositions to respond" in certain ways in particular clinical situations.¹⁶ These will be influenced by both EPCs and VPBs.

Many of these cognitive dispositions to respond, or CDRs, have their origins in heuristics. Heuristics are shortcuts, rules of thumb, or any kind of abbreviated thinking that accomplishes fast and efficient decision making. Heuristic thinking characterizes the emergency physician. For the most part heuristics work well, but occasionally they lead to poor outcomes. When they fail, they are typically described in hindsight by terms such as biases, neglect, fallacies, slips, failures, and errors. These CDRs reflect a "cognitive determinism," the tendency to perceive and respond to a clinical situation in a particular way, based on a summation of historical, prevailing, and ambient factors. Thirty CDRs have been described in the context of emergency medicine, and there are probably more (Table 312-5).

The prevalence of CDRs and their adverse influence on decision making is well recognized.¹⁶ Some effort has been directed at undoing

Aggregate bias	Gender bias	Psych-out errors
Anchoring	Hindsight bias	Representativeness
Ascertainment bias	Multiple alternatives bias	restraint
Availability	Omission bias	Search satisfying
Base-rate neglect	Order effects	Sutton's slip
Commission bias	Outcome bias	Triage-cueing
Confirmation bias	Overconfidence bias	Unpacking principle
Diagnosis momentum	Playing the odds	Vertical line failure
Fundamental attribution error	Posterior probability error	Visceral bias
Gambler's fallacy		Ying-yang out
		Zebra retreat

TABLE 312-5 Cognitive Dispositions to Respond (CDR) That May Lead to Adverse Outcomes

their effects using specific cognitive debiasing approaches. More recently, metacognitive techniques have been employed, aimed at blocking or modifying the CDR through cognitive forcing strategies.¹⁰ For example, the predictable and catastrophic error of using fibrinolytics in a patient with an acute myocardial infarct mimic (left ventricular aneurysm, benign early repolarization, non-AMI ST-segment elevation, aortic dissection, acute pericarditis) has its origin in a combination of CDRs: *representativeness restraint*, *anchoring*, *search satisfying*, and *premature diagnostic closure*. A necessary first step in avoiding this error is to develop an awareness and knowledge of the known CDRs. The second is to recognize the scenario in which the error is likely to occur, and the final step is to apply the cognitive forcing strategy, in this case to metacognitively reflect on competing hypotheses before taking unpropitious action. Considerable further effort will be required to discover and develop additional strategies for minimizing or avoiding the adverse outcomes associated with CDRs.

DEVELOPING A SYSTEMS APPROACH TO PATIENT SAFETY

Critical incident and organizational analysis in health care has been facilitated by integration of knowledge from many different disciplines.¹⁷ *Cognitive science* or *cognitive engineering* provides tools to understand and model cognitive abilities such as perception, learning, language, memory, and problem solving. *Human factors* or *ergonomics* evaluates the specifics of human performance and its interface with the physical environment in which we operate in an effort to maximize user performance. *Systems analysis*, with its background in operations research, models systems and organizations to better understand their functions, including relationships with other systems and subsystems. Each of these approaches has unique attributes and analytic capacity that, when merged, will allow the development of an integrated picture of the ED environment as an environment prone to error.

Vincent and colleagues have proposed a specific safety analysis framework to evaluate adverse incidents in clinical medicine.¹⁷ This framework is designed around a hierarchy of seven types of factors that influence clinical practice (Table 312-6). Ideally, interventions to improve safety should be targeted at each of these factors.¹⁷ It is ironic that interventions at the higher levels, which are more likely to be effective and whose effects are more likely to be long-lasting, are more difficult than short-term, quick fixes at the lower levels.

An important step in selecting or designing corrective interventions is to have some mechanism for finding out when things go wrong and for understanding the ways in which systems of care fail. Thus some form of reporting of incidents (near misses) and accidents

(adverse events), coupled with in-depth investigation of selected episodes, is valuable for guiding interventions. In general, in-depth investigation of a small number of meaningful events tends to be more productive than attempts at comprehensive cataloging of small amounts of information on many events.¹⁸

Three general strategies for reducing incidents and adverse events exist: prevention, recognition, and mitigation. Prevention of slips, lapses, and mistakes is an attractive strategy; for example, eliminating look-alike drug containers prevents mental slips whereby a nurse picks up one container when intending to pick up another, leading to a wrong drug administration. However, the abundance of such errors is so high that it is virtually certain that some will always occur.¹⁷ The second strategic defense, then, is to make such mishaps easily recognized so they can be corrected before they affect a patient. For example, Australian anesthetists have adopted a convention that paralytic agents are always drawn up in red marked syringes, so that it is obvious to everyone in the room when a paralytic is about to be given.¹⁹ If a worker inadvertently picks up the wrong syringe, it is more likely that someone will recognize in time to intervene. Similarly, the practice of repeating back verbal orders ("check-back"), or calling out medications when they are given, allows greater opportunity for failures to be recognized and dealt with promptly.²⁰ The third general strategy, mitigation, involves enhancing the ability to recover from problems by preventing or minimizing their damage. For example, bringing a crash cart, airway equipment, and reversing agents to sites where procedural sedation is performed enhances the likelihood that laryngospasm, hypoventilation, or inadvertent oversedation will be successfully managed without patient injury.

At a more specific level, there are several general tactical approaches that can be used in support of any of the three strategies. The first is simplification of processes. The more steps there are in a process, the more likely it is that something in the process will go wrong, even if the individual steps are executed with a high degree of reliability. For example, there is a 12 percent chance that a 25-step process will contain at least one error, even if each step is executed correctly 99.5 percent of the time; reducing the number of steps to 10 cuts the probability of failure to less than 5 percent. In the clinical area, simplification of fibrinolytic dosing regimens has been shown to reduce dosing errors and led to a 30 percent relative reduction in mortality.²¹ A second general tactic is the use of constraints or "forcing functions." These are design changes that make it difficult to do the wrong thing. For example, gas connectors on anesthesia machines are designed so that oxygen and nitrous oxide tanks can be attached only to the proper ports, eliminating the chance of a gas mix-up with potentially fatal consequences.

TABLE 312-6 Framework of Factors Influencing Clinical Practice

Factor Type	Influencing Contributory Factors	Example
Institutional context	Economic context, regulatory agenda, legal framework and constraints	Inconsistent or conflicting policies and regulations
Organizational and management factors	Organization structure, priorities, organizational safety culture, financial constraints	Lack of senior leadership commitment to a culture of patient safety
Work environment factors	Staffing levels and skills, workload, shift patterns, support structure	High workload with inadequate staffing
Team factors	Communication, supervision and support, leadership, consistency	Limited communication between staff members
Individual (staff) factors	Skills, competence, training	Lack of basic fund of knowledge
Task factors	Task design, clarity, protocol availability, accuracy of results	No or unclear protocols for routine work
Patient factors	Complexity, acuity, language and communication, social factors	Language barrier

Source: Adapted from Vincent et al.¹⁷

Advanced technology, particularly automation and computerization, has great potential for improving safety, but carries with it its own set of hazards.^{22,23} Introducing new technology into a complex system can increase operational demands. It inevitably changes the nature of work, tending to make easy tasks easier and hard tasks harder. It tends to make systems more brittle; they fail less often, but their failures are more likely to be catastrophic.²⁴ New technology should be introduced, but introduced carefully, with preparedness to confront and rapidly resolve new and unexpected problems.

External standards organizations can be expected to play a role in suggesting or even mandating specific corrective actions.²⁵ External regulatory bodies can be important forces for safety, preventing a "race to the bottom" under production pressures, but their actions, although well-intended, can have unforeseen consequences if the recommendations are made without a deep understanding of the nature of work in the emergency department. For example, the Joint Commission on Accreditation of Healthcare Organizations has identified that communication failures leading to delays in therapy are a common cause of sentinel events submitted to it, and the Commission has noted that over half of such cases were "ED-related."²⁶ In 2002, the Joint Commission issued six safety goals that they expect to be fully implemented as of January 1, 2003, including:²⁷

1. Improving accuracy of patient identification, including use of two different patient identifiers and a final verification check before in vasive procedures are performed;
2. Improved communication among caregivers, including check-backs for verbal orders and standardization of abbreviations, acronyms, and symbols;
3. Removal of "high alert" medications from treatment areas (mainly concentrated electrolyte solutions);
4. Eliminating wrong-site, wrong-patient, and wrong-procedure failures, using verification processes and marking;
5. Eliminating infusion pumps that permit free flow; and
6. Ensuring that alarms are "sufficiently audible" given the distance and level of competing noise in the treatment area.

While all these goals are laudable, the specific implementations that surveyors will accept are not known. For some, implementation in the emergency department will be a challenge and may produce unintended consequences.

In addition, the Agency for Healthcare Research and Quality has recently reviewed the evidentiary base for a large number of safety-related practices and recommends several for immediate and widespread implementation because they were supported by strong evidence.²⁸ Several are pertinent to emergency care. The first requires that insertion of central lines should be done under maximum sterile technique (gown, gloves, drape, mask, and cap); that they not be placed blindly, but under ultrasound guidance; and that antibiotic-impregnated catheters be used. The second recommendation was to routinely ask patients to recall and restate what they were told in the process of informed consent, although a close reading suggests this recommendation was based more on ethical grounds than on evidence it improves safety.

Emergency department leaders should expect that external pressure to improve safety in emergency care will continue and they should be constructively engaged in this process. Choosing safety-related interventions for emergency departments is difficult. Little is known in detail about the ways in which emergency care succeeds or fails; superficial learning, resulting in quick fixes, is easy, while the more fundamental lessons are more difficult.²⁹

ETHICAL IMPLICATIONS OF ERROR

When an error or a lapse in patient safety occurs, an important component of the process is the disclosure of the event to the patient. Most professional organizations, including the American Medical Association,

have ethical standards that require the disclosure of unintended medical outcomes. Specific discussion of medical errors has been vague, leaving the interpretation of disclosure of "significant" error or "appropriate" conditions for disclosure to the discretion of the medical provider. Currently, no official professional organization calls for the complete disclosure of all medical error or defines the conditions under which disclosure must occur. Recent regulatory standards have addressed this ambiguity. In 2001, the Joint Commission required hospitals to document that "patients and, when appropriate, their families are informed about the outcomes of care, including unanticipated outcomes."

The medical literature supports the concept that physicians have an ethical duty to disclose errors to a patient when disclosure furthers the patient's health, respects the patient's autonomy, or enables the patient to be compensated for serious irreparable harm.³⁰ Similarly, legal duty requires a physician to disclose to the patient the necessary medical information to permit the patient to make an intelligent decision with regard to treatment, and the physician must reveal all that is in the patient's best interest.³¹ Much has been written about the conflict between the ethical duty to disclose error and the physician's and patient's personal, financial, psychological, and professional well-being, yet we know little about the actual impact of error disclosure on our patients.^{30,31} In a recent ED study of patient preference for medical error disclosure, researchers found that 88 percent of patients would wish to know everything about a mistake, while the remaining 12 percent would want to know about the mistake if it could or did affect their health.³¹ These data suggest that despite limited knowledge of the ramifications of disclosure, patients would like to know about medical errors committed during the course of their care. Therefore, disclosure of medical errors should be our goal in an effort to simply tell the truth.

- Nicardipine
actions, 214
adverse effects profile, 214 dosing and administration, 214 for hypertensive emergency, 399?, 401 indications, 214 pharmacokinetics, 214 Niclosamide, for treatment of parasites, 963?
- Nicotine, 1079
alteration in presentation of poisoned patients, 1019? during pregnancy, 669 NICU (neonatal intensive care unit) graduates. *See* Premature infants
- NIDDM (non-insulin-dependent diabetes mellitus), 1294
- Nifedipine actions, 214
adverse effect profile, 215 associated with drug fever, 580/ for chronic aortic regurgitation, 377 dosing and administration, 215 for hypertensive urgency, 402, 402? indications, 214-215 pharmacokinetics, 214 for premature labor and premature rupture of membranes (PROM), 681?
for prevention and treatment of high-altitude pulmonary edema (HAPE), 1268?, 1269 for renal stones, 624 toxicity of, 1109? Nifurtimox, for treatment of parasites, 963?
- Nightshade, toxicity of
common or woody (*Solanum* species), 1249
- deadly (*Atropa belladonna*), 1249
- Nightstick fractures, 1692
- Nimodipine actions, 215
adverse effect profile, 215 dosing and administration, 215 indications, 215 pharmacokinetics, 215 for vertigo, 1404?
- Nipple discharge, 703, 704? Nipple irritation, 703-704 NIRS (near-infrared spectroscopy), 1444 Nitazoxanide
for treatment of parasites, 963? for zoonotic infections in immunocompromised patients, 978?
- Nitrates
to limit infarct size, 356 for syncope, 361?
- Nitric acid burns, 1131?, 1228 Nitric oxide synthase inhibitors, for septic shock, 241
- Nitrites, for cyanide poisoning, 1167
- Nitrofurantoin
associated with drug fever, 580/ for urinary tract infection (UTI), 610, 610?, 1008?
- Nitrogen, toxicology of, 1154? Nitrogen mustard, use and toxicity of, 710? Nitrogen narcosis, 1217 Nitrogen oxide, toxicology of, 1154?, 1158 Nitroglycerin action, 215 for acute coronary syndromes, 352? adverse effect profile, 216 for congestive heart failure, 368?, 369 dosing and administration, 215-216 for hypertensive emergency, 399?, 400 for hypertensive urgency, 402, 402? indications, 215 pharmacokinetics, 215, 215? for pulmonary edema, 369 Nitroprusside for acute severe mitral incompetence, 375
for aortic incompetence, 377 for congestive heart failure, 368?, 369-370
for hypertensive emergency, 399? for pediatric resuscitation, 81? for pulmonary edema, 369-370 Nitrous oxide for acute pain management in adults, 261 for procedural sedation and analgesia (PSA) in children, 866?, 867
- Nizatidine, for traditional peptic ulcer therapy, 518?
- NMS (neuroleptic malignant syndrome)
- Noisy breathing and stridor, in neonates, 749 Nomifensine, associated with drug fever, 580/
- Nonabsorbable sutures, 292, 293?
- Nonadrenergic vasoconstriction (vasopressin), for cardiopulmonary resuscitation (CPR), 144
- Non-AG metabolic acidosis, 155, 155?
- Nonanticoagulant rodenticides, 1140-1142, 1140?
- Nonbenzodiazepine hypnotosedatives, toxicity of
- buspirone, 1061 chloral hydrate, 1061 ethchlorvynol, 1061-1062 flumazenil, 1063, 1063? 7-hydroxybutyrate and related compounds clinical features of toxicity, 1059-1060
drug facilitated sexual assault, 1060
overview, 1057-1059, 1057? treatment for intoxication, 1060 withdrawal, 1060-1061 glutethimide, 1062 meprobamate, 1062-1063 methaqualone, 1063 overview, 1057, 1057?, 1058?, 1059? zaleplon, 1063 zolpidem, 1063 Nonconvulsive status epilepticus (NCSE), 1396, 1408, 1416
- Nongonococcal septic arthritis, 1798-1799
- Nongonococcal urethritis (NGU), 910
- Noninfectious intertrigo clinical features, 1533 diagnosis, 1533-1534 overview, 1533 treatment, 1534 Non-insulin-dependent diabetes mellitus (NIDDM), 1294
- Noninvasive airway management airway obstruction, 102-103, 103? anatomy and pathophysiology, 102, 102/ bag-valve-mask unit, 104, 104/ esophageal airways esophageal gastric tube airway, 104 esophageal obturator airway, 104 esophageal tracheal Combitube, 104, 105/ laryngeal mask airway (LMA), 104-105, 106/ overview, 104 pharyngotracheal lumen airway, 104, 105/ tracheoesophageal airway, 104, 105/ noninvasive positive-pressure ventilation bilevel positive airway pressure, 106, 107/ complications, 107 continuous positive airway pressure, 105
overview, 105 technique, 106-107 oral/nasal airways, 103-104, 103/ Noninvasive myocardial imaging. *See* Myocardial imaging, noninvasive

TABLE 226-1 Dermatomes

Nerve	Action to Test	Muscle*
Long thoracic	Forward shoulder thrust	Serratus anterior
Dorsal scapular	Elevate scapula	Levator scapulae
Suprascapular	Arm external rotation	Infraspinatus; C5, C6
Axillary	Abduct arm (>90 degrees)	Deltoid; C5
Musculocutaneous	Flex and supinate arm	Biceps brachii
Ulnar	Ulnar flexion of hand Flex DIP of fingers 4 and 5 Thumb adduction Abduction of finger 5 Opposition of finger 5 Flexion of finger 5 Finger abduction and adduction Flex PIP and extend DIP of fingers 4 and 5	Flexor carpi ulnaris; C7, C8,t T1 Flexor digitorum profundus Adductor pollicis; C7, C8+ Abductor digitorum minimi Opponens digitorum minimi Flexor digitorum minimi brevis Interossei; C8, T1 Lumbricals 3 and 4
Median	Forearm pronation Radial hand flexion Hand flexion PIP flexion of fingers 2—5 Abduct thumb at the MCP Flex proximal phalanx thumb	Pronator teres Flexor carpi radialis; C7, C8, T1 Palmaris longus Flexor digitorum superficialis Abductor pollicis brevis Flexor pollicis brevis; C7, C8+
Anterior interosseous	Flex DIP fingers 2-5 Flex thumb IP Oppose thumb Flex PIP and extend DIP of fingers 2 and 3	Flexor digitorum profundus (radial) Flexor pollicis longus Opponens pollicis; C8, T1 + Lumbricals 1 and 2
Posterior interosseous	Extension of digits 2-5 Ulnar hand extension Thumb abduction Thumb extension Index finger extension	Extensor digitorum Extensor carpi ulnaris Abductor pollicis longus Extensor pollicis longus and brevis Extensor indicis proprius
Radial	Forearm extension Forearm flexion Radial hand extension Forearm supination	Triceps brachii; C6, C7,t C8 Brachioradialis; C5, C6 Extensor carpi radialis Supinator

*Dermatomal representations are listed after some muscles.

fPredominant dermatome.

Abbreviations: DIP = distal interphalangeal joint; IP = interphalangeal joint; PIP = proximal interphalangeal joint.

TABLE 229-3 The Mini-Mental State Examination

Maximum Score	Score	
	()	ORIENTATION
	()	What is the: (year) (season) (date) (day) (month)?
	()	Where are we: (state) (county) (town) (hospital) (floor)?
	()	REGISTRATION
	()	Name 3 objects; ask patient to repeat.
	()	ATTENTION AND CALCULATION
	()	The serial 7 test; 1 point for each correct. Stop after 5 answers. Option: spell "world" backwards.
	()	RECALL
	()	Ask for the 3 objects repeated above. 1 point scored for each correct object recalled.
9	()	LANGUAGE
	()	Name a pencil and watch (2 points)
	()	Repeat the following, "No if s, ands, or buts." (1 point)
	()	Follow 3 stage command: "Take a paper in your right hand, fold it in half, and put it on the floor." (3 points)
	()	Read and follow the following printed command:
	()	"Close your eyes" (1 point)
	()	Write a sentence (1 point)
	()	Copy design (1 point)

SCORING: A score of 23 or less may indicate the presence of dementia or another cognitive disorder and suggests the need for further testing and evaluation.

TABLE 295-3 CAGE Questionnaire

C: Have you ever felt that you should *cut* down on your drinking?
 A: Have people ever *annoyed* you by criticizing your drinking?
 G: Have you ever felt bad or *guilty* about your drinking?
 E: Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover (*eye opener*)?

FIG. 199-1. Rule of Nines.

Relative Percentages of Areas Affected by Growth (Age in Years)

	0	1	5	10	15	Adult
A: half of head	9½	8½	6½	5½	4½	3½
B: half of thigh	2¾	3¼	4	4¼	4½	4¾
C: half of leg	2½	2½	2¾	3	3¼	3½

Second-degree _____ and

Third-degree _____ =

Total percent burned _____

FIG. 199-2. Lund and Browder diagram to estimate percentage of pediatric burn.

FIG. 256-6. Spinal cord level.

TABLE 199-2 Parkland Formula

Adults

LR 4 mL × weight (kg) × % BSA* over initial 24 h

Half over the first 8 h from the time of burn

Other half over the subsequent 16 h

Example: 70-kg adult with 40% second- and third-degree burns

4 mL × 70 kg × 40 = 11,200 mL over 24 h

Children

LR 3 mL × weight (kg) × % BSA* over initial 24 h plus

maintenance

Half over the first 8 h from the time of burn

Other half over the subsequent 16 h

*Second- and third-degree burns only.

TABLE 255-2 Glasgow Coma Scale

	4 years to Adult	Child <4 years	Infant
Eye Opening 4 3 2 1	Spontaneous To speech To pain No response	Spontaneous To speech To pain No response	Spontaneous To speech To pain No response
Verbal Response			
5	Alert and oriented	Oriented, social, speaks, interacts	Coos, babbles
4	Disoriented conversation Speaking but nonsensical Moans or unintelligible sounds No response	Confused speech, disoriented, consolable, aware	Irritable cry
3		Inappropriate words, inconsolable, unaware	Cries to pain
2		Incomprehensible, agitated, restless, unaware	Moans to pain
1		No response	No response
Motor Response			
6	Follows commands	Normal, spontaneous movements	Normal, spontaneous moves
5	Localizes pain	Localizes pain Withdraws to pain	Withdraws to touch
4	Movement or withdrawal to pain	Decorticate flexion Decerebrate	Withdraws to pain
3	Decorticate flexion	extension No response	Decorticate flexion
2	Decerebrate extension		Decerebrate extension No
1	No response		response
3-15			

Note: GCS reporting should be modified for intubated and paralyzed patients.

TABLE 274-1 Ottawa Knee Rules

Patient older than 55 years
Tenderness
at the head of the fibula Isolated
tenderness of the patella Inability to
flex knee to 90 degrees
Inability to transfer weight for four steps both immediately after the injury
and in the ED

a) An ankle x-ray series is only required if:
There is any pain in malleolar zone and any of these findings:
i) bone tenderness at A
OR
ii) bone tenderness at B
OR
iii) inability to bear weight both immediately and in ED

b) A foot x-ray series is only required if:
There is any pain in midfoot zone and any of these findings:
i) bone tenderness at C
OR
ii) bone tenderness at D
OR
iii) inability to bear weight both immediately and in ED

FIG. 276-3. Ottawa Ankle Rules.

TABLE 272-1 NEXUS Criteria

According to NEXUS low-risk criteria, cervical spine radiography can be omitted for trauma patients only if they exhibit *all* of the following criteria:

No posterior midline cervical spine tenderness
No evidence of intoxication
Normal level of alertness
No focal neurologic deficit
No painful distracting injuries

TABLE 252-2 Pediatric Trauma Score

	-1	+	+2
Size (kg)	<10	" 10-20	>20
Airway	Unmaintained	Maintained	Normal
Systolic blood pressure (mm Hg)	<50	50-90	>90
Level of consciousness	Comatose	Altered	Awake
Wounds	Major open	Minor open	None
Skeletal trauma	Open/multiple	Closed	None

TABLE 252- Revised Trauma Score

Number	Glasgow Coma Score	Systolic Blood Pressure	Respiratory Rate
4	13-15	>89	10-29
3	9-12	76-89	>29
2	6-8	50-75	6-9
1	4-5	1-49	1-5
0	3	0	0

TABLE 114-1 Pediatric Vital Signs (Awake and Resting)

Age	Heart Rate/min, Upper Limit	Respiratory Rate/min, Upper Limit	Blood Pressure,* Lower Limit	Weight,† kg
0-1 mo	180	60	60/40	3-4
2-12 mo	160	50	70/45	5-10
12-24 mo	140	40	75/50	10-12
2-6 y	120	30	80/55	13-25
6-12 y	110	20	90/60	25-40
>12y	100	20	90/60	40-60

*May be estimated by
systolic blood pressure (5th percentile) = $70 + [2 \times (\text{age in years})]$

†May be estimated by
≤12 mo: weight (kg) = $4 + (\text{age in months}/2)$
1-12 y: weight (kg) = $10 + [2 \times (\text{age in years})]$

TABLE 13-5 Neonatal Resuscitation Drug Chart

Drug, Concentration, and Indication	Syringe Size (mL)	Dose by Weight	PATIENT DOSE		Administration	
			Weight (kg)	VOLUME (mL)		
				IV		ET
Epinephrine 1:10,000(0.1 mg/mL)for bradycardia	1	0.01-0.03 mg/kg	1-2 3-4	0.2 0.4 0.6 0.8	0.5 1 1.5 2	IV push or ET followed by 1 mL NS solution. Repeat q5 min as needed. <i>Do not mix with sodium bicarbonate. Never inject into an artery.</i>
Sodium bicarbonate 4.2% (0.5 mEq/mL) for metabolic acidosis	6, 10, or 12	2 mEq/kg	1-2 3-4	4-8 12 16		IV over at least 2 min. <i>Do not mix with epinephrine.</i> Ensure adequate ventilation.
Whole blood albumin 5%, NS solution, or LR for volume expansion	20 or 35	10mL/kg	1 2-3 4	10 20 30 40		IV over at least 10 min.
Naloxone 0.4 mg/mL for opiate-induced respiratory depression		0.1 mg/kg		0.25 0.50 0.75 1	0.25 0.50 0.75 1	IV push, or ET May repeat 2 to 3 times. <i>Use cautiously if maternal narcotic addiction is suspected.</i>

Abbreviation: ET = endotracheally. **TABLE 14-5 Length-Based Equipment Chart (Length, cm) ***

Item	54-70	70-85	85-95	95-107	107-124	124-141	141-155
Endotracheal tube size (mm)	3.5	4.0	4.5	5.0	5.5	6.0	6.5
Lip-tip length (mm)	10.5	12.0	13.5	15.0	16.5	18.0	19.5
Laryngoscope	1 Straight	1 Straight	2 Straight	2 Straight or curved	2 Straight or curved	2-3 Straight or curved	3 Straight or curved
Suction catheter	8F	8-10F	10F	10F	10F	10F	12F
Stylet	6F	6F	6F	6F	14F	14F	16F
Oral airway	Infant/small child	Small child	Child	Child	Child/small adult	Child-adult	Medium adult
Big-valve mask	Infant	Child	Child	Child	Child	Child-adult	Adult
Oxygen mask	Newborn	Pediatric	Pediatric	Pediatric	Pediatric	Adult	Adult
Vascular access (gauge)	22-24	20-22	18-22	18-22	18-20	18-20	16-20
Catheter Butterfly	23-25	23-25	21-23	21-23	21-23	21-22	18-21
Nasogastric tube	5-8F	8-10F	10F	10-12F	12-14F	14-18F	18F
Urinary catheter	5-8F	8-10F	10F	10-12F	10-12F	12F	12F
Chest tube	10-12F	16-20F	20-24F	20-24F	24-32F	28-32F	32-40F
Blood pressure cuff	Newborn/infant	Infant/child	Child	Child	Child	Child/adult	Adult

*Directions for use: (1) measure patient length with centimeter tape; (2) using measured length in centimeters, access appropriate equipment column.

PLATE 1 Smallpox lesions on skin of trunk. [Reprinted with permission from Public Health Images Library (PHIL) ID #284, Centers for Disease Control and Prevention.]

PLATE 2 (Fig. 135-7). Cutaneous anthrax in a 9-year-old girl. [Reproduced with permission from DOIA (Dermatology Online Atlas) University Erlangen, Department of Dermatology, Nürnberg, Germany, www.dermis.net/index_e.htm.]

PLATE 3 (Fig. 238-8). Positive Seidel test showing aqueous leaking through a full-thickness corneal wound. Aqueous will turn fluorescein lime-green under a cobalt-blue light as it oozes through the wound while being observed at the slit lamp.

PLATE 4 (Fig. 238-9). Hyphema secondary to blunt trauma. Note the blood filling the lower half of the anterior chamber and hazy appearance of cornea suggesting increased IOP.

PLATE 5 (Fig. 238-10). Corneal ulcer with hypopyon. The ulcer is seen as a shaggy white corneal infiltrate surrounding the borders of the epithelial defect. The hypopyon represents the accumulation of white cells layering out in the lower one-sixth of the anterior chamber.

PLATE 6 (Fig. 238-11). Herpes simplex corneal dendrite seen with fluorescein staining and cobalt-blue light.

PLATE 7 (Fig. 238-17). Central retinal artery occlusion. Note macular "cherry red spot" and retinal pallor between macula and disc. The retinal veins appear normal size, but the arteries are barely visible and attenuated.

PLATE 8 (Fig. 238-18). Central retinal vein occlusion "blood and thunder fundus." Note diffuse retinal hemorrhages in all retina quadrants and blurred disc margins.

< PLATE 9 (Fig. 238-22). Optic nerve head edema. Vascular congestion, elevation of the nerve head, and blurred disc margins are characteristically seen in papilledema, papillitis, and compressive lesions of the optic nerve.

► PLATE 10 (Fig. 246- 1A). Erythema multiforme. Symmetrical, plaque-like lesions involve the flexor surface of the upper extremities; these lesions may be misdiagnosed as the immunoglobulin G-mediated urticarial allergic reaction. Also note the erythematous macules on the palms.

PLATE 11 (Fig. 246-1B). Iris or target lesion, a finding strongly suggestive of erythema multiforme. This iris lesion is composed of a central bullous lesion with a dusky, edematous center and an erythematous halo. (Reprinted with permission from Brady W, DeBehnke D, Crosby D: Dermatologic emergencies. *AmJEmerg Med* 12:217, 1994.)

PLATE 12 (Fig. 246-2). Exfoliative dermatitis demonstrated by generalized, warm erythema accompanied by scaling or flaking.

PLATE 13 (Fig. 246-3). Blanching, nonpruritic erythroderma with a "rough" texture in a patient with toxic shock syndrome. (Reprinted with permission from Brady W, DeBehnke D, Croshy D: Dermatologic emergencies. *Am J Emerg Med* 12:217, 1994.)

PLATE 14 (Fig. 246-4). Large bullous lesions on the lower extremity in a patient with streptococcal toxic shock.

PLATE 15 (Fig. 246-5). Single dermatomal involvement in a patient with herpes zoster infection in a thoracic distribution.

PLATE 16 (Fig. 246-6). Herpes zoster ophthalmic infection. Facial zoster involving the ophthalmic branch of the fifth cranial nerve with nasal lesions strongly suggestive of corneal infection.

PLATE 17 (Fig. 246-7). Disseminated herpes simplex virus infection in an immunocompromised adult patient; note the widespread distribution of vesicular lesions on an erythematous base.

PLATE 18 (Fig. 246-8). Disseminated gonococcal infection in a sexually active adult female. The maculopapule has a petechial component and an erythematous periphery on the extensor surface of the wrist.

PLATE 19 (Fig. 246-9). A patient with Rocky Mountain spotted fever with petechiae on the ankles.

PLATE 20 (Fig. 246-10). Early findings of meningococemia with petechiae evolving into purpuric lesions. (Reprinted with permission from Brady W, DeBehnke D, Crosby D: Dermatologic emergencies. *AmJEmerg Med* 12:217, 1994.)

PLATE 21 (Fig. 246-11). Purpura fulminans with hemorrhagic bullae. (Reprinted with permission from Tangoren IA et al: Ecchymoses and epidermal necrosis in a 75-year-old man with bacteremia. *Crit Illness* 13:108, 1998.)

PLATE 22 (Fig. 246-12). Scattered bullous lesions intermixed with erosions and painful inflammatory plaques.

PLATE 23 (Fig. 248-6). Stasis dermatitis. Note the surrounding red-brown pigment and weepy erythema.

PLATE 24 (Fig. 248-7). Erythema nodosum. An erythematous indurated nodule is seen. This patient's disease was diagnosed as cellulitis. However, after no response to antibiotics, a biopsy confirmed the diagnosis of a nodosum. Most patients with a nodosum will have multiple
