POSTEXTRACTION ALVEOLAR OSTEITIS Pain in the initial 24 to 48 h after dental extraction, termed *periosteitis*, is common and responds well to analgesics. Depending on the tooth removed, density of the bone, and amount of associated trauma that occurred during extraction, significant discomfort can occur. *Postextraction alveolar osteitis*, or *dry socket*, usually occurs on the second or third postoperative day and is associated with exquisite oral pain. Displacement of the clot from the socket or fibrinolytic dissolution of the clot results in exposure of the alveolar bone to the oral environment. This initiates an inflammatory response resulting in a localized osteomyelitis of the exposed bone. Risk factors for developing postextraction alveolar osteitis include smoking, preexisting pericoronitis or periodontal disease, a traumatic extraction, a prior history of alveolar osteitis, and hormone replacement therapy.³

The incidence of postextraction alveolar osteitis is 2 to 5 percent of all extractions but is considerably higher (20 to 35 percent) among impacted third molar extractions. Dental radiographs should be taken to ensure the absence of a retained root tip or other foreign body. Thorough irrigation of the dental socket with sterile normal saline and packing it with oil of cloves- or eugenol-impregnated gauze results in an almost immediate improvement in level of comfort. Dental anesthesia may be necessary to adequately irrigate and pack a dry socket. Antibiotic therapy is indicated in the most severe cases, and daily packing changes are important. Thus, referral to a dentist within 24 h is indicated.^{3,4}

Managing postoperative dentoalveolar sequelae is in the realm of emergency medicine. Postoperative pain requiring analgesics, is a common presentation. Pain immediately postoperative is most com-

monly related to the trauma of surgery. Postoperative edema such as with extraction of third molars peaks within the first 24 to 48 h and is best managed with ice packs and elevation of the head of the bed to 30 degrees. Trismus, also common postoperatively, can result from infection, direct injury to the temporomandibular joint, injury to the muscles of mastication during administration of the inferior alveolar nerve block or during the surgery, and most commonly, normal perioperative inflammation. Trismus peaks in the first 24 h and usually decreases thereafter unless an infective process is the etiology. Postoperative trismus persisting for greater than 1 week will usually require stretching exercises prescribed by the oral and maxillofacial surgeon.^{3,4}

POSTRESTORATIVE PAIN Pain may occur after a dental restorative procedure. Normal trauma from mechanical instrumentation of the tooth or direct exposure of the pulpal tissue during instrumentation may result in pain. Pain associated primarily with mastication may be a result of improper occlusion of the new restoration. After endodontic therapy, patients may experience exquisite pain secondary to instrumentation or a buildup of gaseous pressure in the pulp chamber. Providing analgesia and referral to the patient's general dentist are the treatment of choice.

Periodontal Pathology

PERIODONTAL DISEASE Gingival inflammation and bleeding, or *gingivitis*, results from the accumulation of plaque along the gingival margins. Hormonal variations of puberty, adolescence, and pregnancy, as well as many medications such as phenytoin, may exacerbate gingival inflammation. As the inflammatory process progresses, destruction of the periodontal attachment apparatus occurs, and the gingival sulcus deepens, resulting in periodontal pockets and *periodontitis*. Periodontal pockets create a favorable environment for plaque accumulation, maturation, and mineralization into *calculus*. Further destruction of the periodontal attachment results. Eventually, sufficient bone loss causes tooth mobility and tooth loss.^{1,5}

The pathogenesis of periodontal disease is uncertain, but there is a very strong association between adult periodontitis and *Bacteroides gingivalis*. Many other specific bacteria have been shown to have a role in periodontitis. Destruction of tissue collagens, proteoglycans, and the connective tissue matrix is a major feature of gingivitis and periodontitis. Three theories for the etiology of this destruction have been proposed. Tissue destruction may occur as a result of the direct effects of bacterial plaque and their metabolic products, an accelerated host immune response, or immune deficiencies involving neutrophil function or the autologous mixed lymphocyte response.^{1,5}

Four distinctive types of periodontal disease have been identified. These include adult, rapidly progressing, juvenile, and prepubertal periodontitis.⁵ Etiology, age and gender predilection, and clinical course of disease vary by type. A definite association between juvenile periodontitis and *Actinobacillus actinomycetemcomitans* exists. More severe and rapidly progressing periodontitis, especially those types affecting a younger population such as the prepubertal and juvenile periodontitis, appears to be associated with decreased neutrophil chemotaxis or phagocytosis. Systemic illnesses such as human immunodeficiency virus (HIV) infection, diabetes, lazy leukocyte syndrome, Down syndrome, and cyclic neutropenia are associated with severe periodontal disease.¹

Periodontal disease usually progresses painlessly but may present as gingival bleeding or tender, swollen gingival tissue. Treatment is directed at slowing or arresting the progression of disease primarily by the removal of plaque and its by-products.¹ Antibiotics may play a role in treatment. Referral to a dentist for definitive treatment is indicated because the treatment involves extensive dental cleaning, instruction and improvement in oral hygiene, and in some cases, periodontal surgery.

PERIODONTAL ABSCESS When plaque and debris are entrapped in the periodontal pocket, a periodontal abscess may form, resulting in severe pain. Small periodontal abscesses respond to local therapy with warm saline rinses and antibiotics such as penicillin VK 500 mg PO qid or erythromycin 250 mg PO qid. Larger periodontal abscesses require incision and drainage. Saline mouth rinses four times a day are useful. Analgesics are essential.

ACUTE NECROTIZING ULCERATIVE GINGIVITIS Acute necrotizing ulcerative gingivitis (ANUG) is an aggressively destructive process (Figure 242-5). Also known as *Vincent disease* or *trench mouth*, it is part of a spectrum of disease ranging from localized ulceration of the gingiva to often fatal noma, in which localized ulceration and necrosis spread to the adjacent tissues of the cheeks, lips, and underlying facial bones.^{6,7} The diagnostic triad includes pain, ulcerated or "punched out" interdental papillae, and gingival bleeding. Secondary signs include fetid breath, pseudomembrane formation, "wooden teeth" feeling, foul metallic taste, tooth mobility, lymphadenopathy, fever, and malaise.^{7,8}

The differential diagnosis for ANUG is quite extensive, but herpes gingivostomatitis is most difficult to differentiate. Herpes gingivostomatitis usually has smaller vesicular eruptions, less bleeding, more systemic signs, and lack of interdental papilla involvement.^{7,8}

The etiology of ANUG is still poorly understood. It appears to be an opportunistic infection in a host with lowered resistance. It is believed that suppression of the humoral and cell-mediated immune response in HIV infection, severe malnourishment, and perhaps stress may be responsible for a lowered host resistance. Anaerobic bacteria such as *Treponema*, *Selenomonas*, *Fusobacterium*, and *Prevotella* are uniformly identified. These bacteria appear to invade otherwise healthy tissue, resulting in an aggressively destructive disease process.^{7,8}

The most important predisposing factor is HIV infection. Previous necrotizing gingivitis infection is the second most important predisposing factor. Other contributing factors include poor oral hygiene, unusual emotional stress, poor diet, inadequate sleep, white heritage, age less than 21 years, poor socioeconomic status, recent illness, alcohol use, tobacco use, acatalasia, and various infections such as malaria, measles, and intestinal parasites.^{7,8}

Treatment consists primarily of bacterial control. Chlorhexidine oral rinses bid, professional debridement and scaling, and adjunctive antibiotic therapy with metronidazole 250 mg PO tid are the mainstay of treatment. Reduction in pain can be expected within 24 h of institution of this regimen. Identification and resolution of the predisposing factors, and supportive therapy with a soft diet rich in protein, vitamins, and fluids are important in establishing and maintaining a disease-free state.⁷

Cranial Neuralgias

Trigeminal neuralgia is the most common of the cranial neuralgias. Others include postherpetic neuralgia, glossopharyngeal and vagal neuralgia, and superior laryngeal neuralgia. Trigeminal neuralgia is undoubtedly one of the most painful entities involving the face. Most commonly affecting adults 30 to 60 years of age, females constitute 60 percent of the patients. Trigeminal neuralgia is almost always unilateral, following the anatomic distribution of the involved cranial nerve. The maxillary branch of the fifth cranial nerve is most commonly affected. Recurrent episodes of excruciating, electric shock like paroxysmal pain of short duration, separated by pain-free periods are characteristic. Associated contraction of the facial and masticatory muscles is typical, resulting in the term *tic douloureux*. Physical stimulation of a trigger point is the usual inciting event.⁹

The pathogenesis of trigeminal neuralgia is still uncertain. Diagnosis is clinical, requiring the exclusion of organic pathology such as acoustic neuroma or a nasopharyngeal carcinoma. Thus referral to a neurologist is important.⁹

Trigeminal neuralgia may respond well to the administration of carbamazepine (100 mg PO bid initially and gradually increasing as needed to a maximum dose of 1200 mg daily). Surgery is reserved for patients who do not respond to medications.⁹

Nonparoxysmal pain of neuropathic origin may develop 1) in patients who have had long-standing neuralgias, 2) secondary to surgical trauma along the distribution of the affected nerve branch, and 3) in association with viral infections, drugs, or heavy metal intoxication. Other neuropathies such as alcoholic and diabetic sensory neuropathies also may affect the oral cavity.

SOFT TISSUE LESIONS OF THE ORAL CAVITY

Lesions of the oral mucosa are common and, when symptomatic or noticed by patients, may require identification and treatment by the emergency physician. Treatment depends on the appropriate diagnosis. Thus familiarization with common oral pathology is important.

Oral Candidiasis

Candidiasis commonly affects the oral cavity. Many healthy adults harbor candidal microorganisms. Many predisposing factors influence the development of oral candidiasis. These include the extremes of age, intraoral prosthetic devices such as dentures, malnourished states, associated mucosal disorders, concurrent infections, antibiotics, and immunocompromised conditions such as acquired immunodeficiency syndrome (AIDS), transplant recipients, radiation therapy, and chronic immunosuppressive therapy. Three oral clinical types have been described. The most common type is the pseudomembranous type, or thrush with white, curdlike plaques. These plaques can be easily scraped off to reveal an underlying erythematous mucosal base. The second type is atrophic or erythematous and usually involves the dorsum of the tongue. Atrophy of the filiform papillae is seen. Finally, the lesions of hyperplastic candidiasis are raised white plaques that can only be partially removed with scraping due to deeper infiltration into the underlying tissue. Perioral candidiasis, presenting as angular cheilitis or scaling patches of the perioral facial tissues is common. Treatment is with topical oral antifungal agents such as nystatin oral suspension 500,000 units qid or systemic agents such as fluconazole 100to200mgPOperd.^{6,10}

Aphthous Stomatitis

Aphthous stomatitis or ulceration is one of the most common oral lesions, affecting 20 percent of the normal population (Figure 242-6). Evidence suggests that the etiology appears to be a cell-mediated immune response to a yet unidentified triggering agent. Three etiologic

FIG. 242-6. Aphthous stomatitis. (Courtesy of Baldev Singh, BDS, PhD.)

factors are known to predispose aphthous ulcer formation: an immune imbalance, a breach in the mucosal barrier, and an allergic response. Aphthous ulceration involves the nonkeratinized epithelium, especially the labial and buccal mucosa, and begins as an erythematous macule that ulcerates and forms a central fibropurulent eschar. Lesions measure from 2 to 3 mm to several centimeters in diameter, are painful, and frequently are multiple. They usually resolve spontaneously in 10 to 14 days. Aphthous stomatitis occurs in a major and minor form. The major form has larger, deeper ulcers that take up to 6 weeks to heal. A third form, called *herpetiforme aphthae*, has up to 100 ulcers, each 1 to 2 mm in diameter, and takes 7 to 10 days to heal. Treatment consists of topical corticosteroids such as betamethasone syrup or 0.01 percent dexamethasone elixir as a mouth rinse. Fluocinonide 0.05% gel applied topically to isolated lesions is acceptable. Resolution typically occurs 2 days after therapy. Aphthous major is more resistant to therapy and may require intralesional steroid injection or systemic steroid therapy.¹¹

Herpes Simplex

Herpes simplex type 1 most commonly affects the oral cavity. Herpes simplex type 2 can occur orally and is clinically indistinguishable. The primary infection, herpes gingivostomatitis, causes acute painful ulcerations on the gingiva and mucosal surfaces. Fever and lymphadenopathy are commonly associated findings and may occur up to 3 days prior to the appearance of oral lesions. Vesicular lesions appear and rupture after 1 to 2 days, leaving painful ulcers that heal gradually over 1 to 2 weeks. Secondary infection affects mostly the lips but may affect the hard palate and attached gingiva. The virus is harbored in sensory ganglion such as the gasserian ganglion of the trigeminal nerve. Periodic stresses activate the virus from its normally dormant state and results in recurrent lesions along the sensory distribution of the nerve. A prodrome of burning or tingling frequently occurs 1 to 2 days preceding outbreak of the characteristic vesicular lesion. Vesicles rupture within 2 to 3 days, forming small, shallow ulcers that heal in 6 to 10 days. Treatment is usually palliative; however, antiviral therapy with acyclovir 400 mg PO tid or valacyclovir 500 mg PO bid for 5 days initiated during the prodromal phase lessens the severity and duration of the ulceration.⁶

Varicella-Zoster

The varicella-zoster virus causes chickenpox (see Chap. 135) in its primary infection, resulting in the typical vesicular eruption. Vesicular involvement of the oropharynx is common and may precede skin involvement. Special care in maintaining adequate hydration is important when oral lesions are present.

Herpes zoster (see Chap. 143) occurs along the distribution of the trigeminal nerve 15 to 20 percent of the time. Typically beginning as a 1- to 4-day prodrome of exquisite pain in the area innervated by the affected nerve and may be mistaken for a simple headache or toothache. Vesicular eruptions characteristically occur unilaterally, not crossing the midline, and last 7 to 10 days. Isolated intraoral lesions can occur but are not common.

Involvement of the ophthalmic branch of the trigeminal nerve requires urgent ophthalmologic consultation.⁶

Herpangina

Herpangina is most commonly caused by coxsackievirus group A, types 1 to 6, 8, 10, and 22. Usually occurring in the summer and autumn, herpangina presents with a sudden onset of high fever, sore throat, headache, and malaise followed by eruption of oral vesicles 1 to 2 mm in size within 24 to 48 h. The vesicles quickly rupture, leaving numerous shallow, painful ulcers. The soft palate, uvula, posterior pharynx, and tonsillar pillars are usually affected, sparing the buccal mucosa, tongue, and gingiva. The disease lasts 7 to 10 days and can be distinguished from herpetic gingivostomatitis by the lack of gingival involvement.⁶

Hand, Foot, and Mouth Disease

Coxsackievirus type A16 and, occasionally, types A4, A5, A9, and A10 are associated with hand, foot, and mouth disease (see Chap. 135). This entity is characterized by the development of a few small vesicles on the tongue, gingiva, soft palate, and buccal mucosa. These vesicles rupture, resulting in painful, shallow ulcers with a surrounding red halo. The buttocks, palms, and plantar surfaces of the feet may be affected. Fever is usually of short duration, and the disease lasts 5 to 8 days. Treatment is supportive.⁶

Traumatic Lesions

Traumatic ulcers are a result of direct trauma to epithelial tissue. Common sources of trauma include rough or jagged edges on teeth or restorations, ill-fitting dentures, oral hygiene mishaps, and burns to the hard or soft palate secondary to hot foods. Removal of persistent sources of trauma is essential; otherwise, treatment is palliative.

A pyogenic granuloma is a common, benign proliferation of connective tissue in response to local trauma or irritation. It occurs primarily on the gingiva. Despite its name, this lesion is not a true granuloma but rather an accumulation of granulation tissue. A specific pyogenic granuloma occurring in pregnancy is referred to as a *pregnancy tumor* (Figure 242-7). This tumor is benign and usually recurs if removed during pregnancy. If the tumor does not regress 2 to 3 months postpartum, definitive removal is indicated.

Medication-Related Soft Tissue Abnormalities

Gingival hyperplasia is associated with many commonly used medications (Figure 242-8). Approximately 50 percent of patients on phenytoin will develop significant gingival hyperplasia. Many other medications, such as cyclosporine and calcium channel blockers, especially nifedipine, are known to cause gingival hyperplasia. Concomitant use of two such medications results in accelerated gingival proliferation. Enlargement begins in the interdental papillae. The clinical and histologic characteristics of gingival hyperplasia related to phenytoin, cyclosporine, and calcium channel blockers appear to be identical. The clinical appearance of the gingival tissue depends on oral hygiene and secondary inflammation. In the absence of inflammation, gingival proliferation results in dense tissue, normal in coloration, with a smooth, stippled, or granular texture. Inflammation causes edematous changes and an erythematous coloration. Inflamed

FIG. 242-7. Pyogenic granuloma.

tissue bleeds readily. Histologically, an increase in collagen fibers, in fibroblasts, and in glycosaminoglycans is seen. Epithelial acanthosis also occurs. Although the etiology of drug-related gingival hyperplasia remains unclear, poor oral hygiene clearly increases its likelihood and severity. Treatment includes fastidious oral hygiene to slow the hyperplasia and gingivectomy in advance cases.¹²

Many other medications are known to cause abnormalities of the oral mucosa or dental structures. Allergic mucositis, erythema multiforme, and fixed drug-type reactions are examples. Xerostomia and associated mucosal alterations are a side effect of many medications such as anticholinergics, antidepressants, and antihistamines.¹ Stomatitis or mucosal ulcerations secondary to the use of common chemotherapeutic agents is also common.

FIG. 242-8. Gingival hyperplasia secondary to cyclosporine. (Courtesy of Philip J. Hanes, DDS, MS.)

Sexually Transmitted Diseases

Many sexually transmitted diseases can affect the oral cavity. With oral-genital contact, the oral mucosa is as susceptible to the transmission of sexually transmitted diseases as the urogenital mucosa. Gonorrhea most commonly causes a pharyngitis involving the uvula and tonsils and may present with or without pustules or exudates. Oral herpes type 1 and type 2 infections are clinically indistinguishable. Human papillomavirus, associated with HPV-6, -11, and -45, is most commonly associated with *condyloma acuminatum*, or *venereal warts*, and can result in similar oral lesions.^{6,13}

The primary chancre of syphilis can occur orally. Chancre of the lip is the most common oral site involved. Tongue involvement is next in frequency, followed closely by the tonsils. An oral chancre is similar in appearance to its genital counterpart. In secondary syphilis, oral lesions are common and frequently accompany cutaneous lesions. They are usually multiple, oval-shaped, slightly raised ulcers or erosions covered with a gray membrane. Condyloma lata rarely occur intraorally.^{6,13}

Treatment of sexually transmitted diseases of the oral cavity is the same as for genital involvement. The diagnosis of oral sexually transmitted diseases requires maintaining an appropriate level of suspicion. Treatment of the sexual partner is essential to assure reinfection does not occur.

Lesions of the Tongue

Many systemic conditions and local stimuli affect the appearance of the tongue. Many systemic conditions, various vitamins deficiencies, and iron-deficiency anemia cause atrophy of the filiform papillae, resulting in a smooth erythematous appearance. Occurrence of ectopic thyroid tissue on the midline posterior portion of the tongue is called a *lingual thyroid* and is a common finding. Some common conditions affecting the tongue are discussed below.

ERYTHEMA MIGRANS Erythema migrans, geographic tongue, or benign migratory glossitis is a common benign finding on oral examination, occurring in 1 to 3 percent of the population. Females are affected twice as often as males. The typically multiple, well-demarcated zones of erythema on the tongue are caused by atrophy of the filiform papillae. The lesions concentrate on the tip and lateral borders of the tongue and heal in several days, only to quickly reappear in other areas. These lesions usually are asymptomatic; however, a burning sensation or sensitivity to hot or spicy foods has been described. Etiology is yet unknown; however, fluctuations with stress and menstrual cycle occur. Generally, treatment is not indicated because this entity is benign. Reassurance of patients is usually sufficient. In patients in whom discomfort is a major factor, oral topical steroids such as fluocinonide gel applied several times daily may provide relief.¹⁴

MEDIAN RHOMBOID GLOSSITIS Median rhomboid glossitis is believed to be a developmental defect of the dorsal surface of the tongue. It appears as a small 1- by 2-cm ovoid erythematous area just anterior to the circumvallate papillae. The area is devoid of papillae and usually asymptomatic. No treatment is necessary.

STRAWBERRY TONGUE Strawberry tongue is associated with erythrogenic, toxin-producing *Streptococcus pyogenes*. Clinically, the tongue has prominent red spots on a white-coated background. Microscopically, the fungiform papillae are hyperemic with a smooth glossy surface. Treatment is with antibiotics directed at group A streptococci.

Leukoplakia and Erythroplakia

Leukoplakia is a white patch or plaque that cannot be scraped off and cannot be classified as any other disease. Leukoplakia is the most

common oral precancer; however, only 2 to 4 percent of leukoplakic lesions show dysplastic changes. Etiology is unknown, but tobacco, alcohol, ultraviolet radiation, candidiasis, human papillomavirus, tertiary syphilis, and trauma have all been implicated. The most common intraoral site involved is the buccal mucosa. Other sites of involvement include the hard and soft palates, maxillary gingiva, and lip mucosa. Biopsy is mandatory for all persistent leukoplakic lesions. Leukoplakic lesions of the floor of the mouth, tongue, and vermillion border are most likely associated with malignancy. Lesions demonstrating dysplastic changes warrant removal.

Erythroplakia is defined as a red patch that similarly cannot be clinically or pathologically characterized as any other disease. Although erythroplakia is far less common than leukoplakia, it has a greater potential for dysplastic changes.

Oral Cancer

Oral cancer accounts for 2 to 4 percent of the cancers in the United States.¹⁵ More than 90 percent of all oral malignancies are squamous cell carcinoma. Lymphomas, Kaposi sarcoma, and melanoma comprise most of the remainder. Several intrinsic and extrinsic etiologic factors for oral squamous cell carcinoma have been identified. Extrinsic factors include tobacco use, especially chewing tobacco or snuff; excessive alcohol consumption; and sunlight exposure (Figure 242-9). Intrinsic factors include general malnutrition and chronic iron-deficiency anemia. Specific etiologic factors play varying roles in oncogenesis. Oral candidiasis, especially the hyperplastic form, immunosuppressive states such as HIV infection, and oncogenic viruses such as human papillomavirus, herpes simplex virus, and various adenoviruses and retroviruses may play some role in the etiology of oral cancer.

Oral squamous cell carcinoma has four common morphologic presentations. It can be exophytic with an irregular surface, or ulcerative, with irregular depressions and rolled borders. Malignant leukoplakic and erythroplakic lesions are believed to represent squamous cell carcinomas that have yet to form a mass or ulcerate.

The most common site involved in oral cancer is the tongue, particularly the posterolateral border, accounting for approximately 50 percent of oral cancers in the United States. Cancer of the floor of the mouth accounts for nearly 35 percent. Cancer of the lips is common and usually secondary to sunlight exposure. Table 242-3 lists the common signs and symptoms of oral cancer; unfortunately, oral cancer is generally painless, and patients are often unaware of the presence of a mass until it is advanced.¹⁶ Early diagnosis is the key to successful treatment of oral squamous cell carcinoma. All ulcers, erythroplakic lesions, and leukoplakic lesions of the oral cavity that do not respond to palliative treatment in 10 to 14 days warrant biopsy.

Treatment depends on site of involvement and staging of disease. It consists primarily of wide radical excision, radiation therapy, or a combination of the two. Adjunctive chemotherapy has been used to aid in tumor debulking. The prognosis depends on site and tumor stage, but an overall 5-year survival rate for patients with lesions that have not metastasized is 76 percent; overall 5-year survival is 41 percent when cervical nodes are involved, and 9 percent when metastasis below the clavicle has occurred.

Other

Fordyce granules, commonly occurring on the vermillion border of the lips and buccal mucosa, are slightly elevated, cream-colored spots that represent ectopic sebaceous glands. *Linea alba* is a white line on the buccal mucosa at the level of the occlusal surface. It is caused by normal friction from the facial surfaces of the teeth during mastication. Firm exophytic enlargements along the lingual surface of the mandible (*torus mandibularis*) or the maxillary hard palate (*torus palatinus*) are benign exostoses. The etiology is unknown, but no therapeutic intervention is re-

FIG. 242-9. Oral squamous cell carcinoma. A. Squamous cell carcinoma of the lip secondary to sun exposure. B. Squamous cell carcinoma of the hard palate. C. Verrucous carcinoma secondary to dipping snuff. (Courtesy of H. Anthony Neil, DDS.)

quired. Many other disease entities such as pemphigoid, pemphigus, lichen planus, and erythema multiforme affect the oral soft tissues.

OROFACIAL TRAUMA

Dentoalveolar Trauma

The most common dentoalveolar mechanism of injury is falls. Sporting injuries, fights, and motor vehicle collisions account for most of the remainder. Injury to the maxillary central incisors accounts for 70 percent of dental injuries. Management of dentoalveolar trauma

TABLE 242-3 Signs and Symptoms of Oral Cancer**Signs**

Nonhealing ulcer: can be in form of crater with elevated, indurated margins
Bleeding: resulting from ulcerations
Lymphadenopathy
Rigidity: lesions fixed to surrounding tissue
Induration: hardness of the lesion
Functional interference: such as speech and mastication
Symptoms Pain
Secondary to ulceration
Secondary to trauma related to functional interferences
Parosmia Drooling: secondary to functional interferences

depends on the extent of tooth and alveolar involvement, the degree of development of the apex of the tooth, and the age of the patient. In injuries in younger patients, especially those who are younger than 12 years of age, the pulp of anterior teeth is quite large and dental fractures involving the pulp are common. Fortunately, in this age group the apex of the root also is usually incompletely formed, allowing for a greater pulpal regenerative capability. As one ages, more dentin is formed. Thus, in older patients, the pulp chamber may be very small and pulpal exposure highly unlikely. Involvement of the root of the tooth compromises the attachment apparatus and thus the ability of a dentist to adequately restore the tooth to function.

DENTAL FRACTURES A simple classification of dental fractures is the Ellis classification, which is shown in Figure 242-10. The goal of the emergency treatment of a fractured tooth is maintaining pulpal vitality. The proximity of the fracture to the pulp and the length of time before treatment are most important in determining outcome. Treatment is aimed at sealing the dentinal tubules and creating a barrier between the dental pulp and the oral environment. In properly treated uncomplicated dental fractures, 1 to 2 percent of the affected pulps undergo necrosis. Because pulpal necrosis is a process, it can occur at any time after trauma, and serial follow-up with a dentist is recommended.^{7,8}

Ellis class I fractures involve the enamel portion of the tooth only. Generally, no emergent treatment of these fractures is indicated, except

**FIG. 242-10.** Ellis classification for fractures of anterior teeth.

to smooth sharp corners that may irritate the tongue or mucosa. Referral to a general dentist for aesthetic repair depends on the degree of cosmetic concern of the patient.^{17,18}

Ellis class II fractures involve the dentin of the tooth and require intervention. These fractures account for 70 percent of tooth fractures. Generally, patients express sensitivity to hot or cold stimuli as well as air passing over the exposed surface during breathing. The Ellis class II fracture can be identified both by the patient's symptoms and visualization of exposed dentin, which is a creamy yellow color compared with the whiter enamel. Because dentin is microtubular in structure, communication between the oral environment and the dental pulp is established with exposure of the dentin. The thickness of remaining dentin determines the rate of pulpal contamination. Greater than 2 mm of remaining dentin is felt to offer some protection to the pulpal tissue. Microorganism contamination of the pulp, oral irritants, or desiccation from mouth breathing initiates an inflammatory process in the pulpal tissue. A delay in treatment increases the likelihood of pulpal necrosis. Thus it is the responsibility of the emergency physician not only to identify such a fracture but also to cover the exposed dentin to decrease pulpal contamination. This is best achieved using a glass ionomer dental cement that is easily mixed according to the manufacturer's instructions and carefully applied to the dried exposed dentin. Referral to a dentist within 24 h is mandatory to best ensure tooth vitality.^{17,18}

In Ellis class III fractures, exposure of the pulp has occurred. On wiping the fractured surface dry with sterile gauze, blood originating from the pulp of the tooth is easily identified. One should attempt to cover the exposed dentin with a glass ionomer cement or calcium hydroxide base as in class II fractures until urgent dental evaluation can occur. If the pulpal exposure is extremely small, placing a glass ionomer or calcium hydroxide base is adequate until dental evaluation within 24 h. Prompt appropriate treatment lessens the likelihood of pulpal necrosis by minimizing pulpal contamination. For all but the smallest pulpal exposures, definitive treatment is endodontic or root canal therapy. Oral analgesics should be prescribed and topical analgesics avoided.^{17,18}

Root fractures account for 5 percent of all injuries of the permanent dentition. Extraction of the coronal segment is required. If less than one-third of the root is involved, a dentist can perform root canal therapy, and restoration of the tooth may be possible. Careful attention must be paid to identifying fractures of the root because they can be clinically obscure.¹⁸

CONCUSSIONS, LUXATIONS, AND AVULSIONS The same forces that cause dental fractures may result in loosening of a tooth from the attachment apparatus. Careful evaluation of the teeth for tenderness, malpositioning, or mobility must be performed. Luxations account for nearly 50 percent of injuries to teeth. Five distinct types of luxations have been described. 1) *Concussion* injuries are defined as injury to the supporting structures of a tooth with clinical tenderness to percussion but no mobility. 2) *Subluxation* is defined as an injury to the attachment apparatus resulting in mobility without clinical or radiographic evidence of dislodgment of the tooth. 3) *Extrusive luxation* is defined as partial avulsion or dislodgment of a tooth from the alveolar bone. 4) *Lateral luxation* is defined as displacement of a tooth laterally with concomitant fracture of the alveolar bone. 5) *Intrusive luxation* is defined as displacement of a tooth into its socket with associated alveolar fracture. Treatment of luxations depends on the tooth involved, the severity of injury, and the presence of associated root fracture and/or significant associated alveolar fracture.¹⁷

A concussive injury to a tooth represents a minor injury. The degree of tenderness to percussion determines the treatment. Stabilizing the tooth by splinting it to adjacent teeth is not indicated. Management of pain with NSAIDs, soft diet, and referral to a dentist to confirm the diagnosis and exclude more severe injury, are the most appropriate courses of action for the emergency physician. Removal of the oc-

clusal forces from the tooth by a dentist may aid in comfort and healing. Similarly, a subluxed tooth generally does not require splinting. Again, removal from occlusion by a general dentist may be beneficial. Subluxation represents a more significant injury and is associated with a higher incidence of subsequent pulpal necrosis.

An extrusive luxation requires repositioning the tooth in its original position and splinting to stabilize the tooth during healing. Repositioning the tooth may require local anesthesia. Firm, gentle pressure usually will reposition the tooth. If a clot has formed apical to the tooth, then more aggressive manipulation may be required. A flexible wire splint placed by a dentist provides ideal stabilization. In the ED, a temporary splint with Coe-Pak periodontal dressing (Figure 242-11), as described by Medford,¹⁹ is acceptable until the patient can see a dentist or oral and maxillofacial surgeon within 24 h. Care must be taken to avoid excess material placement, especially on the occlusal surface, because interference in occlusion will place stresses on the tooth during mastication. Splinting should be maintained for 1 to 2 weeks. Close follow-up by a dentist is necessary.

A lateral luxation represents a more extensive injury and is associated with crazing or fracture of the surrounding alveolar bone. Repositioning of the tooth is generally more difficult. It usually can be accomplished by manipulating the displaced tooth with the thumb and forefinger. Once the apex has been dislodged from its locked-in position labially, apically directed axial pressure will reposition the tooth. Intraarch stabilization is necessary for a minimum of 2 weeks. Temporary splinting with Coe-Pak periodontal dressing is acceptable if a minimal associated alveolar fracture occurred. Otherwise, splinting by an oral and maxillofacial surgeon or general dentist in the ED is mandatory.

FIG. 242-11. Reimplantation and stabilization of an avulsed tooth. A. Tooth is rinsed. B. Tooth is placed back into socket. C. Splint material is ready for application. D. Packing is molded over reimplanted tooth and two adjacent teeth to each side.

Intrusive luxations are the most serious because significant damage to the alveolar socket and periodontal ligament occurs. Root resorption is common as a result of damage to the periodontal ligament. Recommended treatment is allowing the tooth to erupt on its own or to orthodontically extrude the tooth over 3 to 4 weeks.

Total displacement of a tooth from its socket, or *avulsion*, accounts for up to 16 percent of all injuries to teeth. It is necessary to reimplant avulsed permanent teeth as soon as possible. Reimplantation is possible if performed within 2 to 3 h. To minimize this time, ideally, the patient or health care provider at the scene should reimplant the tooth. The tooth should be rinsed with sterile normal saline or tap water to remove debris. Care should be taken to handle only the crown portion of the tooth, and it should be reimplanted immediately into the socket. If this is not possible, or if the risk of aspiration is high, such as in a child or a patient with a decreased level of consciousness, then the tooth should be transported with the patient to the ED. Acceptable transport media include isotonic solutions such as Hank solution, sterile saline, and milk. Commercial preparations of Hank solution such as Save-A-Tooth (TPS, Biologic Rescue Products, Inc.) are available and come with a useful transport container as part of the system. If the avulsed tooth was not recovered, radiographs to ensure that the tooth was not aspirated are indicated.^{20,22}

Survival of the periodontal ligament fibers that remain attached to the root of an avulsed tooth is key to successful reimplantation. Milk is an acceptable storage medium because of its osmolality and essential concentration of calcium and magnesium ions. Hank solution, a pH-balanced cell culture medium, is the best transport medium and has been found to maintain periodontal ligament cell viability for up to 4 to 6 h. It also has been found that Hank solution can help to restore cell viability in a tooth that has been avulsed longer than 20 and 60 min.^{21,22}

In the ED, prior to reimplantation, the tooth should be thoroughly rinsed clean of dirt and debris with sterile saline or preferably Hank solution. The root of the tooth should not be scrubbed, and care should be taken not to disrupt existing periodontal fibers. If an avulsed tooth with an open apex has been dry for less than 20 min, then the prognosis for reestablishing a vital pulp is good. If the apex is completely closed, then revitalization is not possible. If the tooth has been dry from 20 to 60 min regardless of apices, it is recommended that the tooth be soaked in Hank balanced salt solution for 30 min. This has been found to decrease the chance of ankylosis. For an avulsed tooth that has been dry for greater than 60 min, the periodontal cells are dead, and the goal is to reduce root resorption. It is recommended that the tooth be soaked in citric acid for 5 min, then 2 percent stannous fluoride, and finally doxycycline for 5 min prior to reimplantation.²⁰

Preparation of the dental socket plays little role in the success or failure of the reimplanted tooth. The socket is prepared by carefully removing the clot and irrigating gently with sterile normal saline. As little manipulation as possible of the socket should occur. Local anesthesia is usually required. Reimplantation is accomplished with firm pressure and having the patient bite on gauze until more permanent stabilization can be arranged. Anterior teeth are most commonly affected, and Figure 242-12 illustrates the morphology of the maxillary central incisor to assist reimplantation in the proper orientation. Early improper reimplantation holds a higher success rate for tooth salvage than delayed reimplantation resulting from waiting for an oral and maxillofacial surgeon. Stabilization by an oral and maxillofacial surgeon or using a temporary method such as Coe-Pak periodontal dressing is necessary.^{20,22}

Avulsion or luxation of primary teeth is treated differently from that of permanent teeth. Thus identification of primary teeth in patients aged 6 to 12 years when the dentition is mixed is essential. Avulsed primary teeth are never reimplanted. More severe luxations in primary teeth generally require extraction of the tooth. Repositioning or reimplanting primary teeth risks injuring the underlying permanent teeth and thus is avoided. Intruded primary teeth are an exception and

FIG. 242-12. Illustration of a maxillary left central incisor. Note that the part of the tooth facing medially comes to more of a right angle at the incisal edge than occurs distally. The facial portion of the tooth is more convex.

generally are left alone to reerupt into normal position. Referral to a general dentist for follow-up is essential to ensure optimal long-term outcome.^{17/20}

Posttraumatic sequelae are variable. Pulp canal obliteration, pulpal necrosis, internal external resorption of the root, and ankylosis may occur. The severity of luxation or avulsion is the most important determining factor in sequela occurrence. Transient apical breakdown occurs with all type of luxations but is especially common with extrusive and lateral luxations. More than 50 percent of extrusively luxated teeth undergo pulpal necrosis within 1.5 years of the traumatic event. Close dental follow-up is essential for early identification of these sequelae.

Significant force must occur to dislodge or fracture teeth; consequently, associated alveolar ridge fracture is common. Care to ensure the integrity of the maxilla and mandible is also important. Stabilization of repositioned or reimplanted teeth is essential for optimal results. This is best accomplished with semi rigid fixation placed by a general dentist or oral surgeon. Stabilization is maintained for 1 to 2 weeks depending on the involvement of alveolar bone. With significant alveolar ridge fracture, segments may require intermaxillary stabilization for up to 6 weeks in order to ensure adequate healing.^{17/20}

Soft Tissue Trauma

Traumatic injuries to the soft tissue of the oral cavity are common. Oral lacerations can involve any of the soft tissues of the mouth. Large intraoral lacerations (>1 cm) are susceptible to ulceration and secondary infection and tend to heal in a fibrotic mass. Intraoral lacerations should be inspected carefully for foreign material, including tooth fragments, and irrigated well with sterile NS. Retained foreign bodies serve as a nidus for infection and can result in need for later surgical removal and poor aesthetic outcome. Crushed and nonviable tissue should be debrided. Close approximation of the wound edges rather than a tissue seal is desired to allow drainage. Resorbable suture material such as 4-0 chromic is generally used. Black silk (4-0) is easier to use but requires removal in 7 to 10 days. When resorbable sutures are used, care should be taken to place the sutures so that the knots are buried. Prophylactic antibiotics generally are not indicated except with the most extensive lacerations. Forty-eight-hour follow-up is necessary to monitor healing.

Lacerations of the lips and tongue require special consideration. Care should be taken in wound-edge approximation of lacerations on the dorsum of the tongue because reepithelialization across the wound edge is important. If the edges are not well approximated, the epithelia will migrate downward and will result in an epithelial cleft and a bifid appearance. This is both a cosmetic and a functional problem requiring revision. Small tongue lacerations in children, where the edges remain approximated, do not need to be sutured. Bleeding can be controlled with pressure using gauzes. Extensive tongue lacerations in children require procedural sedation and may be best referred for repair.

Lip lacerations are a potential cosmetic problem, so careful closure is essential. In lacerations involving the vermilion border, alignment of the border is important and should be completed first. The portion of the laceration extraoral to the wet-dry line of the lip and involving the skin of the face should be closed with 6-0 nylon monofilament. The intraoral portion of the laceration is repaired in the same manner as any oral laceration. Because of the musculature of the lips, any deep laceration requires closure of the deep layers using a 4-0 resorbable suture material to decrease the likelihood of the wound edges opening on removal of the suture. As with any laceration involving the face or other aesthetic areas, sutures should be removed as early as possible, generally in 5 days, so as to decrease iatrogenic scarring from the suture material. Careful daily cleansing of the wound and application of a triple-antibiotic ointment makes suture removal easier and improves the aesthetic results.

Controversy concerning closure of through-and-through lip laceration exists. Some advocate leaving the intraoral portion of the laceration open; however, it is my recommendation that mucosal lacerations larger than 1 cm be repaired. Generally, the intraoral component should be repaired first, and then, from an extraoral approach, the laceration should be cleansed and irrigated aggressively. A deep layer of sutures may be necessary in large lacerations. The skin then should be closed aesthetically. Prophylactic antibiotics such as penicillin VK or erythromycin 250 mg PO qid for about 5 days are indicated.

Laceration of the maxillary labial frenulum, unless unusually large, does not require repair. These lacerations can be very painful, so adequate analgesia must be prescribed. Because of the vascularity of adjacent tissue, lacerations to the lingual frenulum usually do need to be repaired. Resorbable suture such as 4-0 chromic is appropriate.

Other soft tissue injuries commonly occur. Intraoral contusions and ecchymoses are prevalent with facial trauma. Ecchymoses and petechial hemorrhages to the soft palate, uvula, and pharynx from direct or indirect trauma are common. Treatment is mainly palliative, with reassurance to the patient and NSAIDs for discomfort.

HEMORRHAGE

Spontaneous Hemorrhage

Spontaneous gingival hemorrhage is not uncommon. A history of recent dental therapy such as periodontal scaling or curettage is important because resulting hemorrhage after scaling is easily controlled with peroxide mouth rinses or direct gingival pressure. A careful medical history must be obtained in order to eliminate systemic diseases such as clotting factor deficiencies, leukemia, and end-stage liver disease as the etiology. Excessive anticoagulation may present as spontaneous gingival bleeding. The need for laboratory evaluation depends on a careful history and physical examination. Treatment depends on the specific cause of bleeding in the event that local measures are unsuccessful.

Postoperative Bleeding

Postextraction bleeding is not uncommon. Displacement of the clot may result in recurrent or continued bleeding. Generally, firm pressure

applied to the extraction site is adequate to control bleeding. This is best accomplished by neatly folding a 2- X 2-in. gauze pad and placing it over the extraction site, applying firm pressure by clenching firmly with the opposing teeth. This pressure must be held firmly, not a chewing action, for 20 min or until hemostasis is complete. If direct pressure is not successful, then application of Gelfoam, Avitene, or Surgicel into the socket may provide a matrix for clot formation. Sutures should be used for holding such agents in place or to close the gingiva over the socket. The gingiva should not be closed under pressure, especially along the suture line, since this may result in necrosis of the gingival flap. If these methods are unsuccessful, then oral and maxillofacial surgical consultation becomes necessary.

ORAL MANIFESTATIONS OF SYSTEMIC DISEASES

Many diseases have common oral manifestations. In some cases, oral findings may be among the first signs and symptoms of disease. Diseases with oral manifestations are so wide-ranging that only a few of the more important entities will be discussed.

Leukemia

Common oral findings in leukemia include spontaneous gingival hemorrhaging and small petechial hemorrhages or bruising of the oral soft tissue secondary to thrombocytopenia. Leukemic patients are more prone to oral candidiasis, herpetic infections, and neutropenic ulceration. These ulcers are typically deep, punched-out lesions with a gray-white necrotic base. They occur most commonly after chemotherapeutics, related to mucosal trauma or opportunistic infections. Acute leukemias, particularly acute monocytic and myelogenous subtypes, cause infiltration of leukemic cells into oral soft tissue, especially gingival tissue, resulting in swollen, boggy hyperplastic gingivitis. Gingival lesions can be a result of direct infiltration, as shown in Figure 242-13, or a result of drug toxicity, from graft-versus-host disease, or secondary to marrow or lymphoid tissue depression.²³

Acquired Immunodeficiency Syndrome

There are numerous oral manifestations of HIV infection. Primary HIV infection, occurring from 1 to 6 weeks after contact, is an acute viral syndrome but may have associated intraoral findings such as a sore throat, mucosal erythema, and focal ulceration. Persistent generalized lymphadenopathy, particularly of the cervical lymph nodes, is present in 70 percent of otherwise asymptomatic HIV-infected patients. The presentation of AIDS is highly variable, and numerous oral manifestations can occur. Oropharyngeal candidiasis is the most com-

mon oral finding and may lead to the initial diagnosis of AIDS. HIV-related gingivitis, more recently termed linear gingival erythema, is distinctive, presenting as a 2- to 3-mm linear band of erythema along the gingival free margin. Periodontitis among the HIV-infected population is common and usually more aggressive and painful in its presentation. Such necrotizing ulcerative periodontitis is distinguished from acute necrotizing ulcerative gingivitis, which is also a common finding, by its distribution and microbiology. Viruses such as herpes simplex virus, varicella-zoster virus, cytomegalovirus, and Epstein-Barr are fairly common and produce more significant disease when present in the immunocompromised patient. Hairy leukoplakia, a somewhat distinctive hyperkeratotic and epithelial hyperplastic lesions on the lateral borders of the tongue, is the second most common oral manifestation of HIV and strongly suggests HIV infection. Oral hairy leukoplakia is thought to be an Epstein-Barr virus-induced epithelial hyperplasia. Kaposi sarcoma, associated with human herpes virus type 8, is the most common malignancy associated with AIDS. It appears orally as a nonblanching brown to purplish macule or papule affecting most commonly the gingiva or hard palate. Lymphoma, primarily non-Hodgkin lymphoma, is the second most commonly associated cancer. All of these common oral findings in HIV are related to advancing immune suppression. With the concurrent use of newer therapeutic agents such as the nonnucleoside inhibitors, protease inhibitors, and the nucleoside inhibitors, fewer oral manifestations of HIV are occurring.²⁴

INFECTIONS AND DISORDERS OF THE NECK AND UPPER AIRWAY

Carol G. Shores

This chapter discusses conditions that can obstruct the upper airway. These disorders must be recognized quickly because early intubation may be lifesaving. Infections of the neck and upper airway include pharyngitis/tonsillitis, peritonsillar abscess, epiglottitis, retropharyngeal abscess, and dental abscess. Cancers, congenital neck masses, ranulas, and mucocoeles present as masses in the neck and upper airway. Noninfectious causes of airway obstruction include posttonsillectomy hemorrhage, airway and esophageal foreign bodies, laryngeal papillomatosis, neck and facial trauma, and angioedema. If there is a possibility of surgical intervention in the neck, the patient should receive nothing by mouth (NPO) after arrival at the emergency department.

NECK AND UPPER AIRWAY INFECTIONS

Pharyngitis/Tonsillitis

Pharyngitis in children is discussed in Chap. 121. Pharyngitis in adults is usually infectious, and viral pharyngitis is the most common (Table 243-1). Group A *p*-hemolytic streptococcus (GABHS) is the most common bacterial organism causing pharyngitis, but rare cases of chlamydial and mycoplasmal pharyngitis have been reported. Noninflammatory conditions such as systemic lupus erythematosus, pemphigoid, or Behcet disease also can cause pharyngitis.

In the vast majority of patients, acute pharyngitis is a self-limiting illness that does not require specific antimicrobial therapy. Patients with pharyngitis should receive symptomatic treatment including gargling with warm saltwater, drinking warm liquids, antipyretics, analgesics, and rest. Dexamethasone 4 mg PO qd can be used for symptomatic relief,¹ and patients unable to tolerate oral fluids or who become dehydrated should be given intravenous fluids.

VIRAL PHARYNGITIS Viral pharyngitis generally displays a vesicular and petechial pattern on the soft palate and tonsils, is associated with rhinorrhea, but is without tonsillar exudate or cervical adenopathy. Most cases of viral pharyngitis require no specific diagnostic testing. There are three notable exceptions: influenza (see Chap. 143), infectious mononucleosis (see Chap. 143), and acute retroviral syndrome (see Chap. 144). More than 70 percent of primary infections with HIV-1 are associated with acute pharyngitis. Symptoms of pharyngitis develop 2 to 4 weeks after exposure^{2,3} and resolve within 2 weeks. Early treatment may decrease the viral load and lead to enhanced immune response, making recognition of acute retroviral syndrome important.³

GABHS PHARYNGITIS *Streptococcus pyogenes* (GABHS) is responsible for 5 to 15 percent of pharyngitis in adults.⁴ Virulent strains of GABHS are associated with acute rheumatic fever (ARF) or acute glomerulonephritis.⁵ Because of these sequelae, as well as local complications of untreated infection such as peritonsillar abscess, early diagnosis and treatment are important.

After an incubation period of 2 to 5 days, patients develop the sudden onset of sore throat, painful swallowing, chills, and fever. Headache, nausea, and vomiting are common associated symptoms. Signs and symptoms of GABHS pharyngitis include marked erythema of the tonsils and tonsillar pillars; tonsillar exudate; enlarged, tender anterior cervical lymph nodes; and uvular edema. Patients tend to have fever, myalgias, and malaise but not rhinorrhea.

The Centers for Disease Control and Prevention (CDC) lists four criteria for GABHS pharyngitis: 1) tonsillar exudate, 2) tender anterior cervical adenopathy, 3) absence of cough, and 4) history of fever.⁶ The CDC recommends no antibiotic treatment for patients with none or only one of these criteria. For patients with two or more criteria, three strategies can be used: 1) Test patients with two, three, or four criteria using a rapid antigen test, and limit antibiotic therapy to patients with positive test results; 2) test patients with two or three criteria using a rapid antigen test, and limit antibiotic therapy to patients with a positive test result or with all four criteria; or 3) do not use any diagnostic tests, and limit antibiotic therapy to patients with three or four criteria. Although throat cultures may be indicated to investigate GABHS outbreaks or antibiotic resistance, they are not recommended for routine evaluation of adult pharyngitis.⁷

Drug resistance is a growing problem and is related directly to the overuse of antibiotics. GABHS is rarely resistant to penicillin, which remains the recommended first-line drug for this disease.^{4,7,8} Adults should receive a single intramuscular dose of 1.2 million units of benzathine penicillin G or 500 mg of penicillin VK PO twice or three times daily for 10 days. Erythromycin is the recommended alternative for penicillin-allergic patients. Close contacts and family members should be screened and treated promptly if they become symptomatic or have a positive rapid antigen test.

Several other bacteria can cause pharyngitis, although these infections are not common (see Table 243-1). If non-GABHS bacterial pharyngitis is suspected clinically, the microbiology laboratory should be notified because many of these bacteria require special growth media and will not be identified on routine throat culture. *Neisseria gonorrhoeae* pharyngitis occurs rarely independently of genital infection and is treated by the same antibiotics as genital infections. Diphtheria is caused by *Corynebacterium diphtheriae* and is rare in well-immunized populations. It is characterized by a slow onset of mild to moderate pharyngeal discomfort and low-grade fever. On physical examination, a gray membrane is seen firmly adherent to the tonsillar or pharyngeal surface and may extend to the uvula, soft palate, pharynx and larynx.

FUNGAL PHARYNGITIS *Candida albicans* can produce painful oropharyngeal moniliasis, or thrush. This is particularly common after a course of antibiotics upsets microbial interactions or if the patient is immunocompromised. Oropharyngeal moniliasis presents with a white, cheesy exudate that can be scraped off an erythematous base. Nystatin oral suspension or clotrimazole troches are usually effective. Immunocompromised patients can develop candidal esophagitis and may require systemic therapy with fluconazole. Other forms of fungal pharyngitis are rare.

All types of pharyngitis can lead to suppurative complications, including cervical lymphadenitis, peritonsillar abscess, retropharyngeal abscess, sinusitis, and otitis media.

Peritonsillar Abscess

Peritonsillar abscess is the most frequently occurring deep-space infection of the head and neck.⁹ It is a collection of purulent material between the tonsillar capsule and the superior constrictor and palatopharyngeus muscles (Figure 243-1). The progression from local cellulitis to abscess can occur despite antibiotic administration. Risk factors include chronic tonsillitis, multiple trials of oral antibiotics, and previous peritonsillar abscess. Peritonsillar abscess is most common during the second and third decades and can be bilateral.^{10,11} Cultures of ab-

TABLE 243-1 Viral and Bacterial Causes of Pharyngitis

Pathogen	Syndrome/Disease	Signs and Symptoms	Percent
Viral			
Rhinovirus and coronavirus	Common cold	Nonexudative; mild to moderate pharyngeal pain; rhinorrhea; odynophagia, fever, myalgia and malaise uncommon	≥25
Adenovirus	Pharyngoconjunctival fever	More common in summer; fever; malaise; HA; dizziness; conjunctivitis	5
Herpes simplex virus (Chap. 150)	Gingivitis, stomatitis	Vesicles and shallow ulcers of the palate; tender cervical adenopathy	4
Parainfluenza virus	Common cold, croup	Otitis media; cough	2
Influenza virus (Chap. 150)	Influenza	Abrupt onset; fever; chills; myalgia; HA; anorexia; severe pharyngeal pain	2
Coxsackievirus A	Herpangina	Soft palate and tonsillar pillar vesicles; fever; severe pharyngeal pain	<1
Epstein-Barr virus (Chap. 150)	Infectious mononucleosis	Fever; tender cervical adenopathy; HA; malaise; splenomegaly	<1
Cytomegalovirus	Infectious mononucleosis	Pharyngitis less severe than with EBV	<1
HIV-1	Acute retroviral syndrome	Similar to mononucleosis; nonexudative pharyngitis; truncal exanthem; aseptic meningitis	<1
Bacterial			
<i>Streptococcus pyogenes</i> (GABHS)	Pharyngitis/tonsillitis, scarlet fever	Fever; fiery red pharynx with patchy grey/yellow exudate; uvula edema; tender cervical adenopathy; rhinorrhea and cough uncommon	5–15
Group C beta-hemolytic streptococcus	Pharyngitis/tonsillitis	Similar to GABHS, but usually less severe	5–10
Mixed anaerobic infection	Pharyngitis (Vincent angina)	Halitosis; purulent exudate	<1
<i>Neisseria gonorrhoeae</i>	Pharyngitis	Mild pharyngitis; usually concurrent genital infection	<1
<i>Corynebacterium diphtheriae</i>	Diphtheria	Slow onset; mild pharyngeal pain; firmly adherent gray tonsillar or pharyngeal membrane	<1
<i>Arcanobacterium haemolyticum</i>	Pharyngitis, scarlatiniform rash	Exudative pharyngitis; extremity and trunk erythematous maculopapular rash	<1
<i>Yersinia enterocolitica</i>	Pharyngitis, enterocolitis	Exudative pharyngitis; fever; cervical adenopathy; abdominal pain ± diarrhea; high mortality	<1
<i>Treponema pallidum</i>	Secondary syphilis	Silvery gray, superficial OP/OC erosions with erythematous base; other typical signs and symptoms; highly contagious	<1
Unknown			>30

cess aspirates characteristically produce a mixture of aerobic and anaerobic flora, but specific identification of the infecting bacterium is not usually needed for treatment.⁹

Symptoms of a peritonsillar abscess include fever, malaise, "hot-potato voice," sore throat, odynophagia, dysphagia, and otalgia. Signs include trismus, inferior and medial displacement of the infected tonsils, contralateral deflection of the swollen uvula, palatal edema, tender cervical lymphadenopathy, drooling, and dehydration (see Figure 243-1). Although easily diagnosed with a neck computed tomographic (CT) scan (with contrast material, Figure 243-2) or ultrasound, aspiration of purulent material with an 18-gauge needle is usually sufficient for diagnosis. The differential diagnosis of a peritonsillar abscess includes cellulitis, infectious mononucleosis, herpes simplex tonsillitis, retropharyngeal abscess, neoplasm, foreign body, and internal artery carotid aneurysm.

The cornerstone of treatment is drainage of the abscess by needle aspiration,¹¹ incision and drainage (I&D), or rarely, immediate tonsillectomy. Choice of treatment depends on clinical symptoms, degree of patient cooperation, history of previous tonsil disease, and patient reliability. Needle aspiration is the least invasive, and 85 percent of patients will be treated effectively after a single needle aspiration.⁹ Only needle aspiration will be discussed here.

Needle aspiration should be performed by an individual trained in the technique. Prior to aspiration, lidocaine spray or gel or benzocaine-

tetracaine spray (Cetacaine) is used to topically anesthetize the overlying mucosa. Then 1 to 2 mL of lidocaine with epinephrine is injected into the mucosa of the anterior tonsillar pillar using a 25-gauge needle (Figure 243-3). Once adequate anesthesia is achieved, an 18-gauge needle should be introduced just lateral to the tonsil, approximately halfway between the base of the uvula and the maxillary alveolar ridge, until the abscess cavity is encountered. The abscess then should be aspirated. **The needle should penetrate no more than 1 cm because the internal carotid artery usually lies laterally and posterior to the posterior edge of the tonsil.** Often, multiple aspirations may be required to find the abscess. A contrast CT scan of the neck is recommended when the results of needle aspiration are negative and a parapharyngeal or retropharyngeal space process is suspected.

Following needle aspiration, 10 days of high-dose penicillin or clindamycin for penicillin-allergic patients is the treatment of choice. Follow-up is needed within 24 h of aspiration. If the patient is not improving, consider repeating the aspiration, otolaryngologic consultation for I&D or tonsillectomy, obtaining a CT scan to confirm the diagnosis, or change antibiotics to ampicillin-clavulanic acid, clindamycin, or cefuroxime plus metronidazole.

Complications of a peritonsillar abscess include airway obstruction, rupture of the abscess with aspiration of the contents, cavernous sinus thrombosis, epiglottitis, septicemia, endocarditis, retropharyngeal abscess, and mediastinitis.

FIG. 243-1. Open-mouth view with retractor on tongue in a patient demonstrating medial right tonsillar displacement, palatal edema, and uvula deviation consistent with a peritonsillar abscess.

Epiglottitis

Epiglottitis can lead to rapid, unpredictable airway obstruction. It is an inflammatory condition, usually infectious, primarily of the epiglottis but often including the entire supraglottic region. Because of this, many clinicians prefer the term *supraglottitis*.

Since most children are inoculated against *Haemophilus influenzae*, most cases of epiglottitis are now seen in adults with a mean age of 46 years.^{12,14} Epiglottitis can be caused by bacteria (most commonly *Haemophilus influenzae* type b, *Streptococcus* species, *Staphylococcus* species), viruses, and fungi, although most frequently no organism can be isolated.¹⁵

FIG. 243-2. Axial CT of a left peritonsillar abscess.

FIG. 243-3. Peritonsillar abscess, demonstrating location for aspiration.

Patients with epiglottitis typically present with a 1- to 2-day history of worsening dysphagia and odynophagia and dyspnea, particularly in the supine position. Symptoms include fever, tachycardia, cervical adenopathy, drooling, and pain with gentle palpation of the larynx and upper trachea. Stridor is primarily inspiratory and is softer and lower-pitched than in croup. Patients often position themselves sitting up, leaning forward, mouth open, head extended, and panting. Thick oropharyngeal secretions are commonly present, with little or no cough.

Diagnosis is made by history, clinical examination, radiographs, and laryngoscopy. Lateral cervical soft tissue radiographs demonstrate obliteration of the vallecula, swelling of the aryepiglottic folds, edema of the prevertebral and retropharyngeal soft tissues, and ballooning of the hypopharynx (Figure 243-4). The epiglottis appears enlarged and thumb-shaped. Direct fiberoptic examination can confirm the diagnosis in adults if necessary but should be done with extreme caution to avoid sudden, unpredictable airway obstruction.

Patients with suspected epiglottitis require immediate otolaryngologic consultation, and the emergency physician must be prepared to establish a definitive airway. Patients should never be left unattended and should be kept sitting up. Initial treatment consists of supplemental humidified oxygen, intravenous hydration, cardiac monitoring, pulse oximetry, and intravenous antibiotics. Humidification and hydration minimize crusting in the airway and can help decrease the risk for sudden airway blockage. Heliox can be given to temporarily decrease airway resistance.

In adults, the need for intubation usually can be determined by fiberoptic examination of the supraglottis. This is generally accomplished by awake fiberoptic intubation in the operating room, with preparations for immediate awake tracheostomy or cricothyrotomy. In cases of airway obstruction in the emergency department, endotracheal intubation must be attempted, but the physician should be prepared for a very difficult intubation secondary to the swollen, distorted anatomy. In the case of intubation failure, the last resorts for preserving the airway in adult and pediatric patients are cricothyrotomy and needle cricothyrotomy, respectively.

Current antibiotic recommendations are cefuroxime as the first-line drug. Alternative antibiotics include ampicillin-sulbactam, cefotaxime, ceftriaxone, or trovafloxacin if the patient has a history of penicillin anaphylaxis.¹⁶ Steroids are used empirically by many otolaryngologists to decrease airway inflammation and edema.

Retropharyngeal Abscess

The retropharyngeal space extends from the base of the skull to the tracheal bifurcation. The two paramedial chains of lymph nodes

FIG. 243-4. Lateral radiograph demonstrating thumbprinting of the epiglottis consistent with epiglottitis.

(nodes of Rouviere), which drain the nasopharynx, adenoids, and posterior nasal sinuses, can be found within this space. In children, retropharyngeal abscesses usually are suppurative changes within a lymph node, with the primary infection elsewhere in the head and neck. In adults, however, a retropharyngeal abscess is generally the direct extension of purulent debris from an adjacent site, such as Ludwig angina. Therefore, retropharyngeal abscess in an adult is more likely to extend into the mediastinum.¹⁷

Signs and symptoms include fever, dysphagia, neck pain, limitation of cervical motion, cervical lymphadenopathy, sore throat, poor oral intake, muffled voice, and respiratory distress. Stridor and neck edema are likely in children but not adults. The intense inflammation and swelling associated with a retropharyngeal abscess can lead to inflammatory torticollis, which is unilateral spasm of the sternocleidomastoid muscle, causing posturing of the head with the occiput rotated toward the affected side.

Cultures from retropharyngeal abscesses are usually polymicrobial. The most common aerobic species isolated are *Streptococcus viridans* and *S. pyogenes*. Most of the staphylococcal species isolated are (3-lactamase-producing, *Bacteroides* and *Peptostreptococcus* are the most commonly isolated anaerobes.¹⁸

A contrast-enhanced CT scan of the neck is the "gold standard" for diagnosis of a retropharyngeal abscess. A lateral soft-tissue radiograph of the neck taken during inspiration with moderate cervical extension can demonstrate thickening and protrusion of the retropharyngeal wall. However, even a small degree of flexion in children normally causes a marked forward bulge of the posterior pharyngeal wall that can be misleading. If the diagnosis is strongly suspected, patients should not be sent unobserved for CT scanning, though the potential for airway compromise may be minimal.¹⁷

All patients with retropharyngeal abscess should have immediate otolaryngologic consultation. Intravenous hydration and antibiotic treatment should be started in the emergency department until the patient can be brought to the operating room for transoral or transcervical incision and drainage. Although a few patients with small abscess cavities may be managed with intravenous antibiotics alone, most patients will require surgical intervention. Clindamycin or ampicillin-sulbactam is recommended.^{17,18}

Catastrophic complications from retropharyngeal abscess include extension of the infection into the mediastinum and upper airway asphyxia from direct pressure or sudden rupture of the abscess.

Dental Abscesses, Ludwig Angina, and Deep Neck Abscesses

If an odontogenic abscess is untreated, the abscess can break through cortical bone of the mandible and spread into soft tissue spaces. This discussion will be limited to spread into the sublingual and submandibular spaces, whereas masticator space abscesses are discussed in Chap. 240.

The mylohyoid muscle forms a sling in the floor of the mouth and attaches along a line on the medial surface of the mandible. The sublingual space is superficial to the mylohyoid, whereas the submandibular space is deep to it. Since the roots of the premolars and first molars usually do not extend below the mylohyoid line, medial spread of apical abscesses from these teeth generally causes sublingual abscesses. Third molar infections generally lead to submandibular abscess, whereas second molar infections can lead to either. Clinically, infections of the sublingual space cause marked floor of mouth edema with little extraoral swelling. Submandibular space abscesses lead to edema spreading from the inferior edge of the mandible to the digastric region and inferiorly to the hyoid bone.

Ludwig angina is an infection of submental, sublingual, and submandibular spaces causing elevation and posterior displacement of the tongue and tense induration between the hyoid bone and the genu of the mandible. Patients usually present with poor dental hygiene, dysphagia, odynophagia, trismus, and edema of the upper midline neck and marked floor of mouth edema. The tongue can rapidly become posteriorly displaced, leading to airway compromise. Early signs and symptoms of imminent airway collapse may be subtle, and many patients with Ludwig angina will require awake fiberoptic intubation or awake tracheostomy.¹⁹ Stridor, difficulty managing secretions, anxiety, and cyanosis are late signs and require emergency airway management.

Dental abscesses may spread into the deep neck spaces, including the parapharyngeal, retropharyngeal, and prevertebral spaces. Presenting symptoms include a neck mass, trismus, fever, leukocytosis, dysphagia, and dyspnea. A contrast-enhanced neck CT scan is diagnostic and also aids in surgical management.

Odontogenic abscesses are caused by *Streptococcus* spp. and oral anaerobes. In an uncomplicated infection in an immunocompetent host, culture is not necessary. Treatment includes incision and drainage with intravenous antibiotics (penicillin, clindamycin, and ampicillin-sulbactam are the preferred choices).

NECK AND UPPER AIRWAY MASSES

Intraoral or Intraparyngeal Masses

Benign lesions usually are covered with normal-appearing mucosa and are nontender and long-standing. Mucocoeles (no epithelial lining) and mucus retention cysts (epithelial lined) arise from minor salivary glands found throughout the oral cavity and are treated with excision or marsupialization. A ranula is a mucus retention cyst of the sublingual gland, and when it extends through the mylohyoid muscle into the

neck, it is called a *plunging ranula*. Papillomas are sessile, warty-appearing lesions that frequently occur on the soft palate and anterior tonsillar pillars and are treated with surgical excision. Laryngeal papillomas can cause life-threatening airway obstruction and are discussed below. Palatine torus and mandibular torus are exostoses of the palate and mandible. Both are bony, smooth, painless masses covered with normal mucosa that slowly enlarge over many years. Usually, no treatment is needed.

Squamous cell carcinoma is the most common malignancy of the upper airway and generally presents with dysphagia, odynophagia, otalgia, weight loss, and/or neck mass in a patient with a significant smoking and/or alcohol history. The tumors are usually ulcerative lesions found anywhere in the upper airway. Patients with stridor and a suspected mass lesion should be evaluated by a bedside nasopharyngeal fiberoptic examination prior to CT scanning to avoid airway compromise when placed supine for the CT scan. The airway should be managed with humidified oxygen and awake fiberoptic intubation versus awake tracheostomy in the operating room.

Lymphomas of Waldeyer ring present with dysphagia and a muffled voice and can be complicated by infection. Posttransplant lymphoproliferative disorder can present with a similar picture.²⁰

Neck Masses

Neck masses can result from congenital, infectious, or neoplastic disorders. Enlargement may lead to airway compromise, dehydration secondary to dysphagia and odynophagia, or systemic progression of a local infection. The patient's age aids in the diagnosis (Table 243-2). Neck masses in infants and children represent benign conditions in the majority of cases and include branchial cleft abnormalities, thyroglossal duct cysts, lymphangiomas, hemangiomas, or benign lymphadenopathy.²¹ Each of these may become acutely infected and presents initially as a painful mass associated with skin erythema, leukocytosis, and fever.

Branchial cleft cysts are round, smooth, and mobile and not tender unless they become infected. They are located along the anterior border of the sternocleidomastoid muscle (Figure 243-5). In contrast, thyroglossal duct cysts are found in a subhyoid position, within 2 cm of midline (Figure 243-6). These cysts commonly enlarge after an upper respiratory illness and, on examination, are soft, mobile, and frequently have a bluish hue.

Thyroid disorder	

FIG. 243-5. Lateral neck mass in an adolescent demonstrates an infected branchial cleft cyst. It can be found anatomically along the sternocleidomastoid muscle.

Neck masses in adolescents and young adults are caused most commonly by infection or neoplasm. Cervical lymphadenopathy, malaise, and pharyngitis are the symptom complex for mononucleosis. A single, large, inflamed anterolateral neck mass in this age group that develops after an upper respiratory infection suggests a branchial cleft cyst. Young adults with multiple, rubbery low-neck masses, night sweats, fever, and malaise may have Hodgkin disease or lymphoma, whereas generalized adenopathy suggests HIV disease.

In patients older than age 40, 75 percent of neck masses are neoplastic.²² The most common cause of a unilateral neck mass is squamous cell carcinoma of the upper aerodigestive tract, metastatic to cervical lymph nodes. Other common neoplasms are tumors of the parotid or submandibular gland, thyroid gland, and lymphoma. Neoplastic lymph nodes usually feel firm and, although initially mobile, become fixed to surrounding structures as the cancer invades. Neoplastic nodes can become acutely infected and present as a neck abscess. Diffuse nodular thyroid enlargement that is present for many years suggests a simple goiter, whereas a solitary thyroid nodule, although usually benign, may represent thyroid cancer. Infectious lymphadenopathy can be seen in adults, and infectious nodes can sometimes be differentiated from their malignant counterparts by their soft and occasionally fluctuant texture.

Prominent normal structures can be mistaken for abnormalities. Normal lymph nodes can be up to 1 cm in diameter, except the jugulodigastric node, which can be up to 1.5 cm. Normal submandibular glands may be ptotic and asymmetrical. A pulsatile carotid bulb or the transverse process of the first cervical vertebra can be quite prominent in a thin neck.

The history often helps to limit the differential diagnosis. Infectious processes usually develop over hours to days and have associated pain, redness, warmth, and fever. Patients often have a preceding upper respiratory tract or dental infection. Infected congenital cysts may have enlarged on earlier occasions and resolved with antibiotics. Salivary gland infections often wax and wane, are exacerbated by eating, and may cause a foul taste in the mouth as the gland decompresses. Hodgkin disease and lymphomas are associated with night sweats, malaise, itching, and/or fever. Neoplastic disease usually occurs in adults with a history of smoking and alcohol abuse.

FIG. 243-6. Midline mass in an adolescent demonstrating a thyroglossal duct cyst.

Further evaluation of a neck mass depends on the history and physical examination. Patients with airway compromise or significant dysphagia and odynophagia should be evaluated by nasopharyngoscopy *prior* to CT scan. Laboratory studies are guided by physical findings and the likely differential diagnosis. CT scan with contrast will delineate the extent of the mass and likely will be required for consultation or surgical intervention. Treatment depends on the differential diagnosis. If no airway compromise or dehydration is present, the patient should be scheduled to return as an outpatient for further evaluation. Empirical antibiotic therapy is used for inflammatory nodes, usually with cephalexin, amoxicillin, or clindamycin, and most will resolve within 2 weeks. Sialoadenitis requires staphylococcal coverage.

POTENTIAL AIRWAY OBSTRUCTION

Posttonsillectomy Bleeding

Postoperative bleeding is a well-known complication of tonsillectomy that can lead to death from airway obstruction or hemorrhagic shock. The incidence ranges from 1 to 6 percent, with approximately half requiring surgical intervention for control of bleeding.^{23,24}

Although bleeding can be seen within 24 h of surgery, most hemorrhage occurs between postoperative days 5 and 10. There is a significantly higher incidence of bleeding in patients between 21 and 30 years of age,²⁴ and hemorrhage is less common in children under the age of 6.²⁵

Posttonsillectomy bleeding can be fatal and requires prompt intervention with control of the airway. An otolaryngologist should be con-

sulted early. The patient should be maintained NPO, monitored with pulse oximetry, and kept upright. Intravenous access should be obtained, and blood should be drawn for a CBC, coagulation studies, and type and crossmatch. Direct pressure can be applied to the bleeding tonsillar bed using a tonsillar pack or a 4 X 4 gauze with a suture through it to prevent loss of the pack into the airway. Pressure exerted on the lateral pharyngeal wall, avoiding midline manipulation, will decrease stimulation of the gag reflex. The packs can be moistened with thrombin or an equivolume solution of 1:1000 epinephrine and 1 percent lidocaine. Massive bleeding is rare, but when it occurs, intubation may be the only means of protecting the airway. This is always difficult, with oropharyngeal edema from recent surgery and blood obscuring visualization of the cords. Plans should be made for an emergent cricothyrotomy prior to attempting intubation.

Pressure alone can be adequate for control of posttonsillectomy hemorrhage until the otolaryngologist arrives. Alternatively, if a bleeding site can be visualized, bleeding may be cauterized with silver nitrate after local infiltration with 1 percent lidocaine with 1:100,000 epinephrine. Otolaryngologic consultation in the emergency department is always needed because patients may have a second or even third posttonsillectomy hemorrhage,²⁴ and surgery or endovascular embolization may be necessary for definitive control.²⁶

Foreign Bodies of the Aerodigestive Tract

Foreign bodies in the upper aerodigestive tract can be life-threatening, and morbidity and mortality increase with delay in diagnosis. In the year 2000, 160 children younger than 15 years of age died from obstruction of the respiratory tract associated with inhaled or ingested foreign bodies, and 17,537 were treated in emergency departments.²⁷ Adults usually present soon after ingestion or aspiration of a foreign body and are able to provide a history of the event. Pediatric foreign-body aspiration or ingestion usually presents with a history of a choking episode, frequently with cyanosis, followed by dysphagia, wheezing, and/or coughing. However, 60 percent of children exhibit mild or absent signs and symptoms at presentation to the emergency department.²⁸

Esophageal foreign bodies lead to dysphagia, odynophagia, drooling, wheezing, and cough. In adults, food boluses are the most common esophageal foreign body, and the signs, symptoms, and history generally make the diagnosis obvious.²⁹ In children, coins are most common.²⁸ See Chap. 76 for detailed discussion of esophageal foreign bodies, including disk battery ingestion.

Retained esophageal foreign bodies can present weeks to years after ingestion and lead to bronchoesophageal fistula, mediastinitis, and fatal aorto-esophageal fistula.³⁰ Symptoms are subtle and include excess salivation, new-onset asthma, and recurrent upper respiratory infections.

There are three stages of signs and symptoms of pulmonary foreign-body aspiration: 1) a choking episode with or without cyanosis and followed by paroxysms of coughing, stridor, wheezing, and unilateral reduced breath sounds, 2) an asymptomatic interval, and 3) recurrent unilateral pneumonia and/or wheezing, worsening or new-onset asthma, and croup.³¹

Food is the most common aspirated foreign body in children, with the most common offenders being nuts, carrot, and popcorn.³¹ Sudden death is associated with the aspiration of balloons, hot dogs, and grapes.³² Chest x-rays frequently are normal, but findings suggesting a foreign body include unilateral hyperexpansion and lobar atelectasis or pneumonia.³³ All suspected foreign-body aspirations require bronchoscopic evaluation. See Chap. 133 for further discussion of foreign-body aspiration in children.

Recurrent Respiratory Papillomatosis

Recurrent respiratory papillomatosis is found in two age groups: children as young as 2 months with a peak onset at age 3 to 4 years and

adults with an onset in the third decade of life or later. Recurrent respiratory papillomatosis is caused by infection with papillomavirus types 6 and 11, with maternal transmission in children and sexual transmission in adults. In both age groups, it can present with chronic cough, hoarseness, stridor, and/or dyspnea. The disease is usually recurrent despite multiple surgical excisions, and many patients presenting with an acute exacerbation will have a known history.³⁴ However, patients with new-onset respiratory papillomatosis can present to the emergency department with acute stridor and require timely diagnosis. Papillomas are usually found at the glottis and are exophytic, wart-like lesions without ulceration. Their outline may be seen on soft tissue x-rays of the neck, and they are visualized by nasopharyngoscopy. An urgent otolaryngologic consult should be obtained in patients with a known diagnosis or symptoms suspicious for recurrent respiratory papillomatosis. Humidified oxygen or heliox may temporize an urgent airway, and intubation should only be attempted in the emergency department if absolutely needed.

Laryngeal Trauma

External laryngeal trauma is a rare but potentially lethal injury occurring in approximately 1 in every 137,000 inpatient admissions.³⁵ Blunt and penetrating neck trauma are discussed in Chap. 258. Blunt trauma to the larynx occurs primarily as the result of motor vehicle accidents (dashboard injuries), personal assaults, or sports injuries. The basic mechanism for blunt external injury is compression of the larynx on the anterior cervical bodies. Injuries include endolaryngeal mucosal tears, cartilaginous fractures, and dislocations of the cricoarytenoid joints. The clothesline injury is a form of blunt laryngeal trauma that typically occurs when the victim is riding a motorcycle or snowmobile and the neck strikes a linear stationary object, such as a wire fence or tree limb. The transfer of such a large amount of force to the neck crushes the thyroid cartilage and may cause laryngotracheal separation. Asphyxiation often occurs at the scene, and survivors of such injuries may have an airway held together precariously by mucous membranes bridging the cartilage. If this injury is suspected, the patient should undergo emergent tracheostomy without attempted intubation.

The signs and symptoms of laryngeal trauma include hoarseness, anterior neck pain to palpation, dyspnea, stridor, dysphagia, cough, and/or hemoptysis. Injuries may be asymptomatic initially, except for a subtle change in voice. With more significant or worsening injury, pain, dyspnea, or cough develop, and subcutaneous emphysema may become evident. When the laryngeal lumen is severely compromised, aphonia and apnea may occur, signaling the need for immediate establishment of an alternative airway.

If the airway is stable, a thorough physical examination of the neck and larynx is required. Bleeding, expanding hematomas, bruits, and loss of pulses are signs associated with vascular injury. Flexible fiberoptic nasopharyngolaryngoscopy with the patient sitting upright allows immediate assessment of airway integrity and should be done before CT scan of the neck. In patients with adequate airways, CT examination can delineate the extent of injury.³⁶ Cervical spine radiographs should be performed to evaluate for vertebral injury, a common concurrent injury.

The two primary goals in the management of acute laryngeal trauma are preservation of life by maintaining the airway and restoration of function. There is some controversy regarding the best way to establish an alternative airway in blunt laryngeal trauma. If the lumen of the laryngeal airway is compromised by ecchymosis and edema but there is no gross disruption of the laryngeal mucosa or displacement of the arytenoids and the tracheal lumen can be identified, then the airway may be secured by intubation or with an endotracheal tube advanced over a flexible bronchoscope.³⁷ When the laryngeal lumen cannot be visualized because of gross anatomic disruption or edema and hemorrhage, urgent tracheostomy is the preferred method of controlling the airway and avoiding further injury to the larynx. An emergent

tracheotomy is performed through a midline vertical skin incision, and the trachea should be entered at a level lower than usual (fourth or fifth tracheal ring). Cricothyrotomy may be difficult because of cervical emphysema and swelling and should be avoided if possible in suspected laryngeal trauma because it may further injure the subglottis.³⁸

Angioedema of the Upper Airway

Angioedema is a nondemarcated swelling of the dermal or submucosal layers of the skin or mucosa. It is usually nonpruritic but can be painful. Angioedema of the upper airway can have sudden onset and rapid progression. There are four main etiologies: 1) congenital or acquired loss of C1 esterase inhibitor, 2) IgE-mediated type I allergic reaction to food, drug, or environmental exposure, 3) adverse reaction to angiotensin-converting enzyme (ACE) inhibitor therapy, and 4) idiopathic. A known diagnosis can direct therapy, but many patients with angioedema have no obvious cause at presentation.

C1 esterase inhibitor is the main regulator of the activation steps of the classical complement pathway, and its genetic deficiency is the cause of hereditary angioedema (HAE).³⁹ The diagnosis should be suspected in patients with a history of recurrent peripheral angioedema and abdominal pain. Forty percent of patients experience the onset of symptoms before age 5 and 75 percent before age 15. The disease is autosomal dominant, so many patients have a family history of recurrent angioedema. Diagnosis is confirmed by measuring blood levels of C1 and C4 esterase inhibitor, although these tests usually cannot be obtained during an acute emergency department visit.⁴⁰ Patients with HAE respond poorly to the usual treatments of angioedema outlined below. Epinephrine can produce some improvement in early acute attacks. Fresh frozen plasma (FFP) replaces the missing inhibitor protein and can improve symptoms. However, a few patients may become more edematous after FFP, and it is not recommended in life-threatening laryngeal edema. Patients with life-threatening edema should undergo fiberoptic intubation with preparation for an emergent surgical airway. Attacks can be prevented with long-term use of acetylated artificial androgens, so patients with suspected HAE should be referred for follow-up to their primary care physicians. Several medications, including estrogens and ACE inhibitors, increase the severity and frequency of HAE attacks, and patients should be advised to stop these.

The use of ACE inhibitors is associated with upper airway angioedema.⁴¹ Sixty percent of cases occur in the first week after starting the drug, but ACE inhibitor-related angioedema can occur after years of treatment. The estimated incidence is 0.1 to 0.2 percent and is more common in African-Americans.⁴¹ Patients must be withdrawn from ACE inhibitors immediately and warned not to use them again.

Treatment of upper airway angioedema usually is empirical. Intravenous access should be established and the airway examined with fiberoptic nasopharyngoscopy as soon as possible. For severe symptoms, epinephrine 1:1000 solution can be given SC in a dose of 0.01 mg/kg, not to exceed 0.3 mg, or the same dose can be administered by inhalation as racemic epinephrine. The dose can be repeated every 15 to 20 min as needed. Classically, diphenhydramine is given IV at 1 to 2 mg/kg, up to a maximum of 50 mg. If the airway is stable, 10 mg of cetirizine can be given PO instead, resulting in less sedation. Methylprednisolone 40 to 125 mg IV should be given, although steroids will not be effective for several hours. If nasopharyngoscopy demonstrates laryngotracheal edema, the patient should be admitted. If there is no airway edema, the patient can be discharged after several hours observation demonstrates clinical improvement.

Uvula Edema

Isolated uvula edema, sometimes referred to as Quincke edema, is a rare presentation of upper airway edema. It is usually caused by the

same etiologic factors as upper airway angioedema, but can be associated with upper airway infections such as peritonsillar abscess, or rare epiglottitis. It can also be idiopathic or associated with drugs such as NSAIDs or ACE inhibitors. If it is an isolated finding, and symptoms are uncomfortable to the patient, dexamethasone, 4 mg IV or PO, can be given as a single dose in the ED.

COMPLICATIONS OF AIRWAY DEVICES

Carol G. Shores Theresa A.
Hackeling Rudolph J.
Triana, Jr.

This chapter discusses complications of airway devices, focusing on endotracheal tubes, tracheostomy tubes, laryngeal stents, and alternative speech devices.

ENDOTRACHEAL TUBES

Acute complications of endotracheal intubation range from minor to catastrophic. Minor complications include lip lacerations, corneal abrasions,¹ dental fractures, and tongue injuries, and are all avoidable with proper technique. More serious complications of endotracheal intubation include damage to the soft tissues of the larynx or pharynx and dislocation of the arytenoid cartilage. Repetitive or blind intubation attempts are more likely to result in this type of injury. Mucosal tears may present early with immediate bleeding and subcutaneous emphysema, or late with septic shock.² If the endotracheal tube tip is placed in the soft tissue of the neck through a mucosal tear, bag ventilation will be very difficult and will likely result in subcutaneous emphysema with pneumothorax. All efforts to ventilate through the tube should be stopped and consideration given to an emergent surgical airway. Tracheal injuries are much more common in women, perhaps because of the use of improperly large tubes.³ Mucosal injuries usually require immediate surgical repair by an otolaryngologist. See Chap. 19 for review of other complications of endotracheal intubation.

The endotracheal tube itself may be the source of complications.⁴ Airway obstruction can result from kinking or biting the tube or inspissated secretions within the tube. In addition, an overinflated cuff may herniate over the end of the tube and obstruct it. If the obstruction cannot be cleared by suctioning or modification of tube position, the tube must be replaced.

TRACHEOSTOMY TUBES

A standard adult tracheostomy is a surgical procedure in which an opening is created between cartilaginous rings in the trachea and the skin of the neck is usually sutured to the anterior tracheal wall (Figure 244-1). In pediatric and some adult tracheotomies, a vertical incision is made through two or three tracheal rings and the lateral edges are tagged with temporary stay sutures. These sutures are usually removed before the patient leaves the hospital.

Skills needed for tracheostomy management in the ED include replacement of an uncuffed with a cuffed tracheostomy tube for mechanical ventilation, replacement after accidental decannulation, correction of tube obstruction, and control of bleeding or infection at the tracheostomy site (Figure 244-2). Key information in managing a tracheostomy includes why and when the procedure was performed and what type of tracheostomy tube is currently being used. Determine if the patient *can be orally intubated* if needed. **Patients who have undergone a laryngectomy or who have tumors or scarring that occlude the upper airway cannot be orally intubated.**

There are many types of tracheostomy tubes available, including tubes made of plastic, silicone, nylon, and metal. Most hospitals stock only a few types of tracheostomy tubes and emergency physicians should be familiar with the types available at their institution. Tra-

FIG. 244-1. Creation of a tracheal flap.

cheostomy tubes can vary in diameter, total length, and the length before and after the curve and the presence or absence of a cuff (Figure 244-3). The tracheostomy tube cuff is similar that of an endotracheal tube. Most adult tracheostomy tubes have a removable inner cannula, which allows secretions to be cleared from the lumen without removing the entire tube from the trachea. Both disposable and reusable inner cannulas are available. In any adult tracheostomy patient, it is ad-

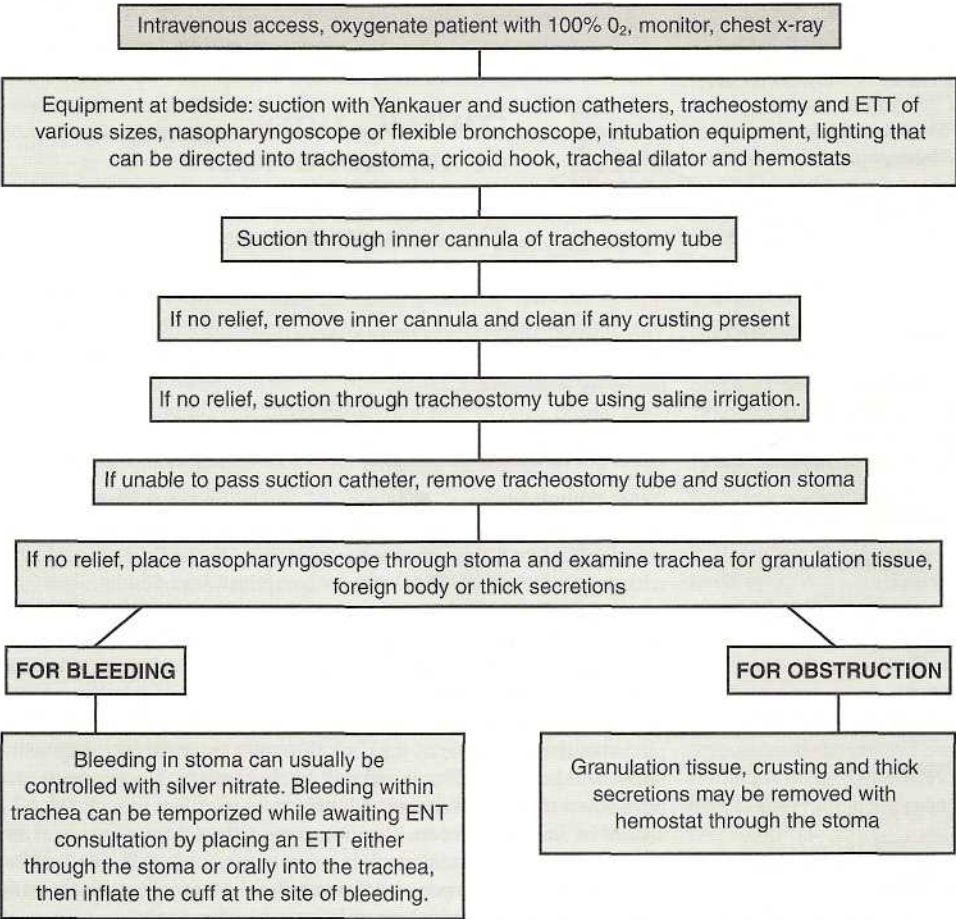

FIG. 244-2. Steps in assessing a tracheostomy patient with respiratory distress. ENT = ear, nose, and throat specialist; ETT = endotracheal tube.

FIG. 244-3. Common components of most tracheostomy tube sets.

visible to remove and examine the inner cannula for crusting or obstruction. Both disposable and reusable inner cannulas can be cleaned with hydrogen peroxide by using a small brush and warm tap water. Because the correct size of disposable inner cannula is rarely available in the ED, the existing inner cannula should be temporarily reused or the entire tracheostomy tube changed. **Pediatric tracheostomy tubes never have an inner cannula because of the small inner diameter;** consequently, the entire tube must be removed for cleaning. The size of the tracheostomy tube is usually defined by the inner diameter, ranging in adults from 5 to 10 mm, and in pediatric tubes from 2.5 to 6.5 mm. Most pediatric and adult tracheostomy tubes have a 15-mm standard respiratory connection that may be used with ventilator tubing and a bag-valve device.

Fenestrated tracheostomy tubes have an opening along the dorsal surface of the body of the tube. The fenestration allows the passage of air through the tracheostomy tube to the vocal cords so the patient can speak. Tubes must be carefully fitted to provide alignment of the fenestration within the trachea with no contact of the fenestration to either the anterior neck tract or the posterior tracheal wall. When the fenestration contacts these structures, slight respiratory movement of the tube will lead to granulation tissue formation. The granulation tissue can extend into the fenestration, leading to bleeding, obstruction, and difficulty removing the tracheostomy tube. If any difficulty is encountered removing a fenestrated tracheostomy tube, otolaryngologic consultation is needed.

Changing a Tracheostomy Tube

The amount of difficulty encountered when changing a tracheostomy tube depends on when the procedure was performed and on patient anatomy. **If the tracheostomy is less than 7 days old, the tract will not be mature and manipulation may easily create a false passage within the soft tissue of the neck. In addition, a tract may easily collapse at any time in patients with obese necks or neck masses.** If the situation is not emergent, and the tracheostomy is less than 7 days old, tracheostomy tubes should be changed by an otolaryngologist or a surgeon familiar with the procedure.

An uneventful tracheostomy change depends on adequate preparation and is best accomplished with an assistant. The spontaneously breathing, stable patient can easily breathe through a patent tracheostoma without the tube in place, so there is no reason to rush through this procedure. The needed equipment is listed in Table 244-1. If a cuffed tube is used, test the balloon before use and make sure the balloon is completely deflated before insertion. If needed, the cricoid hook can be inserted just under the cricoid and used to lift and stabilize the trachea. The dilator is particularly useful if a larger tube is to be inserted, although dilation may require injection of local anesthesia and consideration of otolaryngologic consultation. The physi-

TABLE 244-1 Equipment Needed to Change a Tracheostomy Tube

Suction device with both a Yankauer tip and suction catheters that fit inside the tracheostomy tube
Good lighting directed into the tracheostoma
An appropriate size tracheostomy tube with obturator in place
Another tracheostomy tube one size smaller than planned
Tracheostomy tube tie
Cricoid hook and tracheal dilator (if physician is familiar with their use)

cian should be familiar with both the cricoid hook and tracheal dilator before using them. When the obturator is placed in the tracheostomy tube, the tube presents a solid, rounded end that is less likely to damage the neck soft tissue during tube insertion (see Figure 244-3). To minimize soft tissue damage, obturators should be used whenever a tracheostomy tube is replaced.

After all of the equipment is in place, the patient is placed supine with a shoulder roll to extend the neck, the old tube is removed, the stoma suctioned gently and examined. In most cases, the opening in the trachea and the posterior tracheal wall can be visualized. Gently direct the fresh tube into the opening, curving it downward into the trachea (Figure 244-4). This movement should be smooth and gentle. If resistance is met, the tube is likely caught on the cartilaginous tracheal wall. Remove the tube and reexamine the stoma, then place the tube directly into the tracheal opening. If the tube still cannot be placed, consider placing the smaller tracheostomy tube. However, a smaller tube will also be shorter, and may not be long enough for the patient's neck. Correct tube position can be verified by inserting a suction catheter into the tube. It should easily pass beyond the length of the tracheostomy tube without resistance. If there is a question about placement, a nasopharyngoscope or flexible bronchoscope can be passed through the tube for direct visualization of placement, or an x-ray obtained.

Patients who present with accidental decannulation and are in no distress can have the tracheostomy tube replaced as described above. **If the tube has been out for several hours, the stoma may begin to close and dilation may be needed prior to tube insertion.** If this is the case, and if the stoma is small and/or the tracheostomy is the patient's only airway, otolaryngologic consultation should be considered for tube replacement.

Tracheostomy Tube Obstruction

Although problems with the tracheostomy may be the cause of respiratory distress, all other causes should be considered and if the tracheostomy is found to be patent and in the airway, it should be left in place. Tracheostomy tube obstruction with mucous plugging is a

FIG. 244-4. Insertion and placement of the tracheostomy tube. Cuffed tubes should be inserted with the cuff deflated.

common complication of this airway device. Secretions may act by a ball-valve mechanism, allowing air in but restricting exhalation. As outlined in Figure 244-2, suctioning may relieve the obstruction. However, the inner cannula of the tracheostomy tube and sometimes the entire tracheostomy tube may need to be removed and cleaned. Preoxygenation and placement of sterile saline solution into the trachea will aid in suctioning. Prolonged use of large suction catheters without preoxygenation will cause hypoxemia.

Mechanical Ventilation with a Tracheostomy Tube

If the patient requires mechanical ventilation, an uncuffed tracheostomy tube will have a large air leak. If the patient cannot be effectively ventilated with an uncuffed tube, it should be replaced with a cuffed tube. If a tracheostomy tube is not readily available, an endotracheal tube may be inserted into the stoma in order to maintain airway security. If the stoma cannot be cannulated, the patient may be orotracheally intubated in order to secure the airway.

Laryngectomy Patients

Laryngectomy patients cannot be orally intubated. The only access to the tracheal bronchial tree in laryngectomy patients is through the neck. Occasionally, laryngectomy patients will wear a laryngectomy tube in their stoma, similar in appearance to a tracheostomy tube. **Laryngectomy patients can be distinguished from tracheostomy patients by history and physical examination, and by the fact that laryngectomy patients are unable to vocalize (or breathe) when the laryngectomy tube is occluded.**

Tracheostomy Dislodgement

The tracheostomy tube may be dislodged from the trachea, but not from the neck. In this case, a suction catheter cannot be passed through the tube and tracheostomy tube may extrinsically compress the trachea (Figure 244-5). In this circumstance, the entire tracheostomy tube should be immediately removed. When attempting to properly reinsert the tracheostomy tube, it may be difficult to accurately identify the actual tracheal stoma. A nasopharyngoscope should be inserted into the visible stoma in an attempt to identify the tracheal opening. If the latter still cannot be identified, otolaryngologic consultation is needed. If the patient cannot maintain the airway, oral intubation will be needed while awaiting the otolaryngologist.

Tracheostomy Site Infection

Indwelling tracheostomy tubes are contaminated with normal, and sometimes pathogenic, flora. Stomal skin infection, tracheitis, and bronchitis can be a recurring problem. *Staphylococcus aureus*, *Pseudomonas*, and *Candida* are often identified and broad-spectrum antibiotics are indicated in the setting of clinical disease. Dressing changes with gauze soaked in 0.25 percent acetic acid are effective for local wound infections.

Bleeding

Bleeding can occur immediately after a tracheostomy and in the late postoperative period.⁵ Sources of hemorrhage include granulation tissue in the stoma or trachea, and erosion of thyroid vessels or the gland itself, the tracheal wall (frequently from suction trauma), or the innominate artery. Slow bleeding originating from the stoma may be controlled by packing the site with saline soaked gauze. If this is ineffective, the tube should be removed and the stoma and tracheal wall examined. Local bleeding can be controlled with silver nitrate or electrocautery. With more brisk bleeding, the tracheostomy tube should be replaced with a cuffed endotracheal tube with the cuff below the bleeding site. An endotracheal tube is preferred, as it is difficult to examine the site around the flange of a tracheostomy tube.

FIG. 244-5. A. Patient with a large goiter and a no. 4 Shiley tracheostomy tube with the tip of the tube outside the trachea and compressing the tracheal wall. B. Same patient with a longer no. 6 Shiley tracheostomy tube with the tip of the tube inside the trachea.

Tracheo-innominate artery fistula is a rare but life-threatening complication of tracheostomy.⁶ Bleeding results from direct pressure of the tip of the tracheal cannula against the innominate artery (Figure 244-6). Maneuvers to control brisk bleeding while planning operative intervention include local digital pressure, hyperinflation of the cuff, and mild traction of the tube with manual pressure. Some patients may present with a sentinel bleed or hemoptysis. Such bleeding may be mild to severe and should not be taken lightly, because the potential exists for sudden massive hemorrhage. Immediate otolaryngologic consultation is required, and operative repair is lifesaving.

FIG. 244-6. The arrow points to the position of the tracheostomy tube in relation to the innominate artery. This close approximation facilitates creation of a tracheo-innominate fistula.

Tracheal Stenosis

Tracheal stenosis can present weeks to months after decannulation and results from mucosal necrosis and subsequent scarring. Signs and symptoms include dyspnea, wheezing, stridor, and the inability to clear secretions. A chest radiograph may demonstrate the narrowed airway. Medical treatment includes humidified oxygen, nebulized racemic epinephrine, and early administration of steroids. Operative treatment involves rigid bronchoscopy with laser excision of the scar bands, and stenting or tracheal reconstruction in more severe cases. Immediate otolaryngologic consultation is warranted.

LARYNGEAL STENTS

The surgical management of severe laryngotracheal stenosis often employs the insertion of tracheal stents for various periods of time. Placement of an endolaryngeal stent renders a patient tracheostomy dependent until the stent is removed, a result of blockage of the airway at the laryngeal level by the solid stent (Figure 244-7). Stents and their associated tracheostomy tubes should only be removed by surgeons familiar with their placement. There are many different endolaryngeal

FIG. 244-7. Relation of the tracheostomy tube to the laryngeal stent. The stent lies within the lumen of the trachea, superior to the tracheostomy tube.

stent designs and materials, including silastic molds secured by cutaneous buttons, a stent secured by a strap that exits the tracheal stoma and is attached to the skin, the Aboulker stent complex (a metal tracheostomy tube wired to a silastic stent used in pediatric airway reconstruction), and the Montgomery T-tube stent (Figure 244-8). Although endolaryngeal stents are secured by buttons or straps, a known complication of these devices is dislodgment. If a stent becomes dislodged but the tracheostomy tube remains in position, airway security is usually not an issue. The operating surgeon should be notified when extrusion or dislodgment of any stent occurs.

The Montgomery T-tube configuration is commonly used in adult laryngotracheal reconstruction.⁷ It is a modification of a tracheostomy tube that does not have an inner cannula. Humidification and suctioning of the T tube is essential to prevent mucous plugging. Airway obstruction should be addressed by first suctioning both the upper and lower limbs of the T tube (see Figure 244-8). If suctioning both limbs of the T tube does not relieve the obstruction, the T tube can be removed and the trachea cannulated with an appropriately sized tracheostomy tube or an endotracheal tube.

SPEECH DEVICES

The Passy-Muir valve is a one-way valve that fits directly over the opening of an uncuffed tracheostomy tube and allows the patient hands-free speech. When the patient inhales, the valve opens and allows air to pass into the trachea and lungs. Speech is created when the

FIG. 244-8. Suctioning is required of both the upper and lower limbs of the Montgomery T tube. If necessary the entire T tube can be removed.

FIG. 244-9. The Passy-Muir valve is a one-way valve that fits directly on the opening of the tracheostomy tube. Speech is created when the patient exhales as air is passed up through the vocal cords and out the mouth.

patient exhales hard enough to close the Passy-Muir valve and the air is thus directed around the tracheostomy tube and through the vocal cords (Figure 244-9). Because the patient exhales around the tracheostomy tube, a Passy-Muir valve should never be used with a cuffed tube. If a patient with a Passy-Muir valve develops signs of airway obstruction or an inability to speak, the speaking device should be removed from the tracheostomy tube so that air can pass freely during both inhalation and exhalation. If this does not relieve symptoms, check the tracheostomy tube itself for obstruction.

Speech in post laryngectomy patients has dramatically improved with the use of the tracheo-esophageal prosthesis. This one-way valve is surgically placed between the posterior wall of the tracheal stoma and the anterior wall of the cervical esophagus. To speak, patients exhale while occluding the stoma with their thumb, thus forcing the exhaled air into the esophagus. The air vibrates the esophagus (as a belch does) and the resultant tone is used to provide speech.

Two common complications with tracheo-esophageal prostheses are valve aspiration or extrusion. Aspiration results in persistent cough and respiratory distress. Chest x-ray should be done to visualize the radiopaque valve. Otolaryngologic consultation is indicated if there is suspicion of aspiration, as well as if the prosthesis is dislodged. The tracheo-esophageal puncture site will close quickly after the tube is

dislodged, and can be maintained by insertion of a Foley or red rubber catheter. This should not be attempted if the puncture is less than 2 weeks old, as a false passage may be formed in the neck.

DISORDERS OF THE SKIN

APPROACH TO THE DERMATOLOGIC PATIENT IN THE EMERGENCY DEPARTMENT

William J. Brady
Andrew D. Perron
Marcus L. Martin

The dermatologic syndromes seen in the emergency department span the spectrum of cutaneous disease. Most skin lesions involve infections, irritants, and allergies.¹ Fortunately, few presentations represent life- or limb-threatening skin disorders. Visual diagnosis with the use of pattern recognition is the key to cutaneous diagnosis. The recommended approach to the patient with skin disease in the emergency department (assuming resuscitation or stabilization is not required) is to:

1. Determine the chief complaint
2. Obtain a brief history (duration, rate of progression, and location of lesions)
3. Perform the dermatologic examination (morphology and distribution)
4. Formulate the differential diagnosis based on lesion morphology and distribution
5. Elicit additional concerns from the history (associated complaints, comorbidity, medications, or exposures) and include or exclude syndromes in the differential based on this information
6. Perform ancillary investigations, if necessary
7. Obtain dermatologic consultation, if necessary, and arrange for appropriate referral (primary care or dermatologic)

DIAGNOSTIC APPROACH

The History

Determine the chief complaint and obtain a brief history (discomfort, duration, rate of progression, and location of lesions). The secondary history should include issues relating to the lesion: morphology, evolutionary nature, rate of progression, and distribution. Associated systemic complaints and mucosal systems must be identified. Ask about exposures to medications (over-the-counter, prescription, and illicit), immunizations, toxins, chemicals, foods, animals, insects, plants, and ill contacts. Sexual history, if appropriate, and medical and family histories should be reviewed. Asking about medication use, sun exposure, or particular food ingestion also may yield helpful information.

The Examination

The dermatologic physical examination must be performed on the disrobed patient in a room with adequate lighting. All skin and mucosal surfaces must be inspected, including hair, nails, scalp, and mucous membranes. Then the specific skin lesions must be inspected. A magnifying lens and a portable lamp are helpful for conducting the examination.

The skin should be examined in a systematic, methodical, orderly process. The distribution, pattern, arrangement, morphology, extent, and evolutionary changes of the lesions must be determined. *Distribution* is the location of the skin findings, and the *pattern* is the anatomic, functional, and physiologic arrangements of the lesions. For example, a unilateral band-like arrangement of lesions on the thorax

suggests varicella-zoster infection. Skin diseases often present with a predilection for certain body areas; as such, location will assist in narrowing the diagnostic possibilities. From the anatomic perspective, the skin surfaces that are usually considered as separate areas of distribution include scalp, hair, face, eyelids, mouth, trunk, axilla, perineum, extremities, and nails; the extremities may be further subdivided into upper versus lower, proximal versus distal, wrists versus ankles, and hands versus feet (Figure 245-1). Rashes on exposed portions of the skin should prompt inquiries about sun exposure, jewelry, or topical agents. Refer to Table 245-1 for a differential diagnosis of skin lesions as a function of location. The clinician can use the "burn rule of 9's" (see Chap. 199, "Thermal Burns") to estimate the degree of skin involvement in disorders with widespread distribution. This calculation also may be used to determine the amount of topical medication required for a specific treatment course.

Lesion arrangement refers to the symmetry and configuration. Bilateral symmetry suggests a systemic internal event or symmetric external exposure, as seen in erythema multiforme, with plaque-like lesions on the flexor surfaces of the extremities or contact dermatitis related to a lotion application. An asymmetric arrangement supports a localized process. *Configuration* may apply to a single lesion with reference to its individual features or, alternatively, to multiple lesions and their relation to one another. For instance, internal configuration is illustrated by the relation between the central papule relative to the erythematous ring in the target lesion of erythema multiforme; on the total-body scale, configuration is demonstrated by clustering of lesions in a herpes virus infection or by a linear arrangement as with a reaction from poison ivy or oak. Other terms used to describe the lesion configuration are listed in Table 245-2.

Recognition of the primary lesion is vital in establishing the diagnosis. The primary lesion is the one that has not been altered by secondary issues, including healing, complicating infection, medication application, or scratching. Examples of primary skin lesions are macules, papules, nodules, tumors, cysts, plaques, wheals, vesicles, bullae, and pustules. Secondary lesions have had their appearance altered due to disease evolution or various external factors, as noted above, and include crusts, scales, fissures, erosions, ulcerations, excoriations, atrophy, scarring, and lichenification. See Table 245-3 for a listing with descriptions of the various morphologic descriptors of dermatologic lesions; refer to Tables 245-4 and 245-5 for a differential diagnosis of the various skin disorders relative to primary and secondary lesion morphologies.

Diagnostic Techniques

The KOH preparation is used in patients with suspected molluscum contagiosum and dermatophytic infections. The test is performed on loose skin scales, nail pairings, subungual debris, short residual hairs, or small pearly globules (from a molluscum body). Test steps are as follows:

1. Place material on the slide, gently crush it, and mix it with two drops of 20 percent KOH
2. Warm but do not boil the specimen and then let it sit for 10 min (thick scrapings may need 20 min)
3. Remove excess solution by placing a paper towel at the corner of the slide
4. Place a coverslip for thick specimens with gentle pressure to compress the material adequately for viewing

The material is then viewed under a microscope at low power, with the condenser and light at low levels. As the slide is scanned, rapidly focus

FIG. 245-1. Allergic contact dermatitis. A. Allergic contact dermatitis from exposure to poison ivy. Erythema, vesiculation and bullae are present on the fingers and the dorsal surfaces of the hands. Note the linear streak across the right hand. This finding is a diagnostic clue for rhus contact dermatitis (poison ivy). B. Allergic contact dermatitis to the straps of sandals. Erythema, scale and excoriations are noted in a symmetric patterned distribution matching to this patient's footwear.

up and down. True hyphae are long, branching, green rods of constant width that cross the borders of epithelial cells. Molluscum bodies are oval discs with homogeneous cytoplasm. In hair fragments, the organisms appear as small, round spores packed closely within the hair shaft.

Scabies and lice preparations are useful in patients with possible infestation. In scabies infestations, the rash itself may resemble other dermatologic syndromes; microscopic analysis will confirm the diagnosis. The donor site for skin specimen selection is very important. The best sites include burrows (10-mm, elongated papule with a pustule or vesicle) and papules on the fingers, wrists, and elbows. Within the vesicle or pustule, a small black dot is noted, which is the mite. The point of the scalpel is scraped across the lesion while holding the skin taut; the mite is then removed. A single drop of mineral oil may be applied to the blade to ensure that the scrapings adhere to the instrument. The material is then placed on the microscope slide with an additional drop of mineral oil; gentle pressure on the coverslip will flatten thick specimens. Using low power, the slide is scanned for presence of the mite, eggs, or feces. Mites are eight-legged creatures that are easily identified on thin smears; thick specimens may require additional

TABLE 245-1 Differential Diagnosis Relative to Lesion Distribution and Pattern

Pattern	Differential Diagnosis
Flexural (flexor areas of skin)	Atopic dermatitis, candidiasis, eczema, ichthyosis
Sun exposure (face, upper thorax, distal extremities)	Sunburn, photosensitive drug eruption, photosensitive dermatitis, systemic lupus erythematosus, viral exanthem, porphyria
Acrodermatitis (distal extremities)	Viral exanthem, atopic or contact dermatitides, eczema, Rocky Mountain spotted fever, gonococcemia
Pityriasis rosea (anterior and posterior thorax)	Pityriasis rosea, secondary syphilis, drug eruption, atopic or contact dermatitis, psoriasis
Clothing covered (thorax and distal lower extremities)	Contact dermatitis, psoriasis, folliculitis
Acneiform (face and upper thorax)	Acne, drug-induced acne, irritant dermatitides

viewing to look for the mite. Additional findings supportive of the diagnosis include eggs (smooth ovals) and feces (clusters of red-brown pellets). Lice are usually found on the scalp, eyelashes, and pubic areas and may be visible to the unaided eye. Moving objects in the area should be grasped with forceps and placed on a slide and viewed under low power. Head lice are long and thin, whereas pubic lice are shorter and broad.

The Tzanck smear, useful in blistering disorders, assists in establishing the diagnosis of a herpes infection: herpes simplex, herpes zoster, and varicella. The choice material for examination is obtained from the base of a recently unroofed lesion; purulent fluid at the base of the lesion is removed with a scalpel and placed on a microscope slide. The material is allowed to air dry and then is stained with Giemsa or Wright stain. Using low power, the slide is scanned for epithelial cells. Multinucleated giant cells, indicative of a herpes infec-

TABLE 245-2 Lesion Configuration Descriptors

Descriptor	Configuration
Annular	Ring-like or pertaining to the outer edge
Arcuate	Curved or pertaining to the curve
Circinate	Circular
Confluent	Blending together
Discoid	Solid, round, slightly raised or pertaining to a disk
Discrete	Separate or individual
Grouped	Clustered
Guttate	Scattered
Gyrate	Coiled or winding
Herpetiform	Creeping
Iris	Concentric circles
Linear	In a line
Polycyclic	Overlapping circles or borders of irregular curves
Retiform	Net-like
Serpiginous	Snake-like
Dermatomal	Belt-like or limited to one side of the body in anatomic dermatome

TABLE 245-3 Lesion Morphology

Descriptor	Morphology	Lesion Nature	Height Relative to Adjacent Skin
Erosion	Ruptured vesicle or bulla with denuded epidermis	Secondary	Depressed
Excoriation	Linear erosion	Secondary	Flat
Fissure	Linear cracks on skin surface	Secondary	Flat
Ulcer	Epidermal or dermal tissue loss	Secondary	Depressed
Macule	Flat, circumscribed discoloration ≤ 1 cm in diameter; color varies	Primary	Flat
Petechiae	Nonblanching purple spots <2 mm in diameter	Primary	Flat
Sclerosis	Firm, indurated skin	Secondary	Flat or elevated
Telangiectasia	Small, blanchable superficial capillaries	Primary	Flat
Purpura	Nonblanching purple discoloration of the skin	Primary	Flat
Abscess	Tender, erythematous, fluctuant nodule	Primary	Elevated
Cyst	Sack containing liquid or semisolid material	Primary	Elevated
Nodule	Palpable solid lesion < 1 cm in diameter	Primary	Elevated
Tumor	Palpable solid lesion > 1 cm in diameter	Primary	Elevated
Scar	Sclerotic area of skin	Secondary	Flat or elevated
Wheal	Transient, edematous papule or plaque with peripheral erythema	Primary	Flat or elevated
Vesicle	Circumscribed, thin-walled, elevated blister <5 mm in diameter	Primary	Elevated
Bulla	Circumscribed, thin-walled, elevated blister >5 mm in diameter	Primary	Elevated
Pustule	Vesicle containing purulent fluid	Primary	Elevated
Papule	Elevated, solid, palpable lesion < 1 cm in diameter; color varies	Primary	Elevated
Plaque	Flat-topped elevation formed by confluence of papules >0.5 cm in diameter	Primary	Elevated
Comedo	Papule with an impacted pilosebaceous unit	Primary	Elevated

tion, are a syncytium of epidermal cells with multiple overlapping nuclei. The presence of the multinucleated giant cell does not distinguish between herpes simplex, herpes zoster, and varicella syndromes. Wood light examination is helpful in several different situations, including erythrasma (a superficial *Corynebacterium* infection of moist skin in the groin, axilla, and web spaces), tinea versicolor (a superficial fungal infection), certain pseudomonal skin infections, and porphyria cutanea tarda. Wood light is an ultraviolet source that emits light at a wavelength of 365 nm. The following fluorescent findings are noted in these conditions: erythrasma, red or pink; tinea versicolor, green or yellow; pseudomonas, yellow or green; and porphyria cutanea, orange or yellow (urine only). Other laboratory investigations are of limited value; selected tests are listed in Table 245-6 with the respective dermatologic disease.

TREATMENT

In general, the maxim "if it's dry, wet it, and if it's wet, dry it" applies to the initial therapy of many rashes. Water, protein, and lipid losses characterize dry skin diseases. Emollient creams and lotions restore water and lipids to the epidermis, hasten the healing process, and reduce pruritus and pain. Emollients are moisturizers that reduce skin dryness and decrease skin friction and the sensation of tightness. In patients with chronic drying dermatitides, ointments are best, particularly in the winter months. In warm climates, less viscous, less oily preparations, such as a cream, are better tolerated. Open wet dressings using tap water or normal saline not only reduce discomfort due to the dry-

ing but also clean the skin by painlessly loosening crusts and exudates. The various wet cutaneous syndromes involve similar protein and lipid losses due to excessive flow of transudative or exudative fluid from the diseased skin with leaching of the complex macromolecules of the epithelial cells. Drying agents retard this flow of fluid and associated biologic materials from the body, thus assisting in the curative process.

Corticosteroids

Urticaria, angioedema, and toxicodendron dermatitis (rhus, poison ivy, or poison oak) and other contact or allergic dermatitides are potential indications for systemic corticosteroids. Other dermatologic syndromes, such as erythema multiforme, toxic epidermal necrolysis, and vasculitis, are best treated with systemic steroids only after consultation with a dermatologist. In one study, small bursts of prednisone (40 mg daily for 4 days) markedly reduced the pruritus and hastened the clinical improvement of urticaria.² Patients with poison ivy or oak who require systemic steroids should be treated with oral prednisone (1 mg/kg body weight) with a slow 2- to 3-week taper. Other contact or allergic dermatitides may benefit from an abbreviated course (4 days) of oral prednisone. **However, oral corticosteroids are relatively contraindicated, or must be used with great care, in those with diabetes, hypertension, active peptic ulcer disease, psychiatric disease, and immunodeficiency.** Close follow-up is needed if oral corticosteroids are prescribed to these patients.

Topical corticosteroids are powerful and useful tools in the management of dermatologic disease. Numerous agents are available for

TABLE 245-4 Differential Diagnosis of Selected Skin Disorders Relative to Primary Lesion Morphology*

Lesion Morphology	Differential Considerations
Macule	Drug eruption (fixed or photosensitive), nevus, tattoo (ink), lice infestation, rheumatic fever, syphilis (secondary), viral exanthem erythema multiforme, toxic or infectious erythemas, meningococcemia (early), external trauma (ecchymosis), vitiligo, tinea versicolor, cellulitis (early)
Papule	Acne, basal cell carcinoma, melanoma, nevus, warts, molluscum contagiosum, skin tags, atopic dermatitis, urticaria, eczema, folliculitis, insect bites, vasculitis, psoriasis, scabies, toxicodendron dermatitis (poison ivy, oak, sumac), erythema multiforme, varicella (early), gonococcemia
Plaque	Eczema, pityriasis rosea, tinea corporis and versicolor, psoriasis, seborrheic dermatitis, urticaria, syphilis (secondary), erythema multiforme
Nodule	Basal cell, squamous cell, or metastatic carcinoma, melanoma, erythema nodosum, furuncle, lipoma, warts
Wheal	Urticaria, angioedema, insect bites, erythema multiforme
Pustule	Acne, folliculitis, gonococcemia, hidradenitis suppurativa, herpetic infection (herpes simplex, herpes zoster, varicella), impetigo, psoriasis, rosacea, pyoderma gangrenosum
Vesicle	Herpetic infection (herpes simplex, herpes zoster, varicella), impetigo, toxicodendron dermatitis (poison ivy, oak, sumac), thermal burn, friction blister, toxic epidermal necrolysis, bullous pemphigoid, pemphigus vulgaris
Bulla	Bullous impetigo, toxicodendron dermatitis (poison ivy, oak, sumac), thermal burn, friction blister, toxic epidermal necrolysis, bullous pemphigoid, pemphigus vulgaris

*This list is not exhaustive, but it represents the more common syndromes likely to be encountered by the emergency physician.

use. They **differ** in concentration, base components, and cost. Familiarity with a single agent in each potency class is sufficient to safely and effectively treat any steroid-responsive skin ailment. Corticosteroid potency or strength (i.e., the anti-inflammatory property) is measured by the agent's ability to induce vasoconstriction. Agents' strengths are rated by vasoconstricting ability on a scale of one to seven, with lower scale numbers correlating with more potent corticosteroids: group 1 agents are the most powerful corticosteroids, and group 7 medications are the least potent. Refer to Table 245-7 for a listing of topical corticosteroid agents relative to group potencies. Marked variation in potency is seen among various corticosteroids, whereas much less difference in strength is encountered for individual agents at different concentrations. Many corticosteroids are fluorinated. Fluorination greatly increases the potency but also increases the risk of adverse reactions and should not be used in pregnancy.

Use of the appropriate-strength topical steroid is strongly encouraged at the start of therapy. The use of a less powerful agent is not likely to spare the patient from potential adverse effect or produce adequate control of the disease. Hydrocortisone, perhaps the most frequently used topical corticosteroid in the outpatient setting, is available over the counter in strengths up to 1 percent and by prescription

TABLE 245-5 Differential Diagnosis of Selected Skin Disorders Relative to Secondary Lesion Morphology*

Lesion Morphology	Differential Considerations
Scales	Psoriasis, pityriasis rosea, toxic and infectious erythemas, syphilis (secondary), dermatophytic infection (tinea), tinea versicolor, xerosis (dry skin), thermal burn (first degree)
Crusts	Eczema, dermatophytic infection (tinea), impetigo, contact dermatitis, insect bite
Erosions	Candidiasis, dermatophytic infection (tinea), eczema, toxic epidermal necrolysis, toxic-infectious erythemas, erythema multiforme, primary blistering disorders (bullous pemphigoid and pemphigus vulgaris), brown recluse spider envenomation
Ulcers	Aphthous lesions, chancroid, decubitus ulcer, thermal or friction injury, subacute or chronic ischemia, malignancy, chancre (primary syphilis), primary blistering disorders (bullous pemphigoid and pemphigus vulgaris), brown recluse spider envenomation, pyoderma gangrenosum, stasis ulcer, factitial

*This list is not exhaustive, but it represents the more common syndromes likely to be encountered by the emergency physician.

to a maximum of 2.5 percent. Hydrocortisone is safe and may be used on most body surfaces, including the face, genitalia, flexure creases, and intertriginous zones; it also is safe for use in infants and children. For the treatment of diseases involving the palms and soles, hydrocortisone is a poor choice, because the thickened skin does not allow adequate penetration of this relatively low-potency steroid. Corticosteroids of moderate potency including triamcinolone acetonide and fluocinolone acetonide, are useful in severely inflamed skin and on the thicker skin of the scalp, trunk, extensor surfaces, palms, and soles. These agents should not be applied to the face or genitals or used in the infant. **Fluorinated steroids should not be prescribed to pregnant women.** See Table 245-8 for recommendations of corticosteroid potency relative to dermatologic disease.

Different skin surfaces respond differently to topical corticosteroid therapy; this different response rate varies relative to the absorption of the steroid into the deeper tissues. The relatively thin skin surfaces of the face respond very rapidly to the use of group 7 agents, whereas the thicker skin of the palms and soles requires a highly potent steroid. Irritations that resolve with an effective, higher potency application when using a low-potency agent include raw, inflamed skin (such skin more rapidly and readily absorbs medication), treatment regions involving skin surfaces in frequent contact, such as intertriginous areas (the apposition of two skin surfaces produces enhanced absorption of drug, similar to the effect to an occlusive dressing), and areas of skin surfaces enclosed under tight clothing, such as the diaper area (enhanced absorption of the agent due to the occlusive effect of the

7	Hydrocortisone	Hytone (cream/lotion/oointment)	1, 2.5	1, 2, 4 oz

*Preparations are listed by potency: Group 1 is most potent, and group 7 is least potent.

garment). In general, lower potency agents are acceptable in these situations.

The application of creams, ointments, gels, and lotions is relatively straightforward. The medication, applied in thin layers, should be massaged daily into the skin, as directed. Washing the skin before corticosteroid application is unnecessary. Patients should be advised to follow directions closely, early and late in the treatment course. Early application with extra medication per dose or more frequent medication administrations is not desired; likewise, a reduced frequency of application or a decreased amount of medication as the disease process responds to therapy can cause relapse. Optimum application regimens have not been determined for topical corticosteroids in most dermatologic syndromes. The more potent agents are best applied two to three times daily for 1 to 2 weeks followed by a drug-free week; additional therapy may be required as determined by the disease and by the particular patient's response to the initial therapy. Agents from the less potent steroid groups may be applied three times daily for 2 to 4 weeks followed by a 7-day steroid-free period.

The prescription of the correct amount of topical steroid is at times difficult. The burn rule of 9's may be used to estimate the amount of topical corticosteroid to prescribe. Calculate the percentage of body surface area requiring therapy and then multiply the percentage by a

correction factor of 30. This calculation will provide the amount of topical corticosteroid in grams for a single application. Next, determine the number of administration required in the treatment course. For example, a thrice-daily regimen for a duration of 10 days ultimately requires 30 applications. The number of applications is multiplied by the amount required for a single use. In general, 9 g of topical steroid will cover 9 percent of the body surface area in a thrice-daily application for 1 day. Refer to Table 245-9 for a description of topical corticosteroid amount to be dispensed relative to the coverage area and duration of therapy.

Tachyphylaxis refers to the decrease in responsiveness to a drug as a result of enzyme-mediated events. The term is used in relation to topical corticosteroids in reference to acute tolerance to the vasoconstricting ability. In general, vasoconstriction has been demonstrated to decrease progressively over time after a topical steroid has been applied. Such reductions in strength due to tolerance are encountered as soon as 4 days into the treatment course in all potency groups but are felt to be more important in groups 1 and 2. A reasonable strategy to counter the development of tachyphylaxis is the use of interrupted application schedules; such an interrupted treatment course might include an initial thrice-daily application for 2 weeks, followed by 1 week without using the drug and a repeat of the cycle.

TABLE 245-8 Recommendations of Corticosteroid Potency Relative to Dermatologic Disease

Groups 1 and 2	Groups 3–5	Groups 6 and 7
Psoriasis	Atopic dermatitis	Nonspecific dermatitis, of face, eyelids, and perineum
Eczema, of hand (severe)	Stasis dermatitis	
Poison ivy (severe)	Seborrheic dermatitis	
Atopic dermatitis (severe)	Tinea	
	Scabies	
	Nonspecific dermatitis, of face (severe)

Forearm	Intermediate or low	45
Chest or back	Intermediate or low	180

*Based on thrice-daily applications for 10 days of therapy.

Antihistamine Agents

Antihistamines (H¹ antagonists) are used frequently in the management of dermatologic disease, particularly in the control of pruritus. These agents include the first-generation antihistamines, such as diphenhydramine and hydroxyzine. These H¹ antagonists may be used PO, IM, or IV. The second-generation antihistamine agents, including astemizole, cetirizine, fexofenadine, and loratadine, are newer agents that may be used in certain circumstances. In general, the newer antihistamines offer the advantages of reduced dosing frequency and less sedative effect, but they are more costly. Comparisons of these new medications with hydroxyzine are generally favorable but not in dramatic terms; comparisons among these second-generation agents do not demonstrate significant differences.^{3,4} The use of topical antihistamine preparations is discouraged, because these agents are readily absorbed; dosing is therefore difficult to predict. Accidental overdosage may result in the patient who aggressively applies the preparation or is also using similar oral agents. Refer to Table 245-10 for suggested dosing, administration schedules, and routes of therapy for these antihistamines. H₂ antagonists (ranitidine or famotidine) also have demonstrated some benefit in the patient with an allergic-mediated event, in particular urticaria.

Numerous other antipruritic therapies are recommended, including Domeboro solution (aluminum sulfate diluted 1:10 with water) soaks, potassium permanganate baths, and oatmeal baths.

Antimicrobial Agents

Topical antibacterial agents are used primarily as adjuncts to wound dressings; these agents rarely are useful as primary therapy for superficial bacterial infections of the skin. The exception to this statement is topical mupirocin, which is reportedly as effective as oral antimicrobial agents in the management of impetigo. Concerning wound dressings, the agents commonly used include polymyxin B, bacitracin, neomycin, and silver sulfadiazine. Suggested benefits of these medications include reduced adherence of bandaging material to the wound, reduced coagulum, and decreased bacterial colonization. The impact on the rate of wound healing and the prevention of wound infection are less well characterized. Another use of topical antibacterial agents is the treatment of aphthous stomatitis with oral tetracycline

rinses. Systemic antibiotic therapy is useful in certain dermatologic syndromes and is discussed in other chapters.

Various topical antifungal agents are available for the treatment of *Candida* and the dermatophytic infections. The imidazole and polyene classes of agents are the most commonly used in outpatient medicine. Members of the imidazole class include clotrimazole, miconazole, and ketoconazole, and the polyenes are represented by nystatin and amphotericin B. In general, the imidazoles are effective against yeasts and dermatophytes, whereas the polyenes are useful only in the treatment of candidal infections. Because of diagnostic confusion that may arise in the fungal etiology of the superficial infection, polyene agents are best avoided; imidazole agents will treat all such superficial fungal infections. Dermatophytic and yeast infections should be treated for prolonged periods to reduce the possibility of recurrence; in general, a 2- to 4-week period of therapy is advised. In cases involving significant discomfort, combination agents composed of imidazole and corticosteroid agents reduce discomfort and eradicate the organism. Selenium sulfide shampoo is effective against tinea versicolor when applied daily for 30 min for 14 days.

Acyclovir has been used extensively in patients with various herpes virus infections, including acute varicella, varicella zoster virus infections ("shingles"), and herpes simplex infections. Valacyclovir⁵ and famciclovir⁶ are acceptable therapies.⁷ In general, these agents do not offer significant advantages over acyclovir, with the exception of reduced dosing frequency, perhaps by increasing compliance and, therefore, the possibility of an improved outcome.

Infestations with lice are treated with topical lindane, 1 percent permethrin, or pyrethrins. These agents are reasonably effective against adult lice but are less useful against the unhatched eggs (nits). Consequently, a second application 5 to 10 days after the initial treatment should clear the new generation of lice, which was not affected by the first use. **Central nervous system toxicity has been reported in small infants treated with lindane, so permethrin or pyrethrins should be used in children.** Scabies also may be treated with one overnight application of lindane or 5 percent permethrin covering the entire non-hair-bearing skin surface.

Topical Agent Vehicle Considerations

The *vehicle*, or medication base, is the substance in which the active ingredient is dispersed. The base determines the rate at which the active ingredient is absorbed through the skin. Components of some bases may cause irritation or allergy. Creams, a mixture of oils, water, and preservative, are white in color and greasy in texture. Creams are the most versatile vehicle and can be applied to any body surface area; they are particularly useful in the intertriginous areas. Creams are best used for acute therapy only; chronic application may cause excessive drying. Ointments are composed of greases such as petroleum jelly and are free of preservative; little water is added to this vehicle. This vehicle is translucent and, when applied to the skin, remains greasy. This greasy consistency may aid in the lubrication in particularly dry lesions. In general, ointment vehicles allow deeper tissue penetration when compared with the cream base. Ointments also are occlusive, providing very thorough coverage with deep tissue penetration and allowing little movement in moisture and other material into and out of the skin. Acute exudative syndromes and intertriginous areas of the body should not be treated with topical steroids using the ointment vehicle. Gels are greaseless mixtures of propylene glycol and water and at times includes alcohol. Gels have a translucent appearance and are described as "sticky." Alcohol-containing gels are best for acute exudative lesions, such as poison ivy dermatitis, whereas alcohol-free combinations should be applied to dry, scaling conditions. In denuded areas, the alcohol component may cause discomfort. Gels are of particular use in the scalp area; their presence does not alter the arrangement of the hair and is therefore more tolerable for the patient from the cosmetic perspective. Solutions or lotions may contain water or alco-

indication limited to chronic idiopathic urticaria (see package inserts for details).

f Pediatric use is recommended only in children 6 years or older (see package inserts for details).

{Pediatric use not recommended according to package insert.

hols in addition to other agents. They are clear or milky in appearance; with their liquid consistency, they are best applied to the scalp and other dense hair-bearing areas without leaving significant residue on the hair. In denuded areas, the alcohol component may cause discomfort. Guidelines for specialty consultation or hospital admission are similar. First, extensive skin involvement by erythroderma, bullae, or a palpable purpura suggests the need for rapid emergency department consultation followed by hospital admission. However, certain dermatologic syndromes typically present with generalized involvement and do not require specialty care; classic examples are urticaria and angioedema, acute varicella, and toxicodendron dermatitis. If the diagnosis is in question in the patient with a generalized rash, consider the need for dermatologic consultation.

General medical concerns that might prompt consultation and admission include cardiorespiratory instability, the systemic signs and symptoms, multisystem involvement, significant comorbidity, patient's age, poor home environment, or the need for the initiation of aggressive medical therapy.

The pathogenesis of EM remains largely unknown. Most likely, it is the result of a hypersensitivity reaction with the demonstration of immunoglobulin and complement components in the cutaneous microvasculature on immunofluorescence studies of skin biopsy specimens, circulating immune complexes in the serum, and mononuclear cell infiltrate on histologic examination.^{1,2}

Patients frequently experience malaise, fever, myalgias, and arthralgias. Diffuse pruritus or a generalized burning sensation can occur before the skin develops lesions. The morphologic configuration of the lesions is quite variable, hence the descriptor *multiforme*. Maculopapular (Figure 246-1 A, **Plate 10**) and target (iris, Figure 246-1B, **Plate 11**) lesions are the most characteristic. Erythematous papules appear symmetrically on the dorsum of the hands and feet and on the extensor surfaces of the extremities. The maculopapule evolves into the classic target lesion during the next 24 to 48 h. As the maculopapule enlarges, the central area becomes cyanotic, occasionally accompanied by central purpura or a vesicle. Urticarial plaques also may occur with or without the iris lesion in a similar distribution. Vesiculobullous lesions, which may be pruritic and painful, develop within preexisting maculopapules or plaques, usually on the extensor surface of the arms and legs, less frequently involving the trunk. Vesiculobullous lesions are found most often on mucosal surfaces, including the mouth, eyes, vagina, urethra, and anus; they may also be seen on the trunk. Ocular involvement occurs in approximately 10 percent of patients with EM minor, whereas ophthalmologic lesions in almost 75 percent of patients with SJS.

The various lesions (Table 246-1) develop in successive crops during a 2- to 4-week period, and crops heal over 5 to 7 days. Scarring is rarely a problem except in cases of secondary infection or in heavily pigmented patients in whom hypopigmentation or hyperpigmentation may occur. Recurrence may be noted on repeat exposure to the etiologic agent, a special concern in cases associated with HSV infection or medication use.³ The rate of EM recurrence is very high in children with HSV infection. For example, 75 percent of children with a history of HSV-related EM experienced EM recurrence after HSV reactivation.³ Fluid and electrolyte disorders and secondary infection from cutaneous sites represent the most frequent complications and the most common causes of death in the EM patient. The differential diagnosis of EM includes herpetic (herpes simplex virus and varicella zoster virus) infection, vasculitis, TEN, various primary blistering disorders (pemphigus and pemphigoid), urticaria, Kawasaki disease, and the toxic and infectious erythemas.

Outpatient treatment of EM minor with topical corticosteroids is possible, but steroids should not be applied to eroded areas of the skin. Dermatologic consultation may be required; close follow-up with the primary care doctor is advised. Those patients with extensive disease, systemic toxicity, and/or mucous membrane involvement require hospitalization, optimally in the intensive care or burn unit setting.

Systemic steroids are commonly used and provide symptomatic relief, but are of unproven benefit in influencing the duration and outcome of EM.⁴ Many authorities recommend a short, intensive steroid course of prednisone, 60 to 80 mg per d PO in divided doses, particularly in drug-related cases, with abrupt cessation in 3 to 5 days if no favorable response is noted. Systemic analgesic agents and antihistamines provide symptomatic relief. Stomatitis is treated with diphenhydramine and viscous lidocaine mouth rinses. Caution is advised with oral lidocaine due to its remarkable efficacy and related neurotoxicity if excessively applied. Blisters are treated with cool, wet Burow's solution (5% aluminum acetate) compresses. Ocular involvement should be monitored by an ophthalmologist; unfortunately, burst steroid therapy does not appear to reduce the chance of development or significance of existing ocular lesions. Acyclovir may reduce recurrence of HSV infection and, therefore, lessen the potential for another bout of EM; prolonged, prophylactic acyclovir therapy may reduce the chance of recurrent EM related to HSV.⁵ Erythema multiforme, in particular SJS, has significant morbidity and a mortality of approximately 10 percent despite aggressive therapy.

SERIOUS GENERALIZED SKIN DISORDERS William J. Brady Andrew D. Perron Daniel J. DeBehnke

This chapter describes selected serious generalized skin disorders in adults and discusses their dermatologic diagnosis and treatment. Discussed are erythema multiforme, toxic epidermal necrolysis (TEN), the toxic infectious erythemas, disseminated viral infections, Rocky Mountain spotted fever (RMSF), meningococcemia, purpura fulminans, and the systemic bullous diseases.

ERYTHEMA MULTIFORME

Erythema multiforme (EM) is an acute inflammatory skin disease presenting across a spectrum. It ranges from a localized papular eruption of the skin (EM minor) to a severe, multisystem illness (EM major) with widespread vesiculobullous lesions and erosions of the mucous membranes, known as Stevens-Johnson syndrome (SJS). The disorder strikes all age groups, with the highest incidence in young adults (age range 20 to 40 years), affects males twice as often as females, and occurs commonly in the spring and fall. Infection, especially mycoplasma and herpes simplex virus (HSV), drugs, especially antibiotics and anticonvulsants, and malignancies are common precipitating factors. However, there is no identifiable etiology in approximately 50 percent of cases.¹

FIG. 246-1. A. (PLATE 10). Erythema multiforme. Symmetrical, plaque-like lesions involve the flexor surface of the upper extremities; these lesions may be misdiagnosed as the immunoglobulin G-mediated urticarial allergic reaction. Also note the erythematous macules on the palms. **B. (PLATE 11).** Iris or target lesion, a finding strongly suggestive of erythema multiforme. This iris lesion is composed of a central bullous lesion with a dusky, edematous center and an erythematous halo. (Reprinted with permission from Brady W, DeBehnke D, Crosby D: Dermatologic emergencies. *Am J Emerg Med* 12:217, 1994.)

TOXIC EPIDERMAL NECROLYSIS

Toxic epidermal necrolysis is an explosive dermatosis characterized by tender erythema, bullae formation, and subsequent exfoliation. Pa-

TABLE 246-1 Lesions of Erythema Multiforme

tients may be systemically ill on presentation. Many authorities consider the SJS variant of EM and TEN as the same process.² Toxic epidermal necrolysis is found in all age groups without predilection to sex. The syndrome has multiple possible etiologies, with medications representing the most common cause.¹⁻²⁻⁵ Sulfa and penicillin antibiotics, anticonvulsants, and oxicam nonsteroidal anti-inflammatory drugs are the most frequent drug triggers for TEN.^{6,7} Other causes include malignancy and human immunodeficiency virus.⁵ In many cases, an etiology is not found.

The pathogenesis is poorly understood and may be partly an immunologic and partly a genetic predisposition. The tendency to develop TEN may be linked to a highly specific genetic defect in the detoxification of the culprit drug or its reactive metabolites.⁸ Human lymphocyte antigen typing also has suggested a possible genetic predisposition.

Patients with TEN often present with a 1- to 2-week prodrome of malaise, anorexia, arthralgias, fever, or upper respiratory infection symptoms. Skin tenderness, pruritus, tingling, or burning may be found at this time. Skin signs (Table 246-2) begin with a warm erythema, initially involving only the eyes, nose, mouth, and genitalia, but later becoming generalized. The erythematous areas become tender and confluent within hours. Flaccid, ill-defined bullae then appear within the areas of erythema. Lateral pressure with a finger on normal skin adjacent to a bullous lesion dislodges the epidermis, producing denuded dermis and demonstrating Nikolsky sign. The bullae form along the cleavage plane between the epidermis and the dermis. The epidermis is then shed in large sheets, leaving raw, denuded areas of exposed dermis. The average time of onset after exposure to the inciting agent is 2 weeks. Cutaneous extension follows an unpredictable time course, ranging from 24 h to 15 days, with a minority of severe cases demonstrating rapid, extensive involvement within 24 h.

Perilabial blistering and erosive lesions are disfiguring and often impair adequate oral intake, contributing to hypovolemia. Ocular complications include purulent conjunctivitis, painful erosions, and potential blindness. Anogenital lesions are common. Additional mucous membrane involvement includes the gastrointestinal, urinary, and respiratory tracts. The two major complications and leading causes of death in TEN are infection and hypovolemia with electrolyte disorders. A broad range of pathogens is usually found, with staphylococcal and pseudomonal species predominating. The mortality rate has been reported as being between 25 and 30 percent. These clinical variables are associated with poor prognosis: advanced age, extensive disease, idiopathic nature, multiple medication use, steroid therapy, azotemia, hyperglycemia, leukopenia, and thrombocytopenia.⁶ The differential diagnosis of TEN includes staphylococcal scalded skin syndrome (SSSS), EM, toxic shock syndrome (TSS; staphylococcal and streptococcal), exfoliative drug reactions, primary blistering disorders (pemphigus and pemphigoid), and Kawasaki syndrome.

TABLE 246-2 Lesions of Toxic Epidermal Necrolysis

Warm, tender erythroderma
Vesicle
Bulk
Vesiculobullous
Exfoliation
Mucous membrane involvement

Management of TEN requires hospitalization in a critical care setting or, optimally, a burn unit.⁶ In most cases, therapy is similar to the approach for the burn patient. Immediate concerns center on the airway, because sloughing of airway and respiratory epithelium can occur. Hypovolemia and electrolyte abnormalities should be corrected. Prompt, aggressive antibiotic administration is necessary in suspected or documented infection; initial prophylactic antibiotics are not recommended by most. The advice of the burn center should be followed for any topical dressings that are applied before transfer.

EXFOLIATIVE DERMATITIS

Exfoliative dermatitis, a cutaneous reaction produced in response to a drug or a chemical agent or to an underlying systemic or cutaneous disease, is a condition in which most or all of the skin surface is involved with a scaly erythematous dermatitis. Males are affected twice as often as females, and most patients are older than 40 years. The mechanisms responsible are not known, although drug-induced exfoliative dermatitis may be mediated by an increased activity of sensitizer suppressor or cytotoxic T lymphocytes.

Exfoliative dermatitis can have an abrupt onset, particularly when related to a drug, contact allergen, or malignancy, whereas exacerbations related to an underlying cutaneous disorder usually evolve more slowly. In many cases, exfoliative dermatitis tends to be a chronic condition, with a mean duration of 5 years, when related to a chronic illness; a shorter course often follows suppression of the underlying dermatosis, discontinuation of causative drugs, or avoidance of allergen. Idiopathic and chronic disease-related exfoliative dermatitis can continue for 20 or more years; death is rare.

Generalized erythema and warmth are noted, similar to TEN, but skin tenderness is usually lacking. Erythema is accompanied by scaling or flaking, and the patient often complains of pruritus and skin tightness (Figure 246-2, **Plate 12**). The process usually begins on the face and upper trunk with progression to other skin surfaces. The patient usually has a low-grade fever. Excessive heat loss and hypothermia can complicate erythroderma. Widespread cutaneous vasodilation may result in high-output congestive heart failure. The disruption of the epidermis results in increased transepidermal water loss, and continued exfoliation can result in significant protein loss and negative nitrogen balance. Chronic inflammatory exfoliation produces many changes, such as dystrophic nails, thinning scalp and body hair, and patchy or diffuse pigmentation changes.

The differential diagnosis of exfoliative dermatitis includes SSSS, EM, TEN, TSS (staphylococcal and streptococcal), and Kawasaki disease. Considerable effort must be made to determine the underlying etiology, including evaluation for underlying malignancy, and biopsy

FIG. 246-2. (PLATE 12). Exfoliative dermatitis demonstrated by generalized, warm erythema accompanied by scaling or flaking.

of involved skin. Patients generally require emergent dermatologic consultation and admission. Hypothermia and hypovolemia should be corrected, and systemic corticosteroids are often given after consultation.

TOXIC INFECTIOUS ERYTHEMAS

A number of infectious syndromes caused by toxigenic bacteria with toxin-mediated dermatologic manifestations have been described, including TSS, streptococcal toxic shock syndrome (STSS), SSSS, bullous impetigo, and scarlet fever. In certain cases, the bacteria are colonizers with the disease resulting only from the toxin (e.g., TSS); in other instances, the toxigenic organism produces infection with clinical manifestations developing from the infectious process and the presence of the toxin (e.g., STSS, SSSS, bullous impetigo, and scarlet fever).

Toxic Shock Syndrome

The general features and management of TSS are discussed in Chap. 142, and the dermatologic features are discussed below. The dermatologic hallmark of TSS is nonpruritic, blanching macular erythroderma, a characteristic feature and a major criterion for the diagnosis (Figure 246-3, **Plate 13**). The erythroderma is usually diffuse, although it may be confined to the extremities or trunk and may resemble sunburn. The rash may be subtle and is often missed in heavily pigmented patients or when the patient is examined in a poorly illuminated room. Erythroderma may resolve in 3 to 5 days, and a fine desquamation of the hands and feet follows in 5 to 14 days. Other dermatologic manifestations include conjunctival and mucosal hyperemia, petechiae, alopecia, and fingernail loss. Refer to Table 142-1 for the case definition of TSS. The differential diagnosis is broad and includes scarlet fever, RMSF, leptospirosis, rubeola, meningococcemia, STSS, SSSS, Kawasaki syndrome, TEN, SJS, gram-negative sepsis, and exfoliative drug eruptions.

Streptococcal Toxic Shock Syndrome

Streptococcal TSS is an uncommon clinical syndrome that involves multiple organ systems with fever, hypotension, and skin findings.¹⁰ The causative agent of this clinical disorder is *Streptococcus pyogenes* (group A *Streptococcus*). Streptococcal species produce extracellular

FIG. 246-3. (PLATE 13). Blanching, nonpruritic erythroderma with a "rough" texture in a patient with toxic shock syndrome. (Reprinted with permission from Brady W, DeBehnke D, Crosby D: Dermatologic emergencies. *Am J Emerg Med* 12:217, 1994.)

proteins called *streptococcal pyrogenic exotoxins*. Invasive soft tissue streptococcal infection, such as cellulitis, myositis, or fasciitis, is a common factor in the etiology of STSS.

The clinical presentation of STSS includes fever, hypotension, skin edema, and erythema, or bullae (Figure 246-4, **Plate 14**). Subsequent desquamation occurs less commonly than during staphylococcal TSS. The same major and minor criteria used for the diagnosis of staphylococcal TSS can be helpful in identifying patients with STSS. According to a consensus document,¹¹ clinical features must include isolation of group A streptococci (*S. pyogenes*) and hypoperfusion and evidence of multisystem dysfunction. Because up to 75 percent of cases of STSS have associated soft tissue infection, a thorough skin examination for the site of infection is warranted. Palpate muscle groups for tenderness, indicating possible myositis or fasciitis, and evaluate for secondary compartment syndrome. Treatment is oxygenation and fluid resuscitation. Because soft tissue infection plays a large role in STSS, aggressive management of infection is essential. The site of infection should be identified, incised, and drained, and nonviable tissue should be debrided. Parenteral nafcillin, oxacillin, or vancomycin or a first-generation cephalosporin are often given as initial therapy.

Staphylococcal Scalded Skin Syndrome

Staphylococcal scalded skin syndrome develops in patients with clinically inapparent staphylococcal infections caused by an exotoxin produced by *Staphylococcus aureus*. It occurs primarily in infants and young children and in immunosuppressed adults or those with renal insufficiency. The exotoxins involved, collectively known as *exfoliatin*, are elaborated by the bacteria, released into the circulation, and cause acantholysis and intraepidermal cleavage of the skin.¹²

An episode of SSSS frequently begins as a clinically inapparent staphylococcal infection of the conjunctiva, nasopharynx, or umbilicus. The disease course can be divided into three phases: initial (erythroderma), exfoliative, and desquamation (recovery). Initially, the patient (or parent) notes the sudden appearance of a tender erythroderma, usually diffuse, although localized disease has been described. The involved skin may have a sandpaper texture. Tender erythema is prominent in the perioral, periorbital, and groin regions and in the skin creases of the neck, axilla, popliteal, and antecubital areas. The mucous membranes are spared. The exfoliative stage begins on the second day of the illness. The erythematous skin wrinkles and peels off at sites of minor trauma or with minimal lateral pressure with the examiner's fingertip, illustrating the positive Nikolsky sign (also found in TEN). Large, flaccid, fluid-filled bullae and vesicles then appear. These lesions easily rupture and are shed in large sheets; the underlying tissue resembles scalded skin and rapidly desiccates. After 3 to

5 days of illness, the involved skin desquamates, leaving normal skin in 7 to 10 days. The differential diagnosis for SSSS includes TEN, TSS, exfoliative drug eruptions, and localized bullous impetigo.

Management includes fluid resuscitation, correction of electrolyte abnormalities, and identification and treatment of the source of the toxigenic staphylococcus with oxacillin or vancomycin. Corticosteroids are not recommended.

DISSEMINATED VIRAL INFECTIONS

Infectious Exanthems

Many viral infections are associated with generalized morbilliform cutaneous eruptions. The list is exhaustive but most commonly include adenoviruses, cytomegalovirus, coxsackie and echoviruses, Epstein-Barr virus, hepatitis B virus, human herpesvirus 6, paramyxovirus, respiratory syncytial virus, rotaviruses, rubella virus, and human immunodeficiency virus. Other agents associated with generalized eruptions include mycoplasma, *Borrelia* spp., *Legionella*, *Leptospira*, *Listeria*, meningococci, rickettsiae, and *Treponema pallidum*. Erythematous macules and papules or, less often, vesicles and petechiae usually develop centrally, sparing the palms and soles. Diagnosis and differential diagnosis are based on history and physical examination. Drug eruption should always be considered in the differential. Skin lesions usually resolve in 7 to 10 days and are treated symptomatically.

Herpes Zoster

Varicella zoster infections, also referred to as *shingles* or *zoster*, represent reactivation of the previously dormant virus, *Herpesvirus varicellae*, in a patient with an altered immune response. At reactivation, the virus travels down specific sensory nerves to the skin, resulting in skin manifestations of shingles. Patients with lymphoma, leukemia, or diabetes mellitus and who are immunocompromised are at risk for reactivated or disseminated infection.

The rash of herpes zoster consists of clusters of vesicles and papules grouped on an erythematous base (Table 246-3). Vesicles initially appear clear but become cloudy or purulent over several days. They eventually rupture and crust over. The lesions usually appear along an individual dermatome (Figure 246-5, **Plate 15**); less often, adjacent dermatomes are involved. The lesion clusters are usually discrete and separated by normal skin; in the severe case, the cluster may become confluent along the dermatome. Approximately 60 percent of all zoster infections involve the trunk, followed by the head, extremity, and perineal regions in decreasing incidence.¹³ Unilateral involvement that abruptly halts at the midline is helpful in correctly identifying the rash; occasionally, a few lesions appear immediately beyond the midline. Involvement of the nose should prompt evaluation for corneal involvement (Figure 246-6, **Plate 16**).

Approximately one-half of cases with varicella zoster infection, in particular those patients with acquired immunodeficiency syndrome (AIDS) or reticuloendothelial malignancy, experience viremia and may exhibit solitary lesions, usually fewer than 30 scattered across the body. Patients with AIDS, using immunosuppressive medications, or with active reticuloendothelial malignancy more often demonstrate true dissemination in which widespread vesicular lesions are distrib-

uted evenly across the trunk, extremities, and head. In fact, patients with Hodgkin disease are particularly prone to dissemination, with 15 to 50 percent of cases demonstrating involvement of the skin, lungs, and central nervous system. Patients with disseminated herpes zoster infection require admission and treatment with parenteral antiviral therapy.

Herpes Simplex and Eczema Herpeticum

The vast majority of HSV type 1 or type 2 infections involve only localized areas of skin or mucous membranes. In neonates and in adults with atopic dermatitis, malignancy, immunosuppression, and AIDS, the HSV infection may disseminate, resulting in widespread vesicles, pustules, and ulcerations and causing multisystem involvement. The neonate may acquire the infection in utero due to maternal infection during pregnancy or during delivery. Adults undergoing chemotherapy or transplant recipients who are HSV seropositive may reactivate HSV and develop disseminated disease. Patients with atopic dermatitis are also at risk of disseminated disease, which is called *eczema*

The vesicular rash, initially present in some form in up to 70 percent of patients, ranges from the scattered vesicle to full-body distribution. Lesions are vesicular, of similar size, 2 to 3 mm in diameter, clustered together in groups, and arrayed on an erythematous base (Figure 246-7, **Plate 17**). The lesions frequently umbilicate. Occasionally, the disseminated forms of HSV present cutaneously with different lesion morphology and appearance. Rather than grouped, the lesions may occur singly with a widespread distribution; the lesions also may appear as pustules with purulent blister fluid. Bacterial superinfection is common. Regardless of their initial appearance, the lesions will ulcerate with crusting. A Tzanck preparation, in which fluid from an intact vesicle is applied to a microscope slide and stained with Wright or Giemsa stain, often demonstrates multinucleated giant cells.

If necessary, cultures of vesicle fluid can be obtained for confirmatory diagnosis. The patient's course may be complicated soon after by multiorgan failure. Treatment is admission to a critical care unit with parenteral antiviral therapy and antibiotics for bacterial superinfection.

Eczema herpeticum is an association of two common conditions, atopic dermatitis and HSV infection. The most severe forms of eczema herpeticum tend to occur in the young infant and the immunocompromised adult patient. Lesions appear initially in the area of the preexisting dermatitis but eventually may disseminate. The underlying atopic dermatitis and bacterial superinfection may alter lesion appearance. Dermatologic consultation is usually necessary to aid in disposition decisions. Selected cases of local eczema herpeticum can be managed in the outpatient setting with oral acyclovir and antibiotics. More severe or disseminated cases require admission.

DISSEMINATED GONOCOCCAL INFECTION

About 2 percent of patients with mucosal genitourinary infection will develop disseminated gonococcal infection (DGI). Risk factors for dissemination are not well known, but asymptomatic local disease and active menses seem to be associated in some way. Up to 75 percent of patients with DGI were diagnosed in late pregnancy, the immediate postpartum period, or within 1 week of the onset of menses. Disseminated disease, once common in women, is noted currently to occur with increased frequency in men. Disease manifestations result from organism and immune complex dissemination. Fever, arthralgias, and multiple papular, vesicular, or pustular skin lesions characterize gonococemia. The rash develops on the extensor surfaces of the wrists, palms, and hands and the dorsal aspects of the ankles and feet. The lesions, usually numbering fewer than 10 to 20, initially appear as small red papules or maculopapules (Figure 246-8, **Plate 18**) with a petechial component and an erythematous periphery. Lesions resolve rapidly or evolve into vesicles with purulent fluid, which develop gray

FIG. 246-7. (PLATE 17). Disseminated herpes simplex virus infection in an immunocompromised adult patient; note the widespread distribution of vesicular lesions on an erythematous base.

necrotic centers. The necrotic center is theorized to be the embolic focus of the gonococcal organism. Ultimately, the lesions become hemorrhagic.

The differential diagnosis includes other petechial syndromes, including RMSF, meningococcemia, staphylococcal acute endocarditis, vasculitides (in particular Henoch-Schonlein purpura and leukocytoclastic vasculitis), enteroviral infections, bacterial sepsis (gram-positive and gram-negative) with disseminated intravascular coagulation, and typhus. The distribution of the rash is similar to that encountered in the RJVISF patient, initially seen on the wrists and ankles. The number of lesions in the DGI arthritis-dermatitis patient, however, is markedly smaller compared with the total lesion count in cases of RMSF and meningococcemia. Further, the rash of DGI is pustular rather than obviously petechial and hemorrhagic, as are the lesions of RMSF and meningococcemia. Moreover, the DGI patient usually does not demonstrate systemic toxicity, as commonly seen in patients with RMSF or meningococcemia. Reiter syndrome may be confused with the gonococcal arthritis-dermatitis syndrome. Patients with Reiter syndrome present with urethritis, conjunctivitis, arthritis, and a psoriasis-like cutaneous eruption; patients with Reiter syndrome do not demonstrate petechiae, macules, papules, or maculopapules.

The diagnosis of DGI is made in the sexually active patient with complaints of tenosynovitis, arthralgias, and the appropriate dermatologic

FIG. 246-8. (PLATE 18). Disseminated gonococcal infection in a sexually active adult female. The maculopapule has a petechial component and an erythematous periphery on the extensor surface of the wrist.

logic findings. Gram stain of fluid from unroofed lesions may demonstrate *Neisseria gonorrhoeae*. Blood cultures may be positive with an increased yield in the early phase of illness with active bacteremia, and urethral or cervical specimens can be obtained for culture or gonococcal antigen. Cultures of the various mucosal surfaces (i.e., cervical and vaginal) are frequently sterile in the patient with disseminated disease states. Antimicrobial agents of choice include ceftriaxone and ciprofloxacin; spectinomycin may be used in patients with intolerance to the initial treatment choices. Treatment regimens include ceftriaxone 1 g IV daily for seven doses or parenteral ciprofloxacin over a similar duration.

ROCKY MOUNTAIN SPOTTED FEVER

Rocky Mountain spotted fever, a potentially fatal multisystem illness caused by *Rickettsia rickettsii*, is introduced to humans via the tick vector. Without adequate, timely management, the mortality rate increases to 50 percent. After introduction of the organism to body tissues, it disseminates through the blood stream and invades vascular endothelium, causing a necrotizing vasculitis. Constitutional symptoms of fever, headache, and myalgias develop about 1 week after exposure. The rash in classic RMSF is evident 4 days (range, 1 to 15 days) after the onset of fever and other symptoms. In a minority of patients, usually the adult, the rash is not noted during the entire disease course. This entity, Rocky Mountain "spotless" fever, occurs in approximately 15 percent of cases.

The rash first appears on the wrists and ankles and rapidly spreads to the palms and soles (Figure 246-9, **Plate 19**). As the rash moves centrally, the proximal extremities, trunk, and face are involved. The skin lesions at onset are described as discrete macules or maculopapules that blanch with pressure. The initial lesions evolve into petechiae over 2 to 4 days, fade slowly over 2 to 3 weeks, and heal occasionally with resultant hyperpigmentation. Rarely, the petechiae may coalesce into ecchymotic areas with eventual gangrene of the distal extremities, nose, ear lobes, scrotum, and vulva—purpura fulminans. For further discussion of the treatment of this and other tick-borne diseases, see Chap. 151.

MENINGOCOCCEMIA

Meningococcemia is a potentially fatal infectious illness caused by the gram-negative diplococcus *Neisseria meningitidis*. Meningococcal disease presents across a wide clinical spectrum in the acute and chronic forms. The acute entities include pharyngitis, meningitis, and bacteremia. Meningococci are present in the nasopharynx of 2 to

FIG. 246-9. (PLATE 19). A patient with Rocky Mountain spotted fever with petechiae on the ankles.

20 percent of the general population (the carrier state); during epidemics, the organism is found in up to 30 percent of people without evidence of active disease.

The illness usually strikes patients younger than 20 years, with the vast majority of cases occurring in children and infants younger than 5 years. Epidemic outbreaks occur when a particularly virulent strain of the organism is introduced into a closed, confined population. The highest rates of infection are reported in the winter and spring months, although sporadic cases appear throughout the year. The organism is transmitted through aerosolized droplets of respiratory secretions from asymptomatic carriers and less frequently from actively infected patients. The mortality rate ranges from 5 to 28 percent, although most patients treated appropriately early in the disease course recover. Patients with acute meningococcal infection who exhibit signs of circulatory insufficiency, a peripheral white blood cell count of fewer than 10,000 cells/xL, or a coagulopathy have a high probability of developing organ system failure followed by death.¹⁴

After exposure to the organism, clinical infection develops usually within 3 to 4 days (range, 2 to 10 days) and progresses rapidly to severe illness. The patient may complain of severe headache, sudden fever, altered mental status, nausea, vomiting, myalgias, arthralgia, and a stiff neck. A rash is frequently noted on presentation and is an invaluable clue to the correct diagnosis early in the disease course. The dermatologic manifestations include petechia, urticaria, hemorrhagic vesicles, macules, and/or maculopapules (Figure 246-10, **Plate 20**). The classic petechial lesions are found on the extremities and trunk but also are noted on the palms, soles, head, and mucous membranes. The petechiae evolve into palpable purpura with gray necrotic centers, a pathognomic finding for meningococcal infection. The skin findings result from the organism's invasion and destruction of the endothelium. Histopathologic analysis shows an infectious vasculitis.

Fulminant meningococcal disease is found in fewer than 5 percent of patients and presents with sudden prostration, petechiae with areas of ecchymosis, and distributive shock. This rapidly progressive version of meningococcemia is complicated by purpura fulminans, a severe form of disseminated intravascular coagulation. Large ecchymotic areas (usually the extremities, acral portions of the face, and genitalia) become necrotic or gangrenous.¹⁴

The diagnosis of acute meningococcal disease relies on recognition of an ill-appearing patient with an associated petechial rash and the nonspecific symptoms of fever, headache, altered sensorium, and body aches. Additional historical points, physical findings, and laboratory results supportive of the diagnosis include known exposure to active disease, rapid progression of nonspecific symptoms with the associated petechial rash, Gram stain of skin lesions or cerebral spinal fluid demonstrating gram-negative intracellular diplococci, and latex

FIG. 246-10. (PLATE 20). Early findings of meningococcemia with petechiae evolving into purpuric lesions. (Reprinted with permission from Brady W, DeBehnke D, Crosby D: *Dermatologic emergencies. AmJEmergMed* 12:217, 1994.)

agglutination of the cerebrospinal fluid. The differential diagnosis includes RMSF, TSS, acute gonococcemia, bacterial endocarditis, vasculitis (Henoch-Schonlein purpura or leukocytoclastic vasculitis), enteroviral infections, and bacterial sepsis (gram-positive and gram-negative) with disseminated intravascular coagulation.

Antibiotics must be given as soon as possible in a patient suspected of acute disease. In adults, an appropriate agent is ceftriaxone; due to the increased prevalence of cephalosporin-resistant pneumococcus, parenteral vancomycin also is given, often empirically.

PURPURA FULMINANS

Purpura fulminans is a rare vascular disorder characterized by fever, shock, multiorgan failure, and the rapid development of hemorrhagic skin necrosis. It is associated with dermal vascular thrombosis resulting from vascular collapse and disseminated intravascular coagulation. Purpura fulminans can result from hereditary or acquired protein C deficiency, activated protein C resistance, or protein S deficiency. It may also result from any condition that causes disseminated intravascular coagulation.

Purpura fulminans presents with the dermatologic triad of widespread ecchymoses, hemorrhagic bullae (Figure 246-11, **Plate 21**), and epidermal necrosis. Commonly, cyanosis with initial ecchymoses and ultimate necrosis of the tip of the nose, ears, and genitalia frequently occur; in general, distal tissue areas with end circulation are affected. Large confluent ecchymoses can develop, often on the extremities, from distal to proximal, and on the perineum, buttocks, and abdomen. The extremities are often involved symmetrically. Treatment is directed at the underlying cause.

BULLOUS DISEASES (PEMPHIGUS VULGARIS AND BULLOUS PEMPFIGOID)

Pemphigus vulgaris (PV) is a generalized, mucocutaneous, autoimmune, blistering eruption with a grave prognosis characterized by intraepidermal acantholytic blistering. Bullous pemphigoid (BP) is a generalized mucocutaneous blistering disease of the elderly, with an average age of 70 years at the time of initial diagnosis. Although the blisters are deeper in the skin than in PV (below the epidermal basement membrane), the prognosis of BP is better with less associated comorbidity and a significantly more rapid response to therapy. Refer to Table 246-4 for a listing of the skin lesions seen in these bullous diseases.

The primary lesions of PV are vesicles or bullae (Figure 246-12, Plate 22) that vary in diameter from less than 1 cm to several centimeters; they commonly first affect the head, trunk, and mucous membranes. The blisters are usually clear and tense, originating from normal skin or atop an erythematous or urticarial plaque. Within two to three days, the bullae become turbid and flaccid. Rupture soon follows, producing painful, denuded areas. These erosions are slow to heal and prone to secondary infection. Nikolsky sign is invariably positive in PV and absent in other autoimmune blistering diseases. Mucous membranes are affected in 95 percent of PV patients; in as many as 25 percent, the mucous membranes are the primary sites of involvement. Blisters on mucous membranes are more transitory than blisters on the skin in that they are more vulnerable to rupture; this is particularly true in the mouth, where ragged ulcerative lesions readily develop after inadvertent biting of the tissues.

Bullous pemphigoid is characterized by the presence of tense blisters (up to 10 cm in diameter) that arise from normal skin or from erythematous or urticarial plaques; ulceration with tissue loss follows. Sites of predilection include the intertriginous and flexural areas. Pruritus, occasionally accompanied by a burning sensation, is noted with the appearance of the blistering. Lesions of the oral cavity occur in BP, but with less consistency and severity than in PV. Because the blisters in the oral cavity rupture very easily and heal without scarring, involvement in the mouth is often overlooked. Oral involvement may occur in as many as 40 percent of patients. It is unusual for oral mucosal lesions to precede the cutaneous eruption, as in PV.

The differential diagnosis of PV and BP includes the vesiculobullous diseases; dermatologic consultation is required for diagnosis.

Limited oral intake and accelerated protein, fluid, and electrolyte losses through the involved skin can rapidly lead to hypoalbuminemia, with significant hypovolemia and electrolyte disturbances in PV and BP; therefore, dermatologic consultation is advised for treatment and disposition.

DISORDERS OF THE FACE AND SCALP Dean Morrell Lisa May

The list of cutaneous disorders affecting the face and scalp is quite long. This chapter focuses on those disorders that are more specific to this distribution and likely to be encountered in an acute care setting.

ACNEIFORM ERUPTIONS

Although acne vulgaris is a common chronic problem that likely would not be encountered as a chief complaint in the ED setting, several acneiform eruptions may develop with alarming clinical presentations, prompting a patient to seek immediate attention. As these disorders are uncommon and require a dermatologic consultation, they are discussed only briefly. These disorders include acne fulminans, pyoderma faciale, dissecting cellulitis of the scalp, and acne keloidalis.

Acne fulminans is a severe form of cystic acne with ulcerating cysts. It most commonly affects the chest and back of young males. Severe scarring may result. It may have systemic associations including fever, myalgias, arthralgias, malaise, and anorexia. Treatment includes systemic corticosteroids and isotretinoin (Accutane). As isotretinoin has potentially severe side effects, including devastating teratogenicity in women who become pregnant while on this medication, it should be administered only by those familiar with the use of isotretinoin and able to follow the patient during the entire course of therapy.

Pyoderma faciale is an inflammatory cystic acneiform eruption on the central face of young women. Comedones are absent. Scarring is likely to result and thus treatment should be instituted rapidly. Treatment consists of systemic corticosteroids and isotretinoin. Again, a dermatology consultation is recommended.

Dissecting cellulitis of the scalp is an inflammatory and scarring disease of the scalp and neck. It is most commonly seen in young African American males. Clinically, the disease begins with boggy tender nodules on the scalp and neck. The nodules suppurate and develop sinus tracts. Hair loss develops over these nodules, and with time, a permanent scarring alopecia results. The etiology is unknown. It may be seen in association with acne conglobata and hidradenitis suppurativa, where together these three diseases are referred to as the follicular occlusion triad. Treatment is difficult and often unsuccessful. Therapy includes topical and systemic antibiotics; topical, intralesional, or oral corticosteroids; isotretinoin; and excision. Therapy is best managed by a dermatologist.

Acne keloidalis is a perifollicular inflammatory process of the scalp resulting in hypertrophic and keloid scarring. The exact etiology is unknown. It is most common in African Americans, and it is more common in males than females. The primary lesions are follicular-based papules and pustules on the occipital scalp. The individual keloidal papules enlarge and coalesce to form keloidal plaques with an associated scarring alopecia. Treatment includes topical antibiotics such as clindamycin solution (Cleocin-T solution), topical corticosteroids such as fluocinonide (Lidex) solution, and oral antibiotics such as tetracycline. Repeated intralesional corticosteroids may help relieve pruritus and pain, and soften keloidal plaques. Surgical excision and laser excision are often unsatisfactory.

SEBORRHEIC DERMATITIS

Because seborrheic dermatitis is such a common disorder, its recognition and management are important in any clinical setting, including the ED. Although the exact etiology is unclear, the yeast, *Pityrosporum ovale*, may play a role in the pathogenesis of this disease.

Clinical Features

Clinically, one sees erythema and waxy scale in the skin folds and hair-bearing areas of the face, scalp, chest, and groin. Common sites of involvement include the scalp, the pinna of the ear, the posterior auricular sulcus, the eyebrows, and the alar grooves of the nose. Itching is quite variable but usually mild. Any age may be affected, but the elderly and debilitated are more likely to have extensive involvement. In newborns, seborrheic dermatitis is often referred to as cradle cap. Ex-

tensive seborrheic dermatitis that is poorly responsive to treatment may be seen in association with HIV

Diagnosis

Diagnosis is based on clinical examination. A skin biopsy is rarely necessary. The differential diagnosis includes tinea capitis, psoriasis of the scalp, rosacea, and cutaneous lupus erythematosus. Seborrheic dermatitis is diffuse and rarely associated with hair loss; thus, if hair loss is present or the eruption is focal, fungal cultures should be obtained to exclude tinea capitis. As seborrheic dermatitis is uncommon between infancy and puberty, tinea capitis should always be excluded in this age group. Rosacea and seborrheic dermatitis may overlap, but if the predominant features are inflammatory papules and pustules, the patient should be treated for rosacea.

Treatment

Therapy is aimed at controlling the disease; treatment is not curative. Initial treatment should consist of an antidandruff shampoo containing zinc pyrithione (Head and Shoulders), selenium sulfide (Selsun Blue), salicylic acid (Neutrogena T-Sal), or tar (Polytar or Neutrogena T-Gel). Nizoral shampoo can also be used and is now available over the counter. The shampoo should be lathered into the scalp and left on for 5 to 10 min before rinsing. Shampooing should be performed three times a week. A topical corticosteroid such as fluocinonide solution may be applied to the scalp in severe cases. For the face, hydrocortisone 1 or 2.5 percent applied bid should be the initial management. The use of higher-potency topical corticosteroids on the face can lead to the development of perioral dermatitis and should be avoided. Patients should treat the seborrheic dermatitis until clear, and then as needed.

ERYSIPELAS AND FACIAL CELLULITIS

Erysipelas and cellulitis are infections of the dermis and subcutis with erysipelas being more superficial than cellulitis. The distinction between the two is subtle and therapeutically irrelevant. Erysipelas is more likely to occur in the young and in the elderly.

Cellulitis may be a primary process or it may complicate another dermatosis. On the face, it may begin at a site of minor trauma that is often inapparent. Group A streptococcus is the most likely cause of erysipelas. *Haemophilus influenzae* may be a causative organism in children; although this is not as common because of the widespread use of the *H. influenzae* type b vaccine. *Staphylococcal* spp. and *Streptococcal* spp. are the most likely pathogens of cellulitis.

Clinical Features

Erysipelas and cellulitis of the face presents as a hot, bright red, tender, indurated plaque (Figure 247-1). The area of involvement is sharply demarcated and expands peripherally. They do not clear centrally. Vesicles or bullae may be present. They may be unilateral or bilateral. When unilateral, erysipelas and cellulitis need to be distinguished from early herpes zoster infection. When bilateral, they may be mistaken for the malar eruption of systemic lupus erythematosus. Fever and lymphadenopathy are often present. Periorbital cellulitis can be associated with orbital cellulitis and has the risk of developing an orbital abscess, cerebral abscess, or meningitis.

Diagnosis

Diagnosis is based on clinical presentation. A biopsy is rarely necessary and often not helpful. Needle aspiration of the leading edge for culture has a low yield. A complete blood count and blood cultures should be performed to exclude bacteremia. An imaging study and an ophthalmologic consultation should evaluate periorbital cellulitis.

FIG. 247-1. Facial cellulitis. Erythema and edema involve the cheek, nasal bridge, and the upper and lower eyelids.

Treatment

Cellulitis or erysipelas of the face warrants parenteral therapy in an inpatient setting. Unless history is suggestive of an unusual organism, therapy should be directed toward *Staphylococcal* spp. and *Streptococcal* spp. in adults. Coverage should include these organisms and *H. influenzae* in children. Again, an immediate ophthalmology consultation should be obtained if there is any question of orbital involvement.

HERPES ZOSTER INFECTION

Herpes zoster infections ("shingles") can occur anywhere on the body but most commonly involve the thoracic dermatomes. Involvement of the trigeminal nerve occurs in about 10 percent of herpes zoster infections. Involvement of the face and scalp has the most potentially serious sequelae and thus is discussed here.

Clinical Features

Herpes zoster results from reactivation of latent varicella-zoster virus (VZV). The initial eruption of varicella-zoster virus is chickenpox. Pain or dysesthesia precedes the eruption by 3 to 5 days. Erythematous papules progress to clusters of vesicles with an erythematous base. The vesicles crust in about 1 week. Generalized eruptions may occur in immunocompromised patients.

Any of three branches of the trigeminal nerve may be involved on the face. Involvement of the ophthalmic branch (VI), especially with vesicles on the tip of the nose indicative of involvement of the nasociliary branch, is of serious concern. Involvement of this area raises the possibility of developing keratitis. Therefore, an ophthalmology consult should be obtained.

The virus may spread to motor root ganglia, resulting in motor weakness or paralysis. Ramsay Hunt syndrome results from facial and auditory nerve involvement. The cutaneous eruption consists of zoster lesions in the external auditory canal (Figure 247-2) and on tympanic membrane. Bell palsy and possible deafness or vertigo may result.

Diagnosis

The differential diagnosis includes herpes simplex infections, impetigo, and contact dermatitis. A Tzanck preparation and a viral culture can confirm the diagnosis. The yield is higher when the tests are performed on early intact vesicles. A Tzanck preparation allows for visualization of multinucleated giant cells. It is useful to determine if an

FIG. 247-2. Herpes zoster infection. This example demonstrates clustered intact vesicles and crusts of the pinna and external auditory canal. Patients with this distribution are at risk of developing Ramsay Hunt syndrome with facial nerve involvement resulting in Bell palsy.

eruption is viral in origin; however it is unable to distinguish between herpes simplex and varicella-zoster viruses. Viral culture should be obtained by opening a vesicle and scraping the base of a vesicle onto a synthetic (not cotton) swab to be placed in viral culture media. Growth may take as long as 1 week.

Again, ophthalmic nerve involvement requires an ophthalmology consultation to exclude ocular complications.

Treatment

Antiviral medications are helpful if given within the first 72 h after the eruption begins. Antiviral therapy can shorten the time to healing, decrease new lesion formation, and possibly decrease the pain and duration of postherpetic neuralgia. Acyclovir (800 mg PO five times per day for 7 days), famciclovir (500 mg PO tid for 7 days), or valacyclovir (1 g PO tid for 7 days) are recommended outpatient regimens.

Symptomatic treatment includes Domeboro solution compresses, 1:40 dilution for 15 min qid, followed by Polysporin ointment or Silvadene cream. Analgesics are often necessary as well.

HERPES SIMPLEX VIRUS INFECTIONS

Clinical Features

Herpes simplex virus (HSV) type 1 most commonly occurs on the face. Initial infection occurs during childhood or adolescence and varies in its presentation. Many individuals experience mild symptoms while a few experience a debilitating eruption. Recurrences tend to be mild and occur primarily on the lips, in the nose, and in the oral cavity.

The typical lesions of HSV are painful, grouped vesicles with an erythematous base. The primary eruption may be preceded by constitutional symptoms. The characteristic primary eruption is a gingivostomatitis with herpetic lesions on the lips and in the oral cavity. It may persist for weeks. The differential diagnosis includes erythema multiforme, Coxsackie virus, varicella zoster virus, idiopathic aphthae, and, rarely, Behcet disease and pemphigus vulgaris.

Recurrent HSV is typically seen as herpes labialis ("fever blisters" or "cold sores"). The individual often experiences a prodrome of localized tingling or burning several hours before the onset of the eruption. The herpetic lesion usually occurs along the lip margin and completely heals within 10 days. Ultraviolet light, fever, or local trauma can induce these eruptions.

Diagnosis

The diagnosis is established in the same manner as that for herpes zoster with a positive Tzanck preparation and viral culture.

Treatment

Treatment for primary HSV gingivostomatitis includes symptomatic treatment, as mentioned previously for herpes zoster infections, including compresses and topical antibiotics. If mild, oral antiviral medications are not necessary; in more severe cases, use acyclovir (200 mg PO five times per day for 5 days). Immunocompromised patients with severe involvement require hospitalization for intravenous acyclovir. Treatment can continue for up to 10 days if lesions have not crusted. Recurrent HSV does not require oral antiviral therapy. Patients with recurrent disease should be instructed to avoid triggers, especially the sun, by using sunscreen and a lip balm with ultraviolet light protection.

ECZEMA HERPETICUM

In individuals with cutaneous diseases, most commonly atopic dermatitis, HSV or VZV can infect the dermatitic skin. This disorder is referred to as eczema herpeticum or Kaposi varicelliform eruption. Initially, the infection may be mistaken as an exacerbation or impetiginization of the dermatitis. Pustules and punched-out erosions develop. Constitutional symptoms and adenopathy are usually present. Dissemination of the virus is possible; mortality reports in this disorder are as high as 10 percent. Furthermore, scarring may be extensive if the viral infection is not treated early and aggressively.

An immediate dermatology consultation is warranted if this diagnosis is entertained. Depending on the extent of involvement, oral or intravenous acyclovir should be used. The underlying cutaneous disease requires aggressive treatment as well.

OTHER INFECTIOUS DISEASES OF THE FACE

In children, impetigo on the face is common, as is dermatophyte infections (tinea faciei and tinea barbae). Staphylococcal folliculitis is also seen on the face. The face and scalp are also a common site of involvement in secondary syphilis in which individuals develop "moth-eaten" alopecia, scaly or moist papules around the nose and at the angles of the mouth. Flat warts are frequently seen in males as a result of spreading the virus by shaving. Numerous molluscum contagiosum on the face of an adolescent or adult are suggestive of HIV

CUTANEOUS LUPUS ERYTHEMATOSUS

Lupus erythematosus is a connective tissue disease of uncertain etiology. It may be a systemic disease with many organ systems involved or confined exclusively to the skin. Cutaneous lupus erythematosus can be divided into three major types: acute cutaneous lupus, subacute cutaneous lupus, and chronic cutaneous lupus. All three types may occur on the face. This section focuses on the malar rash of acute cutaneous lupus and the discoid lesions of chronic cutaneous lupus erythematosus.

Acute Cutaneous Lupus Erythematosus

The classic eruption of acute cutaneous lupus is the malar or butterfly rash. In most cases, this eruption is associated with systemic disease. It usually occurs simultaneously with the onset or flare of systemic lupus erythematosus (SLE). This eruption is induced by ultraviolet radiation. The malar rash is more common in whites than in African Americans. Clinically, the malar rash consists of erythema on the medial cheeks and across the bridge of the nose. Induration, scale, or telangiectasias may be present. Occasionally, the eyelids may be involved, which makes the eruption difficult to distinguish from heliotrope rash of dermatomyositis.

Diagnosis is based on clinical examination and the presence of other systemic symptoms suggestive of SLE. This eruption is by no means specific for lupus erythematosus. The differential diagnosis includes rosacea, erysipelas, dermatomyositis, seborrheic dermatitis, medication-induced photosensitivity, polymorphous light eruption, and allergic contact dermatitis. Skin biopsy may be helpful especially if the diagnosis is in question. Initial laboratory evaluation includes a complete blood count, chemistry profile to include blood urea nitrogen (BUN) and creatinine, urinalysis with evaluation of urine sediment, antinuclear antibodies, double-stranded DNA, and complement.

If the diagnosis of SLE is likely, a rheumatology consultation should be obtained for further evaluation and management. The urgency of this consultation is dependent on the patient's systemic complaints. If other signs or symptoms of SLE are not present, the other entities in the differential diagnosis should be explored. A nonemergent consultation with a dermatologist is recommended.

Chronic Cutaneous Lupus Erythematosus

Chronic cutaneous lupus erythematosus is referred to as discoid lupus erythematosus (DLE). It is an eruption that results in scarring and pigmentary changes in the skin. DLE is most commonly seen in African Americans. Only 10 percent of patients with this type of lupus develop systemic disease.

Clinically, the lesions of DLE occur in a photodistributed area, especially on the face, ears, scalp, and neck. The lesions begin as erythematous or hyperpigmented papules or plaques that enlarge leaving central depigmentation (Figure 247-3). Follicular plugging may be visible, especially in ear lesions. On the scalp, a scarring alopecia with typical discoid lesions may occur. More extensive involvement of the trunk and extremities is more likely to be associated with systemic disease.

The lesions of DLE are quite characteristic and the diagnosis can often be made clinically. A skin biopsy is performed to confirm the diagnosis or to make a diagnosis in atypical clinical presentations. As DLE is a chronic disease and individuals suspected of having this disorder should be referred to a dermatologist for long-term management.

PHOTOSENSITIVITY

The types of reactions to ultraviolet light are varied. In many disorders, ultraviolet light aggravates, but does not cause, the disease. Examples

FIG. 247-3. Discoid lupus erythematosus. The external ear and preauricular cheek is a common site of involvement. Central depigmentation with surrounding erythema and hyperpigmentation is typical of discoid lupus erythematosus.

of this type of reaction include lupus erythematosus, porphyria cutanea tarda, dermatitis associated with niacin deficiency (pellagra), and recurrence of HSV. Other disorders are caused primarily by the sun. The most common is a sunburn reaction. Sunburn reaction, exogenously induced photosensitivity, and polymorphous light eruption are discussed here.

Sunburn

A sunburn reaction is the inflammatory response to skin injury as a result of ultraviolet radiation. It may be minimal with little discomfort to the patient, or it may be severe with extensive blistering. Individuals with fair skin, light eyes, and naturally light hair color are more susceptible to sunburns; however, even darker pigmented skin can develop skin injury with large enough ultraviolet light exposure.

The sunburn reaction begins 2 to 6 h after exposure and peaks in 1 to 3 days. Erythema and warmth in sun-exposed areas occurs. Vesiculation may result that is equivalent to a second-degree burn.

The most important part of treatment is prevention. Avoid the midday sun, apply sunscreen liberally and frequently [ultraviolet A (UVA) and B (UVB) protection with sun protection factor (SPF) 15 to 30], wear protective clothing, and seek shade. Sunburns can be treated symptomatically with nonsteroidal anti-inflammatory drugs (NSAIDs), with tepid baths, and by applying topical antibiotics to areas of vesiculation. Emollients may be soothing but will not prevent eventual exfoliation. Individuals should also be advised to avoid the sun until the eruption resolves.

Exogenous Photosensitivity Disorders

These disorders result from topical application or ingestion of an agent that causes the skin to be more sensitive to ultraviolet light. Photosensitivity disorders may be phototoxic or photoallergic. The clinical differences are subtle and do not impact on acute management.

Topical photosensitizers usually result in a cutaneous eruption at their sites of application. Ultraviolet exposure is necessary for the eruption to occur. Furocoumarins are the most common group of agents causing topical photoeruptions. Lime juice applied to the skin, fragrances, figs, celery, and parsnips are examples of furocoumarins. Other topically applied agents causing photosensitivity include *para*-aminobenzoic acid (PABA) esters, topical psoralen, musk ambrette, and salicylanilide antibacterials. The typical clinical eruption is a severe sunburn-like reaction, often with vesiculation. Often a linear appearance suggests that an externally applied substance is the culprit.

Numerous ingested substances can result in a photosensitivity eruption as well (Table 247-1). Because these agents are ingested and distributed throughout the body, the eruption involves all sun-exposed areas. The characteristic distribution of a photosensitivity eruption is the face, posterior neck, dorsal hands, and extensor arms. Certain areas including the creases of the eyelids, the upper lip, the submental anterior neck, and the posterior auricular neck are spared.

TABLE 247-1 Medications Commonly Causing Photosensitivity Eruptions

Amiodarone*
Chlorpromazine
Chloroquine/hydroxychloroquine
Furosemide
Nonsteroidal anti-inflammatory drugs (NSAIDs)
Psoralen
Sulfonamides
Sulfonyleas
Tetracyclines
Thiazides

*Amiodarone also causes a slate-gray pigmentation of the face. Pigmentation is reversible after drug discontinuation.

The diagnosis is based on identifying the offending agent. If the diagnosis is unclear, other photosensitivity disorders, such as lupus erythematosus and polymorphous light eruption, should be excluded. Photopatch testing performed by a dermatologist or allergist may be helpful in identifying the photosensitizing agent.

The causative agent should be discontinued, if possible. Initial management includes topical corticosteroids and management similar to a sunburn reaction. The patient should avoid the sun until the eruption has cleared completely.

CONTACT DERMATITIS OF THE FACE

Two types of contact allergies are likely to result on the face. The first is the result of an aerosolized allergen. The second is direct physical contact that is most prominent on the sensitive skin of the face.

Clinically, allergic contact dermatitis resulting from an aerosolized allergen presents as erythema or scale with or without vesiculation. The involvement is diffuse with upper and lower eyelids affected. This distribution is in contrast with photosensitive eruptions in which non-sun-exposed areas, such as the upper eyelids and the upper lip, are spared. Direct allergic contact dermatitis tends to be most prominent on the most sensitive skin, such as the eyelids. Examples of aerosolized contactants include rhus (poison ivy, poison oak) when the plant has been burned. Examples of common contactants affecting the face include nickel, nail polishes, toothpaste, preservatives in make-up, contact lens solutions, eyeglasses, and hair care products. Chemical-splash injuries are a common cause of facial-irritant contact dermatitis. A thorough history is necessary to uncover the offending agent. Referral to a dermatologist or allergist may be necessary if the history is unrevealing.

Avoiding the offending agent is the most crucial part of treatment. Medical treatment will be of little value if the offending agent is not removed from the patient's environment. Depending on the severity, topical or oral corticosteroids and oral antihistamines are used in medical management. Domeboro solution (aluminum sulfate and calcium acetate) compresses can be beneficial as well. Only short duration (3 to 5 days) of low to medium potency (hydrocortisone valerate 0.2%) topical corticosteroids should be used on the face. Careful application around the eyes is important because topical corticosteroid use has been implicated in causing cataracts and glaucoma. Oftentimes, extensive and severe periocular involvement requires oral prednisone.

HAIR LOSS

Hair loss can be a very alarming event leading to visits to an ED. The causes of hair loss are numerous and are typically divided into scarring and nonscarring alopecia. Nonscarring alopecia may be reversible where as scarring alopecia is rarely reversible. Table 247-2 lists the differential diagnoses for alopecia. Several of the more common types are discussed here.

Tinea Capitis

Tinea capitis is a dermatophyte infection of the scalp. It is most commonly seen in children, particularly African American children.

Clinically one sees areas of alopecia with broken-off hairs and scale at the periphery. The alopecia is patchy and usually nonscarring (Figure 247-4). Occasionally, tinea capitis is associated with an intense inflammatory response. This is manifested as a boggy, tender, indurated plaque with superficial pustules and overlying alopecia. This is referred to as a kerion, and it may result in permanent scarring and alopecia.

Diagnosis is based on a positive potassium hydroxide preparation or positive fungal culture. A potassium hydroxide preparation of the hair is necessary; scraping only the scalp rarely gives a positive potassium hydroxide examination. Culture is often necessary to establish or

TABLE 247-2 Differential Diagnosis of Alopecia

Nonscarring	Scarring
Alopecia areata	Kerion tinea capitis
Secondary syphilis	Herpes zoster infection

Trichotillomania	Folliculitis decalvans
Traction alopecia	Acne keloidalis
Contact dermatitis	Discoid lupus erythematosus
Androgenic alopecia	Lichen planopilaris
Thyroid disorders	Morphea
Telogen effluvium	Sarcoidosis
Medications	Scleroderma
Hair shaft abnormalities	Tumors (squamous cell carcinoma, basal cell carcinoma, melanoma, metastatic disease, cylindroma, lymphoma)

confirm the diagnosis. Wood light examination is becoming less helpful as the current types of dermatophytes fail to fluoresce.

The current first-line therapy is griseofulvin. Topical treatment alone is not effective. Ultramicrosized griseofulvin at doses of 15 to 20 mg/kg per d with meals is recommended. Individuals should be treated for 8 weeks, at which time the patient should be reevaluated to determine whether therapy should be continued longer. Nizoral shampoo at least three times per week is recommended, in addition to griseofulvin, in order to decrease contagiousness.

Other family members, especially children, and other close contacts, such as classmates at school or day care, also should be evaluated. Other affected members should be treated simultaneously to prevent reinfection. Follow-up is crucial and should be stressed as persistent infection may only manifest as scale and go unrecognized by caregivers. Follow-up should be with a primary care provider or a dermatologist.

FIG. 247-4. Tinea capitis. Patchy areas of hair loss with broken-off hairs and scale is characteristic of tinea capitis.

Alopecia Areata

Alopecia areata (Figure 247-5) is disease of unknown etiology that results in nonscarring alopecia. Clinically, one will lose round patches of hair, leaving behind smooth, bald skin. Inflammation or scale is not present. Any hair-bearing area may be affected, but the scalp is the most common site of involvement. Rarely, patients lose all of their scalp or body hair; these are referred to as alopecia totalis and alopecia universalis, respectively. Diagnosis is based on clinical examination. "Exclamation point" hairs may be noted at the periphery. Alopecia areata may be associated with hyperthyroidism; thus, checking a thyroid-stimulating hormone is warranted. Secondary syphilis may result in patchy alopecia described as "moth-eaten" alopecia. Often, scale is present. If secondary syphilis is suspected by history, a screening test, such as an rapid plasma reagent (RPR) or Venereal Disease Research Laboratory (VDRL), should be performed.

Localized alopecia areata usually resolves spontaneously within 12 months. Extensive disease is less likely to resolve. If the disease is extensive, rapidly progressive, or of significant cosmetic concern, the patient should be referred to a dermatologist for treatment. Multiple therapies have been reported including topical, intralesional, and, rarely, systemic corticosteroids; anthralin; contact sensitizers such as dichloronitrobenzene; and photochemotherapy. None is universally successful, and all have potential complications; thus, only those health care providers who can follow the patient long-term to monitor for potential benefit and complications should administer therapy.

Telogen Effluvium

Telogen effluvium is hair loss resulting from a major stressful event. This may include pregnancy and delivery, major surgery, major illness usually requiring hospitalization, or crash diets. The event causes hair to arrest in the telogen growth phase of the hair. Two to 3 months after the event, when new hairs are growing, the telogen hairs are shed. The patient often notices hair clogging the shower drain or numerous hairs on the pillow upon rising in the morning. The patient and the patient's family notice appreciable thinning that is sudden and often quite alarming. Diagnosis is based on diffuse hair loss in the appropriate clinical setting. A related disorder is anagen effluvium, which is secondary to systemic chemotherapeutic agents. Patients should be reassured that complete hair loss is unlikely and actually heralds new hair growth.

FIG. 247-5. Alopecia areata. This patient's hair loss results in areas of complete balding. The etiology is unknown.

248 DISORDERS OF THE HANDS, FEET, AND EXTREMITIES Dean Morrell Lisa May

Dermatologic conditions affecting the hands, feet, and extremities encompass a great majority of skin diseases. This chapter focuses on the disorders that are most likely encountered in an acute care setting. For a comprehensive review of the subject, the reader is referred to standard dermatology texts.

TINEA PEDIS AND TINEA MANUUM

Tinea pedis is a fungal infection of the feet, often referred to as athlete's foot. Tinea manuum is a dermatophyte infection of the hand. It is often unilateral and associated with tinea pedis. Tinea pedis is very common and usually begins in early adulthood. It is rare in children. Men are more often affected than women. Predisposing factors include hot, humid weather, excessive sweating, and occlusive footwear.

Pathophysiology

Dermatophyte infections result from invasion of the stratum corneum by dermatophytes. *Trichophyton rubrum*, *Trichophyton mentagrophytes*, and *Epidermophyton floccosum* are the most common organisms causing tinea pedis/manuum. *T. mentagrophytes* is most likely to cause inflammatory bullous tinea pedis. Dermatophyte infections are transmitted from person-to-person or from animal-to-person via fomites or direct contact.

Clinical Features

There are three main types of tinea pedis. The most common type of tinea pedis is the interdigital type. This type manifests as maceration and scale in the web spaces between the toes. Ulceration may even be present in severe cases with secondary bacterial and candidal infection (Figure 248-1).

The second type, which is also seen in tinea manuum, presents as chronic, dry scales with little, if any, inflammation on the palmar or plantar surfaces. It often extends to the medial and lateral aspects of the feet but not the dorsal surface. When present on the feet in this distribution, it is often described as a moccasin distribution. Polycyclic or annular patterns may be seen. Maceration between the toes is com-

mon. Onychomycosis may be present with numerous, but usually not all, nails having onycholysis (separation of the nail from the nail bed), and thick subungual debris. Oftentimes, if one hand is involved, both feet are involved as well. It is unclear why the other hand is spared in this "two foot, one hand" type of fungal infection (Figure 248-2).

The third type of fungal infection presents as an acute, painful, pruritic vesicular eruption on the palms or soles. Erythema is a prominent feature. Toenails and web spaces are usually not involved.

Diagnosis

Diagnosis is based on clinical examination and identification of fungal elements on a potassium hydroxide preparation or with fungal culture. Involvement between the toes and dystrophic toenails support the diagnosis of a fungal infection. However, psoriasis, and even chronic hand and foot dermatitis, can involve the web spaces and can cause dystrophic nails.

Although a potassium hydroxide (KOH) examination appears to be a simple test, it is often difficult to perform and interpret by inexperienced clinicians. Even in experienced hands, the KOH examination may have a low yield in the noninflammatory type of tinea pedis/manuum. To perform a KOH examination, the area to be scraped (the peripheral scaling margin or vesicle roof) is cleaned with an alcohol swab. With a no. 15 scalpel blade, the scale is scraped onto a glass slide. A coverslip is then placed over the specimen and a drop of 10 percent potassium hydroxide solution is placed at the edge of the coverslip and allowed to diffuse under the coverslip. The specimen is then heated gently under an alcohol flame to aid in dissolving the keratin of the squamous cells. The specimen is then viewed under 10X magnification. Hyphae appear as light-green, thin strands that cross over cells and have branches (Figure 248-3).

If a positive KOH examination cannot be obtained, scraping of scale can be sent to the laboratory for KOH examination and fungal culture.

Treatment

If a positive KOH examination is obtained, nonbullous tinea pedis and manuum can be treated with topical antifungal agents. Imidazole antifungal agents such as clotrimazole (Lotrimin and Mycelex), miconazole (Micatin and Monistat), ketoconazole (Nizoral), or econazole (Spectazole) cream should be used twice a day. Treatment should be continued for 1 week after clearing has occurred. Although econazole cream is more expensive, it is preferred for interdigital tinea pedis as

FIG. 248-1. Ulcerative interdigital tinea pedis. Secondary bacterial and/or *Candida* infection complicate this case of interdigital tinea pedis. This eruption is quite painful and debilitating.

FIG. 248-2. Tinea manuum. The right hand has a markedly scaly palm while the left hand is uninvolved. This presentation is typical of tinea manuum. The feet would likely be involved as well.

FIG. 248-3. Positive potassium hydroxide (KOH) examination. Viewed under 10 X magnification, long, thin branching hyphae are seen.

it has antibacterial properties to treat secondary bacterial (often corynebacterium) infection. Topical terbinafine (Lamisil) cream is a fungicidal agent. It is nonprescription and is used once a day.

Patients should be warned that tinea pedis is often a chronic disease and that recurrences are common. Recurrences or failure to clear with topical medications may warrant treatment with oral agents, and referral to a primary care provider or dermatologist. Patients and physicians should be aware that topical agents do not treat nail infections. Thus, if a patient desires treatment of onychomycosis as well, an oral agent such as itraconazole, fluconazole, or terbinafine is needed, but is best managed by the primary care physician.

If a positive KOH cannot be obtained, but the clinical examination is highly suspicious for a fungal infection, empiric therapy is reasonable. As positive KOH examinations are difficult to obtain after treatment has started, scrapings for fungal cultures should be obtained before beginning therapy, as culture results (whether positive or negative) can help the follow-up physician choose the most appropriate therapy.

Bullous tinea pedis often does not respond to topical treatment. For mild cases, a topical agent can be tried initially. In more severe cases, oral antifungal treatment is necessary. Itraconazole 200 mg PO qd for 14 days or terbinafine 250 mg PO qd for 14 days are effective. The prescribing physician should be familiar with the potential drug interactions and the uncommon but serious side effects (hepatotoxicity and erythema multiforme/toxic epidermal necrolysis) prior to prescribing these medications.

Hands and feet should be kept as dry as possible. After bathing, web spaces should be thoroughly dried. A hair dryer may be helpful for drying. Socks should be changed anytime they become wet with sweat. Shoes and socks should be removed when possible. If the eruption is not clear in 4 to 6 weeks, dermatology referral is needed.

HAND AND FOOT DERMATITIS

Hand and foot dermatitis simply means inflammation of the skin of the hands and/or feet. The term is used to encompass several more specific disorders. These include allergic contact dermatitis, irritant contact dermatitis, dyshidrosis, and atopic dermatitis of the hands.

Pathophysiology

As this term relates to several different diagnoses, the pathophysiology is based on the specific disorder. Allergic contact dermatitis is a delayed hypersensitivity reaction to one of many possible allergens. On the hands, allergens may include rhus (poison ivy/poison oak), nickel, chromate, and rubber components of gloves. Some of the more com-

mon agents that cause allergic contact dermatitis on the foot are rhus, rubber accelerators found in shoes, dyes in leather and socks, and dichromates used in tanning leather.

Irritant contact dermatitis is an immediate nonimmunologic response from chemical damage to the skin. Strong irritants such as acids or phenol may cause severe immediate irritation ("chemical burn"). Weaker irritants including soaps, detergents, friction, and cold, dry air cause a more chronic dermatitis.

The cause of dyshidrosis is unknown. It tends to occur equally in men and women during early to mid adulthood (ages 20 to 40 years).

Atopic dermatitis is more often a disease of infancy and childhood; however, persistence into adulthood is possible. Hand or foot involvement is usually not the only cutaneous finding.

Clinical Features

In acute allergic contact dermatitis, erythema with papules, vesicles, and/or bullae is present. Pruritus is intense and excoriations are present. Chronic allergic contact dermatitis has less prominent vesiculation and more scale, lichenification, and fissuring.

Distribution is the most helpful clue to aid in diagnosis. When the hands or feet are involved in allergic contact dermatitis, the eruption tends to be present on the dorsal surfaces sparing the palms, soles, and web spaces. The thick stratum corneum of the palms and soles prevents penetration of potential allergens. Distribution with linear streaks suggests a plant allergy such as rhus (poison ivy or oak) hypersensitivity (Figure 248-4A). Sharp demarcation of footwear indicates a reaction to a component of the patient's shoes (Figure 248-4B). An eruption also present behind the earlobes, around the neck or at the site of a pant snap suggests a possible nickel allergy.

Irritant dermatitis resulting from a strong irritant like an acid or alkali initially begins as immediate burning in the exposed area. Vesiculation and bullae formation with surrounding erythema follow. In severe reactions, necrosis and ulceration may even be present. Eruptions often occur from accidental exposure. Irritant dermatitis from weaker agents presents as erythema, scale, and fissuring. Vesiculation is less prominent, and often is not present. Irritant contact dermatitis is a common problem in occupations that require frequent handwashing or water exposure, such as health care workers, bartenders, and housewives.

Dyshidrosis initially begins as very small, deep-seated, pruritic vesicles on the lateral aspects and the volar surfaces of the palms and soles. The dorsal surface of the distal phalanges may also become involved. A key feature separating this disorder from other dermatitides is the lack of erythema at the onset. Over time, the vesicles may form pustules or desquamate to leave small collarettes of scales. In chronic cases, erythema and scales become more prominent and may be difficult to distinguish from other forms of hand and foot dermatitis.

Atopic dermatitis of the hands and feet often presents as erythematous, pruritic scaly patches with prominent involvement of the dorsal surfaces as well as the palms and soles. Chronic atopic dermatitis will also have hyperpigmentation and lichenification and fissuring. Oftentimes, other areas of the body are involved. Common areas of involvement include the antecubital and popliteal fossae, the posterior neck, and the wrists and ankles.

Diagnosis

The diagnosis is clinical. Differentiation between the above-mentioned disorders, however, may be extremely difficult or impossible. More than one disorder may be present at a time, such as atopic dermatitis complicated by irritant dermatitis. One should try to elicit an occupational or hobby history that may indicate a specific causative agent. A history of an atopic diathesis (atopic dermatitis, allergic asthma, allergic rhinitis) in the patient or other family members should be sought as well. If an allergen is suspected, referral to a dermatologist for skin patch testing can help determine the exact agent responsible. A fungal

FIG. 248-4. Allergic contact dermatitis. A. Allergic contact dermatitis from exposure to poison ivy. Erythema, vesiculation and bullae are present on the fingers and the dorsal surfaces of the hands. Note the linear streak across the right hand. This finding is a diagnostic clue for rhus contact dermatitis (poison ivy). B. Allergic contact dermatitis to the straps of sandals. Erythema, scale, and excoriations are noted in a symmetric patterned distribution matching to this patient's footwear.

infection should always be considered in the differential diagnosis. A potassium hydroxide preparation can exclude this possibility. A dermatophytid eruption is another possibility. In this disorder, the hands break out in a dermatitic eruption as a result of a dermatophyte infection of the feet. Checking the patient's feet should be part of the clinical examination. Finally, psoriasis, lichen planus, pityriasis rubra pilaris, keratodermas, and autoimmune bullous diseases should be considered in the differential diagnosis. Rarely is a biopsy indicated, as it cannot differentiate between the different types of dermatitis.

Treatment

Offending agents should be removed. All antihistamine, anesthetic, antibiotic, and anti-itch creams should be stopped as they may cause a second allergy. In addition, water, soaps, detergents, and lotions should be avoided, as they may be irritating. The hands or feet should be well protected when performing any potentially irritating activities such as housecleaning, gardening, or hobbies using glues or chemicals. Friction should be avoided as well. Lubrication with products such as petroleum jelly, Eucerin cream, or Aquaphor ointment should be used frequently and liberally.

Acute eruptions with vesiculation can be treated with an astringent soak. The most commonly used astringent is aluminum acetate (Burow solution) (5% aluminum acetate). One Domeboro (aluminum sulfate and calcium acetate) powder packet or tablet is mixed with 1 pint of water and then applied with a towel or gauze to the affected area for 15 to 20 min qid. A high-potency topical corticosteroid such as fluocinonide (Lidex) ointment is then applied two to three times a day. Weaker nonfluorinated topical corticosteroids, such as hydrocortisone 2.5 percent or desonide, should be used on the face and skin folds. Antihistamines are also valuable, especially to relieve nighttime pruritus. Hydroxyzine (Atarax) 25 to 50 mg every 6 h should be tried initially. In severe cases with debilitating eruptions, systemic glucocorticoids are indicated. In allergic contact dermatitis secondary to rhus, oral prednisone beginning at 40 to 60 mg with a 2- to 3-week taper is recommended. Shorter courses of prednisone can result in relapse. Relative contraindications to prednisone use include diabetes, hypertension, active peptic ulcer disease, psychiatric disease, and immunodeficiency. If prednisone is prescribed to such patients, close follow-up is necessary.

Chronic eruptions should be treated with high-potency topical corticosteroids two to three times a day. Ointments are preferred as they help with lubrication. Hydroxyzine can provide symptomatic relief from itching. Systemic glucocorticoids should be avoided in chronic cases. Although they may provide temporary relief, rebound disease after cessation of the glucocorticoid is common. Furthermore, patients become overly dependent on this medication and the chronic effects of corticosteroid therapy then become an issue.

Severe irritant contact dermatitis with skin necrosis should be treated in a similar manner as a thermal burn. Debridement, and even skin grafting, may be necessary. Immediate referral to burn specialists or a burn center is warranted.

Hospitalization is rarely indicated except in instances of severe chemical burns. Follow up with a primary care physician or dermatologist is needed if the diagnosis is uncertain, if the eruption does not clear in three to four weeks, if systemic glucocorticoids are begun in the emergency department, or if patch testing is necessary. Chronic dermatitis should be seen by a primary care physician or dermatologist in 2 to 3 weeks to assess the need for prolonged treatment and to follow for possible complications of topical corticosteroids.

PSORIASIS

Psoriasis vulgaris or plaque-type psoriasis may involve only the palms and soles, but often extends to other areas especially the elbows, knees, scalp, and gluteal cleft. If pustules are present, the disorder is called pustular psoriasis.

Pathophysiology

Psoriasis is an inherited disease in which the principal abnormality is a shortening of the keratinocyte cell cycle resulting in an overproduction of cells up to 28 times normal. The causes underlying this rapid cell cycle are not clear; however, immunologic factors play a complex role in this process.

Clinical Features

In psoriasis vulgaris, erythema, scales, and fissures are seen in discrete plaques on the palms or soles (Figure 248-5A). Extensive disease may extend over the entire palms, soles, and dorsal surfaces of the hands or feet. Onycholysis (separation of the nail plate from the nail bed), nail pits, and yellow discoloration of the nails help support the diagnosis of psoriasis. Hand and foot dermatitis, lichen simplex chronicus, and Reiter syndrome should be included in the differential diagnosis.

In pustular psoriasis of the palms and soles, erythema, minimal scale, and numerous sterile pustules are seen. The pustules are in var-

FIG. 248-5. Psoriasis. A. In plaque-type psoriasis, erythematous plaques with thick scale are present on the palms. Hand dermatitis and lichen simplex chronicus may be difficult to differentiate clinically from this type of psoriasis. B. Pustules in various stages of evolution are seen in this typical example of palmoplantar pustulosis.

ious stages of evolution from small pustules to larger confluent "lakes of pus" to crusts to rings of scale (Figure 248-5B). It is most commonly seen bilaterally in the instep of the foot and the thenar and hypothenar eminences of the hands. The differential diagnosis includes tinea pedis or manuum, *Staphylococcus aureus* infection, herpes simplex infection, and dyshidrosis.

Diagnosis

Complete examination of the skin focusing on the sites commonly affected by psoriasis including the elbows, knees, scalp, lower back, gluteal cleft, and nails may reveal other areas of involvement to aid in diagnosing psoriasis. If no other psoriatic plaques are noted, differentiation from hand and foot dermatitis can be difficult. A biopsy may be helpful in this instance. A KOH examination should be performed to exclude a dermatophyte infection. Bacterial and viral cultures should be obtained when disease is localized to one area.

Treatment

Initial treatment includes the use of topical corticosteroids, tar preparations, and lubrication. A tar solution containing 1 teaspoon of a tar emulsion such as Balnetar or Zetar in a quart of water, should be used to soak the palms and soles for 15 to 20 min bid. Application of a high- or ultrahigh-potency topical corticosteroid such as fluocinonide

(Lidex), clobetasol propionate 0.05 percent (Temovate), or betamethasone dipropionate (Diprolene) 0.05 percent ointment follows this soak. Liberal use of emollients such as petroleum jelly, Aquaphor healing ointment, or Eucerin cream should be encouraged.

The disease is chronic and slow to respond to treatment. Psoriasis of the palms and soles is exceedingly difficult to treat. Because of the chronicity of this disorder, follow-up with a dermatologist within 4 weeks is recommended. Other treatments, such as acitretin (Soriatane), psoralen-ultraviolet light A, or methotrexate, can be instituted by the dermatologist.

LICHEN SIMPLEX CHRONICUS

Lichen simplex chronicus (LSC) is an extremely pruritic eruption that can involve any part of the body. Most commonly, the ankles, lower extremities, neck, scrotum, and vulva are involved. In LSC, the inciting event is often unknown. The pruritus is intense, thus leading to scratching. Scratching intensifies the itching, which then perpetuates the scratching.

Clinical Features

LSC presents as a one or several intensely pruritic well-demarcated plaques. As a result of chronic scratching and rubbing, lichenification is the prominent feature (see Figure 249-3). Erythema, hyperpigmentation, and excoriations are also present. Scale is minimal. The ankles, shins, dorsal feet, and hands may be affected.

Diagnosis

The diagnosis is based on history and clinical examination. The differential diagnosis includes a dermatophyte infection, nummular eczema, psoriasis, and squamous cell carcinoma. A KOH examination is helpful to rule out a dermatophyte infection. Psoriasis oftentimes involves numerous areas of the body, most commonly the elbows, knees, the lower back, the gluteal cleft, and the scalp. Psoriasis tends to have less pruritus, less lichenification, and more silvery scale. Nummular eczema is characterized by more lesions and less lichenification. If the diagnosis is in question, a skin biopsy is suggested.

Treatment

Interrupting the scratch-itch cycle is the most important aspect of treatment. High-potency topical corticosteroids such as fluocinonide (Lidex) ointment should be applied to the plaque two to three times a day. Antihistamines should be used for pruritus and nighttime sedation. Diphenhydramine or hydroxyzine 25 to 100 mg every 6 h is recommended.

The chronicity of the disease and its slow response to treatment should be discussed with the patient. Furthermore, the sedating nature of antihistamines and their avoidance when driving or operating heavy machinery should also be discussed. Follow-up with a primary care provider or a dermatologist should be arranged in 4 to 6 weeks, especially if response to treatment has been minimal.

VENOUS STASIS DERMATITIS AND VENOUS LEG ULCERS

The vast majority of leg ulcers are venous stasis ulcers resulting from chronic venous insufficiency.

Pathophysiology

Chronic venous insufficiency is the cause of stasis dermatitis and venous leg ulcers. Chronic venous insufficiency is usually caused by episodes of phlebitis or varicose veins. This results in poor venous

return from the lower extremities leading to increased hydrostatic pressure and lower extremity edema. It is most common on the medial ankle where the inferior perforate connects the superior and deep venous systems and the hydrostatic pressures are the greatest.

Clinical Features

Dependent edema, erythema, and orange-brown hyperpigmentation characterize early stasis dermatitis. The medial distal legs and the pretibial leg are the areas most frequently affected. More chronic and severe cases may have bright weepy erythema and even ulceration (Figure 248-6, **Plate 23**). Like other dermatitic processes, pruritus is common. Bacterial infection may complicate stasis dermatitis. The presence of honey-colored crust and pustules suggest secondary bacterial infection. Cellulitis and lymphangitis may even be present.

Stasis ulcers often begin within areas of stasis dermatitis. The medial and lateral malleolus and the medial aspect of the calf are the most common sites of involvement. The ulcer often has an aching quality with dependency. The ulcer has a punched out appearance with orange-brown hyperpigmentation at the borders and a moist pink base. Peripheral pulses are usually present.

Diagnosis

Diagnosis of stasis dermatitis is based on the history and physical examination. Other disorders to consider include allergic contact dermatitis (especially to topical preparations used to treat underlying stasis changes), lichen simplex chronicus, and xerotic dermatitis. Especially in association with acute exacerbation, secondary infection with *Staphylococcus aureus* should be excluded with a bacterial culture.

Stasis ulcers are also diagnosed on the basis of a history and physical examination. Bacterial cultures should be obtained if secondary bacterial infection is suspected. The differential diagnosis of leg ulcers is quite long and broad. If the ulcer does not have the clinical findings mentioned above, other diagnoses should be considered, and appropri-

FIG. 248-6. (PLATE 23). Stasis dermatitis. Note the surrounding red-brown pigmentation and the central weepy erythema on the pretibial leg.

ate history sought and tests performed. This is particularly important for certain disorders, such as arterial ulcerations, pyoderma gangrenosum, and polyarteritis nodosa, that require immediate attention. For instance, if peripheral pulses are absent and the patient has a history of claudication, vascular blood flow studies should be performed to exclude arterial ulcers. If the patient reports a rapidly developing ulcer that began as a pustule or erythematous nodule and has violaceous overhanging borders, pyoderma gangrenosum should be suspected. If the diagnosis is in question, consultation with a dermatologist is indicated.

Treatment

Venous hypertension should be reduced by leg elevation and the use of support stockings. Weeping eruptions should be treated with an astringent compress like Domeboro solution. A low- to midpotency topical steroid such as fluocinolone acetonide (Synalar) 0.025 percent cream or hydrocortisone 2.5 percent cream should be used bid. The patient should be told the medication is used to treat the erythema, scale, and pruritus. Hyperpigmentation will not respond to treatment; therefore, the medication should be discontinued when erythema, scale, and pruritus resolve. Oral antihistamines, such as diphenhydramine or hydroxyzine, should be used for pruritus and for nighttime sedation. Secondary bacterial infection should be treated with cephalexin, dicloxacillin, or ciprofloxacin for 7 to 10 days. Evidence of cellulitis or lymphangitis may require hospitalization for intravenous antibiotics. Topical neomycin, antihistamine creams, and anesthetic creams should be avoided as they may cause allergic contact dermatitis.

Because venous leg ulcers are chronic and slow to heal, ED treatment should focus on treating underlying causes of edema, stasis dermatitis, secondarily infected ulcers, cellulitis, or lymphangitis. Follow-up should be arranged with a dermatologist, with a vascular surgeon, or at a leg ulcer clinic for further treatment.

ERYTHEMA NODOSUM

Erythema nodosum is an inflammatory eruption of the subcutaneous fat. It has numerous possible etiologies. As a result, all age groups can be affected (Figure 248-7, **Plate 24**).

Pathophysiology

Erythema nodosum is classified as a panniculitis, that is, inflammation of the subcutaneous fat. Table 248-1 lists many of the potential causes of erythema nodosum. In approximately 40 percent of cases, the etiology remains unknown.

Clinical Features

Tender, warm, ill-defined erythematous nodules characterize erythema nodosum. It is most commonly seen on the pretibial area of the lower extremities. The upper extremities and trunk can occasionally be involved. Numerous lesions are usually present. Ulceration is not a feature of erythema nodosum and suggests the possibility of another type of panniculitis.

Diagnosis

Clinical examination is characteristic of a panniculitis. Individual lesions may be mistaken for bacterial cellulitis; however, the nodular component supports the diagnosis of erythema nodosum. If a presumed bacterial cellulitis has no obvious portal of bacterial entry, erythema nodosum should be considered in the differential diagnosis. If the diagnosis is unclear, a deep punch biopsy or an incisional biopsy including subcutaneous fat is indicated. After the diagnosis of erythema nodosum is established, one must search for possible etiologies.

FIG. 248-7. (PLATE 24). Erythema nodosum. An erythematous indurated nodule is seen. This patient's disease was initially diagnosed as cellulitis. However, after no response to antibiotics, a biopsy confirmed the diagnosis of erythema nodosum. Most patients with erythema nodosum will have multiple lesions.

The history may suggest possible causes (see Table 248-1). Further evaluation, as directed by history and physical findings, may include a throat culture, a stool culture, a complete blood count, a chest radiograph to rule out sarcoidosis, and placement of a purified protein derivative (PPD).

Treatment

Therapy focuses on treatment of the underlying cause. If such a cause is not clearly established, symptomatic relief can be obtained with bedrest, leg elevation, and nonsteroidal anti-inflammatory agents. These measures can be instituted in the emergency department until the patient can be seen by dermatologist. Other treatments, including oral potassium iodide and systemic corticosteroids, may be required; however, they should not be started until the etiology is established.

PYOGENIC GRANULOMA

A pyogenic granuloma is a benign proliferation of immature capillaries occurring at the site of minor skin trauma. The name is a misnomer as it is neither an infection nor a granuloma. It most commonly occurs in children, young adults, and pregnant women. In pregnant women, it is called granuloma gravidarum.

Clinical Features

A pyogenic granuloma initially presents as a bright red, shiny papule with a thin collarette of hyperkeratosis. It may be ulcerated and tends to bleed profusely with minor injury. Later, the lesion reepithelializes and becomes a dull red to purple color. Although these lesions can occur anywhere on the body, the extremities, especially the hands, are the most common sites of involvement. The differential diagnosis includes

amelanotic melanoma, squamous cell carcinoma, bacillary angiomatosis, and cutaneous metastasis.

Diagnosis

The diagnosis is often suspected on clinical grounds; however, a biopsy of the lesion should be performed to confirm the diagnosis and to exclude the above-mentioned disorders, especially an amelanotic melanoma. These two disorders can be indistinguishable by clinical examination alone.

Treatment

Referral to a dermatologist for biopsy is indicated. If the lesion is bleeding profusely in the acute setting, hemostasis can be obtained with pressure and chemical or electrocautery. Destruction of the lesion, excision, or a shave biopsy followed by laser therapy or electrodesiccation and curettage are the treatments of choice. Lesions will rarely resolve completely without treatment.

OTHER DISORDERS AFFECTING THE HANDS AND FEET

Several other generalized skin disorders have classic clinical findings on the palms and soles. Some of these disorders are discussed in more detail in Chap. 246.

Erythema multiforme has characteristic findings on the palms and soles. The lesions are erythematous macules with a violaceous, dusky or bullous center. They are commonly referred to as target or iris lesions. Discovering such lesions should incite a search for similar lesions on the rest of the body, hemorrhagic erosions on the mucosal surfaces, and conjunctival hemorrhage in the eyes.

Secondary syphilis also has characteristic palm and sole lesions. These lesions are asymptomatic red-brown to brown macules on the palms and soles. Although patients with darker pigmented skin may

FIG. 248-8. Crusted scabies. The thick scale, erythema, and exudate resemble a foot dermatitis. This disorder should not be forgotten when presented with a patient with extremely pruritic scaly eruption. Crusted scabies is more common in immunocompromised and debilitated patients.

have several hyperpigmented macules as a normal finding, recent onset or failure of the patient to recall such lesions should increase suspicion for secondary syphilis. Appropriate laboratory serology should then be obtained.

Rocky Mountain spotted fever may also present initially with palm or sole lesions, which begin as blanching erythematous macules that later become nonblanching petechial lesions. Lesions start distally and spread proximally.

Kawasaki disease, scarlet fever, and toxic shock syndrome may all have palmar erythema as a prominent feature. The palms and soles will desquamate as these diseases progress.

Furthermore, when considering pruritic eruptions of the extremities, one must always think about scabies. The hands, feet, and elbows along with the groin are the most common areas of involvement. Diagnostic burrows will most likely be found in the hyperkeratotic skin of the palms and soles particularly along the web spaces and the wrist. When the scabietic mite burden becomes quite high, crusted scabies results. Thick hyperkeratosis resembling dermatitis results (Figure 248-8). See Chap. 250 for further discussion.

Finally, all the major types of skin cancer including malignant melanoma, squamous cell carcinoma, and basal cell carcinoma can occur on the extremities.

as hidradenitis suppurativa occur predominantly in this area. Although many skin diseases can affect the skin folds to some degree, this chapter focuses on common disorders where skin fold eruptions are the main cutaneous finding.

TINEA CRURIS

Tinea cruris is a fungal infection of the groin commonly called jock itch. It is very common in males, uncommon in females, and exceedingly rare in children. Tinea cruris results from invasion of the stratum corneum by the dermatophyte types of fungi. It is transmitted from person to person via fomites and from animal (usually kittens or puppies) to person via direct contact or fomites.

Clinical Features

One sees erythema with a peripheral annular slightly scaly edge in the groin and extending onto the inner thighs (Figure 249-1) and even the buttocks. The penis and scrotum are not affected. This feature is important in distinguishing tinea cruris from other eruptions in the groin as most other eruptions will affect the scrotum.

Other common disorders to be included in the differential diagnosis include candidiasis, erythrasma, lichen simplex chronicus, allergic and irritant contact dermatitis, and extramammary Paget disease. Table 249-1 provides a more extensive list of inflammatory processes of the intertriginous areas. See the description under "Candida Intertrigo" below for a comparison of the features of these disorders.

Diagnosis

The diagnosis is established by a positive potassium hydroxide (KOH) examination. A KOH preparation will demonstrate branching hyphae (see Figure 248-3). If a KOH examination is negative, one of the other above-mentioned disorders should be considered.

Treatment

Antifungal creams such as clotrimazole (Lotrimin or Mycelex), ketoconazole (Nizoral), or econazole (Spectazole) twice a day is the initial treatment. Clotrimazole is suggested initially as it is of low cost and is nonprescription. Spectazole also has antibacterial properties and is preferred if maceration is present. Treatment also includes keeping the affected area as cool and dry as possible. Wearing loose-fitting clothing is recommended. Antifungal powders such as Zeasorb AF should be used on a daily basis to prevent recurrences. The patient should fol-

249 DISORDERS OF THE GROIN AND SKIN FOLDS Dean Morrell Lisa May

The skin folds of the body include the groin, intergluteal cleft, axilla, inframammary folds, and pannus folds. The skin folds have unique characteristics that set them apart from other regions of the body. For one, these areas are almost continuously occluded. As a result, scale does not develop; maceration and fissuring develop instead. This alters the appearance of papulosquamous diseases and inflammatory processes in this region. The occlusion also allows for the development of a warm, moist environment favorable to the growth of fungi, yeast, and bacteria. Finally, the skin folds—in particular, the groin, intergluteal cleft, and the axilla—are the major sites in the body of apocrine glands. Thus, certain disease processes of these structures such

low up with a primary care provider or dermatologist if the eruption has not resolved in 4 to 6 weeks.

CANDIDA INTERTRIGO

Candidal infections of the skin favor moist, occluded areas of the body. Although any skin fold may be involved, superficial *Candida* infections are commonly seen in the diaper area of infants, the vulva and groin of women, the glans penis (balanitis) in uncircumcised males, and the inframammary and pannus folds of obese patients. Antibiotic therapy, systemic corticosteroid therapy, urinary or fecal incontinence, immunocompromised states, and obesity are predisposing factors. Women with vulvar or inner thigh involvement will often have vaginal candidiasis as well. Frequently, intertrigo is multifactorial with *Candida* complicating other inflammatory intertriginous disorders.

Clinical Features

The typical presentation is erythema and maceration with surrounding small erythematous papules or pustules (Figure 249-2). These satellite pustules are a characteristic finding differentiating *Candida* intertrigo from other inflammatory disorders affecting the skin folds. Patients will complain of burning or itching. The other inflammatory disorders listed in Table 249-1 should be considered in the differential diagnosis.

Diagnosis

The rim of satellite pustules helps to distinguish *Candida* intertrigo from other eruptions of the skin folds. A KOH preparation of the pustules or a leading edge scale may demonstrate short hyphae and spores, but these may be difficult to find in cases with just erythema and maceration. If *Candida* is suspected but not visualized on KOH preparation, and the diagnosis is in question, a fungal culture should be obtained. A thorough evaluation should be done if a primary disorder is resulting in secondary *Candida* infection.

Treatment

Keeping the affected area dry and cool is a cornerstone of treatment. After bathing, air drying or drying with a hair dryer should be en-

FIG. 249-2. *Candida* intertrigo. Note the bright-red erythema, erosions, and satellite papules and pustules in this striking example of inframammary *Candida* intertrigo. A KOH examination will confirm the diagnosis.

couraged. Clothing should be loose and lightweight. Astringent solutions such as (Burow solution, 5% aluminum acetate) aid in drying weepy inflamed eruptions. One Domeboro powder packet or tablet is mixed with 1 pint of water, then applied with a towel or gauze to the affected area for 10 to 15 min bid. A topical antifungal cream such as clotrimazole, ketoconazole (Nizoral), or econazole (Spectazole) should be applied bid. Spectazole is also antibacterial but is more expensive. The addition of hydrocortisone 1 percent cream bid can speed symptomatic relief and healing. Furthermore, drying powders, such as Zeasorb AF, should be used on a daily basis.

Patients with vulvar candidiasis should be evaluated for *Candida* vaginitis and treated appropriately if found. Patients with *Candida* balanitis often have a female sexual partner with *Candida* vaginitis, so this person should be evaluated and treated as well. In infants or in adults with urinary or fecal incontinence, diapers or sanitary pads should be changed frequently. Zinc oxide paste applied over the antifungal agent provides a barrier to the irritation of urine and feces.

NONINFECTIOUS INTERTRIGO

Intertrigo is an irritant dermatitis of the skin folds resulting from moisture, heat, friction, and irritating substances like urine and feces. Intertrigo is common in the skin folds of obese patients where sweating and maceration occur. It is also a frequent occurrence in the diaper area of infants where it is referred to as diaper dermatitis.

Clinical Features

Intertrigo presents as erythema, maceration, and fissures in the occluded area of skin folds, especially the groin and inframammary fold. Satellite papules and pustules are absent. Burning and pruritus are present.

Diagnosis

Intertrigo is a diagnosis of exclusion. Other causes of skin fold erythema and fissuring such as *Candida* intertrigo, erythrasma, tinea cruris, allergic contact dermatitis, seborrheic dermatitis, inverse psoriasis, and extramammary Paget disease must be considered. Differentiating *Candida* intertrigo from inflammatory intertrigo can be difficult. *Candida* intertrigo will have satellite pustules as a prominent feature. If positive, a KOH examination supports the diagnosis of *Candida* intertrigo. A negative KOH examination, however, does not exclude this

possibility, as yeast is difficult to obtain and visualize with this procedure. A scraping of peripheral scale or a pustule to send for fungal culture is suggested.

Clinically, irritant dermatitis cannot always be distinguished from allergic contact dermatitis. A history should be taken to uncover any possible contact allergens or irritants such as neomycin-containing ointments, anesthetic creams, diphenhydramine cream, deodorants, feminine hygiene sprays, or other lotions, solutions, or home remedies.

Complete skin examination will help to uncover other signs of seborrheic dermatitis or psoriasis. Furthermore, extramammary Paget disease and Bowen disease (squamous cell carcinoma in situ) may be clinically indistinguishable from intertrigo—they may even be secondarily infected with *Candida*.

Treatment

As this eruption results from irritation by moisture, heat, and friction, these factors should be eliminated. Keeping the areas dry and cool is helpful. The patient should avoid tight-fitting clothing, especially undergarments. Weight loss can help as well. All potential irritants should be avoided. In diaper dermatitis, disposable diapers are preferred because of their highly absorbent properties. Diapers should be changed frequently, and periods free of diaper wear to dry and cool the affected skin is recommended. Zinc oxide paste provides an excellent barrier to urine and fecal material.

It is a common occurrence for the practitioner to be uncertain of the diagnosis. As a result, treatment is often aimed at both anticandidal and anti-inflammatory therapy. Several pitfalls of this approach exist. First, if used alone, topical corticosteroids can cause persistence or worsening of *Candida* intertrigo. Second, the commonly prescribed combination medications, Lotrisone and Mycolog, contain a high-potency fluorinated corticosteroid. The occlusive nature of skin folds allows for better and deeper penetration of these high-potency corticosteroids, resulting in an increased risk of steroid-induced atrophy and striae. If combination therapy is warranted, Vytone-HC 1 percent (Vioform and 1 percent hydrocortisone) has anticandidal effects with a mild topical corticosteroid more appropriate for use in the intertriginous areas.

For moist, weepy intertrigo, astringent compresses can be used. Domeboro compresses, as described above for *Candida* intertrigo, are recommended.

Secondary bacterial impetiginization can occur and should be treated with oral antibiotics with staphylococcal and streptococcal coverage.

Little or no response to therapy are indications to biopsy the affected area to exclude the serious diagnoses listed above.

SEBORRHEIC DERMATITIS

Seborrheic dermatitis is one of the most common skin disorders. It most notably affects the scalp ("dandruff") and creases of the face and ears; however, other skin folds such as the intergluteal cleft, groin, the axilla, inframammary folds, and the umbilicus can be affected. Severe and extensive seborrheic dermatitis is more common in debilitated patients, patients with HIV, and patients with Parkinson disease.

The exact cause of seborrheic dermatitis is unknown. Overgrowth of *Pityrosporon ovale*, a yeast that normally inhabits hair follicles and sebaceous ducts, with resultant inflammatory response is implicated.

Clinical Features

Seborrheic dermatitis of the scalp and skin folds of the face presents as erythema with a waxy yellow scale. When seborrheic dermatitis affects other skin folds, erythema and maceration are noted. Extension of the eruption onto the pubic area and central chest may be seen.

Diagnosis

The diagnosis is made on clinical examination of the skin folds with special attention to the scalp and creases of the face. Without examination of the face and scalp, the groin or other skin fold involvement is hard to differentiate from the other inflammatory disorders such as *Candida* intertrigo, inverse psoriasis, allergic contact dermatitis, or erythrasma.

Treatment

Treatment can relieve signs and symptoms but there is no cure. The eruption will return after treatment ceases. Shampoos can be used on the scalp and other hair-bearing areas. These include shampoos containing zinc pyrithione (Head and Shoulders), selenium sulfide (Selsun or extra-strength Head and Shoulders), salicylic acid (Neutrogena T-Sal), or tar preparations (Neutrogena T-Gel). Nizoral shampoo can be effective as well and is now available over-the-counter. Seborrheic dermatitis is very responsive to low-potency corticosteroids. Hydrocortisone 1 percent cream can be used in mild cases, while hydrocortisone 2.5 percent cream or desonide (DesOwen) cream or lotion may be required initially in more severe cases. If these initial treatment options fail, dermatology referral is recommended.

LICHEN SIMPLEX CHRONICUS

The scrotum, vulva, and perianal area are common sites of involvement with lichen simplex chronicus. Clinically, lichenification, hyperpigmentation, and excoriation are prominent features (Figure 249-3). Treatment is the same as for lichen simplex chronicus in other areas except that low-potency corticosteroid (hydrocortisone 2.5 percent or desonide) ointments should be used. In cases of perianal lichen simplex chronicus, patients should be instructed to cleanse the perianal area thoroughly to remove fecal debris and tissue paper that may be irritating. Witch hazel pads are recommended for cleansing.

SEXUALLY TRANSMITTED DISEASES

Sexually transmitted diseases can occur in the intergluteal cleft, the perianal area, and the groin with or without genital involvement. The chancre of primary syphilis, condyloma lata, condyloma acuminata, or primary or recurrent herpes simplex virus should be considered. Pediculosis pubis ("crabs") and scabies can cause pruritic excoriated eruptions of the groin and axilla. The clinical findings in granuloma inguinale and lymphogranuloma venereum predominate in the inguinal folds.

FIG. 249-3. Lichen simplex chronicus. Pronounced lichenification and hyperpigmentation is typical of lichen simplex chronicus. The scrotum is a common site of involvement.

INFESTATIONS

Dean Morrell Lisa

May

HUMAN SCABIES

Human scabies is an infestation of the skin by *Sarcoptes scabiei*. Human scabies occurs worldwide and affects all races and social classes. The mite is transmitted from person to person by close physical contact. Although children and young adults are most commonly affected, infestation can occur at any age.

The scabietic mite resides in a burrow within the stratum corneum. Most individuals have an average of 12 mites at any given time. When the mite burden becomes high, numbering in the millions, a form of involvement called crusted scabies develops. It is most commonly seen in association with an immunocompromised state, particularly HIV, mental retardation, dementia, or physical disability. The time from infestation to clinical symptoms is about 3 to 4 weeks.

Clinical Features

Scabies tends to be an extremely pruritic eruption, often disturbing sleep (except crusted scabies, which tends to have minimal associated pruritus). The most common sites of involvement include the hands, feet, flexural surfaces of the elbows and knees, umbilicus, groin, and genitals. Facial involvement is usually seen only in infants. The pathognomonic lesion, or burrow, is a fine erythematous linear or curved lesion with central scale (Figure 250-1). Burrows are most often visible in the web spaces of the fingers, the lateral aspects of the fingers, the volar surface of the wrists, the instep of the foot, and the shaft of the penis. Often, however, burrows are not present, especially in patients with excellent hygiene. Excoriations and pruritic papules may be the only visible cutaneous feature. Vesicles are often seen in infants and young children.

In crusted scabies (see Figure 248-8), one develops thick, dirty-appearing hyperkeratosis on the hands and feet. The nails are often affected as well. Because of the large mite burden, this form of scabies is highly contagious.

FIG. 250-1. Human scabies. Numerous scabietic burrows are visible near the axilla of this infant infested with scabies.

Diagnosis

The diagnosis is based on a high clinical suspicion and a positive scabies preparation. The diagnosis should be entertained when more than one family member itches. Other disorders to consider in the differential diagnosis include other bite reactions, body lice, atopic dermatitis, neurotic excoriations, and delusions of parasitosis. Suspected cases of scabies should be confirmed by performing a scabies preparation. To perform a scabies preparation, one scrapes or superficially shaves a lesion (preferably a burrow) with a no. 15 blade. The sample is placed on a glass slide, covered with immersion oil and a cover slip, and examined under the microscope. Mites, eggs, or scybala (feces) will be visible (Figure 250-2). When possible, the diagnosis should be confirmed with a scraping prior to treatment.

Treatment

Topical scabicides are the treatments of choice. The topical preparation should be applied from the neck down to the feet, with special attention paid to applying the lotion around and under fingernails, in the web spaces of the fingers and toes, and in the umbilicus.

Permethrin 5 percent cream (Elimite) and lindane 1 percent lotion (Kwell) are equally effective. Either preparation should be left on overnight and rinsed off the following morning. Lindane is easier to apply and less expensive than permethrin, but lindane resistance has been reported. Lindane is neurotoxic to infants, children, and pregnant women, and is contraindicated in those groups. Patients with extensive involvement should be treated again in 1 week.

All household members and sexual contacts at high risk of acquiring scabies should be treated concurrently, even if they are asymptomatic, because a delay from the time of infestation to the development of symptoms exists. Nursing homes, institutions, hospital staff, and schools should be notified, and any symptomatic individuals should be treated. Bed linens, towels, and clothing should be washed and dried in a dryer on high heat.

Antihistamines, such as diphenhydramine or hydroxyzine, should be prescribed for pruritus. A mid-potency topical corticosteroid may also provide relief from itching. Clinically evident secondary bacterial infection should be treated with an antistaphylococcal agent.

Itching may take weeks to subside. Persistence of lesions or itching after 2 weeks requires referral and retreatment.

FIG. 250-2. Scabies preparation. The immature mite, ova, and scybala (fecal pellets) are present in this scraping of a burrow. The presence of any one of these elements is considered a positive scabies preparation result.

PEDICULOSIS

Pediculosis capitis (head lice) is an infestation of the hair and scalp by the mite *Pediculus capitis*. *Pediculus corporis* is the body louse, and pubic lice is an infestation of the pubic hair by *Phthirus pubis*.

Head Lice

This disorder is most commonly seen in school-aged children or in children attending day-care centers. However, any age group can be affected. It is very uncommon in African Americans. The louse is passed from person to person via close contact. The organism may live away from a host on furniture, clothing, linens, hats, or hairbrushes for several weeks, and thus may be passed to another who comes in contact with these articles. Head lice feed off human blood and therefore remain close to the scalp. When the louse lays its eggs, the ova, or nits, are cemented to the hair shaft. The ova hatch within 7 days. The ova encasement remains attached to the hair shaft and grows out with the hair. By the time the nits are a distance of 1 cm or more away from scalp, they have hatched.

CLINICAL FEATURES Itching may be mild or quite intense. The occiput and posterior neck are common sites of pruritus, and excoriations on the neck may be noted.

DIAGNOSIS The diagnosis is made on clinical inspection of the scalp for lice and nits (Figure 250-3). Unlike flakes of scale, which can easily be moved up and down the hair shaft, nits are firmly attached to the shaft. If the diagnosis is in question, suspected organisms or ova can be viewed underneath a microscope.

TREATMENT Two important aspects of treatment should be addressed: treating the current infection and preventing reinfestation. Several agents may be used to treat the infestation. Permethrin 1 percent (Nix) rinse should be used as first-line therapy. Unlike lindane and pyrethrins, permethrin is ovicidal as well as pediculicidal. After shampooing, the treatment should be applied to the scalp for 10 min. For cosmetic reasons, nits can be removed by rinsing the hair in a 50 percent vinegar solution and then combing the hair with a fine-toothed comb.

To prevent reinfestation, all close contacts should be examined and affected individuals treated, including family members, classmates at school or day care, roommates, or health care workers in an institutional setting. Schools and day-care centers should be notified so that appropriate measures can be undertaken to evaluate other individuals.

FIG. 250-3. Head lice. Nits are clearly visible, firmly attached to the hair shafts.

Clothing, hats, and bed linens should be washed with hot water and dried in a dryer on high heat for 20 to 30 min. Carpets and sofas should be thoroughly vacuumed. Hairbrushes should be washed in hot water with the pediculicide product.

Patients should be reexamined in 7 to 10 days.

Pediculosis Pubis

In general, pubic lice is a sexually transmitted disease. Affected individuals should be evaluated for other sexually transmitted diseases. In children, the possibility of sexual abuse should be considered. Rarely, it may be passed from person to person via infested clothing, bed linens, and so on.

As with head lice, the main complaint is itching, which may vary in intensity. Pubic hair of the groin is most commonly infested, but body hair and eyelashes may be affected as well. Close inspection reveals the lice and nits (Figure 250-4).

Treatment is the same as for head lice. Permethrin (Nix) is the preferred initial therapy and should be applied to the affected area for 10 min and then rinsed. Eyelash infestations should be treated by manually removing as many lice and nits as possible, and then applying petrolatum to the lashes two to three times a day for 10 days.

Pediculosis Corporis

Body lice are currently uncommon in the United States. Infestation is more likely to occur in persons with poor hygiene or overcrowded living conditions. The lice reside on hair-bearing areas of the body but attach their nits to clothing. The lice and nits can survive as long as 30 days without contact with a human host. Clinically, the bite is often not perceived by an individual, but leaves a pruritic red urticarial papule. This lesion is not distinguishable from other bite reactions. A clue to diagnosis is that areas not covered by clothing, such as the face and hands, are usually spared. A high index of suspicion is needed, especially in patients with poor hygiene. Close inspection of clothing reveals nits, especially along clothing seams.

The body louse is the vector for epidemic typhus fever (*Rickettsia prowazekii*), trench fever (*Rickettsia quintana*), and relapsing fever (*Borrelia recurrentis*).

Treatment is as for head or pubic lice. Because the nits can survive long periods without human contact, infested clothing and linens should be destroyed. If they are not destroyed, recommendations include washing and drying on hot cycles and ironing the seams of the textiles. Oral antihistamines and topical corticosteroids may be necessary when itching is severe. Secondary infection, if present, should be treated.

FIG. 250-4. Pubic lice. Pubic lice are seen on the skin surface, and nits are attached to the pubic hairs.

INITIAL APPROACH TO TRAUMA

Edward E. Cornwell III

Recent cataclysmic events have made Americans more cognizant of the need for trauma systems and trauma centers. Yet, it is the everyday "unspectacular" injuries that account for nearly 150,000 deaths each year. Injury is the fourth leading killer of Americans and the single greatest cause of death before the age of 45 years.¹ The predominant causes of death following trauma (i.e., head, chest, and major vascular injuries) imply that the organization of trauma centers and trauma systems should be predicated on the concepts of rapid triage, diagnosis, and therapeutic intervention.²

TRAUMA SYSTEMS AND TIMELY TRIAGE

The importance of a systems approach to trauma care becomes clear when the timing of death occurring secondary to traumatic injuries is considered.³ The pattern of mortality takes on roughly a trimodal distribution where three peak occurrences are seen. The *first peak* occurs in the prehospital setting, largely a result of devastating head and major vascular injuries. Efforts to reduce deaths in this setting are largely societal, complex, and multidisciplinary, and include such multifaceted activities as drunk driving laws; safe road construction; seat belt, helmet, and airbag laws; and violence-prevention activities such as counseling, education and outreach efforts, handgun control, and dissemination of conflict resolution skills.^{4,5} A *second peak* incidence of deaths as a result of traumatic injuries occurs in the early minutes and hours after a patient's arrival at the hospital. Deaths in this peak are largely a result of major head, chest, and abdominal injuries. The most important function of a trauma system is to decrease deaths in this phase by rapid transport of patients to the most appropriate facility and prompt resuscitation and identification of injuries requiring surgical intervention. The *third peak* in the trimodal distribution of deaths occurs in the intensive care unit, where the sequelae of organ hypoperfusion experienced in the early postinjury period are seen. Specifically, patients who have survived the initial injury, transport, and operative resuscitation die in this setting as a result of the systemic inflammatory response syndrome and multisystem organ failure.

In recognition of the need to establish a system in which injured patients are rapidly triaged to the most appropriate setting, Congress passed the Trauma Care Systems Planning and Development Act of 1991.⁵ This Act required the development of a Model Trauma Care System Plan to be used as a reference document for each state to develop its system. Recent appropriations for this originally unfunded mandate have allowed a growing number of states to initiate the development of a comprehensive trauma system. Ultimately, each state must determine the appropriate facility for various types of injuries, and some states have come to rely on a verification process offered by the American College of Surgeons in order to designate certain hospitals as trauma centers.² Table 251-1 lists examples of requirements of various levels of trauma centers. In addition to the listed essentials, a trauma center must have all the required features of lower-level trauma centers. An effective trauma program requires the teamwork of emergency medicine, trauma surgery, and trauma care subspecialists.

In short, trauma centers are verified on the basis of commitment of personnel and resources needed to maintain a state of readiness to receive critically injured patients. A well-functioning trauma system ensures that not only are there appropriately designated trauma centers

but that there are also specific triage criteria to designate which patients should be transported to these centers (Table 251-2).

PRIMARY SURVEY

In accordance with the principles of advanced trauma life support, injured patients are assessed and treated in a fashion that establishes priorities based on their presenting vital signs, mental status, and injury mechanism.⁷ The initial approach to trauma care is a process that consists of an initial primary assessment, rapid resuscitation, and a more thorough secondary survey followed by diagnostic tests and ultimate disposition constitutes (Table 251-3).

When available, a history obtained from a patient, witnesses, or prehospital provider may provide important information regarding circumstances of the injury (single-car accident, a fall, exposure, smoke inhalation), preexisting medical conditions (depression, cardiac disease, pregnancy), or medications (steroids, (3-blockers) that may suggest certain patterns of injury or the physiologic response to injury.

A *primary survey* is undertaken quickly with the goal of identifying and treating life-threatening conditions. Specific lethal problems (discussed in further detail below) that should be identified immediately and addressed during the primary survey are airway obstruction, tension pneumothorax, massive hemorrhage, open pneumothorax, flail chest, and cardiac tamponade. The assessment of the ABCs (airway, breathing, and circulation) is such that evidence for or against the presence of these conditions is sought. During the primary survey, the following are quickly assessed:

- Airway maintenance with C-spine control
- .Breathing/ventilation
- Circulation with hemorrhage control
- Neurologic disability
- .Exposure, where the patient is completely undressed

Some specific points are emphasized regarding the various components of the trauma evaluation.

Airway with Cervical Spine Control

Rapid assessment for airway patency includes inspecting for foreign bodies or maxillofacial fractures that may result in airway obstruction. The chin-lift or jaw-thrust maneuver or the insertion of an oral or nasal airway is a first response for the patient making inadequate respiratory effort. A two-person technique whenever possible is suggested, where one devotes undivided attention to maintaining in-line immobilization and preventing excessive movement of the cervical spine. Comatose patients (Glasgow Coma Scale score 3 to 8; see "Disability" below) should be intubated tracheally to protect the airway and to prevent the secondary brain injury that occurs with hypoxemia. Logrolling and pharyngeal suction may be necessary to prevent aspiration if the patient vomits. Patients whose anatomy or severe maxillofacial injury precludes endotracheal intubation may require a surgical airway by means of cricothyroidotomy. Agitated trauma patients suffering from head injury, hypoxia, or drug- or alcohol-induced delirium may present a danger to themselves. In these circumstances, paralyzing agents such as succinylcholine or vecuronium, along with a small dose of diazepam or midazolam, may be necessary to enable safe airway management. See Chap. 19 for details, dosages, and techniques.

The issue of cervical spine (C-spine) clearance is one that has received much attention in the recent past. Ultimately, "clearance" of a C-spine is both a radiologic and a clinical undertaking. This implies that

TABLE 251-1 Essential Characteristics of Levels I, II, III and IV Trauma Centers

Level I (not required of levels II, III, and IV trauma centers)
24-h availability of all surgical subspecialties (including cardiac surgery/bypass capability)
Neuroradiology, hemodialysis available 24 h
Program that establishes and monitors effect of injury prevention/education efforts
Organized trauma research program
Level II (not required of levels III and IV trauma centers)
Cardiology, ophthalmology, plastic surgery, gynecologic surgery available
Operating room ready 24 h a day
Neurosurgery department in hospital
Trauma multidisciplinary quality assurance committee
Level III (not required of level IV trauma centers)
Trauma and emergency medicine services
24-h radiology capability
Pulse oximetry, central venous and arterial catheter monitoring capability
Thermal control equipment for blood and fluids
Published on-call schedule for surgeons, subspecialists
Trauma registry
Level IV
Initial care capabilities only
Mechanism for prompt transfer
Transfer agreements and protocols

patients who do not demonstrate evidence of bony fractures or subluxation on x-ray may still have significant injuries that are not appreciated if they cannot cooperate with a thorough physical examination. On the other hand, precious time should not be expended on multiple views in patients who have critical head, thoracic, and abdominal injuries that may require rapid intervention. In these patients, after a cross-table lateral view of the C-spine, the cervical collar should be left in place until the patient ultimately can cooperate with the clinical examination or undergo more sophisticated studies [e.g., computed tomography (CT) scans or magnetic resonance imaging (MRI) of the spine].

Finally, the practice of obtaining multiple C-spine x-rays in awake, alert patients with normal examinations (no pain or tenderness with the

TABLE 251-2 Maryland Criteria for Mandatory Transport to a Trauma Center

Abnormal vital signs (GCS <14 or systolic BP <90) (respiratory rate <10 or >29)
Multiple-system trauma
Penetrating wound to
Head, neck, or torso
Gunshot wound(s) to extremities proximal to elbow and knee
An extremity with neurovascular compromise
CNS injury (head, spine) Suspected pelvic fracture
Mechanism of injury
Vehicular deformity
Intrusion into passenger compartment greater than 12 in
Major vehicular deformity greater than 20 in
Ejection Entrapment
Falls greater than three times the patient's height
Fatality in same passenger compartment Rapid deceleration
Auto-pedestrian/auto-bicycle injury with significant impact (>5 mi/h)
Vehicular rollover Exposure to blast/explosion

Abbreviations: BP = blood pressure; CNS = central nervous system; GCS = Glasgow Coma Scale.

TABLE 251-3 A Step-by-Step Procedure for Trauma Resuscitation

1. <i>Notification by Prehospital Personnel:</i> The receiving emergency department should be informed about:
Airway patency
Pulse and respirations
Level of consciousness
Immobilization
Mechanism of injury and blood loss at the scene
Anatomic sites of apparent injury
2. <i>Preparation for Receiving the Trauma Victim</i>
Assign tasks to team members
Check and prepare vital equipment
Summon surgical consultant and other team members not present
3. <i>Primary Survey:</i> The most immediately lethal injuries are taken care of as they are identified.
Airway
Clear airway: chin lift, suction, finger sweep
Protect airway
Depressed level of consciousness of bleeding, tracheal intubation without neck movement
Surgical airway
Breathing
Ventilate with 100% oxygen
Check thorax and neck
Deviated trachea
Tension pneumothorax (intervention—needle decompression)
Chest wounds and chest wall motion
Sucking chest wound (intervention—occlusive dressing)
Neck and chest crepitation
Multiple broken ribs
Fractured sternum
Pneumothorax
Listen for breath sounds
Correct tracheal tube placement?
Hemothorax?
Chest tube(s)—38-Fr
Collect blood for autotransfusion
Circulation
Apply pressure to sites of external exsanguination
Assure that two large-bore IVs established
Begin with rapid infusion of warm crystalloid solution
If arm sites unavailable, insert a large central line or perform a saphenous cutdown at the ankle
Assess for blood volume status
Radial and carotid pulse, BP determination
Jugular venous filling
Quality of heart tones
Beck triad present?
Pericardiocentesis or echocardiogram
Decompress tamponade
Pericardiocentesis
Thoracotomy with pericardiectomy
Hypovolemia
After 2 L of crystalloid begin blood infusion if still hypovolemic; in children use two 20-mL/kg boluses then 10-mL/kg blood boluses if still unstable
Near-term pregnant patient—place roll under right hip
Disability
Brief neurologic examination
Pupil size and reactivity
Limb movement
Glasgow Coma Scale
Exposure
Completely disrobe the patient
Logroll to inspect back
Continuing resuscitation
Monitor fluid administration
Consider central line for CVP monitoring
Use fetal heart rate as indicator in pregnant women
Record all events

(Continued)

TABLE 251-3 A Step-by-Step Procedure for Trauma Resuscitation (Continued)

4. *Secondary Survey:* A thorough search for injuries is carried out in order to set further priorities.

Trauma series x-rays: lateral cervical spine, supine chest, AP pelvis
 Head-to-toe examination looking and feeling; quickly bring problems under control as they are discovered
 Scalp wound bleeding controlled with Raney clips
 Hemotympanum?
 Facial stability?
 Epistaxis tamponaded with balloons if severe
 Avulsed teeth, broken jaw?
 Penetrating injuries?
 Abdominal distention and tenderness?
 Pelvic stability?
 Perineal laceration/hematoma?
 Urethral meatus blood?
 Rectal examination for tone, blood, and prostate position
 Bimanual vaginal examination
 Peripheral pulses
 Deformities, open fractures
 Reflexes, sensation Large gastric tube st 18-Fr inserted Foley catheter inserted
 Blood?
 Pregnancy test Logroll the patient to feel and see the back, flanks, and buttocks if not already done
 Splint unstable fractures/dislocations Assure that tetanus prophylaxis is given Consult with surgeon regarding further tests or immediate need for
 surgery or preferred IV medications; consider:
 Emergency thoracotomy to provide aortic compression of cross-clamping
 Aortogram or upright chest x-ray to rule out ruptured aorta
 Cystogram if pelvic fracture present or blood in urine
 IVP or enhanced CT scan of the abdomen
 FAST or diagnostic peritoneal lavage
 Head CT scan
 IV mannitol for neurologic decompensation
 IV steroids for possible spinal cord injury
 IV antibiotics for possible ruptured abdominal viscus
 IV antibiotics for perineal, vaginal, or rectal lacerations
 Pelvic arteriogram and embolization for pelvic hemorrhage

Abbreviations: CVP = central venous pressure; FAST = focused assessment with sonography for trauma; IVP = intravenous pyelography.

neck in neutral position and rotated in all four directions) is excessive. A large multicenter study, the National Emergency X-Radiography Utilization Study (NEXUS) has helped to develop clinical screening criteria that will spare the time and expense of cervical films.⁸ The screening criteria that obviate need for C-spine imaging are:

1. No posterior midline C-spine tenderness
2. No evidence of intoxication
3. Alert mental status
4. No focal neurologic deficits
5. No painful distracting injuries

In a cohort of 34,069 patients with 578 clinically significant C-spine injuries, these criteria had a 99.6 percent sensitivity and 99.9 percent negative predictive value.

Breathing

With the patient breathing or now intubated and ventilated with 100 percent oxygen, the thorax and neck should be inspected, auscultated, and palpated to detect abnormalities such as a deviated trachea (tension pneumothorax); crepitus (pneumothorax); paradoxical movement of a chest wall segment (flail chest); sucking chest wound; fractured sternum; and absence of breath sounds on either side of the chest

(pneumothorax, tension pneumothorax, massive pneumothorax). Possible interventions here include application of an occlusive dressing to a sucking chest wound, needle thoracostomy for tension pneumothorax, withdrawal of the endotracheal tube from the right mainstem bronchus; reintubation of the trachea if no breath sounds are heard, and insertion of large chest tubes (3 8-Fr) to relieve hemopneumothorax. Evacuated blood should be collected in an autotransfusion device. The volume of blood that returns should be noted immediately, because 1500 mL of hemorrhage may require a thoracotomy.

Circulation with Hemorrhage Control

Hemorrhagic shock, a common cause of postinjury death, should be assumed to be present in any hypotensive trauma patient until proven otherwise. Direct pressure should be used to control obvious external bleeding, and a rapid assessment of hemodynamic status is essential during the primary survey. This includes evaluation of level of consciousness, skin color, and presence and magnitude of peripheral pulses. Attention should be paid to the specifics of heart rate and blood pulse pressure (systolic minus diastolic blood pressure), particularly in young, previously healthy trauma patients (Table 251-4).

Not all hemorrhage produces hemorrhagic shock, and the unsuspecting clinician may fail to appreciate ongoing hemorrhage with blood loss of up to 30 percent of the circulating blood volume.⁷ While class I hemorrhage (loss of up to 15 percent of circulating blood volume) is associated with minimal symptoms in most patients and is clearly not shock, class III hemorrhage associated with gross hypotension is readily appreciated as a state of hypoperfusion. Yet consider a young, healthy male trauma victim who has lost 25 percent of circulating blood volume (class II hemorrhage) and had a preinjury blood pressure of 130/70 mm Hg and a pulse rate of 60 beats/min. If this patient experiences a 50 percent increase in his pulse rate (to a rate of 90 beats/min) and a greater than 50 percent decrement of his pulse pressure (from 130/70 mm Hg pulse pressure of 60 beats/min to 116/90 mm Hg pulse pressure of 26 beats/min), the unsuspecting clinician may assume that the patient is "hemodynamically stable." A false sense of security may lead to delays in aggressively pursuing the source of bleeding (ultrasound, peritoneal lavage, operative exploration). From this example it should be clear that the practice of omitting diastolic blood pressures (and reporting "116/palpable," thus omitting the pulse pressure) is potentially hazardous. The alert, suspicious clinician identifies hemorrhage before it reaches the class III category of obvious shock.

Two large intravenous lines should be established and blood obtained for laboratory studies. While there are varying preferences, a percutaneous large line in the groin for unstable patients in whom upper extremity veins are not available is appropriate. This is so because subclavian lines are potentially dangerous in the hypovolemic patient with upper body trauma, saphenous vein cutdown at the ankle may not be appropriate for the patient with an injured lower extremity, and complications encountered from the femoral venous line may be minimized if the line is removed quickly on completion of resuscitation in the early postoperative period. Unstable patients without an obvious indication for surgery should be assessed for their response to 2 L of rapid infusion of crystalloids. If there is not marked improvement, type O blood should be transfused (O-negative for females of child-bearing age). Auscultation for breath sounds and heart sounds and inspection of neck veins are included in the assessment of circulation because two major causes of hypotension may be present in trauma patients with minimal blood loss: *cardiac tamponade* (hypotension, agitation, distended neck veins, muffled heart sounds) and *tension pneumothorax* (hypotension, distended neck veins, absent breath sounds, deviated trachea, tympanic percussion of chest wall).

Echocardiography and abdominal ultrasonography, now becoming available in many emergency departments, are rapid, noninvasive ways to assess for fluid in the pericardium and peritoneal cavity.⁹ This

TABLE 251-4 Estimated Fluid and Blood Losses Based on Patient's Initial Presentation

	Class I	Class II	Class III	Class IV
Blood loss (mL)*	Up to 750	750-1500	1500-2000	>2000
Blood loss (percent blood volume)	Up to 15	15-30	30-40	40
Pulse rate	<100	100-120	120-140	>140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure (mm Hg)	Normal or increased	Decreased	Decreased	Decreased

* Assumes a 70-kg patient with a preinjury circulating blood volume of 5 L.

allows rapid determination of the bleeding source in the unstable multiply injured patient.

A discussion of the long-standing controversies involving *fluid resuscitation* is beyond the scope of this chapter. However, reference must be made to a landmark paper published by Bickell and associates.¹⁰ In their prospective, randomized study of victims of penetrating torso injuries in Houston, patients were randomized to receiving immediate intravenous fluid resuscitation versus withholding fluid until operative intervention could be undertaken. A lower mortality was identified among the group with delayed fluid resuscitation, prompting the authors to speculate that giving fluids before operative control could be achieved is harmful. However one interprets this study, the fact that there were inordinate delays (sometimes >50 min) between hospital arrival and surgical intervention should help achieve consensus around at least one concept: the importance of rapid triage of critically injured patients, particularly those with penetrating trauma, to an appropriate trauma center. One is hard-pressed to identify any beneficial interventions that would justify a delay in rapid transport.

The inability, after nearly three decades, to demonstrate an unequivocal advantage of colloid therapy (which is more expensive than crystalloids) has led to near-universal acceptance of a balanced salt crystalloid (NS or LR) as the fluid of choice for initial resuscitation.

Disability

An abbreviated neurologic evaluation should now be performed, including level of consciousness, pupil size and reactivity, and motor function. The Glasgow Coma Scale (GCS) (see Table 255-2) should be used to quantify the patient's level of consciousness: possible scores range from 3 (no response) to 15 (high response on all measures). Despite the common comorbid presence of drug and alcohol abuse in trauma patients, it is only safe to assume that patients presenting with a GCS score of less than 15 and an appropriate mechanism have a head injury until proven otherwise. The GCS can be used to determine the severity of injury (minor injury GCS 13 and 14, moderate injury GCS 9 to 12, severe injury-coma GCS 3 to 8) and therefore the urgency with which the CT scan is obtained. New head injury guidelines have been formulated by an evidence-based methodology performed by the Brain Trauma Foundation in conjunction with the American Association of Neurological Surgeons.^{11,12} Among the updated recommendations are 1) a suggested guideline for the placement of devices for intracranial pressure (ICP) monitoring for head-injured patients with GCS scores of 3 to 8 and a traumatic intracranial lesion and 2) concerns about prolonged prophylactic hyperventilation in the absence of an identified increase in ICP. The result of these two recommendations produces a heightened emphasis on the importance of the head CT scan. Only a head CT scan would identify the intracranial lesion that would lead to placement of an ICP catheter, and it is only with identification of such an increase in ICP that prolonged hyperventilation (until recently a practice routinely taught) can be justified. Accordingly, patients who are comatose after head injury should be intubated with in-line neck immobilization and transported to the CT scanner with the same sense of urgency that a hypotensive patient with a gunshot wound to the abdomen would be rushed to the operating room.

Exposure

No primary survey is complete without thoroughly disrobing the patient and examining the total body surface area carefully for otherwise hidden bruises, lacerations, impaled foreign bodies, and open fractures. If hemodynamically stable and if the airway is ensured, the patient should be logrolled, with one attendant assigned to maintain cervical stabilization. Check the back and thoracic and lumbar spine for tenderness. Check the gluteal cleft and perineum for injury. When the examination is completed, the patient should be covered with warm blankets to prevent hypothermia.

When derangements in any of the components of the primary survey are identified, treatment is undertaken immediately. Once the primary survey is complete, securing of the airway, intravenous catheters as well as urinary and gastric catheters, and monitors should be achieved. At this point a *secondary survey*, a more thorough head-to-toe evaluation, is undertaken. It should be stressed that the secondary survey is not initiated until the primary survey (ABCs) is assessed to be adequate and resuscitation has been initiated.

SPECIFIC INJURIES OF IMPORTANCE

Having discussed the initial assessment of the injured patient, emphasis is placed on specific injuries of importance. These injuries are critical in that they are identified during the primary survey, represent impending demise, and require an immediate response.

Traumatic Arrests

In most emergency medical systems, paramedics transport patients without vital signs to a hospital while CPR is initiated (unless obvious signs of death are present). On arrival to the ED, a critical decision must be made regarding the level of intervention. A series analyzing 862 patients undergoing ED thoracotomy at a regional trauma center yields interesting information.¹³ The overall number of neurologically intact survivors was 3.9 percent. Among patients with blunt trauma and no vital signs in the field there were no survivors. This is a consistent finding among other series, and clearly ED thoracotomy for this group of patients should be abandoned. The greatest proportion of neurologically intact survivors was among patients with stab wounds to the chest. Further analysis revealed that survival rate was 23 percent among thoracic stab wound victims with vital signs in the field, and 38 percent among those who were moribund but had some vital signs on arrival to the ED. Therefore, the strongest recommendation for ED thoracotomy can be made for victims with penetrating chest trauma with witnessed signs of life in transport or in the ED and at least cardiac electrical activity on arrival.^{13,15} More liberal indications (although not with total consensus) would include victims with abdominal trauma with cardiac electrical activity, in whom thoracotomy is performed for resuscitation and aortic cross-clamping before operating room laparotomy (rather than for hemorrhage control), and patients with blunt torso trauma who have some vital signs on arrival. Patients with blunt trauma and absent vital signs or sign of life on arrival should not undergo thoracotomy.

Severe Head Trauma

Head trauma with coma (GCS 3 to 8) suggests that rapid assessment of the intracranial injury must be undertaken and the patient should be intubated for airway protection and to avoid secondary brain injury associated with hypoxemia. These patients present a dilemma, because ultimately they may be found to have anything ranging from a normal head CT scan to a devastating, nonsurvivable brain injury. The challenge is to quickly identify patients with intracranial injuries that may benefit from neurosurgical evacuation. In such cases, minutes may make a difference in the ultimate patient outcome. Accordingly, all nonessential procedures (i.e., those that do not address a problem discovered during the primary survey) should be prioritized to a time after the head CT is performed. The patient is intubated with in-line neck immobilization, and the C-spine collar is reapplied. A rapid chest x-ray may be justifiable to exclude pneumothorax and to assess endotracheal tube placement, particularly if the film can be developed as the patient is being transported to the CT scan suite. This implies that in the well-run trauma center the critically multisystem-injured patient has ongoing diagnostic workup and therapeutic resuscitation occurring in a smooth transition between ED, x-ray suite, operating room, and postoperative intensive care setting.

Tension Pneumothorax, Open Pneumothorax, and Massive Hemothorax

These are all diagnoses that should be made during the primary survey and subsequently require rapid placement of a chest tube. Absent breath sounds on the side of a gunshot wound, stab wound, or chest wall ecchymosis (associated with tympany in the case of pneumothorax and percussion dullness in the case of hemothorax) in a patient with respiratory distress and tachycardia suggest the diagnosis. These are discussed in detail in Chap. 259.

Abdominal Gunshot Wounds with Hypotension

This deserves special mention. Palpation tenderness elicited on ED admission identifies the need for surgery and should prompt *immediate transport to the operating room* without further workup. Placement of nasogastric, urinary, and intravenous catheters should proceed in the operating room as the patient is being prepared for general anesthesia. The importance of time is emphasized because of the large amount of hemorrhage necessary (>2 L in the 70-kg patient) to produce severe hypotension in a young, previously healthy patient.⁷ A false sense of security with these patients brought on by the absence of hypotension is hazardous.

Deeply Impaled Objects

Deeply impaled objects of the chest and abdomen should be left in situ and the patient rapidly transported to the operating room for surgical removal under direct vision to ensure hemostasis.¹⁶ The object can be shortened to facilitate transport.

SECONDARY SURVEY

While resuscitation continues, a secondary survey should be undertaken. The secondary survey is a rapid but thorough physical examination for the purpose of identifying as many injuries as possible. With this information, the resuscitating physician and his or her surgical colleagues can set logical priorities for evaluation and management. Frequent assessments of the patient's blood pressure, pulse rate, and central venous pressure should continue.

The examination is conducted in a head-to-toe fashion, beginning with the scalp. Scalp lacerations can bleed profusely. This bleeding can be controlled with plastic Raney clips that grasp the full thickness of

the scalp and galea. The tympanic membranes should be visualized to detect hemotympanum, and the pupil examination should be repeated. If epistaxis is a problem, a balloon-tipped urinary catheter or a nasal balloon should be inserted to provide posterior tamponade. The examination continues over the neck and thorax. A lateral cervical spine x-ray (if not already obtained), a chest x-ray, and an anteroposterior pelvic x-ray should be obtained while the secondary survey continues. A gastric tube should be inserted into the stomach and connected to suction. When there is facial trauma or basilar skull fracture, the gastric tube should be inserted through the mouth rather than the nose. The urinary meatus, scrotum, and perineum are inspected for the presence of blood, hematoma, or laceration.

A rectal examination is done, noting sphincter function and whether the prostate is boggy or displaced. Rectal blood should be noted. If the prostate is normal and there is no blood at the urethral meatus, a urinary drainage catheter can be placed in the bladder. If a urethral injury is suspected (meatal blood present), a urethrogram should be obtained prior to passing the catheter. If the prostate is displaced, it should be assumed that the urethra is disrupted. Catheterization should not be attempted if the urethra is injured. The urine should be examined for blood. If the patient is a woman of childbearing age, a pregnancy test should be obtained. If there is vaginal bleeding, a manual and speculum examination is necessary to identify a possible vaginal laceration in the presence of a pelvic fracture. Palpate all peripheral pulses. The patient should be logrolled to either side while keeping the neck immobilized so that every inch of the patient's body is seen and felt. The extremities should be evaluated for fracture and soft tissue injury. Peripheral pulses should be felt. A more thorough neurologic examination can now be done, carefully checking motor and sensory function.

There are many conditions that may be delayed or not evident during the secondary survey unless specifically sought. The secondary survey should be directed toward evidence of the presence or absence of the following conditions: tracheal disruption, aortic disruption, esophageal disruption, pulmonary contusion, cardiac contusion, and diaphragmatic hernia. The latter five are discussed in Chap. 259.

Some of these are not evident even with diligent search during the secondary survey. Vigilance should be maintained during the ED visit, observation period, and any subsequent hospital stay for delayed presentations. Although usually not life-threatening, missed conditions are most likely to be orthopedic in nature. Careful consideration of extremity orthopedic injuries can be easily overlooked in patients whose presentations require a multitrauma evaluation.

Radiographic Imaging

In patients who are not rapidly transported to the operating suite or the CT scanner after the initial assessment, standard radiographic imaging includes *lateral C-spine, chest, and pelvic radiographs*. The chest x-ray and pelvic films image the three regions (left hemithorax, right hemithorax, and extraperitoneal pelvis) outside the true peritoneal cavity that can accommodate volumes of hemorrhage sufficient to produce gross hypotension. X-rays in penetrating trauma are dictated by bullet entry site and include a chest x-ray for patients with torso penetrating trauma and appropriate extremity films to exclude fractures in patients with penetrating extremity injuries.

Echocardiography has become a useful diagnostic tool for emergency physicians and trauma surgeons.¹⁷ A focused abdominal sonographic examination for trauma (FAST) is a rapid diagnostic tool performed with a 3.5-MHz transducer that assesses for fluid in 1) the pericardium, 2) the hepatorenal recess of Morrison (a common location for blood in patients with hemoperitoneum), 3) the pelvis around the bladder, and 4) the perisplenic region. Abdominal sonography in the trauma patient is rapidly supplanting *diagnostic peritoneal lavage* as the procedure of choice to detect hemoperitoneum in the unstable trauma patient for whom transport to the CT suite is unsafe.⁹

DISPOSITION

Options include moving the patient to the operating room, admission to the hospital, or transfer to another facility. The primary and secondary survey must have been completed, and a gastric tube and a urinary drainage catheter should be in place unless a urethral injury was detected. In most urban level I hospitals, the trauma surgeon should have been present for the secondary survey and should assume direction of the diagnostic workup and disposition of the case at that time. In rural hospitals that transfer severe trauma cases, the resuscitating physician should relate all the physical findings discovered during the primary and secondary surveys to the physician receiving the patient. Laboratory results, x-rays, and the flow sheet showing blood pressure, pulse, fluids infused, urine output, gastric output, and neurologic findings should accompany the patient. If a diagnostic peritoneal lavage was performed, a sample of the lavage fluid should accompany the patient. A patient who is being transported to another facility should be accompanied by personnel capable of administering fluids and monitoring vital signs and pupillary changes. Mannitol should be available if there is neurologic deterioration en route.

The hallmark of trauma care in patients without obvious indications for surgery identified on the initial assessment is *serial examination*. An *observation area* is extremely useful for these patients. Such an area (typically with nursing care provisions analogous to those of an intermediate care unit in most hospitals) allows for serial observations of 1) patients with closed head trauma who have regained consciousness but who require repeat neurologic examinations; 2) patients with penetrating abdominal wounds (stab wounds or tangential gunshot wounds) who require repeat abdominal examinations; 3) patients receiving repeat chest x-rays for penetrating chest trauma without pneumothoraces; 4) patients with blunt abdominal trauma with normal physical examination on initial evaluation; and 5) patients with documented blunt injuries to the liver, spleen, or kidney who are clinically stable and are being managed nonoperatively. An observation area for these patients should allow for more rapid triage from the ED and for serial evaluations of multiple patients in a convenient setting and should provide for rapid transport to the operating room in patients whose clinical examination deteriorates.

PEDIATRIC TRAUMA

William E. Hauda II

Trauma is the leading cause of death and disability in children over 1 year of age. The most common reason for injury is a motor vehicle crash. Because children have different anatomy and physiology, the management of injuries in children differs in some respects from that of adults. Knowledge of these differences is crucial for emergency physicians to provide expedient and effective care to injured children. Many injuries can be initially managed in a general hospital ED, but care of the most seriously injured children requires prompt triage and transportation to a designated pediatric trauma center.

EPIDEMIOLOGY

Head injury is the most frequent cause of traumatic death in children.¹ Motor vehicle injuries are the leading cause of death among children over the age of 1 year, accounting for 18 percent of all deaths and 37 percent of all deaths due to trauma. Motor vehicle crashes are also the most frequent cause of injury.¹ Alcohol use by a driver is a factor in almost 25 percent of these crashes.³ Under the age of 1 year, suffocation is the most common cause of death due to injury.² The other leading causes of death are drowning, fire/burn, and firearms. Death rates for boys over the age of 5 is twice the rate for girls.² Children who are economically disadvantaged are 2.6 times more likely to die from trauma.

Homicide accounts for about 25 percent of pediatric deaths. Infants are 10 times more likely to die from homicide than are children 5 to 9 years of age.² Rates of death from injury among children have declined over the past 10 years in the United States in all categories except for firearms, suffocation, and poisoning.

TRAUMA RESUSCITATION PRIORITIES

The priorities in managing children with traumatic injuries do not differ from those of injured adults (see Chap. 251). Injuries and conditions that require immediate lifesaving intervention are treated during the primary survey (Table 252-1). All other conditions are identified and managed during the secondary survey.

TABLE 252-1 Primary Survey Goals

Identify	Intervene
Airway	
Airway obstruction	Open airway, remove obstruction
Breathing	
Apnea	Positive pressure ventilation
Hypoxia	Supplemental oxygen administration
Tension pneumothorax	Needle thoracostomy, tube thoracostomy
Massive hemothorax	Tube thoracostomy
Open pneumothorax	Occlusive dressing, tube thoracostomy
Circulation	
Shock	Fluid bolus, blood products
Pericardial tamponade	Fluid bolus, pericardiocentesis, thoracotomy
Cardiac arrest	Thoracotomy if penetrating trauma
Disability	
Spinal cord injury	Immobilization, steroids
Cerebral herniation	Hyperventilation, mannitol
Exposure	
Hypothermia	Warmed fluids, external warming
Exsanguinating hemorrhage	Direct pressure, air splints

istration of medications and fluids. A team leader not directly involved in patient care can facilitate the overall management of the patient because that person is not dedicated to a particular task.

Airway

The most important step in trauma care for children is airway intervention. Proficient management of a child's airway requires an understanding of the anatomy of children, basic airway techniques, principles of pediatric intubation, and methods for establishing a surgical airway. All these are covered in detail in Chap. 15. Ketamine should not be used in children with head injury because it causes increased cerebral blood flow and can increase intracranial pressure.

Cervical Spine

The cervical spine must be immobilized for head injury and suspected spinal injury until cervical spine injury can be excluded. No studies have been completed in children to reliably predict which patients require immobilization. Some criteria include spinal pain or tenderness, significant multiple system trauma, severe head or facial trauma, numbness or weakness in any extremity, loss of consciousness, significant distracting injury, and altered mental status with the possibility of trauma. In one study of 102 cases of pediatric spine injuries, 40 percent were associated with head injury.⁴ A properly fitting rigid collar should be used. Because a collar does not provide complete immobilization, the head should be secured to the spine board by using towel rolls or commercially available head blocks and tape applied across the forehead and under the chin of the collar.^{5,6} If a collar is not used, tape should not be applied under the chin, because this may prevent the mouth from opening. The child's body is secured to the board by straps or wide cloth tape. Blanket rolls should be placed on either side of the child to prevent lateral movement of the child if logrolling becomes necessary to clear the airway. Clearance of the child's cervical spine by clinical or radiographic methods should be delayed until the primary survey is completed.

Breathing

All trauma patients should receive supplemental oxygen. Assessment of breathing should identify inadequate oxygenation or ventilation or the potential for deterioration. Children with respiratory failure should

have positive-pressure ventilation (PPV) (e.g., bag-valve-mask) started immediately. PPV may change an innocuous pneumothorax into a compromising injury, so patients must be actively monitored for such changes. If the presence of a small pneumothorax is already known, a tube thoracostomy may be appropriate early in the resuscitation efforts. Cyanosis, agitation, poor capillary refill, bradycardia, and desaturation on pulse oximetry are signs of hypoxemia. Signs of inadequate ventilation in the young child include tachypnea, nasal flaring, grunting, retractions, and stridor or wheezing. Auscultation of the chest can identify a large pneumothorax or hemothorax. Because breath sounds are easily transmitted across a small chest, they should be assessed in both axillae. If signs of inadequate oxygenation do not improve rapidly with high-flow oxygen administration, then PPV must be started.

TENSION PNEUMOTHORAX The classic presentation of a tension pneumothorax is absent ipsilateral breath sounds, ipsilateral tympany, relatively fixed expanded ipsilateral chest wall, hypotension, and jugular venous distention due to high intrathoracic pressures. If tension pneumothorax is suspected during the primary survey, a catheter decompression should be performed without radiographic confirmation. Tube thoracostomy can be placed later.

MASSIVE HEMOTHORAX The classic presentation of a massive hemothorax is absent ipsilateral breath sounds, ipsilateral dullness to percussion, poor to absent ipsilateral chest wall motion with ventilation, and hypotension. Jugular venous distention is unlikely because the circulatory volume is low. Tube thoracostomy is needed for effective management. Operative thoracotomy should be considered if the initial drainage is greater than 15 mL/kg or the chest tube output exceeds 4 mL/kg per h.

OPEN PNEUMOTHORAX The skin wound of an open pneumothorax should be occluded on three sides with a dressing of petrolatum gauze, a plastic sheet, or a commercially available device such as an Ashermann Chest Seal. If the dressing is completely occlusive, an open pneumothorax may be converted to tension pneumothorax. Leaving one side of the dressing open to act as a flutter valve will minimize the development of a tension pneumothorax. A tube thoracostomy need only be performed after completing the primary survey.

Circulation

Signs of shock include tachycardia, cool extremities, altered level of consciousness, weak distal pulses, low urine output, and capillary refill time longer than 3 s. Capillary refill in children can be prolonged by hypothermia.

For shock, crystalloid fluid boluses of 20 mL/kg are given rapidly. If three boluses of crystalloid fail to correct signs of shock, then blood (packed red blood cells) should be given using 10-mL/kg boluses.

CARDIAC ARREST Absent pulses in a child with traumatic injuries portends a poor outcome. In children with penetrating chest or abdominal trauma, a resuscitative thoracotomy can be lifesaving if vital signs were recently lost. In children with arrest from blunt trauma, the outcome is always death.⁷ Standard advanced cardiac life-support algorithms are followed, but most injured children will have asystole or pulseless electrical activity if in traumatic cardiac arrest. Treatment includes early administration of blood products and rapid correction of life-threatening injuries.

CARDIAC TAMPONADE AND AORTIC RUPTURE These conditions are rare in children. Most commonly they result from penetrating trauma or severe blunt trauma.⁸ Cardiac tamponade is suggested by the Beck triad of hypotension, muffled heart sounds, and jugular venous distention. Diagnosis of tamponade can be confirmed by echocardiography prior to treatment. Initial fluid boluses may be temporizing, but

pericardiocentesis and resuscitative thoracotomy can be lifesaving. Management of aortic rupture is the same as in adults.

VASCULAR ACCESS Achieving vascular access is one of the most difficult tasks in an injured child. In a child, placing a single functioning intravenous line is often considered a success. Ideally two lines are placed so that blood and medications or fluids can be given simultaneously. Consideration should be given to early intraosseous line placement, because any fluids, medications, or blood products can be given through this line. The femoral vein is the next easiest site because of the identifiable landmarks and the relative ease of the procedure compared with other locations for central venous lines in children (see Chap. 21).

Disability

Level of consciousness is assessed using either the Glasgow Coma Scale (GCS) or the AVPU system, wherein the child's consciousness is rated as (present or absent): alert, responds to Verbal stimuli, responds to Painful stimuli, or is unresponsive. The GCS is commonly used in trauma databases, and lower scores have been associated with increased mortality. An arbitrary cutoff of 8 is often quoted as the score that should prompt endotracheal intubation in trauma patients. This point has been chosen because the mortality rate is greatly increased with scores below this level, and children with low scores appear to benefit from intubation.⁹ The AVPU system is recommended by the American Heart Association due to its ease of use.¹⁰

Examination of cranial nerves and pupillary responsiveness is next, and examination of the motor strength of each limb concludes the disability examination. Gross strength is all that is noted during the primary survey, so that paralysis from a spinal cord or central neurologic event is recognized. If a spinal cord injury is strongly suspected, then intravenous steroids are recommended¹¹ (see "Spinal Trauma," below).

Exposure

The final part of the primary survey serves to identify any important wounds and to detect and correct hypothermia. Actively bleeding wounds or penetrating wounds will direct the priority of actions taken during the resuscitation and secondary survey. Bleeding is controlled by direct pressure, using air splints on the extremities if needed. A rectal temperature should be obtained. Children become hypothermic much more easily than adults due to their high body surface area. Hypothermia can develop in the emergency department despite a seemingly comfortable ambient temperature. Whenever possible, keep the child covered and use external warming devices. Warm fluids to 40°C (104.0°F) if large amounts of intravenous fluids or blood products are used.

Prehospital Considerations

Standards for prehospital pediatric care have been developing slowly. Many pediatric patients are being treated in systems that lack the experience and standards of care that are needed to manage children appropriately. Intravenous access is the prehospital advanced life-support intervention that is most often performed, although the beneficial effects may be rare. Intravenous success rates are as high as 93 percent. Airway management, however, is often more difficult, with many studies showing success rates from 57 to 79 percent, far lower than the success rates with adult patients. Minimizing scene times is an important issue in pediatric trauma management. Placing intravenous lines en route to the hospital unless a prolonged extrication is required can shorten field times.

POSTRESUSCITATION PRIORITIES

Secondary Survey

The goal of the secondary survey is to identify all other injuries to a trauma patient. It does not begin until the completion of the primary survey. All body areas are completely examined. Resuscitation priorities are established, and any life-threatening injuries should already have been managed. Any needed x-rays, laboratory studies, or diagnostic procedures in the ED are also performed during this phase.

The presence of family will often be helpful to calm and console frightened and injured children. Additionally, during this phase a complete history should be obtained using the AMPLE format (Allergies, Medications, Past medical history, time of Last meal, and Events leading up to the injury).

Stabilization

In this phase, all of the child's injuries are managed definitively, or the child is stabilized sufficiently to allow safe transfer to a facility that can provide a higher level of care. Continual reassessment is crucial, because some injuries may only be manifest over time, and complications from therapeutic interventions can occur. Emphasis is placed on monitoring the airway and circulation. Endotracheal tube dislodgment, development of a pneumothorax, regurgitation of stomach contents, occult hemorrhage causing shock, and worsening neurologic function are important to continue to anticipate. Careful monitoring of fluid administration will prevent inadvertent overhydration. Analgesia and sedation should be appropriately given, as pain treatment is often neglected in children.

Referral to a Pediatric Center

Pediatric trauma center designation is done by a governmental authority, and the requirements vary from state to state.

Several capabilities define the ideal for the pediatric trauma center.¹³ The hospital should have a dedicated pediatric trauma service directed by a pediatric trauma surgeon. Comprehensive pediatric services should be available from scene care to rehabilitation and reintegration into the family and society. The trauma team should be immediately available at all times and be capable of treating at least two patients simultaneously. Other pediatric specialists should be on site or immediately available, including emergency medicine, anesthesiology, neurosurgery, radiology, orthopedics, pediatric intensive care, and nursing. A pediatric intensive care unit is essential.

Use of trauma triage scores can help identify a child who needs a more experienced team for care. However, not all scoring systems are easy to use. Two common scores used are the pediatric trauma score (PTS) and revised trauma score (RTS) (Tables 252-2 and 252-3). Advantages of these scores over other systems are that they include physiologic variables instead of relying only on anatomic variables. Higher

TABLE 252-2 Pediatric Trauma Score

	-1	+1	+2
Size (kg)	<10	10-20	>20
Airway	Unmaintained	Maintained	Normal
Systolic blood pressure (mm Hg)	<50	50-90	>90
Level of consciousness	Comatose	Altered	Awake
Wounds	Major open	Minor open	None
Skeletal trauma	Open/multiple	Closed	None

TABLE 252-3 Revised Trauma Score

Number	Glasgow Coma Score	Systolic Blood Pressure	Respiratory Rate
4	13-15	>89	10-29
3	9-12	76-89	>29
2	6-8	50-75	6-9
1	4-5	1-49	1-5
0	3	0	0

numbers are associated with a higher likelihood of survival, and thus a reduced need for trauma center care. A child with an RTS of less than 12 or a PTS of less than 8 should be taken to a trauma center.¹⁴

Some common indications for transfer to a pediatric trauma center are listed in Table 252-4.¹⁵ Even low-level falls (0.68 m, or 27 in.) can cause serious injury, especially with a hard impact surface,¹⁶ and intracranial injuries are frequently associated with low-level falls.¹⁷ Therefore low fall height does not necessarily exclude the need for specialized pediatric trauma care.

Transfer to a pediatric trauma center is best done by a pediatric transport team or a critical care transport team with some pediatric experience (pediatric nurse or pediatrician) traveling with the child (see Chap. 4).

SPECIFIC PEDIATRIC INJURIES

Head Trauma

Cerebral trauma is the leading cause of death due to injury in children. Most of these deaths occur outside of the hospital. The most common mechanisms of injury differ by age. Falls, even low-height falls,¹⁶ are the most frequent cause in children less than 2 years of age. Preschoolers also are most frequently injured in falls, but motor vehicle crashes account for 25 percent. In school-age children, falls and motor vehicle crashes occur with equal frequency. Lastly, in adolescents, sports injuries and motor vehicle crashes are about equal.

Children frequently have head injuries because of several factors. A child's head encompasses a relatively larger proportion of body mass and area. The bones of the neck are not fully developed, so the head is attached on a largely ligamentous connection. The incompletely myelinated brain is more susceptible to shear forces during trauma. Because of cartilage in the skull and the presence of open sutures, young children are better able to tolerate increased intracranial pressure than are adolescents and adults.

CLINICAL FINDINGS Most children will have suffered a mild head injury and present with no or few symptoms in the ED. Common symptoms associated with head injury include vomiting, headache,

TABLE 252-4 Indications for Transfer to a Pediatric Trauma Center

Mechanism of injury	Ejected from motor vehicle Fall from low- or higher-level height ^{15,16} Prolonged extrication Death of another occupant in motor vehicle
Anatomic injury	Multiple severe trauma More than three long-bone fractures Spinal fractures or spinal cord injury Amputations Severe head or facial trauma Penetrating head, chest, or abdominal trauma

Source: Adapted from Harris et al.,¹³ with permission.

and lethargy. For children with more significant cerebral injuries, the signs and symptoms are not markedly different from those for adults. The most difficult aspect of evaluation is often the neurologic examination. It is difficult to ascertain inappropriate behavior or mental status, particularly in the very young. Level of consciousness can be rated by the AVPU system or the GCS. A pupillary exam can identify impending herniation even in a child without distress. Asymmetry of spontaneous movements is, of course, a telling sign, while older children can then be asked to move their fingers and toes. Sensory function should be assessed by withdrawal from pain or the ability to feel touch in older children. In young children, look for signs of fontanel fullness (increased intracranial pressure; ICP) or retinal hemorrhages (shaken baby syndrome).

INCREASED INTRACRANIAL PRESSURE Signs of increased ICP in children are most commonly vomiting, dizziness, headache, irritability, and decreased level of consciousness. Management is not remarkably different from adult management of acutely increased ICP. As in adults, aggressive hyperventilation in children has been associated with worsened cerebral ischemia as compared with more moderate hyperventilation in head-injured children.¹⁸ Children with suspected increased ICP should be mildly hyperventilated (Paco₂ 30 to 34 mm Hg) and should have their hemodynamic status maximized with fluids and blood to correct shock. Fluid restriction should not be an acute consideration. To optimize venous drainage, the head of the bed should be elevated to 20° to 30°, and the neck should be straight. Intravenous mannitol in a dose of 0.5 to 1.0 g/kg can be used to lower ICP. Mannitol may acutely lower ICP by removal of free water and decreased blood viscosity. Local preferences will dictate practice. Furosemide (1.0 mg/kg) may decrease edema as well. To date, no studies have shown steroids to be helpful.¹⁹ ICP monitoring is generally done to monitor and treat increased ICP, but its effect on ultimate outcome is as yet uncertain.¹⁹

POSTTRAUMATIC SEIZURES Seizures following traumatic head injury are relatively uncommon, occurring in about 5 percent of hospitalized patients.²⁰ About half will never have a seizure again. Of the remaining half, 50 percent have rare seizures and 50 percent have frequent seizures. Children with loss of consciousness, lower GCS, longer duration of coma, and computed tomography (CT) scan abnormalities are at increased risk for seizures. Intracranial injuries most commonly seen are subdural hemorrhages, depressed skull fractures, and intracranial lacerations.²⁰ Only 50 percent of children with post-traumatic seizures will have abnormalities on CT scanning.²⁰ Use of anticonvulsant medication as prophylaxis in the absence of a seizure or following a single seizure is controversial. Children with two or more seizures, or seizures lasting more than a few minutes, should receive anticonvulsant therapy. Prophylactic anticonvulsant therapy should be strongly considered in a child with a GCS under 8, even if no seizures have yet occurred, because the risk of developing acute posttraumatic seizures is high and many of these children already have high ICPs that will increase further with a seizure.²⁰

Phenytoin or fosphenytoin is used to treat acute seizures. Dosage is the same (10 to 20 mg/kg intravenous load) except that fosphenytoin is measured in phenytoin equivalents. Acute seizures should be managed with a benzodiazepine such as lorazepam, midazolam, or diazepam.

As with adults, proximity of seizure to the event predicts long-term likelihood of epilepsy. Immediate seizures are least likely to result in long-term sequelae.²⁰

RADIOGRAPHY The primary goal of patient evaluation is to identify traumatic brain injury and to identify intracranial injuries that require surgical intervention. Radiographic studies such as CT and MRI can assist in making this diagnosis.

There are no good predictors for intracranial injury in children <2 years of age. The best predictors seem to be 1) any neurologic abnormality, 2) any altered mental status, 3) any scalp abnormalities (contusion, abrasion, laceration, cephalohematoma), and 4) vomiting.²¹ Young children can tolerate increased ICP because sutures are not fused, but once sutures reach their maximal excursion, ICP rises very quickly. CT is the imaging modality of choice. Skull films are better to identify fractures, but the identification of a skull fracture requires CT scanning. The absence of skull fracture does not exclude intracranial injury. Skull films may be indicated in addition to CT scanning for penetrating injury (such as dog bite) or suspected foreign body.

Recommendations for radiographic evaluation of children over 2 years of age who were previously healthy with an isolated minor closed head injury and who are medically evaluated within 24 h of injury were published by the American Academy of Pediatrics and the American Academy of Family Physicians.²² Children excluded from this practice parameter include children with multiple trauma, unobserved loss of consciousness, suspected cervical spine injury, history of bleeding diathesis, neurologic disorders aggravated by trauma (such as arteriovenous malformations), suspected nonaccidental trauma, and a significant language barrier. A child having a minor closed head injury is defined as a child with a normal mental status, a normal neurologic examination, and no signs suggestive of skull fracture. If the child suffered no loss of consciousness at the time of injury, then no imaging is felt necessary by these authors. If the child suffered a brief loss of consciousness, then observation and CT scan are felt appropriate. A CT scan is also indicated in children who fall into a moderate- or high-risk category (Table 252-5).²²

For children less than 2 years of age, risks for intracranial injury have not been validated. A higher threshold for CT evaluation should be used in this age group,²³ especially in falls from low heights.¹⁶

MANAGEMENT Children in the negligible- to low-risk categories with a normal evaluation can be safely discharged home (assuming no home-bound risks) for 24-h observation and follow-up with the primary care provider.²⁴ Discharge instructions should clearly state the need to return to the ED if any symptoms in the moderate-risk category occur. Children in the moderate- and high-risk categories should be admitted with NS referral as appropriate for skull fracture, persistent neurologic findings, or abnormal CT. See Chap. 255 for detailed discussion of head injury.

Children with any LOC or any symptoms after head injuries from sports should be kept out of play for 1 week and reevaluated before return to play.²⁵

Spinal Trauma

Spinal trauma is relatively uncommon in young children, and is more commonly seen in adolescents.²⁶ Cervical spine injuries predominate, although thoracic and lumbar injuries also occur (as in the lap-belt

syndrome). Motor vehicle crashes are the most common reason for spinal injury, followed by falls and sports events. In young children, falls predominate, and in older children motor vehicle crashes predominate. Due to increased flexibility of the spine and spinal column in younger children, fractures and dislocations rarely occur with minor trauma, and spinal cord injury without radiographic abnormality (SCIWORA) can occur. Adolescents more commonly have fracture patterns similar to those of adults. Also, 50 percent of spinal injuries and 67 percent of cervical spinal injuries in children under the age of 12 occur between the occiput and C2. By comparison, adolescents and adults more commonly experience lower cervical spine injuries.²⁶ Younger children also less frequently have thoracic or lumbar injuries. Part of the reason for this pattern of injury is that an immature child's spine and an adult's spine have several differences (Table 252-6).

Children with incomplete spinal cord deficits have a better prognosis for improvement of neurologic condition than those children with complete spinal cord injuries. Children with spinal cord trauma have a higher mortality rate than adults.

CLINICAL FINDINGS Presentation is related to the presence or absence of a spinal cord injury. Children with fractures only will have pain, tenderness, or overlying soft tissue injury. Children with spinal cord injuries with or without fracture will have paresthesias, paralysis, and other findings based upon the level or type of spinal cord injury (see Chap. 256).

Over 50 percent of children with SCIWORA have a delayed onset of paralysis, sometimes up to 4 days.²⁷ Many of these children have transient paresthesias, numbness, or weakness at the time of or shortly after the injury. Because most spinal injuries fail to improve substantially, even in children, the most important factor in prognosis is the initial neurologic status.²⁷ Children with fractures and neurologic symptoms do worse than children with SCIWORA alone.²⁷ Despite advances in imaging, SCIWORA remains a problem.²⁸

RADIOGRAPHY Decision algorithms for cervical spine imaging have been based upon adult patient populations. In the National Emergency X-Radiography Utilization Study (NEXUS), the authors showed that in the presence of all of the following one may safely forgo cervical spine radiography: absence of tenderness at the posterior midline of the cervical spine, absence of focal neurologic deficit, normal level of alertness, no evidence of intoxication, and absence of clinically apparent pain that might distract the patient from pain of a cervical spine injury.²⁹ Only 2.5 percent of the studied patients were 8 years of age or younger in this study, however. In young children, fear and agitation from cervical spine immobilization and the absence of comforting caregivers may make the NEXUS criteria difficult to apply. Until more conclusive pediatric studies can be accomplished, cervical spine imaging in children should be accomplished for the following: 1) moderate- or high-risk head injury; 2) multiple trauma; 3) signs or symptoms of spine injury; 4) mechanism of injury for spine injury; 5) altered mental status or focal neurologic findings; and 6) distracting painful injury with possible mechanism for spine injury. Images should include at a minimum three views: lateral, anteroposterior, and odontoid. The single lateral cervical spine radiograph has been shown to miss fractures and result in a delay in diagnosis.³⁰

TABLE 252-5 Risk Groups for Pediatric Head Injury*

NEGLECTIBLE	LOW RISK†	MODERATE-HIGH RISK
Normal exam	Normal exam	Children <2 years old
No symptoms	LOC < 1 min	Altered mental status
No LOC	Amnesia	Persistent vomiting
	Headache	LOC 1 min
	Vomiting	Seizures
	Lethargy	Facial injury
		Multiple trauma
		Abnormal examination
Observation	CT scan	CT scan
	Observation	Referral as indicated

*Defined as ages 2-20 years; previously healthy; isolated head injury.

†Risk of positive CT up to 7 percent.

TABLE 252 Characteristics of the Spinal Column Children 15,24 cm

Ligamentous laxity
Underdevelopment of supporting muscles
Partially ossified vertebrae
Wedge-shaped vertebrae
Horizontal facet joints
Higher fulcrum of flexion
Instability of atlantooccipital joint

CT scanning of the cervical spine is also an acceptable alternative, especially if a head CT scan is also being obtained.

Up to 66 percent of spinal cord injuries in children have no radiographic abnormality and thus fall under the rubric of SCIWORA.²⁷ Widening of the prevertebral soft tissues to 8 mm or more in front of C2 or more than 75 percent of the adjacent vertebral body width is considered abnormal. In infants, however, this becomes less reliable.

Occult fractures and misinterpretation of plain films do occur, so if there is any doubt, a CT scan should be obtained. If the child had paresthesias, numbness, or weakness, or currently has neurologic symptoms, a CT scan is also recommended.²⁷ If all radiographs are negative but the diagnosis of SCIWORA is being entertained, then an MRI should be obtained. The role of flexion and extension lateral cervical spine x-rays is controversial. They should not be obtained if there are neurologic signs or symptoms. Anytime the diagnosis of SCIWORA is considered, the child requires a neurosurgical consultation from the ED and admission for observation.²⁷ Cervical spine immobilization should be maintained throughout this entire procedure.

MANAGEMENT Treatment of spinal cord injuries in the prehospital and ED settings consists of immobilization, diagnosis of the specific injury, and, possibly, steroid administration. Prehospital personnel must be instructed that an infant's relatively large head may cause the neck to flex in the standard supine position, so they require padding behind the shoulders. Steroids can be given if there is evidence of a neurologic deficit. The loading dose is 30 mg/kg of methylprednisolone.¹¹ Steroids should be started within 8 h of the injury. Those who receive steroids within 3 h should be maintained on steroids for 24 h. Those who receive steroids 3 to 8 h after the injury require maintenance for 48 h. The maintenance dose is 5.4 mg/kg per h. The maintenance dose is initiated 45 min after the initial bolus. Children with a spinal cord injury require immediate neurosurgical consultation. If a spinal fracture is also present, a pediatric orthopedist should also be consulted.

Chest Trauma

Children, with their relatively compliant chest walls, may not show external evidence of serious intrathoracic trauma. Blunt trauma occurs more frequently than penetrating trauma and may be equally as serious. Isolated chest trauma in children carries a 4 to 12 percent mortality rate. Most children with chest trauma will have other significant injuries. In a multiply-injured child, death is 10 times more likely if chest trauma is present.³¹ Penetrating chest injuries are becoming more frequent as the number of firearm injuries steadily increases in the United States. Children under the age of 12 are more likely to be injured in unintentional crossfire and require a longer hospitalization than adolescents and adults.

Evaluation of a patient who has evidence of, or who has a good mechanism for, chest injury should include a thorough physical examination to look for bony defects, crepitus, paradoxical chest movement, and unequal breath sounds. A chest x-ray should be taken. To minimize interruption of the resuscitation, a supine chest x-ray can be initially obtained. A rib fracture is a sensitive indicator of serious underlying injury. The most common injury is pulmonary contusion, but this may not be visible on the early ED chest x-ray.³¹

Most injuries requiring emergent treatment can be identified on the standard supine anteroposterior chest x-ray. Mediastinal widening is common on supine chest x-rays, but aortic injury is rare in children who survive to the ED.⁸ An upright chest x-ray, preferably using posteroanterior technique, will often obviate the need for additional studies. Aortography is still considered essential to exclude aortic injury when suspected, although contrast-enhanced spiral CT scanning may also identify aortic injury. If an abdominal CT scan is obtained, additional occult chest injuries are often detected.

Tube thoracostomy alone is usually sufficient management for pneumothorax or hemothorax (same size tube for either), both of

which are uncommonly associated with blunt trauma in children. Other specific injuries should be managed as outlined in the primary survey section. Emergent thoracotomy should be performed selectively as with adults. Survival from pulseless arrest at the scene or en route to the ED is rare in both blunt and penetrating trauma.¹¹ Only children who have sustained penetrating trauma and experience a loss of vital signs in the ED should have a resuscitative thoracotomy performed. In all other cases, the attempt is futile and the financial costs are high.⁷

Abdominal Trauma

DIAGNOSIS The physical examination of a child's abdomen is frequently misleading in the detection of intraabdominal injury. Children with severe injuries can have minimal physical findings, while other children may have serious occult injuries. Physical examination is not a sensitive indicator of abdominal injury. In most children with abdominal symptoms or a mechanism of injury to the abdomen, a CT scan should be obtained.

Diagnostic peritoneal lavage (DPL) is accurate in the identification of serious intraabdominal injury in children,³² but it has largely been replaced by abdominal CT scanning. Advantages of CT scanning include its noninvasiveness and the ability to visualize the retroperitoneum. Disadvantages of CT scanning include time spent in radiology away from the trauma room, lower accuracy for hollow organ and pancreatic injury, and radiation exposure. Indications for obtaining a CT scan in children include abdominal tenderness, abdominal distention, abdominal bruising, hematuria, vomiting, neurologic obtundation, dropping or low hematocrit, and absent bowel sounds.³³ CT scan and operative findings correlate well with splenic injury grade level.³⁴ Normal CT findings in blunt trauma are strongly predictive of both no future deterioration and no need for future operative intervention.³³ Subtle CT findings such as unexplained peritoneal fluid, bowel wall enhancement, duodenal hematoma, and bowel wall thickening are associated with bowel trauma.^{33,35}

Ultrasound examination of the abdomen may be useful,³⁶ but currently there is insufficient reported experience to recommend its routine use in the evaluation of pediatric trauma patients³⁷ or for ultrasound to serve as a substitute for CT.

Splenic Trauma

The spleen is the most commonly injured abdominal organ in children. Children are more likely to be hemodynamically stable than adults, even with the same degree of splenic injury.³⁴ Children with splenic injuries are more likely to be managed nonoperatively than adults.³⁴ Several reasons are thought to explain this difference. The spleen in children has a thicker capsule. There are larger amounts of elastin and smooth muscle in both the capsule and the splenic vessels. Children tend to have lower-velocity injuries and overall lower Injury Severity Scores.³⁴

Children who are more likely to require operative intervention include those with a higher Injury Severity Score, an injury sustained in a motor vehicle crash, or a greater amount of hemoperitoneum. Any child who requires a splenectomy should receive pneumococcal vaccine to prevent postsplenectomy sepsis.

Hepatic Trauma

The liver is the second most commonly injured abdominal organ in children. Similar to splenic trauma, these injuries can often be managed conservatively. The rate of fatal hemorrhage is higher with hepatic injury than with splenic injury. Diagnosis is often made by abdominal CT scanning in stable trauma patients. Unstable patients often require operative intervention to control hemorrhage.

Pancreatic Trauma

Although pancreatic trauma is uncommon in children, trauma is the most common cause of acute pancreatitis. Handlebar injuries are the most common mechanism of injury and often cause isolated pancreatic trauma.³⁸ A high index of suspicion is required because symptoms are often delayed and morbidity is related to delay in diagnosis. Serum amylase levels are often elevated, but the degree of elevation does not correlate with the degree of pancreatic injury.³⁸ CT scanning has at best an 85 percent sensitivity to identify pancreatic injury in the acute setting.³⁸ Sensitivity is highest when both oral and IV contrast are used. Children with abdominal pain and an elevated serum amylase require an abdominal CT scan and should be hospitalized for observation even if the CT scan findings are normal.³⁸ Complications of pancreatic injury include pseudocyst formation, acute pancreatitis, and relapsing pancreatitis.

Bowel Trauma

Intestinal injuries occur in less than 5 percent of children with blunt abdominal trauma. The jejunum is most frequently injured, followed by the ileum and cecum. The duodenum is particularly prone to the development of hematomas in the wall, leading to obstruction. The physical examination is often quoted as being unreliable in diagnosing bowel injury following blunt trauma. Children with abdominal wall injuries (bruising or abrasions), tenderness on palpation, or a mechanism of a direct blow to the abdomen require further investigation to exclude bowel injury. In hemodynamically stable patients, a contrast-enhanced CT scan can often increase the suspicion of a bowel injury. CT scans are diagnostic for bowel injury in a minority of cases. Pneumoperitoneum or extravasation of enteral contrast is considered diagnostic of bowel injury and requires immediate laparotomy. Nondiagnostic findings include free peritoneal fluid without solid organ injury and bowel wall enhancement or thickening. A child with a tender abdomen and these nondiagnostic but suggestive radiographic findings requires an exploratory laparotomy or DPL to exclude an intestinal perforation.³⁹ Complications of bowel injury include peritonitis, obstruction, and intestinal structures.

Bowel injury is associated with seat-belt use in less than 5 percent of children admitted to trauma centers. A particular entity, the lap-belt complex, consists of intestinal or mesenteric injury with a concomitant lumbar spine injury due to a lap belt. It has also been shown to occur with three-point restraints (lap belt/shoulder-harness restraints) when the lap belt is incorrectly positioned over the abdomen. The intraabdominal injury often occurs at the midlumbar level. Most commonly, the jejunum is injured. Any child with a lumbar fracture or an anterior abdominal bruise from a seat belt must have a thorough search for intraabdominal injury. If a spinal injury is present, but the CT scan is negative, the child should be admitted for observation and serial examinations.

Pelvic and Genitourinary Trauma

Trauma to the genitourinary (GU) tract should be considered in all children with multiple trauma, a pelvic fracture, or injury to the flank, back, or groin. GU injuries are uncommon in children. Symptoms and physical findings are often nonspecific, including back pain, abdominal pain, hypotension, and abdominal wall trauma. Pelvic fractures, particularly anterior ring fractures, are associated with urethral and bladder injury. Children are less likely to die of hemorrhage from a pelvic fracture than are adults. Often, other coexisting injuries mask the signs and symptoms of GU trauma in a multiply injured child.

Hematuria is considered the hallmark finding in GU trauma, although it is a nonspecific finding. The degree of hematuria does correlate with the severity of injury, although renal pedicle disruption can be associated with no hematuria.⁴⁰ The radiographic evaluation of an

injured child with hematuria is based on clinical presentation. Children with gross hematuria or more than 20 RBCs/hpf and unstable vital signs or the emergent need for operative intervention for other injuries require an intravenous pyelogram (IVP) in the ED. Children who have hematuria of more than 10 RBCs/hpf and stable vital signs should have CT of the abdomen performed. Asymptomatic microscopic hematuria in children with blunt trauma and no apparent injuries is a low-yield indication for emergent abdominal CT scanning. These cases can be followed as outpatients.

Cystourethrography is required on all patients with suspected lower urinary tract injuries (for example, blood at the urethral meatus, high prostate, or anterior pelvic fracture). Straddle injuries account for 20 percent of the cases of urethral injury (motor vehicle crashes account for most of the other 80 percent). Straddle injuries are also associated with pubic fractures, testicular injuries, and labial or scrotal hematomas and lacerations. Sexual abuse should be considered in a girl with a straddle injury and a history that does not seem compatible with the injury.

ACKNOWLEDGMENT

Thanks to Dr. Doug Trocenski for his assistance in this manuscript.

from the 1980 census figures. The Census Bureau projects that those older than 65 years will increase to 52 million by 2020 and to 80 million by 2050 (representing 20 percent of the total population).¹ The number of people older than 85 years of age also are growing at an accelerated pace, with estimates that they will number 14 million by the year 2040.¹

While persons older than 65 years of age represent 12 percent of the population, they account for 36 percent of all ambulance transports, 25 percent of hospitalizations, and 25 percent of total trauma costs.² Geriatric trauma patients represent between 8 and 12 percent of the general trauma population. While male trauma victims are predominant in the younger age groups, males and females are equally represented in the geriatric trauma population.³ Trauma ranks as the seventh leading cause of death in this age group, although the rate per 100,000 is 92, as compared with 35.7 for all age groups.³ Although the elderly are less likely to be involved in trauma as compared to other age groups, they are more likely to have fatal outcomes when they are injured. Approximately 28 percent of deaths due to accidental causes involve persons 65 years and older. Also, the elderly have the highest population-based mortality rate of any age group.²

Definitions

Defining the term "elderly" is a difficult task because it involves both chronologic and physiologic components. The literature has divided the elderly population into two groups: the "young old" (65 to 80 years of age) and the "old old" (80 years of age and older).² Although this is a somewhat arbitrary division, it is helpful in interpreting the literature of geriatric trauma.

One of the difficulties in describing the elderly population is the potential discrepancy between chronologic age and physiologic age. Chronologic age is the actual number of years the individual has lived. Physiologic age describes the actual functional capacity of the patients' organ systems in a physiologic sense. Physiologic reserve describes the various levels of functioning of the patients' organ systems that allows them to compensate for traumatic derangement. Comorbid disease states such as diabetes mellitus, coronary artery disease, arthritis, renal disease, and pulmonary disease can decrease the physiologic reserve of certain patients, which makes it more difficult for them to recover from injury.⁴

PATHOPHYSIOLOGY

Common Mechanisms of Injury

The elderly will experience similar types of injuries that younger individuals do. There are differences, however, in the incidence and patterns of injury for elderly patients compared to younger persons.

Falls

Falls are the most common cause of injury in patients over 65 years of age.^{5,6} Fifty percent of elderly persons who fall do so repeatedly. Most individuals who fall will do so on a level surface and most will suffer an isolated orthopedic injury.^{3,7} Falls are reported as the underlying cause of 9500 deaths each year in patients older than age of 65 years. Many falls in the elderly population occur in residential institutions such as nursing homes. In the > 85-year-old age group, 20 percent of fatal falls occur in nursing homes.⁷

There are age-related changes in postural stability, balance, motor strength, coordination, and reaction time that make the elderly more prone to tripping and falling, and may explain the increased incidence of falls. Also, decreased visual acuity and increased memory loss can cause the patient difficulty in recognizing and avoiding environmental hazards. Acute, preexisting, and chronic diseases also may lead to falls.

GERIATRIC TRAUMA

O. John Ma Stephen
W. Meldon

Although the elderly experience the same type of trauma that younger individuals do, there are differences in the incidence and patterns of injury, and age-related changes may produce a diminished physiologic reserve.

EPIDEMIOLOGY

Persons 65 years of age and older represent a large and growing segment of the population. In 1997, more than 34 million people, 12.7 percent of the total population, were 65 years of age or older.¹ This represents a 21.3 percent increase in this segment of the population

SECTION 22 • TRAUMA

Syncope has been implicated in many cases of elderly patients who fall and this may be secondary to dysrhythmias, venous pooling, autonomic derangement, hypoxia, anemia, or hypoglycemia. Other contributing factors include alcohol and medications, most notably sedative, antihypertensive, antidepressant, diuretic, and hypoglycemic agents.⁷

Motor Vehicle Crashes

Motor vehicle crashes rank as the second leading mechanism of injury that brings elderly patients to a trauma center in the United States, and are the most common mechanism for fatal incidents in elderly persons through 80 years of age.² Data show that the crash fatality rate among the elderly is considerably higher than for younger age groups.⁸ As noted above, similar effects of acute and chronic medical conditions can influence the incidence of motor vehicle crashes. Older persons may have decreased cerebral and motor skills and memory and judgment losses that can compound the difficulty in operating a motor vehicle. Older drivers also are more likely to have decreased auditory or visual acuity, which may make it more difficult to recognize dangerous traffic situations. Furthermore, decreased strength and slower reaction times may hinder an individual's ability to respond to a hazardous traffic situation.² Older drivers are more likely to be involved in crashes during daylight hours, in good weather, at intersections, and those involving two vehicles.

Pedestrian-Motor Vehicle Collisions

The elderly are second only to children as victims of pedestrian-motor vehicle collisions. The 65-year-and-older age group accounts for 22 percent of pedestrian-automobile fatalities in the United States.³ Elderly pedestrians struck by a motor vehicle are much more likely to die than are struck younger pedestrians. Pedestrian-motor vehicle collisions are one of the most lethal mechanisms of injury in this age group, with a 53 percent case-fatality rate.³ A number of factors contribute to the increased risk of older persons becoming victims of pedestrian-vehicle collisions. Reduced peripheral vision and decreased hearing may limit access to information needed to make rational decisions about crossing the street. Cognitive, memory, and judgment skills are often diminished, and may increase the risk of older pedestrians being struck by automobiles. Postural changes due to musculoskeletal decline may lead to kyphosis, which results in difficulty in lifting the head to see and obey traffic signals. Traffic signals operate at a crossing rate of 4 feet per second, an insufficient amount for some elderly to safely cross some intersections.²

Burns

The elderly constitute between 13 and 20 percent of admissions to burn units, but have the highest case fatality of any age group. The majority of burn injuries in this age group are a result of careless activity in the home setting and are a result of either flame injuries from smoking or cooking or tub scald injuries. The elderly have a higher fatality rate than do younger adults with the same extent of burn, and even nonmajor burns (less than 20 percent body surface area) may be significant. Increasing age, male gender, burn size, presence of full-thickness burn, and presence of inhalation injury contribute to mortality.⁹ The relationship between higher age and increased burn mortality has been long recognized, and geriatric patients with burns of 70 percent or greater usually do not survive, even with aggressive management. The Baux Index, a simple addition of age and percentage body surface area burned, has continuing prognostic value. A Baux Index of 75 represents a severe burn and an index of 100 is usually fatal.⁹

Violence

While the overall increase in violent crimes in the United States has not spared the elderly, related injury is generally lower in this demo-

graphic group. Violent assaults account for 6 percent of trauma admissions in the elderly, as compared with 25 percent in a younger cohort.⁵ Elderly persons are seen as ideal targets for robberies because they may possess various age-related physical deficiencies. Just as in the younger population, ethanol consumption by the assailant or victim has been found to be involved in the majority of fatal assaults. Emergency physicians also should have a heightened suspicion for elder or parental abuse in the geriatric trauma patient (see Chap. 300).

CLINICAL FEATURES

Out-of-Hospital Considerations

Following injury, older patients have higher admission rates, longer hospital stays, increased long-term morbidity, and higher mortality rates despite lower injury severity.¹⁰ Emergency medical services (EMS) providers should recognize that seemingly minor trauma mechanisms, such as low-level falls and low-speed motor vehicle crashes, may result in significant injury to older persons. For these reasons, it has been recommended that the threshold for scene triage or transfer to a trauma center be lower for elderly patients than for younger patients.

Despite these recommendations, there is evidence that elderly patients are disproportionately underrepresented at trauma centers.^{11>Ua} Whether this is secondary to minor injury mechanisms, an initial assessment that underestimates the severity of their trauma, existing pre-hospital triage protocols or a bias against aggressively treating elderly patients is not clear. Most trauma protocols typically rely on anatomic and physiologic criteria to mandate transfer to a trauma center, and patient age greater than 55 years is often listed as one of several comorbid conditions that should be considered. Consideration of patient age should be a component of out-of-hospital trauma protocols that direct the triage and transport of injured patients.

History

Because elderly patients may have a significant past medical history that impacts their trauma care, obtaining a precise history is vital. Often, the time frame for obtaining information about the traumatic event, past medical history, medications, and allergies is quite short. Medical records and consultation with the patient's family physician may be helpful. Family members also may be able to provide information regarding the traumatic event and the patient's previous level of function. Medications must be carefully listed, as many elderly patients are on cardiac agents, diuretics, psychotropic agents, and anticoagulants.

Vital Signs

The clinician should not be led into a false sense of security by "normal" vital signs. In a study by Scalea and coinvestigators, 8 of 15 geriatric blunt trauma patients initially considered to be hemodynamically "stable" had cardiac outputs less than 3.5 L/min and none had an adequate response to volume loading. Of 7 patients with a normal cardiac output, 5 had inadequate oxygen delivery.¹²

There is progressive stiffening of the myocardium with age that results in a decreased effectiveness of the pumping mechanism. An 80-year-old will have approximately 50 percent of the cardiac output of a 20-year-old, even without significant atherosclerotic coronary artery disease. The myocardium also becomes less sensitive to endogenous and exogenous catecholamines. Conduction defects may be exacerbated by the stress of illness or trauma. A normal tachycardic response to pain, hypovolemia, or anxiety may be absent or blunted in the elderly trauma patient. Medications such as β -blockers may mask tachycardia and hinder the evaluation of the elderly patient. Blood pressures

also may be misleading because the prevalence of preexisting hypertension in this age group approaches 70 percent. Emergency physicians should be wary of a "normal" heart rate and blood pressure in the geriatric trauma victim.

DIAGNOSIS AND DIFFERENTIAL

As in all trauma patients, the primary survey should be initiated expeditiously. Special attention should be paid to anatomic variation that may make airway management more difficult. These include the presence of dentures (which may occlude the airway), cervical arthritis (which adds danger to extending the neck), or temporomandibular joint arthritis (which may hinder mouth opening).

A thorough secondary survey is essential to uncover less-serious injuries. These injuries, which include various orthopedic and "minor" head trauma, may not be severe enough to cause problems during the initial resuscitation, but cumulatively may cause significant morbidity and mortality. An important point to note is that patients with no apparent life-threatening injuries can actually have potentially fatal injuries if there is some degree of limited physiologic reserve. Seemingly stable geriatric trauma patients can deteriorate rapidly and without warning.

RECOGNITION AND DIAGNOSIS OF COMMON INJURY PATTERNS

Head Injury

With aging, the brain undergoes progressive atrophy and decreases in size by about 10 percent between the ages of 30 and 70 years.¹³ Subtle changes in cognition, memory, and data acquisition may confound the emergency physician's evaluation of the elderly patient's mental status. When evaluating the patient's mental status during the neurologic examination, it would be a grave error to assume that alterations in mental status are due solely to any underlying dementia or senility. In a 1978 study, elderly persons experienced a much lower incidence of epidural hematomas than the general population.¹³ This was attributed to the relatively more dense fibrous bond between the dura mater and the inner table of the skull in older individuals. There is, however, a higher incidence of subdural hematomas in elderly patients. As the brain mass decreases with advancing age, there is greater stretching and tension of the bridging veins that pass from the brain to the dural sinuses. The increased "dead space" within the skull may delay symptoms of intracranial bleeding. More liberal indications for computed tomography (CT) scanning of the head are justified.

Cervical Spine Injuries

Spine injuries may be difficult to evaluate in geriatric patients. Cognitive problems or brain injury may make the clinical evaluation of the spine more difficult. A careful history from the patient or family will provide valuable information regarding the presence of previous neurologic deficits. The Canadian C-Spine Rule for radiography in alert and stable patients following blunt head/neck trauma identified age (≥65 years) as a high risk factor for C-spine injury, even among those with stable vital signs and Glasgow Coma Scale score of 15.¹⁴ Thus, C-spine imaging in all such elderly patients is warranted.

One study found the incidence of cervical spine injury to be twice as great in geriatric patients as it was in a younger cohort of blunt trauma patients. Odontoid fractures were particularly common in geriatric patients, accounting for 20 percent of geriatric cervical spine fractures, as compared with 5 percent of nongeriatric fractures.¹⁵ When the elderly trauma patient presents with neck pain, emergency physicians need to place special emphasis on maintaining cervical immobilization until the cervical spine is properly assessed. Because un-

derlying cervical arthritis may obscure fracture lines, the elderly patient with persistent neck pain and negative plain radiographs should undergo CT scanning of the cervical spine.

Preexisting cervical spine pathology, such as osteoarthritis, may predispose elderly patients to spinal cord injuries. With hyperextension injuries, elderly patients may develop a central cord syndrome. This injury should be suspected in patients with upper greater than lower extremity weakness and sensory loss.

Chest Trauma

Chest trauma, both minor and severe, can compromise elderly individuals. In blunt trauma, rib fractures are the most common injury found. The pain associated with rib fractures, along with any decreased physiologic reserve, may predispose patients to respiratory complications.² More severe thoracic injuries, such as hemothorax, pulmonary contusion, flail chest, and cardiac contusion, can quickly lead to decompensation in elderly individuals whose baseline oxygenation status may already be diminished.

Geriatric patients are more susceptible to the development of hypoxia and respiratory infections following trauma. In the elderly, diminished elasticity of the lungs along with progressive changes in the chest wall can lead to a reduction in pulmonary compliance and in the ability to cough effectively. Total lung surface area decreases as alveolar and small airway support diminishes with advancing age. There also is reduced mucociliary clearance of foreign material and bacteria and increased colonization of the oropharynx with gram-negative organisms. All of these factors result in an increased risk for nosocomial gram-negative pneumonia.²

The main therapeutic goal is aggressively maintaining adequate oxygen delivery. Frequent arterial blood gas analysis may provide early insight into elderly patients' respiratory function and reserve. Prompt tracheal intubation and use of mechanical ventilation should be considered in patients with more severe injuries, respiratory rates greater than 40 breaths per minute, or when the partial pressure of arterial oxygen (P_{aO_2}) is <60 mm Hg or the partial pressure of carbon dioxide in arterial gas (P_{aCO_2}) is >50 mm Hg. While nonventilatory therapy helps to prevent respiratory infections and is always desirable, early mechanical ventilation may avert the disastrous results associated with hypoxia.²

Chest trauma alone does not necessarily forecast a bleak outcome. In one series, most patients with blunt chest injuries were discharged home to their preinjury level of independence.²

Abdominal Trauma

Significant abdominal injuries are diagnosed in approximately one-third of geriatric trauma patients.² The abdominal examination in elderly patients is notoriously unreliable as compared to younger patients. Even with an initially benign physical examination, emergency physicians must have a high index of suspicion for intraabdominal injuries in patients who have associated pelvic and lower rib cage fractures. For older patients, the adhesions associated with previous abdominal surgical procedures may increase the risk of performing diagnostic peritoneal lavage in the emergency department. Therefore, CT scanning with contrast is a valuable diagnostic test. It is important to ensure adequate hydration and baseline assessment of renal function prior to the contrast load for the CT scan. Some patients may be volume depleted as a consequence of medications such as diuretics. Hypovolemia coupled with contrast administration may exacerbate underlying renal pathology.² For unstable patients, and especially those with multiple scars on the abdominal wall from previous procedures, the focused assessment with sonography for trauma (FAST) examination is the ideal diagnostic study to detect free intraperitoneal fluid. In prospective studies by emergency physicians and trauma surgeons, ultrasonography has been demonstrated to be highly sensitive and specific for the

SECTION 22 • TRAUMA

identification of free intraperitoneal fluid. It also is rapid, portable, noninvasive, and easily repeatable.

Orthopedic Injuries

HIP FRACTURES Many elderly patients are predisposed to orthopedic injuries as a consequence of skeletal osteopenic and osteoporotic changes. Hip fracture is the single most common diagnosis that leads to hospitalization in all age groups in the United States. Hip fractures occur primarily in four areas: intertrochanteric, transcervical, subcapital, and subtrochanteric. Intertrochanteric fractures are the most common, followed by transcervical fractures.² Bleeding from closed pelvic and long-bone fractures can cause hypovolemia in elderly patients. Timely orthopedic consultation, evaluation, and treatment with open reduction and internal fixation should be coordinated with the diagnosis and management of other injuries.

LONG-BONE FRACTURES Long-bone fractures of the femur, tibia, and humerus may produce a loss of mobility with a resulting decrease in the independent lifestyle of elderly patients.¹⁶ Geriatric patients who present with femoral fractures have been found to have a significantly higher rate of preexisting medical conditions than patients with proximal humeral fractures.¹⁶ Early orthopedic consultation for placing intramedullary rods may result in earlier mobilization.

UPPER EXTREMITY INJURIES Falls on the outstretched hand increase the risk for Colles fractures. After the diagnosis is confirmed by radiographs, these fractures can usually be treated with closed reduction and immobilization. The incidence of humeral head and surgical neck fractures in elderly patients also are increased by falls on the outstretched hand or elbow.¹⁶ Localized tenderness, swelling, and ecchymosis of the proximal humerus are characteristic signs of these injuries. Early orthopedic consultation and treatment with a shoulder immobilizer or surgical fixation should be arranged. Social services may need to be contacted to arrange for assistance with routine daily activities for some elderly patients being discharged home after an orthopedic injury.

EMERGENCY DEPARTMENT MANAGEMENT AND DISPOSITION

Special Management Principles

The work by Scalea and coinvestigators demonstrated that trauma physicians frequently fail to recognize the severity of hemodynamic instability in geriatric patients. Therefore, early invasive monitoring has been advocated to help physicians assess the elderly patient's hemodynamic status. Scalea and colleagues showed that by reducing the time to invasive monitoring in elderly trauma patients from 5.5 h to 2.2 h (thus recognizing and appropriately treating occult shock), the survival rate increased from 7 to 53 percent. Survival was likely improved secondary to enhanced oxygen delivery through the use of adequate volume loading and inotropic support.¹²

The insertion of invasive monitoring lines may not be a frequent occurrence in many emergency departments because of institutional practice and availability of equipment. Thus, every effort should be made by emergency physicians to expedite emergency department care of elderly trauma patients and prevent unnecessary delays. In the emergency department evaluation of blunt trauma patients, the chest radiograph, cervical spine series, and pelvic radiographs are necessary diagnostic tests during the secondary survey. Only a few radiologic studies, such as emergent head and abdominal computed tomography scans, should take precedence over obtaining vital information from invasive monitoring. Elderly trauma patients may benefit the most from an expeditious transfer to the intensive care unit for further mon-

itoring so that hemodynamic status can be more adequately assessed. After assurance that hemodynamic status has been stabilized, patients can be transported back to the radiology suite for further plain radiographic studies.

In the emergency department, one must make critical management decisions regarding volume resuscitation without the benefit of sophisticated invasive monitoring devices. Geriatric trauma patients can decompensate from overly aggressive volume repletion just as quickly as they can with inadequate resuscitation. Elderly patients with underlying coronary artery disease and cerebrovascular disease are at a much greater risk of suffering the consequences of ischemia to vital organs when they become hypotensive after trauma. During the initial resuscitative phase, crystalloid, while the primary option, should be administered judiciously because elderly patients with diminished cardiac compliance are more susceptible to volume overload.

Serial crystalloid fluid boluses of 250 to 500 mL should be administered, with frequent monitoring of blood pressure, pulmonary examination, and urinary output. Strong consideration should be made for early and more liberal use of red blood cell transfusion. Depending on the type of injury and severity of blood loss, switching to blood transfusion after 1 to 2 L of crystalloid resuscitation should be considered. This practice early in the resuscitation may enhance oxygen delivery and help to minimize tissue ischemia.

Prevention, Prognosis, and Outcome

For elderly patients who are discharged home after sustaining an injury from a fall, a home safety assessment should be encouraged, through social services or the primary care physician, to help prevent future falls. Chronic medications that may adversely affect the vestibular system, cause profound sedation, or produce postural hypotension, should be identified; patients can then discuss alternative therapies or dosages with their primary care physicians.⁷ When providing a prescription for new medication, select drugs that are the least centrally acting, least associated with postural hypotension, and have the shortest duration of action.

Among geriatric trauma patients who are hospitalized, the mortality rate has been reported to be between 15 and 30 percent. These figures far exceed the mortality rate of 4 to 8 percent found in younger patients.² In general, late trauma deaths from multiple organ failure and sepsis occur more often in the elderly. Geriatric patients also are more likely to die following minor traumatic events.⁶

Several markers for poor outcome in elderly trauma victims have been determined. Age greater than 75 years, Glasgow Coma Scale score less than 7, presence of shock upon admission, severe head injury, and the development of sepsis are associated with worse outcome and higher mortality figures.¹⁷ Although the Injury Severity Score (ISS) correlates with mortality rates, it does not fully capture the potential for mortality in this age group. For example, mortality rates for minor trauma (ISS < 10) and nonmajor trauma (ISS < 15) may be significant in the elderly. Survival probabilities that use ISS also perform less well with low-level falls than with other injury patterns. In the older trauma patient, the number of injuries, and not just the body system with most severe injuries, is a strong and independent contributor to mortality.¹⁸ Comorbidities are common in this age group; however, studies addressing preexisting diseases and trauma mortality in this age group are equivocal and the magnitude of the effect is uncertain. Several studies indicate that preexisting diseases clearly affect trauma outcomes. Other studies, however, have not shown a clear correlation between preexisting diseases and trauma mortality. Explanation for these divergent results may be found in the results of Richmond and coinvestigators.¹⁸ They noted that the presence of preexisting comorbid medical conditions increased the odds of experiencing a complication greater than threefold. Complications themselves were a significant predictor of mortality. For example, cardiovascular complications tripled and pulmonary complications doubled the mortality risk.

The ultimate goal in the care of elderly trauma patients is to return them to their preinjury state of function. Recent data suggest that immediately after discharge, one-third of trauma survivors return to independent living, one-third return to dependent status but living at home, and one-third require nursing home facilities. In the long term, almost 90 percent of trauma survivors ultimately return home and a majority return to independent living.^{17,19} Increasing age, total number of injuries, injury to extremities, injuries as a result of falls, and lower functional levels predict discharge to a skilled nursing facility.¹⁸

In light of investigations showing that elderly patients often return to preexisting health status after trauma and the value of early invasive monitoring, it appears that **aggressive resuscitation efforts for geriatric trauma patients are warranted.**

that in traumatic events (particularly apparently minor ones), the severity of maternal injuries may be a poor predictor of fetal distress and outcome.^{1,3} Successful outcomes for both mother and fetus require a collaborative effort among the prehospital provider, emergency physician, trauma surgeon, obstetrician, and neonatologist.

EPIDEMIOLOGY

It has been consistently estimated that significant trauma complicates 6 to 8 percent of all pregnancies.¹ Trauma during pregnancy is associated with an increased risk of preterm labor, placental abruption, fetal-maternal hemorrhage, and pregnancy loss. The maternal trauma-related mortality rate does not appear to be different from that of nonpregnant women.⁴ Substance abuse has previously been shown to be a contributing factor, with one study finding a positive toxicology screen in up to 16 percent of patients tested.⁵

The most common cause of blunt abdominal trauma is motor vehicle crashes, accounting for up to 70 percent of acute injuries. This is followed by falls and direct assault in decreasing order of frequency.^{1,6} The incidence of falls appears to increase with advancement of pregnancies, presumably due to alterations in maternal balance and coordination. Even minor abdominal trauma can result in fetal demise. Up to 5 percent with minor trauma may experience abruption. The role of domestic violence during pregnancy is of significant concern, with one large series describing more than 31 percent of trauma in pregnant women as intentional injuries, and most studies cite rates of violence during pregnancy at 4 to 8 percent.⁷ As many as 88 percent of those cases may involve the husband or boyfriend as the perpetrator.⁸

Penetrating injuries are less common than blunt trauma during pregnancy. Gunshot wounds are the most common form of penetrating trauma. Some of these injuries may be self-inflicted and represent attempts to terminate pregnancies. Fetal mortality rates in penetrating injuries are as high as 70 percent. While the rate of maternal visceral injuries is 19 to 38 percent, there remains a 60 to 90 percent chance of fetal injury. This is presumably due to the protective effect of the gravid uterus on maternal viscera.

INJURY PREVENTION

Substantial evidence has demonstrated that motor vehicle seat belt use during pregnancy helps protect both the mother and the fetus, and current recommendations suggest that safety belts be worn throughout pregnancy. One study found that the best predictors of fetal loss or adverse outcome were crash severity and lack of, or improper, seat belt use.⁹ The American College of Obstetricians and Gynecologists (ACOG) and the National Highway Traffic Safety Administration (NHTSA) recommend that the lap belt be placed as low as possible under the gravid uterus (across both the anterior superior iliac spines and the pubic symphysis) and that the shoulder harness be positioned snugly between the breasts but off to the side of the uterus. According to the NHTSA, seatbelt use in the general public increased to its highest level ever of 75 percent in 2002,¹⁰ but the most recent studies in pregnant patients showed that 46 percent of pregnant patients involved in motor vehicle crashes were not wearing seat belts.¹¹

One leading panel of expert physicians on the subject has recommended that air bags not be disconnected for pregnant women.¹² While there is a risk of injury to the more proximally located gravid uterus, it is also known that the leading cause of fetal death in motor vehicle crashes is maternal death. With the pregnant woman properly seated as far away as possible from an airbag, the benefits of these restraint devices currently appear to outweigh the apparent risks.

PHYSIOLOGIC CHANGES OF PREGNANCY

Physiologic changes in pregnancy are discussed in detail in Chap. 104. In addition to the normal physiologic changes associated with pregnancy,

TRAUMA IN PREGNANCY

Nelson Tang Drew White

Trauma remains the leading cause of nonobstetric morbidity and mortality in pregnant women. The conventional paradigm that fetal survival depends wholly on maternal stabilization and well-being is fundamentally accurate. It has become increasingly apparent, however,

SECTION 22 • TRAUMA

non-trauma related complications of pregnancy must also be considered. Conditions such as pregnancy-induced hypertension, placenta previa, preeclampsia, and eclampsia may significantly alter the presentation and complicate evaluation and treatment in the setting of trauma (see Chap. 106).

Maternal blood volume begins to expand at approximately week 10 of gestation and peaks at about a 45 percent increase from baseline at week 28, resulting in a state of hypervolemia. Red cell mass increases to a lesser extent, leading to the relative physiologic anemia of pregnancy. Cardiac output is increased by 1.0 to 1.5 L/min at week 10 of pregnancy, and remains elevated until the end of pregnancy. Heart rate in the mother is generally increased by 10 to 20 beats/min in the second trimester, accompanied by decreases in systolic and diastolic blood pressures of 10 to 15 mm Hg.

The relative hypervolemic state can mislead the clinician during maternal resuscitation in trauma and make clinical findings difficult to interpret. A pregnant woman may lose 30 to 35 percent of circulating blood volume before manifesting hypotension or clinical signs of shock.¹ Uterine arteries constrict, resulting in diminished fetal blood flow and tissue oxygenation, before significant evidence of maternal hypovolemia appears.

After week 12 of gestation, the uterus becomes an intra-abdominal organ, removing it from the relative protection of the maternal pelvis and making it more susceptible to direct injuries. The bladder also moves anteriorly into the abdomen in the third trimester of pregnancy, increasing its susceptibility to injury. Uterine blood flow may increase to upward of 600 mL/min, making severe maternal hemorrhage from uterine injury possible. The gravid uterus also causes passive stretching of the abdominal wall and peritoneum as it enlarges and may lead to diminished sensitivity to injury and irritation from intraperitoneal blood. At or about weeks 18 to 20 of gestation, the expanding mass of the gravid uterus may lead to the "supine hypotension syndrome," in which venous return and cardiac output are diminished by compression of the maternal inferior vena cava in the supine position. The enlarging uterus may additionally cause engorgement of lower extremity and lower abdominal vessels, predisposing the patient to severe retroperitoneal hemorrhages with acute injuries to these areas. Placement of intravenous lines in the groin and lower extremity should be avoided if possible because of inferior vena cava compression by the uterus and to avoid pooling in engorged or injured pelvic veins.

As pregnancy progresses, the diaphragm is elevated by as much as 4 cm and tidal volume increases by 40 percent as residual volume diminishes by 25 percent. Functional residual capacity is similarly decreased, and the compensatory increase in ventilation typically results in respiratory alkalosis. Serum pH is usually maintained at normal values by renal compensation. These changes may significantly impair the ability of a pregnant trauma patient to compensate for respiratory compromise. Diaphragmatic elevation should also be considered when thoracostomy tube placement is indicated during maternal resuscitation.

The gastrointestinal tract demonstrates diminished motility, and there is delayed gastric emptying during pregnancy. This increases the likelihood of gastroesophageal reflux and the potential for aspiration from acute injuries as well as from resuscitative interventions, including endotracheal intubation. The small bowel is moved upward in the abdomen by the enlarging uterus, protecting the small bowel to some degree from lower abdominal injuries. It does, however, increase the chance of complex bowel injuries in penetrating trauma of the upper abdomen.⁶ The liver is typically unaffected by pregnancy, and the most common etiology of abdominal hemorrhage remains splenic injury, as in nonpregnant patients.

MATERNAL AND FETAL INJURIES

Direct fetal injury is relatively rare in blunt abdominal trauma during the first trimester of pregnancy. When fetal injuries do occur, they are typically seen later in gestation and tend to involve the fetal skull and

brain. These injuries are frequently sustained in association with fractures to the maternal pelvis when the fetal head is engaged. When the uterus is penetrated by a sharp object or projectile, the fetus has a high probability of sustaining injury.

Uterine rupture is a relatively uncommon complication of blunt trauma sustained during pregnancy. Its incidence has been reported to be 0.6 to 1.0 percent of injuries in pregnancy, and is more likely to occur during the late second and third trimesters and when there is direct and forceful impact upon the uterus.^{6,13} The fetal mortality rate in such cases is nearly 100 percent, whereas maternal mortality is less than 10 percent. The presentation of uterine rupture may be quite nonspecific, but loss of the palpable uterine contour, ease of palpation of fetal parts, or radiologic evidence of abnormal fetal location is suggestive of the diagnosis.

Uterine irritability and the onset of preterm labor may be precipitated by acute abdominal trauma during pregnancy. Numerous reports have noted the management of premature labor in pregnant trauma patients with tocolytic agents, but their use has not been generally recommended and requires individualization. Tocolytic agents have numerous adverse side effects, such as fetal and maternal tachycardia, which may complicate the evaluation of trauma patients. Additionally, their use may further impair the ability to diagnose other significant traumatic injuries, specifically placental abruption. If tocolytics are considered, an obstetrician should be consulted prior to administration.

Second only to maternal death, abruptio placentae is the most common cause of fetal death. Abruptio placentae complicates 1 to 5 percent of minor injuries during pregnancy and up to 40 to 50 percent of major trauma.⁶ Placental abruption has been described as being caused by the deformation of the elastic uterus around the relatively inelastic placenta, and is independent of placental location. Further exacerbated by increased intrauterine pressures, shear forces are applied to the placental base, leading to separation from the uterine wall. Findings consistent with abruptio placentae include abdominal pain, vaginal bleeding, and tetanic uterine contractions, classically described as painful vaginal bleeding in the third trimester. Placental abruption may also lead to the introduction of placental products into the maternal circulation, stimulating disseminated intravascular coagulation (DIC) or amniotic fluid embolism. The correlation and predictive value of DIC with respect to fetal mortality remains unsettled.^{8,14}

The incidence of fetal-maternal hemorrhage (fetal red blood cells entering the maternal bloodstream) in trauma during pregnancy is four to five times that which occurs in pregnancies not complicated by injury.⁶ Fetal-maternal hemorrhage occurs in over 30 percent of significant trauma in pregnant patients and is implicated in the sensitization and subsequent isoimmunization of Rh-negative patients. Fetal hemorrhage itself poses the direct risks of fetal hypovolemia, anemia, distress, and death. Anterior placental location appears to be associated with an increased risk of fetal-maternal hemorrhage.

EMERGENCY TREATMENT

Prehospital Care

An effort to ascertain the possibility of pregnancy should be made during the initial evaluation of all acutely injured women of childbearing age. As in the care of all trauma victims, initial priorities remain the ABCs of resuscitation directed at the mother. All pregnant trauma patients should receive supplemental oxygen, as the gravida becomes less able to compensate for hypoxia. Similarly, early intubation must be considered when indicated by the nature or severity of injuries. Peripheral intravenous lines with crystalloid infusions should be initiated in the prehospital setting.

For pregnant patients beyond 20 weeks of gestation who must be transported in the supine position or in whom spinal immobilization is indicated, a wedge should be placed under the right hip area, tilting the pa-

tient approximately 30 degrees toward her left side, to avoid hypotension from inferior vena cava compression by the gravid uterus. Alternatively, the uterus may be manually maneuvered to the left side of the abdomen by transport personnel. Pneumatic antishock trousers are rarely used now, but if considered in a pregnant patient, the abdominal compartment must not be inflated, because that may cause uteroplacental compression and impair venous return to the heart. An integral part of the prehospital role in trauma management is triage to an appropriate hospital. If pregnancy in a trauma patient is identified or suspected, transport should be initiated to a designated trauma center with sufficient capabilities to manage both mother and fetus. Advance notification of the receiving facility should be made to enable the assembly of the appropriate hospital personnel to continue the resuscitation and management efforts.

Emergency Department Management

Upon arrival in the emergency department, the prehospital resuscitative measures already undertaken should be reviewed and continued as appropriate. Since maternal stability and survival offer the best chance for fetal well-being, **initial efforts must be directed toward the adequate resuscitation of the mother prior to evaluation of the fetus.** No critical interventions or diagnostic procedures should be withheld from the treatment of pregnant trauma patients out of concerns for potential adverse fetal consequences. A trauma surgeon and obstetrician should be involved early in the evaluation and management of a significantly traumatized pregnant patient.

Volume Resuscitation

The initial sequence of trauma resuscitation is unchanged in the emergency treatment of an injured pregnant patient. The patient is kept in the left lateral decubitus position to the extent possible to minimize vena caval compression. Since aortocaval compression has also been demonstrated to decrease the effectiveness of chest compressions, maneuvers such as a lateral tilt or manual displacement of the uterus should also be performed during CPR.¹⁶ Securing the airway and ensuring the adequacy of ventilation in addition to the administration of supplemental oxygenation are of primary concern. Gastric tube decompression must be performed early, since delayed stomach emptying makes the possibility of aspiration a particular concern during pregnancy. Sources of hemorrhage should be identified and controlled, because maternal blood loss and hypovolemia occur at the expense of fetal hypoperfusion. Adequate large-bore vascular access is essential, and crystalloid infusions may need to be adjusted upward by as much as 50 percent to account for the additional plasma volume in pregnancy. The use of vasopressor agents poses a risk of impaired uterine perfusion and should not be initiated until adequate volume replacement has been administered. Their use should not be restricted, however, if required for maternal resuscitation. Initial laboratory studies include complete blood counts, blood typing, and Rh status, as well as coagulation profiles with fibrin degradation products and fibrinogen to determine the possibility of DIC. Low serum bicarbonate levels have been shown to be associated with adverse fetal outcomes, and routine determination of the levels may be of predictive value.¹ After the primary trauma survey, an organized and methodical secondary system survey must be performed to ensure the identification of all potential injuries.

Gestational Age Assessment

Attention should next be turned to the evaluation of the gravid abdomen and fetus. Gestational age can be assessed rapidly by palpating uterine fundal height. At week 12 of gestation the uterine fundus may be palpated at or about the level of the pubic symphysis, and at approximately week 20 it may be felt at about the level of the umbilicus. The abdomen and uterus should be examined for evidence of injury as well as palpated for uterine tenderness or contractions.

Pelvic Examination

If abdominal or pelvic trauma is suspected, a sterile pelvic examination is indicated to inspect for injuries of the lower genital tract, vaginal bleeding, or rupture of amniotic membranes. Fluid with a pH of 7 in the vaginal canal is suggestive of amniotic fluid, whereas a pH of 5 is consistent with vaginal secretions. A branchlike pattern upon drying of vaginal fluid on a microscope slide or "ferning" is also diagnostic of amniotic fluid.

Fetomaternal Hemorrhage

Fetomaternal hemorrhage (FMH) should be suspected if there is uterine tenderness, uterine contractions, vaginal bleeding, or in the presence of direct or indirect maternal abdominal trauma. The occurrence and degree of FMH can be assessed by the Apt test or the Kleihauer-Betke (KB) test. The Apt test is a qualitative determination of the presence of fetal hemoglobin in maternal blood. The KB test applies acid elution to an aliquot of maternal blood, and then maternal and fetal red blood cells are counted under the microscope. An extrapolation is then made to the volume of FMH. Neither test is available on an emergency basis, however, and the KB test has poor sensitivity to detect <5 |xL of FMH. The recognition of FMH is important because if the mother is Rh-negative and the fetus is Rh-positive, as little as 0.1 |xL of fetal blood can sensitize the mother¹⁵ and endanger this and subsequent pregnancies.

Rh^oD Immune Globulin

The American College of Obstetricians and Gynecologists recommends that consideration be given to administering Rh^oD immune globulin (Rhogam, BayRhoD, MICRhoGAM, WinRho) to all unsensitized D-negative (Rh-negative) pregnant women with abdominal trauma.⁶ Exceptions are 1) prior maternal sensitization; 2) a known Rh-negative fetus; 3) or a known Rh-negative father. History of the latter is often unreliable or unavailable. Rh^oD immune globulin protects against Rh isoimmunization if given within 72 h of FMH.

DOSAGE There is no uniform agreement on the dose, but two options are available: **50 fig for gestation 12 weeks or less and 300 fig for gestation 13 weeks or more OR 300 fig for all gestational ages.** The rationale for the lower dose for 12 weeks or less gestation is that the total fetal blood volume at 12 weeks gestation is about 4.2 |xL, and a 50-|xL dose will be effective for up to 5 (xL of FMH. A 300-|xL dose will protect up to 30 |xL of FMH.

The obstetrician can best determine if doses larger than 300 |xg should be administered. The 72-h window for Rh^oD immune globulin administration allows for more thorough FMH testing in the hospital.

Tetanus Prophylaxis

Tetanus prophylaxis has no deleterious fetal effects and should be routinely administered as indicated following trauma. Given that the tetanus antibody crosses the placenta, it can also reduce the incidence of neonatal tetanus.

Diagnostic Imaging

The use of diagnostic radiologic imaging in the emergency treatment of pregnant trauma patients adheres to the fundamental principles of trauma management. While the judicious acquisition of studies is indicated to minimize fetal exposure to the potential effects of ionizing radiation (see Radiation Exposure to Uterus/Fetus, Table 104-3), no tests should be withheld if they are necessary for appropriate maternal evaluation and treatment. The principal concerns regarding radiation exposure in utero are the possibilities of childhood neoplasia, fetal

loss, congenital malformations, and microcephaly.¹⁷ Thus studies should be limited to those that are essential, as radiation exposure sequelae are cumulative.

The greatest risk to fetal viability is within the first 2 weeks following conception, and the highest potential for malformation is during embryonic organogenesis from 2 to 8 weeks after conception.¹⁷ Adverse fetal effects due to radiation exposure are negligible from doses of less than 10 rad. The standard trauma plain radiographs, such as cervical spine, chest, and pelvis films, deliver significantly less than 1 rad each.¹⁷ Fetal exposure can be further decreased by appropriate shielding of the maternal abdomen and pelvis during many studies.

Abdominopelvic CT scanning, pelvic angiography, and pelvic fluoroscopy result in the highest delivered doses of radiation. The amount is typically 2 to 5 rad, with some variation due to equipment quality, techniques used, and duration of study.¹⁷ A recent study demonstrated that the sensitivity and specificity of abdominal ultrasound for the evaluation of abdominal trauma in pregnancy is similar to that in non-pregnant patients.¹⁸ Radiation exposure in CT may be reduced by performing modified studies and the use of dose-reducing techniques, such as decreasing the number of imaging slices obtained.¹⁷ Diagnostic evaluations with magnetic resonance imaging and ventilation-perfusion scanning have not been reported to cause adverse pregnancy outcomes. Potential effects of contrast agents have not been definitively studied, and their use requires individualization.

DPL and Laparotomy

The indications for emergent laparotomy remain unchanged in the evaluation of pregnant trauma patients. Similarly, diagnostic peritoneal lavage (DPL) is an effective modality for the evaluation of intra-abdominal injuries from acute trauma. DPL should be performed with an open, supraumbilical technique in patients with evidence of a gravid uterus. The fetus appears to tolerate surgery and anesthesia well if adequate oxygenation and uterine perfusion are maintained.⁶ The performance of emergent DPL and surgery have not been shown to have an association with fetal loss, and these procedures should not be withheld out of concern for fetal compromise when indicated in trauma.¹ Additionally, a large multi-institutional retrospective review has shown that emergent cesarean delivery results in a fetal survival rate as high as 75 percent when gestation is at or greater than 26 weeks, fetal heart tones are present on admission, and the procedure is performed at the earliest indication of fetal distress.³

Fetal Assessment

A rapid assessment of fetal condition should be initiated with auscultation of fetal heart tones to determine fetal viability and identify fetal distress. Assessment of fetal heart tones may be augmented by use of a Doppler stethoscope or ultrasound. It has been suggested that fetal viability in the setting of trauma is directly related to the presence or absence of fetal heart tones on presentation, and that if these are confirmed absent, then the remainder of treatment efforts be directed solely at maternal resuscitation.³ Normal fetal heart rates are in the range of 120 to 160 beats/min. The most likely cause of fetal bradycardia is acute hypoxia. In acute injuries, maternal hypotension, hypothermia, respiratory compromise, or placental abruption are likely etiologies. Similarly, in the setting of acute trauma, the finding of fetal tachycardia may also represent a hypoxic or hypovolemic state. The use of bedside ultrasound has become an increasingly valuable adjunct to initial trauma assessment and management. Portable ultrasound in this setting has been shown to be rapid, noninvasive, and facilitates serial examinations.¹⁹ In cases of trauma during pregnancy, ultrasonography may also be of particular value in the evaluation of general fetal condition. Fetal size and estimated gestational age, the presence of fetal heart motion, fetal activity or demise, placental location, and amniotic fluid volume can be assessed.²⁰ The efficacy of ul-

trasound, however, for the diagnosis of specific trauma-related injuries remains unproven. Several reports have suggested the relative inability of ultrasound to diagnose uterine rupture or fetal-placental injuries, and its sensitivity is insufficient to exclude the diagnosis of placental abruption.^{17,20} The intra-abdominal anatomic distortions of late third-trimester pregnancy may further limit the diagnostic capability of ultrasound in acute trauma.

In the management of blunt trauma during pregnancy, external fetal monitoring is indicated for gestational age estimated beyond 20 weeks and is more predictive than ultrasound for abruptio placentae. The initiation of fetal tocodynamometry is recommended at the earliest possible stage of evaluation following maternal stabilization, preferably in the emergency department with obstetric consultation, because abruptio placentae usually becomes apparent shortly after the injury. Fetal monitoring is utilized to assess both uterine contractile activity as well as fetal heart rate. Beyond the viable gestational age of 23 weeks, the presence of fetal tachycardia, lack of beat-to-beat or long-term variability, or late decelerations on tocodynamometry are diagnostic of fetal distress and may be indications for emergent cesarean delivery.

The identification of frequent uterine activity on external fetal monitoring has been shown to be a sensitive predictor of abruptio placentae beyond 20 weeks of gestation. In a major prospective study, no cases of abruptio placentae were identified if there were fewer than 8 contractions per h during the first 4 h of tocodynamometry. A minimum of 4 h of external tocodynamometric monitoring of the potentially viable fetus appears to be predictive of immediate adverse pregnancy outcomes and is indicated for all pregnant patients evaluated for trauma, even those without obvious abdominal injury. Patients demonstrating 3 to 7 contractions per h or persistent uterine irritability should have tocodynamometry extended to a minimum of 24 h. They may subsequently be safely discharged if uterine contractions abate and other reasons for further evaluation do not exist. Patients with fewer than 3 contractions per h during an initial 4-h observation period can be safely discharged in conjunction with the consulting obstetrician. This approach has been shown to have the same pregnancy outcomes among discharged patients when compared with uninjured controls.

PERIMORTEM CESAREAN DELIVERY

The need to perform perimortem cesarean delivery in cases of maternal cardiac arrest arises extremely rarely. Nevertheless, it involves complex ethical, medical, and emotional considerations. The largest review of reported attempts to date in the literature revealed fewer than 200 successful fetal outcomes from the procedure.²² The time to delivery from the onset of maternal arrest was found to be critical to fetal survival with good neurologic outcome. Excellent outcomes were reported when delivery took place within 5 min of maternal death. Survival was unlikely if delivery occurred after 20 min of maternal arrest. It has since been recommended that the procedure be performed after 4 min of maternal resuscitation, such that the fetus will be delivered within a total of 5 min from initiation of CPR.²² Successful out-of-hospital perimortem cesarean delivery has been reported, although with a prolonged interval between maternal collapse and delivery and severe neurologic deficits in the infant.

Consideration of perimortem cesarean delivery must be made only after immediate and optimal advanced maternal cardiopulmonary resuscitative measures have been instituted. The procedure may be attempted in gestations estimated at beyond 23 weeks. Full maternal resuscitation must continue unabated while preparing for and during the actual delivery. It is universally recommended that the procedure be performed rapidly with the most readily available materials, and that a single vertical incision be made to enter the peritoneum, followed by a vertical uterine incision to deliver the fetus. Successful maternal revival following fetal delivery has been reported. Improved venous return to the central circulation, increased maternal oxygen

delivery following removal of the high uterine demand, and decreased pooling of blood in the uteroplacental circulation have all been suggested as explanations.

DISPOSITION

The decision to admit or discharge after the emergency assessment and management of a pregnant trauma patient is ultimately based on the nature and severity of presenting injuries. Patients suffering severe multisystem trauma will have their further care and management assumed by trauma surgeons and consultant obstetricians. Even in cases of seemingly minor but potentially significant injuries, admission to a trauma service capable of further observation and management is appropriate. Patients who demonstrate evidence of fetal distress or uterine irritability during the initial assessment require admission under the extended evaluation and care of an obstetrician capable of emergency delivery as necessary. Patients who must be transferred to other facilities for definitive trauma or obstetric care must be appropriately stabilized prior to transfer, with provisions for an appropriate level of care during transport. There must be strict adherence to transfer policies that comply with federal regulations. Clearly, the ongoing need for an interdisciplinary approach to patient management in such cases remains even after admission.

Although external fetal monitoring may be initiated in the emergency department with consultation, the monitoring is typically continued in the labor and delivery suite under the direction of an obstetrician. If the extended period of monitoring demonstrates no evidence to suggest fetal or maternal injury or distress, the patient may be discharged. Upon discharge, the patient must be carefully advised to seek medical attention immediately if she should develop abdominal pain or cramping, vaginal bleeding, leakage of fluid, or perception of diminished fetal activity. The decision to discharge an injured pregnant patient from the emergency department must be made carefully. A high index of suspicion should be maintained for occult injuries as well as a low threshold for obstetric consultation when indicated. To screen for the possibility of interpersonal violence, a thorough social services evaluation or referral should be made in all but the most obvious cases of accidental injury. Adequate obstetric follow-up care must be ensured for all pregnant trauma patients when discharged from the emergency department.

HEAD INJURY Thomas
D. Kirsch Christopher A.
Lipinski

EPIDEMIOLOGY

Injuries are the leading cause of death in persons younger than 45 years old with approximately one-third of these deaths a result of head trauma. Traumatic brain injury (TBI) results from either direct or indirect forces to the brain matter. Direct injury is immediate and caused by the force of an object striking or penetrating the head. Indirect injuries from acceleration/deceleration forces are generated by the variable movements of different areas of the brain against one another and by the impact of the brain against the skull.

Annually, in the United States, there are approximately 1.5 million nonfatal TBIs, 370,000 persons hospitalized as a result of a TBI, and 52,000 persons who die from TBI.¹ TBI also leads to 80,000 annual cases of residual neurologic disability. The costs for treatment of both acute and chronic TBI are estimated to be \$4 billion dollars annually.²

The peak incidence of TBI occurs in males between the ages of 15 and 24 years, but ethanol-intoxicated individuals, the elderly, and young children are at increased risk of TBI because of underlying anatomic and physiologic factors. The cause of TBI varies greatly by age and demographic factors. For example, for 15- to 24-year-olds the leading cause is gunshot wounds, while for those older than age 65 years it is falls.

ANATOMY

The outermost layer, the scalp, is composed of five layers: skin, subcutaneous tissue, galea, areolar tissue, and the pericranium. Because of the rich blood supply, the scalp has a major role in temperature regulation, being capable of liberating 50 percent of our total body heat. This same generous blood supply, combined with the loose areolar connection to the pericranium, can lead to severe blood loss after injury.

The calvaria or skull is a rigid container made up of eight major bones. These bones are composed of two solid layers separated by cancellous bone, which adds rigidity and strength. The cranial sutures between bones initially serve as expansion joints, but eventually fuse, halting expandability in adults.

Because the basilar skull is the exit and entry point for the cranial nerves and blood vessels basilar fractures places these structures at risk. The *inion* is the anatomic meeting point of the frontal, sphenoid, temporal, and parietal bones. Fractures of the skull at this point can disrupt the underlying middle meningeal artery, leading to epidural hematoma.

The adult brain weighs between 1300 and 1500 g and occupies 80 percent of the total volume of the skull. The brain's three basic structures—the cerebral hemispheres, the cerebellum, and the brainstem—are divided by two major fixed dura attachments. The *falx cerebri* vertically separates the cerebral hemispheres down to the brainstem. The *tentorium cerebelli* separates the cerebellum and brainstem from the cerebrum at the base of the skull. The inner edge of the tentorium cerebelli is the site of the most common brain herniation syndrome, uncal herniation. The cerebrum is further anatomically divided into major lobes named after the bones overlying them: frontal, temporal, parietal, occipital. The cortices encase the deeper brain structures such as the basal ganglia, the major systems integration site. The cerebellum occupies the posterior cranial fossa, and is responsible to pattern motor memory and balance. The brainstem contains the cranial nerve nuclei and the inflow and outflow functional somatic tracts.

The brain is covered with multiple anatomic layers and potential spaces. The outermost layer, the *dura mater*, is firmly adhered to the inner skull and has fixed attachments at the cranial sutures. At some edges of dural reflections, the dura separates into two layers and forms channels called the dural venous sinuses, which serve to drain blood and cerebrospinal fluid from the brain. Underneath the dura mater is a thinner connective tissue layer called the *arachnoid mater*. The arachnoid mater perforates the dura mater at the venous sinuses where it forms arachnoid granulations. The arachnoid granulations serve as filtration and drainage points for the cerebrospinal fluid. The arachnoid mater is loosely adhered to the pia mater making possible the potential subarachnoid space. The *pia mater* is closely associated with the gray matter of the brain and is the innermost layer. Between the arachnoid and the pia is the *subarachnoid space*, where cerebrospinal fluid (CSF) circulates. In the average adult, there is 150 mL of CSF surrounding the brain and spinal cord. Approximately 500 mL of CFS is produced in the choroid plexus of the lateral ventricles each day.

Several subarachnoid spaces known as *cisternae* surround the brain and correspond to large cortical surface irregularities. These include the ambient, prepontine, supracerebellar, cerebellomedullary, interpeduncular, superior, and magna. There are four spaces contained within the brain known as *ventricles*: two lateral ventricles (separated by the septum pellucidum), a third ventricle, and a fourth ventricle. These CSF-containing spaces communicate by foramina: Monroe (between the lateral and third ventricle), aqueduct of Sylvius (between the third and fourth ventricle), and foramen of Luschka and Magendie (outlets from the fourth ventricle into the cerebellomedullary cistern and cisterna magna).

PATHOPHYSIOLOGY

Acute brain injury is usually divided into primary and secondary phases. In the case of traumatic brain injury, the acute or primary phase describes the cellular injury and death that are a direct result of force of the injury. Primary cell death is irreversible and only preventing the injury event and mitigation of the injury forces on the brain reduce morbidity and mortality.

Secondary injury cascades can extend the damage to cells that are not initially irreversibly damaged. In the hours to weeks after the injury, local tissue ischemia from compressive forces or vascular injury lead to secondary cellular death. Prevention of the ischemia and hypoxia are the main therapeutic goals for treating patients with TBI.

Normal Physiology

The cerebrovascular system delivers energy substrates and oxygen while simultaneously removing the byproducts of metabolism. The

brain accounts for only 2 percent of total body weight, but consumes 20 percent of the body's total oxygen requirement and 15 percent of total cardiac output. Maintaining adequate brain tissue perfusion is critical to avoid secondary brain injury. The cerebral perfusion pressure (CPP) is the difference between inflow and outflow (AP) and is essentially the driving pressure for cerebral blood flow (CBF). Estimates of CPP assume that the relevant inflow pressure is equivalent to the mean arterial pressure (MAP) and the outflow is related to intracranial pressure (ICP). The ICP is used to estimate outflow pressure because the venous system is collapsible at the entry point into the sinuses and changes in this outflow pressure occurs in parallel with increases in the ICP. The CPP is calculated in lieu of CBF:

$$CPP = MAP - ICP$$

The local adjustment of CBF within the brain microcirculation that result from changes in arterial pressure is termed "autoregulation." Autoregulation of CBF is functional with CPP between 50 and 150 mm Hg, but is often lost in patients with TBI where normal relationship between flow and perfusion may be affected. A pressure-volume relationship occurs in the brain microvasculature that illustrates cerebral autoregulation (Figure 255-1). Under normal circumstances the major regulatory mechanisms of CBF are the partial pressure of carbon dioxide (P_{CO_2}), blood pressure, and blood pH. Hypotension or hypoventilation leads to increased P_{CO_2} and decreased pH. Under these circumstances, the cerebral vasculature dilates to increase CBF and deliver more oxygen. Hypertension, hypocarbia, and alkalosis cause vasoconstriction. Decreased partial pressure of oxygen (P_{O_2}) also leads to increased CBF by causing cerebral vasodilation.

Pressure-Volume Relationship in Brain Injury

Circulation to the brain is vulnerable to conditions that increase the intracranial volume. Normal ICP is less than 15 mm Hg and is determined by the volume of the three intracranial compartments: the brain parenchyma (—1300 mL in the adult), cerebrospinal fluid (100 to 150 mL), and intravascular blood (100 to 150 mL). When one compartment expands there must be a compensatory reduction in the volume of another or the ICP will increase.

When the ICP is outside its normal range autoregulation is lost, and the CBF follows a more linear passive-pressure relationship to CPP. As a result, normal cerebral blood flow may not be restored until the CPP is increased to greater than 90 mm Hg.³ Cerebral blood flow is generally maintained when the CPP is above 60 to 70 mm Hg in the setting of hypotension and elevated ICP. This CPP level is considered the lower limit of autoregulation, below which local control of CBF cannot be adjusted to maintain flow adequate for function.

Rapid rises in the ICP that cause compression of the brain can lead to a phenomenon known as the *Cushing reflex* (hypertension, bradycardia, and respiratory irregularity). This triad is classic for an acute rise in ICP, but is seen in only one-third of cases, and is more common in children than adults.

Mechanisms of Secondary Cellular Death

Neurons that survive the primary insult face several secondary injury mechanisms that are characterized as *excitotoxicity*, *oxidative stress*, *inflammation*, and *apoptosis* (programmed cell death).

Immediately following the acute injury event there is a decrease in the production of ATP, affecting ATP-dependent processes. This results in influx of sodium and water leading to cellular edema, cellular acidosis from anaerobic metabolism, and calcium influx with the release of the excitatory amino acid glutamate. Glutamate is the central initiator of excitotoxicity, leading to multiple lethal reactions that alter the structural and functional integrity of the cell. If the tissue is reperfused, the damage is compounded as free radicals are produced (oxidative stress). Iron-dependent lipid peroxidation products lead to further membrane damage.

FIG. 255-1. Normal cerebral blood flow (CBF) autoregulation curve and the abnormal curve with TBI. Normal autoregulatory control (*black line*) maintains a relatively constant CBF over a broad range of mean arterial pressure (MAP). Loss of autoregulation results in a more linear relationship between CBF and MAP, potentially resulting in increased edema and intracranial pressure (ICP) (*red line*). Increases in ICP may result in a net loss in CBF.

The local production of cytokines causes the inflammatory component of secondary injury. Migration of neutrophils, monocytes, and macrophages into the site of injury amplifies the injury to surviving cells. These cells contribute to the oxidative stress and inflammatory cascades by releasing proteases, free radicals, and vasoconstrictive mediators.

Finally, cells that escape early death may die from an endogenous mechanisms of cell death, broadly called *apoptosis*. The cellular triggers and mediators of apoptosis are beginning to be defined. Treatments that disrupt these secondary cellular injury pathways are still being developed, so the primary clinical treatment remains the prevention of increased ICP, ischemia, and hypoxia.

INITIAL EVALUATION AND MANAGEMENT

Because preventing secondary brain injury is the major goal of TBI management, correcting or preventing hypoxemia, hypotension, anemia, hyperglycemia, and hyperthermia, and evacuation of intracranial masses is critically important. Hypotension [systolic blood pressure (SBP) <90 mm Hg] and hypoxemia (P_{aO_2} <60) are associated with a doubling of TBI mortality.³ Anemia (hematocrit <30 percent) also leads to increased mortality because of decreased oxygen-carrying capacity.

Airway control with cervical spine stabilization, breathing, and circulation are the first priorities for all trauma patients. Only then can a neurologic and mental status examination be conducted to evaluate disability. Early recognition and treatment of hypoxemia, hypotension, and anemia are essential.

Prehospital Care

The care of the head-injured patient begins with emergency medical services (EMS) personnel in the prehospital setting. In addition to the ABCs (airway, breathing, circulation), assessing the history of the event and the patient's condition and mental status immediately after the injury is important. Hypoxia and hypotension need to be identified and corrected rapidly on the scene. There is no indication for prehospital hyperventilation or use of mannitol for patients with TBI.

ED Resuscitation

Important historical points include the mechanism of injury, the patient's condition before and after the trauma, the past medical history, and the recent use of drugs or alcohol. Important information regarding the condition after the injury includes the length of the loss of con-

sciousness, vomiting, and if seizure activity occurred. A history of anticoagulant use or a coagulopathy should be determined. As with all patients with altered mental status, the potential for other injuries such as hypothermia, inhalation injuries, and toxic exposures should be investigated.

AIRWAY AND BREATHING Hypoxia increases mortality from TBI, therefore aggressive airway and breathing management is needed. All patients with severe TBI require intubation and ventilation initially with 100 percent O_2 . In-line cervical spine stabilization is essential until cervical spine injury or fracture is definitively excluded. Orotracheal rapid-sequence intubation (RSI) using appropriate agents optimizes the patient's physiology, prevents increased ICP, and has the lowest complication rate (see Chap. 19). The ideal induction agent should both blunt the increase in ICP and yet not decrease the MAP. Because some of the drugs commonly used for RSI (Table 255-1) cause hypotension, strict attention needs to be paid to assure hemodynamic stability during the procedure.

Lidocaine has been used as a pretreatment agent because of its potential to prevent hemodynamic changes and elevation of intracranial pressure, but recent reports question its utility.⁴ A defasciculating dose of succinylcholine (0.1 mg/kg IV), vecuronium (0.01 mg/kg IV), or pancuronium (0.01 mg/kg IV) given 2 to 3 min prior to succinylcholine has been used to prevent RSI-induced increases in ICP, but again, to date there are no clinical trials that demonstrate improved outcome with preinduction agents.

Barbiturates decrease ICP and decrease cerebral metabolic oxygen demand. Therefore, a short-acting barbiturate can be used as an induction agent. Thiopental (3 to 5 mg/kg IV) has a rapid onset and is

TABLE 255-1 Recommended Agents for Rapid Sequence Intubation of Patients with Severe TBI

Preinduction agents* (prevent ICP elevation)
Succinylcholine 0.1 mg/kg IV <i>or</i>
Vecuronium 0.01 mg/kg IV <i>or</i> pancuronium 0.01 mg/kg IV
Induction agents (sedative/hypnotics and analgesia)
Thiopental 3-5 mg/kg IV (normotensive) <i>or</i> 0.5-1.0 mg/kg IV (hypotensive)
Fentanyl 3-5 (Ag/kg IV
Propofol 1-4 mg/kg IV
Neuromuscular blocking agents (long-acting agents are not recommended for TBI patients)
• Succinylcholine 1.0–1.5 mg/kg IV

*Not clinically validated to improve outcome in TBI patients.

SECTION 22 • TRAUMA

short-acting. Because thiopental is a cardiovascular depressant, patients who are hypotensive should receive only 0.5 to 1 mg/kg or another inducing agent, such as etomidate (0.3 mg/kg). Ketamine has traditionally been avoided as it was thought to cause ICP elevation; however, some studies have shown a decrease in ICP when ventilation is controlled. There is renewed interest in ketamine because it blocks potentially deleterious amino acid [iV-methyl-D-aspartate (NMDA)] receptors in the brain.⁵ Further study in the ED, however, is warranted before a recommendation can be made.

The use of etomidate (0.3 mg/kg) for induction in the ED has not been studied extensively. Those studies that have looked at the effects of etomidate administration on ICP and CPP (in either the intensive care unit or operating room) in head-injured patients have been inconclusive, with mixed reports.⁶

Propofol as an induction agent has several theoretical benefits (rapid onset/recovery and minimal hemodynamic effects). Propofol is commonly used for RSI in the operating setting; however, few reports exist for use in the ED for severely head-injured patients.

Neuromuscular blocking drugs (NMBDs) are used to facilitate airway control and to prevent complications without increasing ICP. The use of NMBDs prevents any meaningful neurologic exam and limits the ability to detect changes in the condition of the patient (e.g., seizure). Therefore the shortest-acting agent, succinylcholine is usually chosen.

RSI techniques should also be used for comatose patients, who are susceptible to increases in ICP with laryngoscope and intubation. Nasotracheal intubation is not specifically contraindicated in TBI, but it should rarely be used because of its higher complication rate, lower success rate, and potential for marked increase in ICP. In the presence of a basilar skull fracture, nasotracheal intubation also leads to an increased risk of meningitis.

CIRCULATION Improved blood pressure resuscitation decreases mortality for patients with severe TBI.⁷ Therefore, aggressive fluid resuscitation may be required to prevent hypotension and secondary brain injury. Adequate fluid resuscitation has not been shown to increase ICP and guidelines recommend that the MAP be maintained at 90 mm Hg (systolic blood pressure of 120 to 140 mm Hg) to achieve adequate cerebral perfusion.⁸ Isolated head injury rarely produces hypotension, except as a preterminal event. Hypovolemic shock may be seen in infants because of epidural bleeding or subgaleal hematoma or with massive blood loss from scalp lacerations in any age group. If

fluid resuscitation is not effective, vasopressors should be used to maintain MAP at 90 mm Hg to preserve CPP. External and internal bleeding need to be controlled quickly and the hematocrit should be maintained above 30 percent.

Hypertension is a critical finding and must be assumed to be an indicator of increased ICP in a patient with a head injury. This *Cushing reflex* requires immediate measures to decrease the intracranial pressure. If hypertension exists independent of increased ICP, then the systemic pressure should be lowered by no more than 30 percent of the MAP by using labetalol.

DISABILITY AND THE NEUROLOGIC EXAMINATION The neurologic examination that is part of the primary survey describes the patient's level of consciousness with the AVPU system: *alert*, responds to *verbal* stimuli, responds to *painful* stimuli, or *unresponsive*. This same assessment provides most of the information needed to calculate the Glasgow Coma Scale (Table 255-2). The GCS is only one component of a complete neurologic examination. The best possible neurologic examination should be conducted as soon as the initial resuscitation is complete, to serve as a baseline for subsequent serial examinations and to dictate treatment.

The GCS was developed as a standardized scoring system to allow reliable interobserver neurologic assessment of patients with TBI. An accurate GCS score is used to direct treatment and predict outcome. Accurate GCS scores can only be obtained after resuscitation, and prior to sedation or intubation. The postresuscitation GCS is based upon three factors: eye opening, verbal function, and motor function. When assessing the GCS in the severely obtunded, noxious stimuli need to be delivered in the form of nailbed pressure on both sides of the body or severe sternal pressure. This is important for grading the depth of disability at the level of more rudimentary reflexes. The best response from each category is added for a score of 3 to 15. The GCS for intubated patients cannot be assessed for verbal response, and paralyzed patients cannot be assessed at all. For nonintubated, nonsedated postresuscitation patients **a GCS of less than 9 is considered a severe TBI, moderate is 9 to 13, and mild is 14 to 15.**

The other important aspect of the neurologic examination is pupil assessment (size, reactivity, and anisocoria). In an unresponsive patient a single fixed and dilated pupil may indicate an ipsilateral intracranial hematoma with uncal herniation that requires rapid operative decompression. Direct ocular trauma should also be considered. Bilateral fixed and dilated pupils suggest increased ICP with poor

TABLE 255-2 The Glasgow Coma Scale for All Age Groups

	4 years to Adult	Child <4 years	Infant
Eye Opening			
4	Spontaneous	Spontaneous	Spontaneous
3	To speech	To speech	To speech
2	To pain	To pain	To pain
1	No response	No response	No response
Verbal Response			
5	Alert and oriented	Oriented, social, speaks, interacts	Coos, babbles
4	Disoriented conversation	Confused speech, disoriented, consolable, aware	Irritable cry
3	Speaking but nonsensical	Inappropriate words, inconsolable, unaware	Cries to pain
2	Moans or unintelligible sounds	Incomprehensible, agitated, restless, unaware	Moans to pain
1	No response	No response	No response
Motor Response			
6	Follows commands	Normal, spontaneous movements	Normal, spontaneous moves
5	Localizes pain	Localizes pain	Withdraws to touch
4	Movement or withdrawal to pain	Withdraws to pain	Withdraws to pain
3	Decorticate flexion	Decorticate flexion	Decorticate flexion
2	Decerebrate extension	Decerebrate extension	Decerebrate extension
1	No response	No response	No response
3-15			

Note: GCS reporting should be modified for intubated and paralyzed patients.

brain perfusion, bilateral uncal herniation, drug effect or severe hypoxia, whereas bilateral pinpoint pupils suggest either opiate use or a pontine lesion.

Altered motor function can indicate brain, spinal cord, or peripheral nerve injuries. Movement in unresponsive patients is assessed by noxious stimuli to a nail bed in all extremities. Decorticate posturing (upper extremity flexion and lower extremity extension) indicates an injury above the midbrain. Decerebrate posturing (arm extension and internal rotation with wrist and finger flexion and internal rotation and extension of the lower extremities) is from a more caudal injury and predicts a worse outcome. For completely unresponsive patients, the respiratory pattern and eye movements will provide information regarding brainstem function. Oculovestibular (cold calories) and oculoccephalic (doll's eyes) responses are not checked until the cervical spine has been fully cleared.

After the primary survey a secondary survey is needed to identify other significant injuries.

THE CLINICAL SPECTRUM OF TBI

Mild Traumatic Brain Injury

Severity grading of TBI uses the GCS score to categorize patients based on their potential outcomes. Mild TBI has traditionally included head-injured patients with a history of loss of consciousness, amnesia or loss of memory to the event, any change in mental status at the time of event, and/or persistent or transient focal neurological deficit. The convention has been to include patients with GCS scores of 13 to 15 in the mild group, which accounts for most TBI patients. However, because of the wide variation in outcomes those previously described as "mild head injury," are further subdivided into "low risk," "medium risk" or "high risk" mild head injury.⁸ Low-risk mild-injury patients include those with a GCS of 15 without a history of loss of consciousness, amnesia, vomiting, or diffuse headache. The risk for intracranial hematoma requiring surgical evacuation is less than 0.1 percent. Medium-risk patients have a GCS of 15 along with one or more of the following: loss of consciousness, amnesia, vomiting, or diffuse headache. These patients have a 1 to 3 percent risk of intracranial hematoma requiring surgical evacuation and CT scans should be obtained for such patients. If computed tomography (CT) is not available, skull x-rays are recommended, and those patients with fractures should be placed in the *high-risk* category and be emergency trans-

ferred to a facility with neurosurgical availability (Figure 255-2). The medium-risk mild TBI group includes those patients meeting diagnostic criteria for postconcussion syndrome (PCS).

High-risk mild head-injury patients are those with an admission GCS of 14 or 15, with a skull fracture and/or neurologic deficits. As many as 10 percent of the patients in this *high-risk* mild TBI group will require surgical evacuation of intracranial hematomas. Patients with coagulopathy, drug or alcohol consumption, previous neurosurgical procedures, epilepsy, or age greater than 60 years should be included in the high-risk group independent of their clinical presentation.

The rate of injury findings on brain CT scans increases within this mild injury group as a function of the GCS.⁹ Regardless of the need for neurosurgical intervention, nearly 10 percent of high-risk, mild TBI patients with a GCS of 15 will have a positive brain CT, as compared to 40 percent in those with a GCS of 13.⁹

Mild TBI patients with a GCS of 15, no indication for head CT or a negative CT, and adequate supervision may be safely discharged home from the emergency department. Those patients with a GCS of 14 and a negative head CT should be observed for 6 to 12 h for deterioration (accumulation of edema, seizure, etc.). Those patients with a positive CT scan or persistent neurologic findings require neurosurgical consultation and hospital admission (Figure 255-3).

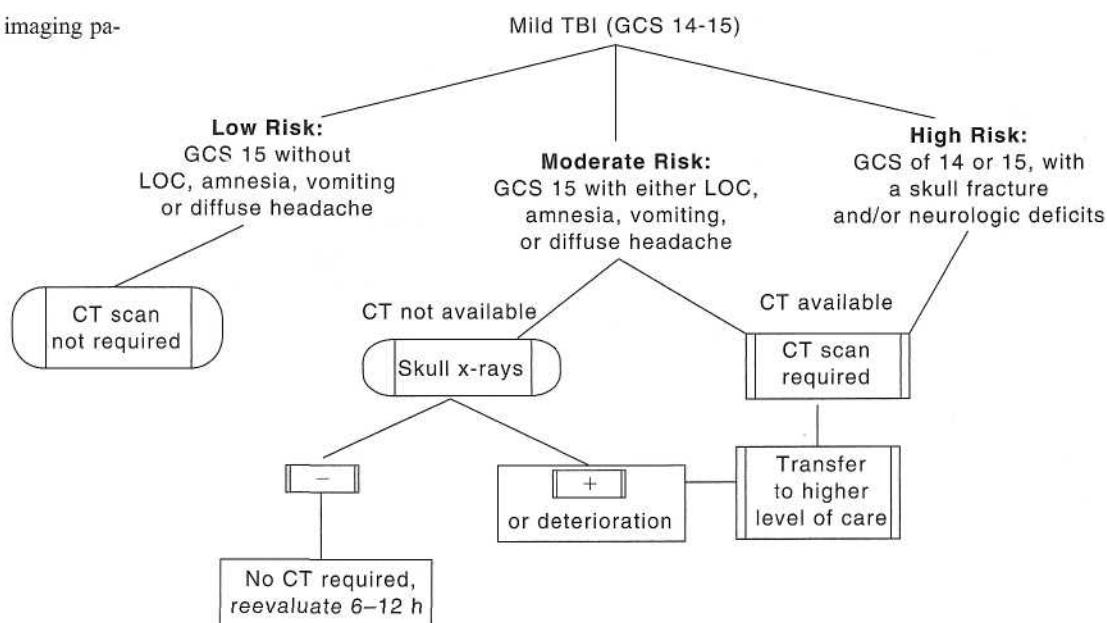

Moderate Traumatic Brain Injury

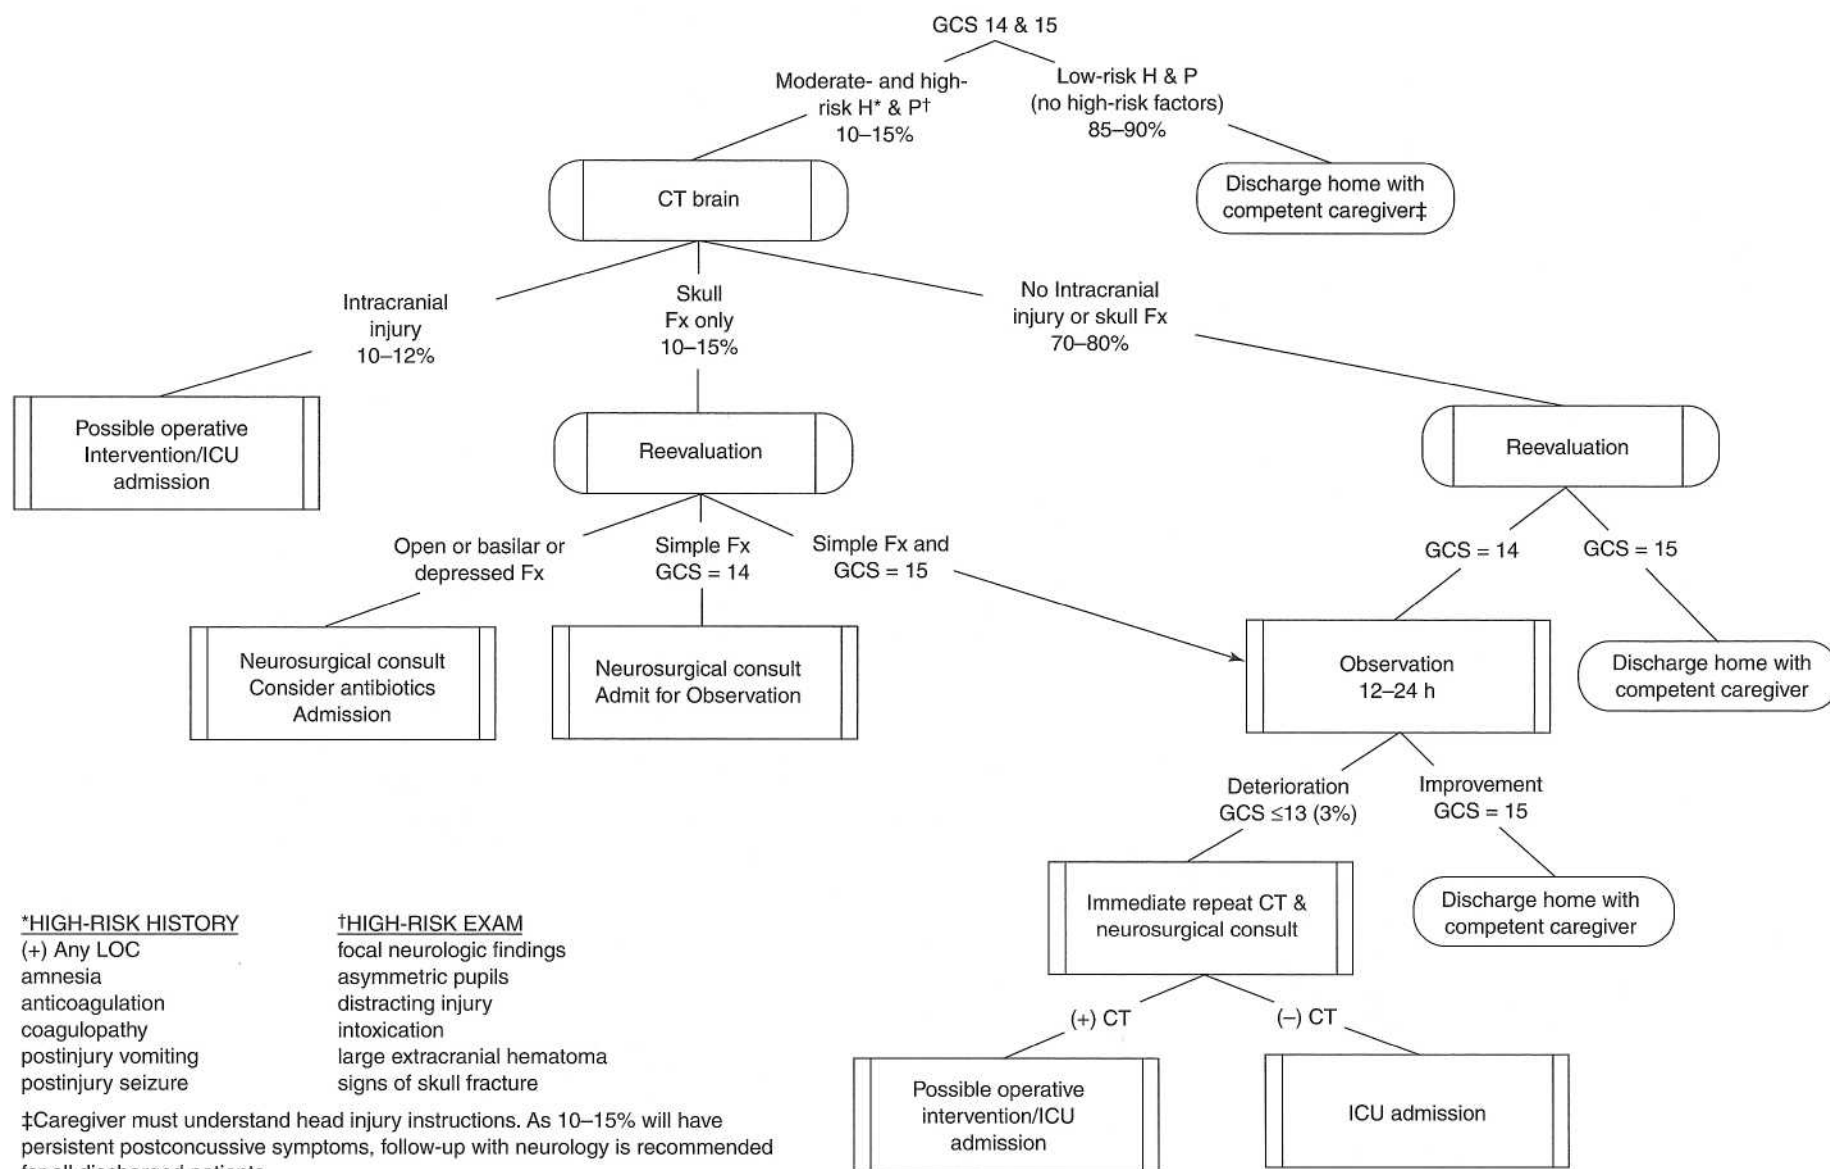

Moderate TBI (GCS 9 to 13) accounts for approximately 10 percent of patients with head injuries. Mortality rates for patients with isolated moderate TBI is less than 20 percent, but long-term disability is as high as 50 percent. Overall, 40 percent of moderate TBI patients have a finding on CT scan and 8 percent require neurosurgical intervention.¹⁰ Patients with moderate TBI should be admitted to try to prevent deterioration from secondary brain injury and progression to severe TBI (Figure 255-4). Most patients in this category should be intubated, receive neurosurgical consultation, and admission to a monitored unit.

Severe Traumatic Brain Injury

In severe TBI (GCS <9), mortality approaches 40 percent, with most deaths occurring within 48 h. Less than 10 percent of these patients make even a moderate recovery. The management of patients with severe TBI has three primary goals: to identify other life-threatening

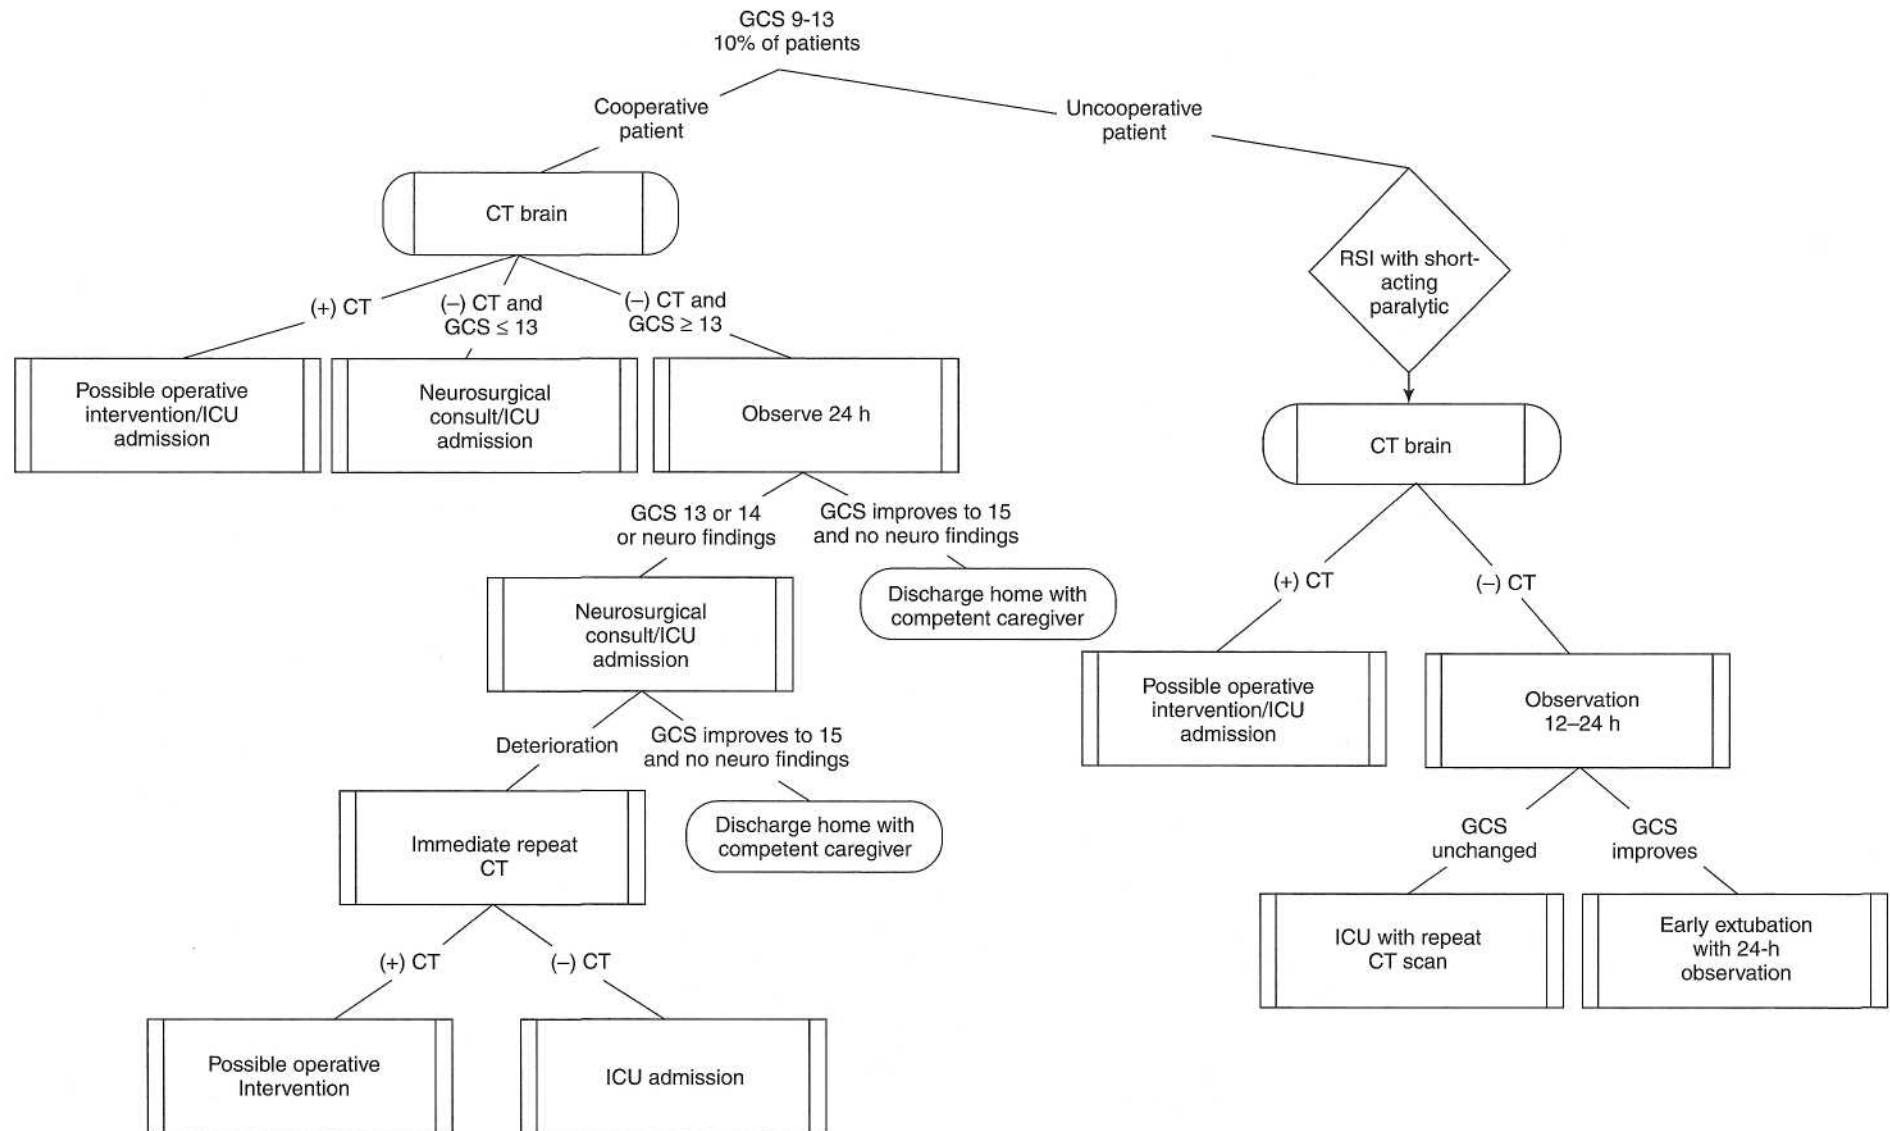

FIG. 255-4. Algorithm for the evaluation and treatment of moderate brain injury.

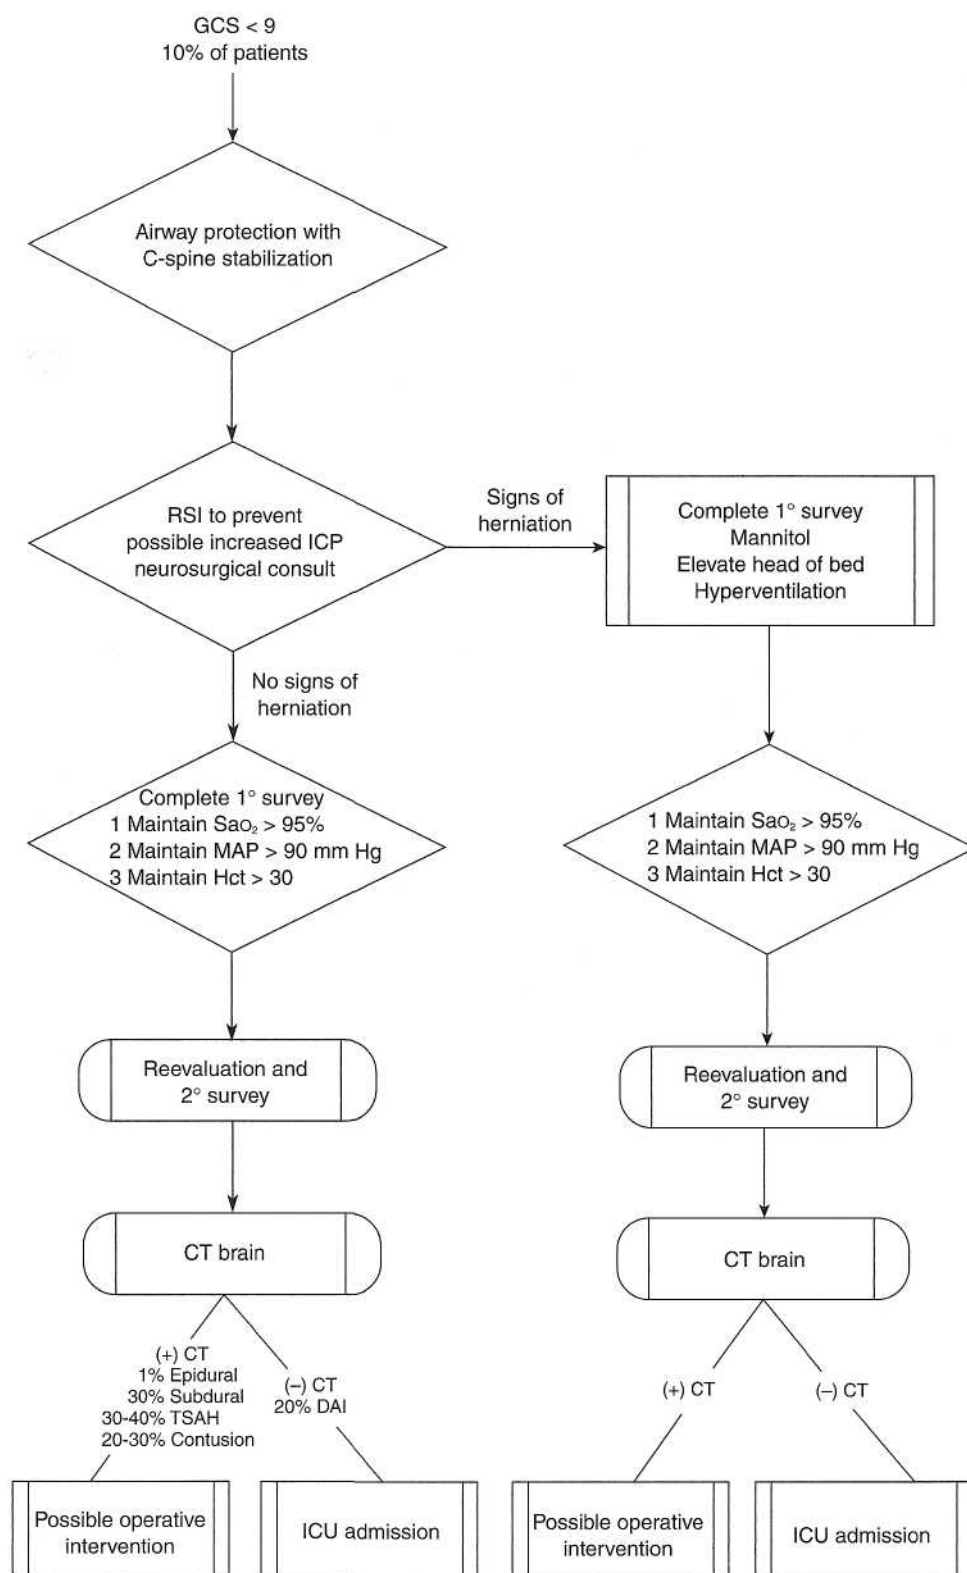

injuries, to prevent further secondary brain injury, and to identify treatable mass lesions. All patients with severe TBI require a CT scan and should be admitted to an intensive care unit in a hospital with neurosurgical capabilities (Figure 255-5).

DIAGNOSTIC RADIOGRAPHY FOR TBI

All patients with moderate to severe TBI require urgent head CT scans after stabilization. Delays in obtaining a CT scan can lead to a cata-

strophic delay in emergent neurosurgical interventions. Therefore, **if a patient with TBI is uncooperative or combative, RSI is often the best option.** If this is undertaken, a GCS score and the best neurologic exam possible should be performed prior to intubation. Sedation alone should be used infrequently as it is often ineffective and may put patients at risk for further injury or aspiration. Other means to control agitated patients with TBI include haloperidol (5 to 10 mg IM or IV, may repeat), midazolam (1 to 2 mg IV), and propofol (20 mg every 10 s to desired effect). A CT scan is generally diagnostic but there have been

FIG. 255-5. Algorithm for the evaluation and treatment of severe brain injury.

reports of delayed intracranial hematomas, especially subdural hematomas, for patients with nonfocal neurologic examinations with negative initial CT scans.¹¹

CT of the head is indicated for all patients with a GCS of 14 or less. There are numerous factors that dictate the need for a CT in patients with a GCS of 15 (Table 255-3). In addition, liberal use of head CT in patients of older than 60 years of age is recommended.¹²

INCREASED ICP AFTER TBI

An intracranial pressure of greater than 20 to 25 mm Hg in the TBI patient increases subsequent morbidity and mortality. In the ED, ICP monitoring is rarely available, therefore physical findings must be used to identify increased ICP and to direct therapy. Indicators of increased ICP include signs of transtentorial herniation (unilateral or bilateral dilated pupils, hemiparesis, motor posturing) and progressive neurologic deterioration (as determined by repetitive AVPU and GCS examinations). Several strategies may be used to lower ICP. All patients with severe TBI and evidence of increased ICP should have the head of the bed elevated to 30 degrees, volume resuscitation to a MAP of 90 mm Hg or a 30 percent reduction in MAP if hypertensive, and maintenance of arterial oxygenation. After these steps mannitol should be used.

Mannitol

Mannitol is the best osmotic agent to reduce ICP. It has beneficial effects on the ICP, CBF, CPP, and brain metabolism. Additionally, mannitol is known to scavenge free radicals. It reduces ICP within 30 min and lasts variably up to 6 to 8 h. Mannitol has the additional benefit of expanding volume, initially reducing hypotension, and improving the blood's oxygen-carrying capacity. Mannitol is administered by repetitive bolus (0.25 g/kg to 1 g/kg), not by constant infusion. Because there is no dose-dependent effect seen with mannitol, some authors advocate the lower range of the suggested dose. Mannitol will lead to a net intravascular volume loss because of its diuretic effect, therefore adequate glomerular filtration rate (GFR) hemodynamic and input-output monitoring is required to maintain euolemia.

Hyperventilation

Hyperventilation is no longer recommended as a prophylactic intervention during the first 24 h after a severe TBI.¹⁴ Nor is hyperventilation below a P_{aO_2} of 25 mm Hg ever indicated. Hyperventilation does reduce the ICP, but the vasoconstriction caused by reducing carbon dioxide (CO_2) levels also leads to cerebral ischemia. Hyperventilation is still used as a last resort for hospitalized patients with signs of increasing ICP despite other therapeutic measures. In this case it is a temporary measure and the P_{aO_2} is monitored closely to maintain the range of 30 to 35 mm Hg.

TABLE 255-3
Indications for CT Scanning for Patients with Mild TBI

<i>Signs</i>	
A Glasgow Coma Scale 13-14	
A skull fracture or large subgaleal swelling	
Focal neurologic findings	
Unexplained asymmetric pupils	
Distracting injuries or intoxication	
<i>Symptoms</i>	
A reported loss of consciousness or posttraumatic seizure	
A history of coagulopathy	
Continued diffuse headache	
Amnesia	
Vomiting	

Other Modalities

Initiation of barbiturate coma is not indicated in the ED, but there is evidence that it may be considered for hemodynamically stable patients with severe TBI who have continued increased ICP despite other therapies. The recommended dose of pentobarbital is 10 mg/kg over 30 min.

There is some indication that prophylactic anticonvulsants reduce the occurrence of early post-traumatic seizures, but no evidence that these drugs improve long-term outcome. They should be used in consultation with a neurosurgeon. There is no indication to use steroids for the treatment of TBI or increased ICP.¹³

Intracranial Pressure Monitoring

Internal monitoring of ICP should be initiated on all patients with evidence of increased ICP, herniation, and a GCS score of less than 9. This treatment has the most favorable risk:benefit ratio. A ventricular catheter offers the best method to directly monitor ICP and thus calculate CPP. Increases in the ICP above 20 to 25 mm Hg may be reduced by CSF drainage. If CSF drainage is not effective in reducing ICP, then mannitol should be administered, (assuming adequate MAP).

TREATMENT OF SPECIFIC HEAD INJURIES

Scalp Lacerations

Scalp lacerations can lead to massive blood loss. Scalp hemorrhages should be controlled as rapidly as possible. If direct pressure is not effective, lidocaine with epinephrine can be infiltrated locally, and vessels can be clamped or ligated. Wounds should be carefully examined prior to closure for underlying fractures and galeal lacerations. Large galeal disruptions should be repaired, but small ones can be left alone.

Skull Fractures

All patients suspected or found to have a skull fracture require a head CT scan (see Table 255-3). Skull fractures are usually categorized by location (basilar vs. the skull convexity), pattern (linear, depressed, or comminuted) and whether they are open or closed. A careful examination and wound exploration of scalp lacerations is needed to identify a skull fracture in the patient without a loss of consciousness or neurologic findings. Complicated skull fractures include those that are open or depressed, those that involve a sinus, and those that cause intracranial air (pneumocephalus).

LINEAR AND COMMUNUTED FRACTURES The management of linear and simple comminuted skull fractures is the same. Isolated fractures with an overlying laceration require careful evaluation, cleaning, and repair. Wounds should be explored gently so as not to drive bone fragments into the brain. The use of prophylactic antibiotics following an open skull fracture is controversial and should be discussed with the neurosurgeon.

Particular care should be taken in evaluating fractures that cross the middle meningeal artery or a major venous sinus. Linear occipital fractures also have higher intracerebral complication rates. Fractures that are depressed beyond the outer table of the skull require operative repair.

BASILAR SKULL FRACTURE The most common basilar skull fracture involves the petrous portion of the temporal bone, the external auditory canal, and the tympanic membrane. It is commonly associated with a torn dura leading to CSF leakage from the ear. Signs and symptoms associated with basilar skull fractures include CSF otorrhea or rhinorrhea, mastoid ecchymosis (Battle sign), periorbital ecchymoses (raccoon eyes), hemotympanum, vertigo, decreased hearing or deafness,

and seventh nerve palsy. Periorbital and mastoid ecchymoses develop gradually over hours after an injury and are often absent in the ED. CSF leaks are difficult to diagnose. A simple but nonsensitive test for a basilar skull fracture with a CSF leak is to see if the fluid leaves a single or double ring when dripped onto a paper towel. Leaking fluid can also be tested for a specific CSF protein, transferrin. Patients with a basilar skull fracture should be hospitalized.

Patients with CSF fistulas can develop meningitis. Prophylactic antibiotics reduce the incidence of meningitis for patients with basilar skull fractures, thus prophylactic antibiotics in those patients with a basilar skull fracture is recommended.¹⁴ Administration of antibiotics should be done in consultation with a neurosurgeon who will be following the patient. If prophylactic antibiotics are instituted, they should have broad coverage with good penetration into the meninges. A third-generation cephalosporin such as ceftriaxone at 1 to 2 g per day is a reasonable choice.

Brain Herniation

There are four major brain herniation syndromes: uncal and central transtentorial, cerebellotonsillar, and upward posterior fossa. The most common is uncal and it occurs when the uncus of the temporal lobe is displaced inferiorly through the medial edge of the tentorium (Figure 255-6). This is usually caused by an expanding lesion in the temporal lobe or lateral middle fossa. Uncal transtentorial herniation leads to compression of the third cranial (oculomotor) nerve, causing an ipsilateral fixed and dilated pupil. Further herniation compresses the pyramidal tract leading to contralateral motor paralysis. In some cases, the pupillary changes are contralateral, or motor changes are ipsilateral.

Central transtentorial herniation is less common and occurs with midline lesions in the frontal or occipital lobes, or in the vertex. The most prominent symptoms are initial bilateral pinpoint pupils, bilateral Babinski signs, and increased muscle tone. Fixed midpoint pupils follow along with prolonged hyperventilation and decorticate posturing.

FIG. 255-6. Anterior view of a transtentorial uncal herniation caused by a large hematoma under a skull fracture.

Cerebellotonsillar herniation occurs when the cerebellar tonsils herniate through the foramen magnum. This causes pinpoint pupils, flaccid paralysis, and sudden death. Upward transtentorial herniation results from a posterior fossa lesion and leads to a conjugate downward gaze with absence of vertical eye movements, pinpoint pupils, and rapid death.

When all other methods to control the ICP have failed, patients with signs of herniation may need emergency decompression by trephination ("burr holes"). CT scanning before attempting trephination is recommended to localize the lesion and direct the decompression site. If CT scan is unavailable, or the patient is unstable for CT because of signs of rapidly progressive neurologic deterioration and herniation, then emergency department trephination should be considered.

Cerebral Contusion/Intracerebral Hemorrhage

Contusions are one of the most frequent types of TBI. Contusions most commonly occur in the subfrontal cortex, in the frontal and temporal lobes, and, occasionally, in the occipital lobes. They are often associated with a subarachnoid hemorrhage. Contusions may occur at the site of the blunt trauma or the opposite site of the brain, known as a "contre-coup" injury.

Intracerebral hemorrhage can occur days after significant blunt trauma, often at the site of resolving contusions. This complication is more common with patients with a coagulopathy. CT scans in the immediate postinjury phase can be normal.

Subarachnoid Hemorrhage

Traumatic subarachnoid hemorrhage (tSAH) results from the disruption of subarachnoid vessels and presents with blood in the CSF (Figure 255-7). Patients can present with mild to severe TBI. Those with isolated tSAH often present with a headache and photophobia and mild meningeal signs. tSAH is probably the most common CT abnormality in patients with moderate to severe TBI. Patients with a tSAH are twice as likely to suffer from death, persistent vegetative state, or severe disability. Early development of tSAH (42 percent) represents a trifold mortality risk (42 vs. 14 percent), as compared to those without tSAH.¹⁵ The amount of blood seen on the CT scan is inversely related to the presenting GCS and percent of patients with a positive outcome. Some tSAH can be missed on early CT scans. Generally, scans performed 6 to 8 h after injury are more sensitive for detecting tSAH. Unfortunately, findings may be delayed in a few patients. Careful follow-up instructions, referral for reexamination by a physician, and discharge in the care of a competent adult are necessary, even with a normal CT scan.

The use of nimodipine in patients with tSAH reduces the likelihood of death or severe disability by 55 percent as compared to placebo.¹⁶ Nimodipine should be started as soon as possible after stabilization at 2 mg per h for 7 to 10 days followed by 360 mg daily until day 21. Patient with tSAH requires immediate neurosurgical consultation and admission to an intensive care unit.

Epidural Hematoma

Epidural hematomas are the result of blood collecting in the potential space between the skull and the dura mater (Figure 255-8). Most epidural hematomas result from blunt trauma to the temporal or temporoparietal area with an associated skull fracture and middle meningeal arterial disruption. Occasionally, trauma to the parieto-occipital region or the posterior fossa causes tears of the venous sinuses with epidural hematomas. Almost all epidural hematomas are associated with skull fractures, and some will have additional cerebral lesions.

The classic history of an epidural hematoma is a lucid period following immediate loss of consciousness after significant blunt head

FIG. 255-7. Computed tomography scan illustrating a subarachnoid hemorrhage. *Arrow 1* illustrates prepontine cisternal blood and *arrow 2* represents blood in the ambient cistern.

FIG. 255-8. Computed tomography scan illustrating a lenticular epidural hematoma. Note that the hematoma does not cross the suture lines.

trauma. The patient then awakens prior to again falling unconscious. This clinical pattern occurs in a minority of cases. Most patients either never lose consciousness or never regain consciousness after the injury. The diagnosis of an epidural hematoma is based on CT scan and physical findings. On CT scans, epidural hematomas appear biconvex (football shaped), typically in the temporal region.

The high-pressure arterial bleeding of an epidural hematoma can lead to herniation within hours after an injury. Therefore, early recognition and evacuation is key to reduce morbidity and mortality. Bilateral emergency department trephination (burr holes) is only indicated if definitive neurosurgical care is not available. Full recovery can be expected if the hematoma is evacuated prior to herniation or the development of neurologic deficits.

Subdural Hematoma

Subdural hematomas (SDHs) are caused by sudden acceleration-deceleration of brain parenchyma with subsequent tearing of the bridging veins. This results in blood clots forming between the dura mater and the arachnoid (Figure 255-9). Brains with extensive atrophy, as in the elderly and in alcoholics, are more susceptible to subdural hematomas. Children younger than age 2 years are also at increased risk of subdural hematomas. This is related to transfer of the force that limits the risk of sustaining epidural hematomas.

Blood tends to collect more slowly than in epidural hematomas because of its venous origin. However, SDHs are often associated with other brain injuries.

Traditionally, subdural hematomas have been classified as acute, subacute, or chronic, depending on time they present. Acute SDH symptoms usually develop within 14 days of the injury. After 2 weeks,

patients are defined as having a chronic SDH. There is no specific clinical syndrome associated with a subdural hematoma. Acute cases usually present immediately after severe trauma and often the victim is unconscious. Chronic subdural hematomas may present in the elderly or in alcoholics with vague complaints or mental status changes. These patients often do not recall an injury. On CT scan, acute SDHs are hyperdense (white), crescent-shaped lesions that cross suture lines. Subacute SDHs are isodense and more difficult to identify. A CT scan with intravenous contrast can assist in identifying a subacute SDH. A chronic SDH appears hypodense (dark) as the iron in the blood is phagocytized.

The definitive treatment of subdural hematomas depends on the type and on associated brain injuries. Mortality and the need for surgical repair are greater for acute and subacute SDH. Chronic subdural hematomas can sometimes be managed without surgery depending on the severity of the symptoms. Table 255-4 compares intracranial hematomas.

Diffuse Axonal Injury

Diffuse axonal injury (DAI) is the disruption of axonal fibers in the white matter and brainstem. Shearing forces on the neurons generated by sudden deceleration cause DAI. Classically, DAI is seen after blunt trauma, such as from a motor vehicle accident. In infants, the "shaken-baby syndrome" is a well-described tragic cause.

Injury occurs immediately and is essentially irreversible. There is a rapid or immediate increase in ICP. Patients present unresponsive. The state may be prolonged or permanent until death. A CT scan of a patient with DAI may be normal, but the classic CT demonstrates hemorrhagic injury to the mostly the deep structures of the brain. The

FIG. 255-9. Computed tomography scan of a subdural hematoma (arrow 1). Note that the hematoma crosses the suture lines. Arrow 2 demonstrates midline shift.

treatment options for DAI are very limited, but attempt to prevent secondary damage by reducing cerebral edema.

Penetrating Injury

As a bullet passes through the brain, it creates a cavity three to four times greater than its diameter (see Chap. 264). Direct penetration of the bullet through the brain substance and the transfer of kinetic energy cause the majority of the destruction. The GCS can be used to predict the prognosis of unintoxicated patients with a gunshot wound to the brain. Patients with a GCS >8 and reactive pupils have a 25 percent mortality risk, while those with a GCS <5 approach 100 percent

mortality. All patients with a penetrating gunshot wound to the brain should be intubated and treated with prophylactic antibiotics.

Stab wounds have very low energy and impart only direct damage to the area contacted by the penetrating object. This results in a much lower morbidity and mortality than from gunshot wounds. Essentially all patients sustain penetrating injury require admission, broad-spectrum antibiotics and operative intervention. Impaled objects should be left in place until surgical removal.

COMPLICATIONS/LONG-TERM PROBLEMS

Seizures

The reported incidence of early posttraumatic seizures ranges from 2 to 5 percent, but this incidence rises to near 30 percent in children, alcoholics, and those with intracranial hematomas. A significant association exists between early posttraumatic seizures and unfavorable outcome, but this association is small by comparison to subdural hematoma and cerebral contusion.¹⁷ Prophylactic antiepileptic drugs given after TBI decreases the incidence of early posttraumatic seizures, but there has been no observed reduction in the occurrence of late-seizures, death, or neurologic disability.¹⁸ Thus, at the present time, **use of prophylactic antiepileptic drugs is not supported by the literature.** Acute management of early posttraumatic seizures is the same as for managing any seizure in the ED, but requires close hemodynamic monitoring to prevent antiepileptic drug-induced hypotension or hypoventilation.

Concussion and Postconcussive Syndrome

Concussion is defined as any alteration of cerebral function caused by a force to the head resulting in one or more of the following: a brief loss of consciousness; light-headedness; vertigo; headache; nausea; vomiting; photophobia; cognitive and memory dysfunction; tinnitus; blurred vision; difficulty concentrating; amnesia; fatigue; personality change; or a balance disturbance.¹⁹ In 30 to 80 percent of patients with TBI, symptoms will remain 3 months postinjury; in 15 percent of patients, symptoms will remain at 1 year.²⁰ Persistence of these signs or symptoms has been termed "postconcussion syndrome" (PCS) (Table 255-5). Prior to discharge from the ED patients should be warned that their symptoms usually clear, but the time needed is generally weeks to months. In addition, they should be referred to a neurologist for long-term care.

Postconcussive syndrome patients continue to have complaints such as headaches, dizziness, inability to concentrate, and memory changes. After 1 year, 85 to 90 percent of these patients recover. The remaining

TABLE 255-4 Intracranial Hematomas

	Type of Patient	Anatomic Location	CT Findings	Common Cause	Classic Symptoms
Epidural	Young, rare in the elderly and age <2 years	Potential space between skull and dura mater	Biconvex, football-shaped hematoma	Skull fracture with tear of the middle meningeal artery	Immediate LOC with a "lucid" period prior to deterioration (only occurs in about 20%)
Subdural	More risk for the elderly and alcoholics	Space between dura mater and arachnoid	Crescent- or sickle-shaped hematoma	Acceleration-deceleration with tearing of the bridging veins	Acute: rapid LOC-lucid period possible Chronic: altered MS and behavior with gradual decrease in consciousness
Subarachnoid	Any age group following blunt trauma	Subarachnoid	Blood in the basilar cisterns and hemispheric sulci and fissures	Acceleration—deceleration with tearing of the subarachnoid vessels	Mild to moderate TBI with meningeal signs and symptoms
Contusion/ intracerebral hematoma	Any age group following blunt trauma	Usually anterior temporal or posterior frontal lobe	May be normal initially with delayed bleed	Severe or penetrating trauma; shaken-baby syndrome	Symptoms range from normal to unconscious

Abbreviations: LOC = loss of consciousness; MS = mental state; TBI = traumatic brain injury.

patients have "persistent postconcussion syndrome" (PPCS). Risk factors for patients PPCS are female sex, ongoing litigation, and low socioeconomic status. While all PCS and PPCS patients should be referred to their primary physicians or neurologist, amitriptyline at 25 to 50 mg PO per d helps with headaches, depression, and insomnia.

Sports-related concussions are common injuries, but their true incidence is greatly underreported. Sports most commonly associated with concussion are boxing, football, soccer, baseball, and basketball. The management of any patient with TBI or concussion is the same as described above. However, for the athlete with a concussion, special consideration must be made for their safe return to a sporting activity. Neurophysiologic assessment instruments are typically used in the hours following TBI and then repeated 5 days after the injury. Some of the tools used for this assessment include the Trail-making test, Stroop test, and the Digit span from the Wechsler Memory Scale, Revised.¹⁹

When athletes present with symptoms of concussion, they should be referred for testing prior to being cleared to return to sports.

Infections

Several factors increase the risk for infections following a head injury. Skull fractures and CSF leaks are risk factors for meningitis. In addition to central nervous system (CNS) infections, intubated patients on neuromuscular blockade have longer intensive care unit stays, an increased risk for aspiration pneumonias, and tend toward sepsis. Because of controversies regarding use of prophylactic antibiotics, consultation with the neurosurgeon or intensivist should be obtained prior to their administration.

Patients who present with a history of a skull fracture and fever or other symptoms of meningitis should be treated with antibiotics immediately. The source of infection depends on the time since the injury. In the first 72 h after a head injury, pneumococcus is generally the cause. After that, gram-negative organisms and *Staphylococcus aureus* become more common. Patients should be given vancomycin (1 g IV q12h) and a third-generation cephalosporin, such as cef-tazidime 1 g IV q8h, until cultures confirm the cause.

**SPINAL CORD INJURIES**

Bonny J. Baron Thomas M.
Scalea

EPIDEMIOLOGY

Spinal injuries are probably the most devastating of all trauma-related injuries. The incidence of traumatic spinal cord injury (SCI) in the United States is estimated to be 30 cases per million population at risk. Thus, 8000 to 10,000 new cases can be expected annually. The actual incidence is probably higher. Minor injuries are often not reported, and those associated with trauma fatalities may go unnoticed. SCI is predominantly a disease of young men. The most comprehensive data available indicates the mean age has been reported as 33.5 years,¹ with a male-to-female predominance of 4 to 1. Spinal injury occurs more frequently on weekends and holidays and during summer months. The majority (90 percent) of cases are caused by blunt trauma with most of these from motor vehicle crashes.

FUNCTIONAL ANATOMY

The vertebral column serves as the central supporting structure for the head and trunk and provides bony protection for the spinal cord. It consists of 33 vertebrae: 7 cervical, 12 thoracic, 5 lumbar, 5 sacral (fused to form the sacrum), and 4 coccygeal, which are usually fused.

Vertebrae

In accordance with their weight-bearing function, the vertebrae become larger toward the lower end of the column, but all are built on the same fundamental plan. A typical vertebra is composed of a body anteriorly and a vertebral arch posteriorly (Figure 256-1). Between the body and arch is the vertebral foramen through which the spinal cord runs. The vertebral arch is made up of two pedicles, two laminae, and seven processes (one spinous, two transverse, and four articular). The spine has the potential to move in flexion, extension, lateral flexion, rotation, or circumduction (combination of all movements). The articular processes form synovial joints that act as pivots of the spinal column. The orientation of these articular facet joints changes at different levels of the spine. Differences in orientation of the facet joints account for variations in motion of specific regions of the vertebral column. A series of ligaments serve to maintain the alignment of the spinal column. The anterior and posterior longitudinal ligaments run along the vertebral bodies. Surrounding the vertebral arch are the ligamentum flavum and the supraspinous, interspinous, intertransverse, and capsular ligaments. The intervertebral disks lie between adjacent vertebral bodies. Each disk consists of a peripheral annulus fibrosus and a central nucleus pulposus. The annulus fibrosus is composed of fibrocartilage. The nucleus pulposus is a semifluid, gelatinous structure made up of water and cartilage fibers. With advancing age, the proportion of water decreases and fibrocartilage increases. The disks act as shock absorbers to distribute axial load. When compressive forces exceed the absorptive capacity of the disk, the annulus fibrosus ruptures, allowing the nucleus pulposus to protrude into the vertebral canal. This may result in spinal nerve or spinal cord compression.

Spinal Stability

The determination of spinal stability is an important factor in the evaluation of the injured spine. White and Panjabi define stability as the ability of the spine to limit patterns of displacement under physiologic loads so as not to damage or irritate the spinal cord or nerve roots and

to prevent incapacitating deformity or pain because of structural changes.² Computed tomography (CT) evaluation applied to the Denis three-column system for classification of thoracolumbar injuries can be used to assess spinal stability.³ The anterior column is formed by the anterior part of the vertebral body, the anterior annulus fibrosus, and the anterior longitudinal ligament. The middle column is formed by the posterior wall of the vertebral body, the posterior annulus fibrosus, and the posterior longitudinal ligament. The posterior column includes the bony complex of the posterior vertebral arch and the posterior ligamentous complex. For an injury to be unstable, there must be disruption of at least two columns. In evaluating stability, it is also important to include the degree of compression of the vertebral body. Vertebral body compressions of more than 50 percent are generally considered unstable.

Thoracic and Lumbar Spine

The thoracic spine is a rigid segment. The additional support provided by its articulation with the rib cage imparts a stiffness 2.5 times that of the ligamentous spine alone. Relative to other regions of the vertebral column, a large force is necessary to overcome the intrinsic stability of the thoracic spine. While injury to the thoracic spine is less common than in other regions, when it does occur it is usually significant. The spinal canal is narrower than that found in either the cervical or lumbar spine. The large spinal cord diameter relative to canal diameter increases the risk of cord injury. When cord injuries occur, most are neurologically complete (see discussion later). Of additional importance is the association between fractures of the thoracic spine and severe pulmonary injuries, including mediastinal hemorrhage. Patients with blunt chest trauma and mediastinal widening should be evaluated for both aortic and thoracic spine injuries.⁴

The spine is divided into alternating mobile and fixed segments. The thoracolumbar junction (T11-L2) is considered a transitional zone between the fixed thoracic and mobile lumbar regions. This distinction is important because the transitional zones sustain the greatest amount of stress during motion, and these are the areas most vulnerable to traumatic injuries. In addition to this change in bony anatomy, the thoracolumbar junction serves as the level of transition from the end of the spinal cord (about L1) to the nerve roots of the cauda equina. Relative to the thoracic spine, the width of the spinal canal is greater. Despite a large number of vertebral injuries at the thoracolumbar junction, most are associated with normal neurologic examinations or incomplete neurologic findings.

Relative to the thoracic and thoracolumbar regions, the lower lumbar spine is the most mobile. Isolated fractures of the lower lumbar spine rarely result in complete neurologic injuries. When neurologic injuries occur, they are usually complete cauda equina lesions or isolated nerve root injuries.

Sacrum and Coccyx

The sacrum supports the lumbar vertebral column and transmits loads from the trunk to the pelvic girdle and into the lower limbs. The upper border articulates with the fifth lumbar vertebra. The inferior border articulates with the coccyx. Laterally, the sacrum articulates with the iliac bones to form the sacroiliac joints. The vertebral foramina together form the sacral canal. The sacral canal contains the nerve roots of the lumbar, sacral, and coccygeal spinal nerves and the filum terminate.

The coccyx, which articulates with the sacrum, consists of four vertebrae fused together. Except for the first vertebra, the remaining coccygeal vertebrae consist of bodies only.

Injuries of the sacral spine and nerve roots are very unusual. When they occur, they are frequently associated with fractures of the pelvis. There are multiple different classification schemes of sacral fractures that help to predict neurologic deficits and establish treatment proto-

FIG. 256-1. Vertebra. Each vertebra consists of a vertebral body and posterior element. Vertebrae are stabilized by an anterior longitudinal ligament, posterior ligament, and interspinous ligament.

cols. In general, transverse fractures through the body are most significant in that they cause injury to part or all of the cauda equina. Longitudinal fractures may cause radiculopathy. If there is involvement of the central sacral canal, however, bowel or bladder dysfunction may also occur.⁵ Careful neurologic evaluation is essential. Motor and sensory evaluation of the sacral nerve roots should be performed. Rectal examination will assess anal sphincter tone and the bulbocavernosus reflex. Coccygeal injuries are usually associated with direct falls onto the buttocks. Patients typically describe intense pain with sitting and straining. Diagnosis of fracture is made on rectal examination. Pain will be elicited with motion of the coccyx. X-rays are not needed to diagnose coccygeal fractures. Treatment is symptomatic, and includes analgesics and use of a rubber doughnut pillow.

Spinal Cord

The spinal cord is a cylindrical structure that begins at the foramen magnum, where it is continuous with the medulla oblongata of the brain. Inferiorly, it terminates in the tapered conus medullaris at the lower border of the first lumbar vertebra. The conus is continued at its apex by a prolongation of the pia mater, the filum terminale, which extends to the base of the coccyx. The spinal cord gives rise to 31 pairs of spinal nerves: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal. Each spinal nerve emerges through the intervertebral foramen corresponding to the appropriate spinal cord level. There is disproportionate growth in the length of the spinal cord and the vertebral column. As a result of this inequality, the length of the nerve roots increases progressively from above downward. The lower nerve roots, inferior to the conus medullaris, form an array of nerves around the filum terminale; this is called the *cauda equina*.

MECHANISM OF INJURY

Motor vehicle crashes are the principal cause of traumatic injury to the spinal cord. Other etiologies, in descending order of frequency, include falls, gunshot wounds, and injuries secondary to sports or recreational activities.

Fractures of the spine can be divided into minor and major injuries. Minor injuries are those that are localized to part of a column and do not cause instability. These fractures often result from direct blunt trauma to the posterior elements of the spine. Minor injuries include isolated fractures of the transverse, spinous, and articular processes. Major spinal injuries can be classified into four categories: 1) compression (wedge) fractures; 2) burst fractures; 3) flexion-distraction (seat belt-type injuries); and 4) fracture/dislocations.

Compression fractures result from axial loading and flexion, with subsequent failure of the anterior column (Figure 256-2). The middle column remains intact. These injuries are usually stable unless they are greater than 50 percent. They are unlikely to be directly responsible for neurologic damage.

Burst fractures occur following failure of the vertebral body under axial load (Figure 256-3). In contrast to compression fractures, both the anterior and middle columns fail. There is retropulsion of bone and disk fragments into the canal. This may cause spinal cord compression.

Flexion-distraction injuries are commonly seen following seat belt-type injuries, particularly where lap belts alone are used (Figure 256-4). The seat belt serves as the axis of rotation during distraction, and there is failure of both the posterior and middle columns. The intact anterior column prevents subluxation. Typical radiographic findings reveal increased height of the posterior vertebral body, fracture of the posterior wall of the vertebral body, and posterior opening of the disk space.

Fracture-dislocations are the most damaging of injuries (Figure 256-5). Compression, flexion, distraction, rotation, or shearing forces lead to failure of all three columns. The end result is subluxation or dislocation.

Blunt Injury

MOTOR VEHICLE-RELATED INJURIES Motor vehicle crashes usually result in acceleration-deceleration injuries. The cervical spine is the most susceptible to injury by this mechanism, but the thoracic and lumbar regions are also at risk. The majority of victims are involved in low-impact crashes. Most commonly, the soft tissues are injured. Patients complain of pain in the posterior neck and back. High-speed, high-energy crashes are more likely to result in structural damage to the spine. Lap-only seat belts are associated with thoracolumbar injuries.

Pedestrians struck by vehicles and motorcyclists are at considerable risk for multiple skeletal injuries, including spinal injuries.

Obvious neurologic deficits mandate emergent treatment for an unstable injury. In the absence of deficits, the mechanism of injury with an understanding of the forces involved should guide management. When in doubt, it is best initially to overtreat and overstudy in order to avoid missing a significant injury.

Falls

Falls from a height are associated with fractures of the lower extremities, pelvis, and spine. Scalea et al. studied 161 patients who fell from a height of one or more stories, nearly one-fourth of whom suffered spine fractures.⁶ Of the latter, 74 percent sustained a major compression or burst fracture. The most common site of injury was the thoracolumbar junction. A thorough neurologic evaluation must be part of the early assessment of patients with vertical deceleration injury. All patients must be presumed to have unstable spine fractures until proven otherwise.

Sports Injuries

Spinal injuries occur in both contact and noncontact sports. The specific injury is related to the mechanism, the force involved, and the point of application of the force, rather than to the specific sport. The majority of injuries are self-limiting soft tissue injuries. Injuries at the level of the disk result in disk herniation or degeneration. Those that occur at the level of the bone can range from minimal avulsion-type fractures to compressions or fracture dislocations. Most bony injuries are not associated with neurologic sequelae. Rarely, however, sports injuries do result in significant neurologic compromise. When neurologic impairment occurs, it is usually secondary to direct axial forces. Catastrophic injuries have been associated with football, water sports (especially diving), gymnastics, rugby, and ice hockey.⁷

Penetrating Injury

The majority of penetrating spinal cord lesions are caused by gunshot wounds. These wounds may be localized to the spine or may involve transperitoneal trajectories. The spinal cord may be injured by direct contact with the bullet, by bony fragments, or from concussive forces.⁸ Most gunshot wounds result in stable vertebral injuries, although cord lesions are often complete. Stabbing injuries are much less common. These may be inflicted by a variety of implements including knives, axes, ice picks, screwdrivers, and glass fragments. The majority of stab wounds involve incomplete Brown-Sequard lesions of the thoracic cord. Among incomplete spinal injuries, these have the best prognosis. The prognosis for patients with stab injuries to the spine and incomplete paralysis is significantly better than that for patients with gunshot wounds to the spine and a similar extent of paralysis.

CLINICAL FEATURES

Damage to the spinal cord is the result of two types of injury. First is the direct mechanical injury from traumatic impact. This insult sets

Wedge compression fracture

into motion a series of vascular and chemical processes that lead to secondary injury. The initial phase is characterized by hemorrhage into the cord and formation of edema at the injured site and surrounding region. Local spinal cord blood flow is diminished owing to vasospasm and thrombosis of the small arterioles within the gray and white matter. Extension of edema may further compromise blood flow and increase ischemia. A secondary tissue degeneration phase begins within hours of injury. This is associated with the release of membrane-stabilizing enzymes, mediators of inflammation, and disturbance of

electrophysiologic coupling by disruption of calcium channel pathways. Lipid peroxidation and hydrolysis appear to play a major role in this secondary phase of spinal cord injury.

Spinal Cord Lesions

It is important to distinguish between complete and incomplete spinal cord injuries. The severity of injury determines the prognosis for recovery of function. The American Spinal Injury Association defines a

FIG. 256-3. Burst fractures are also caused by axial loading. Both anterior and middle columns have failed. A. Schematic of the forces transmitted. B. Note the retropulsion of elements into the spinal canal.

complete neurologic lesion as the absence of sensory and motor function below the level of injury. This includes loss of function to the level of the lowest sacral segment. In contrast, a lesion is incomplete if sensory, motor, or both functions are partially present below the neurologic level of injury. This may consist only of sacral sensation at the

anal mucocutaneous junction or voluntary contraction of the external anal sphincter upon digital examination.³ In assessing neurologic function, spinal shock must be considered. Patients in spinal shock lose all reflex activities. This generally resolves over 24 to 48 h, with the return of the bulbocavernosus reflex occurring first. Lesions

cannot be deemed complete until spinal shock has resolved. Complete lesions have a minimal chance of functional motor recovery. Patients with incomplete lesions are expected to have at least some degree of recovery.

Clinical syndromes classify incomplete spinal cord lesions. Damage to specific sections of the spinal cord results in predictable physical findings (Table 256-1). A discussion of the anatomy may be helpful.

A large number of descending and ascending tracts have been identified in the spinal cord. The three most important of these in terms of neuroanatomic localization of cord lesions are the corticospinal tracts, spinothalamic tracts, and dorsal (posterior) columns.

The corticospinal tract is a descending motor pathway. Its fibers descend from the cerebral cortex through the internal capsule and the middle of the eras cerebri. The tract then breaks up into bundles in the pons and finally collects into a discrete bundle, forming the pyramid of the medulla. In the lower medulla, approximately 90 percent of the fibers cross (decussate) to the side opposite that of their origin and descend through the spinal cord as the lateral corticospinal tract. These fibers synapse on lower motor neurons in the spinal cord. The 10 percent of corticospinal fibers that do not decussate in the medulla descend in the anterior funiculus of the cervical and upper thoracic cord levels as the ventral corticospinal tract. Damage to the corticospinal tract neurons (upper motor neurons) in the spinal cord results in ipsilateral clinical findings such as muscle weakness, spasticity, increased deep tendon reflexes, and a Babinski sign.

The two major ascending pathways that transmit sensory information are the spinothalamic tracts and the dorsal columns. The first neurons of both of these afferent systems begin as sensory receptors situated in the skin and stretch receptors of muscles. Their cell bodies are located in the dorsal root ganglia of the spinal nerves. The spinothalamic tract transmits pain and temperature sensation. As the axons of the first neurons enter the spinal cord, most rise one or two levels before entering the dorsal gray of the spinal cord, where they synapse with the second neuron of the spinothalamic tract. The second neuron immediately crosses the midline in the anterior commissure of the spinal cord and ascends in the anterolateral funiculus as the lateral spinothalamic tract. When the spinothalamic tract is damaged in the spinal cord, the patient experiences loss of pain and temperature sensation in the contralateral half of the body. The (pain and temperature) sensory loss begins one or two segments below the level of the lesion. The dorsal columns transmit vibration and proprioceptive information. Neurons enter the spinal cord proximal to pain and temperature neurons. They

differ from pain and temperature neurons in that they do not immediately synapse. Instead, these axons enter the ipsilateral dorsal column and do not synapse until they reach the gracile or cuneate nuclei of the medulla. From these nuclei, fibers cross the midline and ascend in the medial lemniscus to the thalamus. Injury to one side of the dorsal columns will result in ipsilateral loss of vibration and position sense. The sensory loss begins at the level of the lesion. Light touch is transmitted through both the spinothalamic tracts and the dorsal columns. Therefore, light touch is not completely lost unless there is damage to both the spinothalamic tracts and the dorsal columns.

Concerning the spinal nerves and their relationship to the vertebrae, each spinal nerve is named for its adjacent vertebral body. Because there is an additional pair of spinal nerve roots compared to the number of vertebral bodies, the first seven spinal nerves are named for the first seven cervical vertebrae, each exiting through the intervertebral foramen above its corresponding vertebral body. The spinal nerve exiting below C7, however, is referred to as the C8 spinal nerve, although no eighth cervical vertebra exists. All subsequent nerve roots, beginning with T1, exit below the vertebral body for which they are named.

During fetal development, the downward growth of the vertebral column is greater than that of the spinal cord. Because the adult spinal cord ends as the conus medullaris at the level of the lower border of the first lumbar vertebra, the lumbar and sacral nerve roots must continue inferiorly below the termination of the spinal cord to exit from their respective intervertebral foramina. These nerve roots form the cauda equina. A potential consequence of this arrangement is that injury to a single lower vertebra can involve multiple nerve roots in the cauda equina. For example, an injury at the L3 vertebra can involve the L3 nerve root as well as the lower nerve roots that are progressing to a level caudal to the L3 vertebra.

Anterior Cord Syndrome

The anterior cord syndrome results from damage to the corticospinal and spinothalamic pathways, with preservation of posterior column function. This is manifest by loss of motor function and pain and temperature sensation distal to the lesion. Only vibration, position, and crude touch are preserved. This syndrome may occur following direct injury to the anterior spinal cord. Flexion of the cervical spine may result in cord contusion or bone injury with secondary cord injury. Alternatively, thrombosis of the anterior spinal artery can cause ischemic injury to the anterior cord. Immediate evaluation with CT or magnetic

TABLE 256-1 Spinal Cord Syndromes

Syndrome	Etiology	Symptoms	Prognosis
Anterior cord	Direct anterior cord compression Flexion of cervical spine Thrombosis of anterior spinal artery	Complete paralysis below the lesion with loss of pain and temperature sensation Preservation of proprioception and vibratory function	Poor
Central cord	Hyperextension injuries Disruption of blood flow to the spinal cord Cervical spinal stenosis	Quadriparesis—greater in the upper extremities than the lower extremities. Some loss of pain and temperature sensation, also greater in the upper extremities	Good
Brown-Sequard	Transverse hemisection of the spinal cord Unilateral cord compression	Ipsilateral spastic paresis, loss of proprioception and vibratory sensation and contralateral loss of pain and temperature sensation	Good
Cauda equina	Peripheral nerve injury	Variable motor and sensory loss in the lower extremities, sciatica, bowel/bladder dysfunction and "saddle anesthesia"	Good
Spinal shock	Partial or complete injury usually at the T6 level and above	Areflexia, loss of sensation, and flaccid paralysis below the level of the lesion; a flaccid bladder and loss of rectal tone; bradycardia and hypotension	Complete lesions have a poor prognosis Incomplete lesions have some degree of recovery

resonance imaging (MRI) may reveal an extrinsic mass that is amenable to surgical decompression. The overall prognosis for recovery of function historically has been poor and remains so today.⁹

Central Cord Syndrome

The central cord syndrome is usually seen in older patients with pre-existing cervical spondylosis who sustain a hyperextension injury. The injury preferentially involves the central portion of the cord more than the peripheral. The centrally located fibers of the corticospinal and spinothalamic tracts are affected. The neural tracts providing function to the upper extremities are most medial in position. The thoracic, lower extremity, and sacral fibers have a more lateral distribution. Clinically, patients present with decreased strength, and to a lesser degree, decreased pain and temperature sensation, more in the upper than the lower extremities. Spastic paraparesis or spastic quadriparesis can also be seen. The majority will have bowel and bladder control, although this may be impaired in the more severe cases. Prognosis for recovery of function is good; however, most patients do not regain fine motor use of their upper extremities.⁹

Brown-Sequard Syndrome

The Brown-Sequard syndrome results from hemisection of the cord. It is manifest by ipsilateral loss of motor function, proprioception, and vibratory sensation, and contralateral loss of pain and temperature sensation. The most common cause of this syndrome is penetrating injury. It can also be caused by lateral cord compression secondary to disk protrusion, hematomas, bone injury, or tumors. Of all of the incomplete cord lesions, this has the best prognosis for recovery.⁹

Cauda Equina Syndrome

The cauda equina is composed entirely of lumbar, sacral, and coccygeal nerve roots. An injury in this region produces a peripheral nerve injury rather than a direct injury to the spinal cord. Symptoms may include variable motor and sensory loss in the lower extremities, sciatica, bowel and bladder dysfunction, and "saddle anesthesia" (loss of pain sensation over the perineum). Because peripheral nerves possess the ability to regenerate, the prognosis for recovery is better than that for spinal cord lesions.

GENERAL APPROACH

Prehospital Care

The prehospital treatment of patients with spinal cord injury involves recognition of patients at risk, triage to an appropriate facility, and early care. All patients who have complaints of neck or back pain or who have tenderness on prehospital assessment must be presumed to have a spine injury until proven otherwise. Traditionally, all patients with significant injury above the clavicle are also presumed to have cervical spine injury regardless of related complaints. All patients with neurologic complaints must be presumed to have a spinal cord injury. Sometimes this is obvious, as in a patient with flaccid paraplegia. More often, symptoms are much more subtle (numbness or tingling in an extremity). Appropriate triage is imperative, as the results of the treatment for spinal cord injury are somewhat time related. Therefore, initial triage to a center that is capable of rapid diagnostics and therapeutics is essential to optimize outcome following spinal cord injury. Triage can be difficult. Patients may be asymptomatic or may have suffered a concomitant head injury that makes them unable to describe their injuries and hence does not allow for neurologic assessment in the field. Other injuries may preclude accurate neurologic assessment. The mechanism of injury is an important criterion on which prehospi-

tal providers can rely. High-speed or rollover vehicular accidents, falls from a substantial height (injuries to the thoracolumbar junction), and diving and surfing accidents typically produce cervical spine injuries. Any patient at risk by mechanism of injury must be presumed to have a spinal cord injury. While this may result in a substantial rate of overtriage, the consequences of undertriage can be devastating.

Prehospital care for spinal injuries involves immobilization of the entire spine and initial fluid therapy as proposed by the American College of Surgeons.¹⁰ Patients should be transported completely immobilized. The entire cervical spine can be immobilized with a rigid cervical collar supplemented with sandbags and tape. The thoracic and lumbar spine can be immobilized using a long backboard. Patients are "papoosed" onto the boards to maintain spinal alignment. While there is little scientific evidence to support any single target for systolic or mean arterial blood pressure in patients with spinal cord injuries, a mean arterial pressure of 65 to 70 mm Hg seems a reasonable target. Optimal perfusion of the spinal cord is one of the therapies that can be implemented in the field to lessen the chances of secondary spinal injury.

All efforts should be made to rapidly deliver patients with symptomatic spinal injuries to the areawide spine center. Delays engendered by transport to a different site can result in morbidity. Clearly, patients who are not hemodynamically stable must be taken to the closest available hospital.

Emergency Department Stabilization

ED evaluation should not differ substantially from any patient with multiple injuries (see Chap. 251). Consideration should be given to immediate airway control in patients with cervical spine injuries no matter how apparently stable at the time of presentation. The higher the level of spinal injury, the more compelling the indication for early airway intervention. The roots of the phrenic nerve, which supply the diaphragm, emerge at the third, fourth, and fifth cervical vertebral levels. Thus, **any patient with an injury at C5 or above should be intubated**. It may be prudent to intubate patients with cervical cord lesions even below this level. Significant spinal cord edema may progress rostrally to involve the roots of the phrenic nerve. Many patients can initially support ventilatory function utilizing intercostal muscles or abdominal breathing, but they eventually tire and then develop respiratory failure. As the evaluation process for these patients often involves transport outside of the ED, the authors feel strongly that early airway control is the safest route. Patients who develop respiratory failure in the CT scanner or the MRI suite may suffer respiratory arrest before it can be recognized and the airway secured.

AIRWAY It is important to perform a complete neurologic assessment, if possible, before patients are intubated and sedated. The spine must be kept immobilized while the airway is managed. In general, this is accomplished using orotracheal intubation with in-line cervical stabilization (without distraction force) and cricoid pressure. Nasal intubation can be performed in patients while maintaining spine immobilization, although it is not a preferred method because nasal intubation is generally a blind technique. Virtually all patients with potential cervical spine trauma require sedation before nasal intubation can be accomplished; but if respirations become substantially depressed, nasotracheal intubation may not be possible. If patients are inadequately prepared, they may resist intubation. Motion of an unstable fracture can worsen spinal injury. If patients are oversedated, they may become hypoxic and lose the ability to protect the airway. Also, nasal intubation is performed with a smaller endotracheal tube, which can compromise respiratory therapy later during the hospitalization. Fiberoptic bronchoscopy may later be required for diagnostic purposes, particularly in those with pulmonary injuries or significant atelectasis, to facilitate removal of inspissated mucous plugs or blood. A relatively large endotracheal tube (8 mm or greater in size) is needed during fiberoptic bronchoscopy to ensure that ventilation is not compromised

SECTION 22 • TRAUMA

during the procedure. An 8-mm endotracheal tube is often too large for nasotracheal intubation. In addition, the limiting factor in minimizing tube size is the increasing respiratory resistance to gas flow imposing increased work for the patient with each spontaneous breath. Thus, the work of breathing is greater with tubes of 6 to 7 mm internal diameter, sometimes used for nasal intubation, than with tubes of 8 mm or greater internal diameter. The most limiting aspect of nasal intubation is the inability to move the cervical spine to attain the "sniff" position, optimal for the procedure. Finally, nasal intubation increases the risk of sinusitis. If nasal intubation is selected, fiberoptic guidance is a useful technique. While the concerns of nasal intubation remain, with fiberoptic guidance, it is not a blind technique.

HYPOTENSION Following airway stabilization, hemodynamic stability is the most pressing concern. Fluid therapy is generally the treatment of choice to support cardiovascular functioning. Patients with spinal cord injuries often present with hypotension, which must be differentiated as to its cause: spinal cord injury, blood loss, cardiac injury, or a combination. Injury to the spinal cord at the level of the cervical or thoracic vertebrae causes sympathetic denervation. There is a loss of α -adrenergic tone and dilatation of the arterial and venous vessels. Elimination of sympathetic arterial tone results in decreased systemic vascular resistance. Loss of sympathetic innervation to the heart (T1 through T4 cord levels) leaves the parasympathetic cardiac innervation via the vagus nerve unopposed, resulting in bradycardia. While it is true that neurogenic shock is associated with bradycardia, it should never be assumed that a patient with hypotension and bradycardia is suffering from isolated neurogenic shock. Vital signs are often non-specific. Patients with neurogenic shock may have concomitant hemorrhagic shock and may not be able to mount a tachycardic response. **Blood loss must be presumed to be the cause of hypotension until proven otherwise.** In general, patients with neurogenic shock are warm, peripherally vasodilated, and bradycardic. They seem to tolerate hypotension relatively well. This makes some sense, as peripheral oxygen delivery is presumably normal. They have incurred mechanical sympathectomy, thus cardiovascular function is not impaired.

The mechanism of injury is important in determining whether hypotension is from spinal cord injury or blood loss. Factors other than spinal cord injury (mostly blood loss) are responsible at least in part for the hypotension seen in patients with blunt trauma.¹¹ More than 90 percent of hypotensive patients with penetrating spinal cord injury have blood loss to at least partly explain their hypotension.¹²

In all patients, a rapid search for potential blood loss should be undertaken. A chest x-ray will usually identify blood loss within the thorax. Retroperitoneal blood loss can come from concomitant pelvic fractures or may be secondary to lumbar arterial bleeding from spine fractures, especially in patients with substantial falls from a height. Every patient with a spinal fracture should have an abdominal diagnostic investigation. In hemodynamically unstable patients, CT scanning is often impractical; therefore ultrasonography or diagnostic peritoneal lavage should be used. Retroperitoneal bleeding should be suspected in patients without evidence of intraabdominal blood loss who develop abdominal distention or tenderness.⁶ Plain x-rays that demonstrate spinal fractures should help with the diagnosis. Angiography may be necessary for both diagnosis and treatment of active bleeding.

NEUROLOGIC EXAMINATION Once patients are stabilized and other life-threatening injuries have been excluded or treated, a detailed neurologic examination should be performed. Details of history include whether the patient has had a loss of consciousness. A patient who was asymptomatic in the field and has neurologic deterioration in the ED requires emergent therapy. The presence of neck or back pain, or urinary or fecal incontinence clearly defines the patient at risk for spinal cord injury.

Physical examination should delineate the level of spinal cord injury (Figure 256-6). A complete initial neurologic examination must

FIG. 256-6. Spinal cord level. This level can be delineated by physical examination, including a detailed neurologic examination.

be documented for appropriate comparison should a patient deteriorate later. The presence or absence of neck or back tenderness should be noted. Motor function for muscle groups should be tested and recorded on a scale of 0 to 5 (Table 256-2). The level of sensory loss should be determined. Gross proprioception or vibratory function must be investigated to examine posterior column function. Deep tendon reflexes should be tested. Anogenital reflexes should also be tested, because "sacral sparing" with preservation of the reflexes denotes an incomplete spinal cord level even if the patient has complete sensory and motor loss. To test the bulbocavernosus reflex, the penis is squeezed to determine whether the anal sphincter simultaneously contracts. Rectal tone can be assessed at the same time. Priapism implies a complete spinal cord injury. The cremasteric reflex is tested by running a pin or a blunt instrument up the medial aspect of the thigh. If the scrotum rises, there is some spinal cord integrity. The area around the anus should be tested with a pin. An "anal wink" (contraction of the anal musculature) indicates at least some sacral sparing.

Diagnostic Imaging

Certainly one of the real dilemmas facing the clinician in the ED is identifying which patient requires evaluation for a potential spinal cord injury (Figure 256-7). Blind application of expensive diagnostic testing risks inappropriately increasing the cost of medical care and potentially rendering resources unavailable to other patients. Diagnostic testing must evaluate the possibility of injury to both bone and spinal cord. It is difficult to limit diagnostic testing to those who obviously require it. For example, removing a collar or allowing a patient to walk with an unstable spine risks converting a patient with no spinal cord injury to one with a complete level. Thus, it is prudent to completely image and evaluate all patients with the possibility of spinal cord pathology.

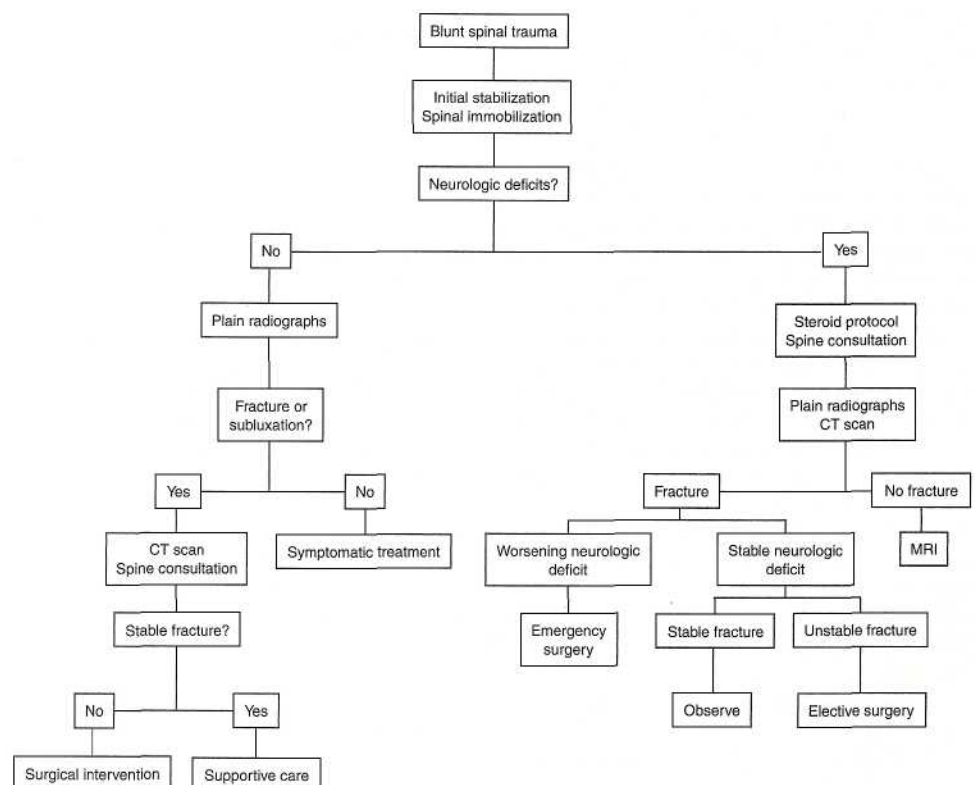

C-SPINE In general, an x-ray of the cervical spine is part of the standard triage for blunt trauma. Patients with possible head or neck trauma who are not fully alert [Glasgow Coma Scale (GCS) <15] should have imaging of their cervical spines. The frequency of cervical spine injury in association with blunt head trauma is approximately 2 to 5 percent. However, it increases to almost 9 percent in patients with significant head injury, defined as a GCS score <10.¹³

The utility of plain films of the cervical spine in patients who are alert, oriented, and have no neck or back pain or tenderness is questionable. The National Emergency X-Radiography Utilization Study (NEXUS) group identified five clinical criteria (absence of midline cervical tenderness; normal level of alertness; no evidence of intoxication; absence of focal neurologic deficit; absence of painful dis-

tracting injury) as factors that should be present to eliminate the performance of cervical radiographs.¹⁴ The NEXUS criteria were 99 percent sensitive for detecting clinically significant cervical spine (C-spine) injuries. The specificity of the criteria, however, was only 12.9 percent, raising concerns that use of the NEXUS criteria would actually increase the use of radiography. The "Canadian C-Spine Rule for Radiography" was subsequently developed for alert, stable trauma patients to further reduce practice variation and inefficiency in ED use of C-spine radiography.¹⁵ The Canadian Rule consists of three questions: 1) Are there any high-risk factors that mandate radiography? 2) Are there any low-risk factors that would allow a safe assessment of range of motion? and 3) Is the patient able to actively rotate the neck 45 degrees to the left and to the right? High-risk factors include age 65 years or older, a dangerous mechanism of injury (fall from a height of 5 m; an axial loading injury; high-speed motor vehicle crash, rollover, or ejection; motorized recreational vehicle or bicycle collision), or the presence of paresthesias in the extremities. Low-risk factors include simple rear-end motor vehicle crashes, patient able to sit up in the ED, patient ambulatory at any time, delayed onset of neck pain, or the absence of midline cervical tenderness. The Canadian C-Spine Rule had 100 percent sensitivity and 42.5 percent specificity for identifying patients with "clinically important" cervical spine injuries. Stiell et al. suggest that their rule could significantly reduce the use of C-spine radiographs ordered for alert, stable trauma patients.

The "gold standard" for the identification of bony cervical injury includes three views of the cervical spine: anteroposterior (AP), lateral, and odontoid. They allow for imaging of the entire cervical spine. It is important that all seven cervical vertebrae be imaged, including the junction between the seventh cervical and the first thoracic vertebrae. A single lateral cervical spine film will identify 90 percent of injuries to bone and ligaments.¹⁶ The film must be examined for the presence or absence of prevertebral swelling. The prevertebral space anterior to C3 should be less than 5 mm. The predental space should be less than 3 mm. The open-mouth odontoid view will identify many of the remaining abnormalities. Cervical immobilization must be maintained until the patient also has an AP and open-mouth odontoid

FIG. 256-7. Algorithm for blunt spinal trauma.

view. If the initial lateral view is normal and the patient is neurologically intact, the AP and open-mouth views can be delayed until other injuries are adequately stabilized. The combination of lateral, AP, and odontoid views is generally adequate to identify or at least raise the suspicion of cervical spine injury.

Alternatively, CT scanning can be used to visualize the entire cervical spine. Patients can have a cervical spine injury even with normal plain films. The current trend in many trauma centers is to CT the entire C-spine. Plain films are poor for imaging C₁ and C₂. The only possible advantage to plain films is for visualization of prevertebral swelling and spinous process. Further, visualization of the entire cervical spine via plain films often can be problematic. Patients' body habitus or the presence of upper-extremity injuries may limit the clinician's ability to pull on the arms, a maneuver necessary to visualize all seven vertebral bodies. An alternative is a swimmer's view, which is aimed through the axilla in an attempt to image the lower cervical spine. Oblique views (45 degrees) can also be obtained. These views have the added advantage of showing the neural foramina well. They demonstrate the pedicles as well as the laminae, which should stack like shingles on a roof. Plain and even CT films of the neck may not identify patients with pure ligamentous injuries. In these patients, ligaments are disrupted but the spine spontaneously reduces to a normal position. Motion, however, risks neurologic injury.

Flexion and extension views demonstrate the degree of spinal column stability. In general, these views are obtained when patients have pain or tenderness but normal plain films. They can only be obtained in a fully awake, unsedated, cooperative patient. The patient carefully and slowly flexes and extends the neck. Motion should be limited by increasing pain or the appearance of any neurologic symptomatology. A stepoff of 3.7 mm or an angulation of greater than 11 degrees denotes cervical spine instability.¹⁷ It is possible to have ligamentous injury even with normal flexion/extension films, because muscle tone can splint the bones in a stable configuration. Most patients in this latter category note pain improvement with analgesics after a few days.

Reliable patients without a substantial mechanism of injury with persistent pain but normal radiographs, including flexion/extension views, can be discharged in a hard collar with outpatient follow-up in 3 to 5 days. Most patients' symptoms will resolve over a few days. A patient with persistent symptoms will require additional outpatient workup. Unreliable patients or those with a significant mechanism of injury or risk factors, such as advanced age, should undergo MRI although this is rarely indicated as part of the initial investigation.

THORACOLUMBAR SPINE Plain films of the thoracic and lumbar spine are the initial examinations generally used to image these spinal levels. Many of the same principles used for cervical spine imaging are important for thoracic and lumbar imaging. All patients with a mechanism of injury, those with complaints of back pain, and those who have tenderness on physical examination must be assumed to have a fracture of the thoracic or lumbar spine. They must be kept immobilized. AP and lateral films are generally obtained and examined for abnormality. In general, the lateral x-rays are much more easily obtained with patients still on a backboard. Skin breakdown and pressure sores can develop very quickly, particularly in obese patients. Our goal is to remove patients from the backboard in less than 2 h. Patients can then be nursed supine in a bed as long as they are logrolled. **A standard hospital mattress provides adequate spinal support.** However, patients must be carefully moved and care must be taken to keep spinal immobilization complete in transfers from bed to stretcher. It may be helpful to place patients back on a backboard for the transportation phases of their care. Alternatively, a scoop stretcher may be used for transport.

It can be difficult to image the upper thoracic spine adequately, even if maximal power of the x-ray beam is used. One alternative is to clear the reliable patient by physical examination. Unreliable or unexamined patients with a concerning mechanism should be logrolled

until the thoracic spine can be appropriately evaluated. Patients with point tenderness and normal films are a special subset. CT scanning can be useful in this subset, although the yield is low. The thoracic spine has inherent stability from the rib cage. Few fractures in these patients will be unstable. Alternatively, patients can be treated with analgesics and investigated selectively if symptoms persist.

More recently, CT has assumed a much more important role in the imaging of spine injuries. Plain films can be imperfect and may miss a number of such patients. Newer-generation helical scanning is rapid, and CT allows for a complete three-dimensional imaging of bony structures. CT scanning is indicated in almost all patients with proven bony spinal injury, subluxations, for patients with neurologic deficits but no apparent abnormalities on plain films, those with severe neck or back pain and normal plain films, and those in whom the thoracic and lumbar spine should be examined to define the anatomy of a fracture and the extent of impingement on the spinal canal. CT can reveal the exact anatomy of an osseous injury, the extent of spinal canal impingement by bone fragments, and the stability of an injury. CT scans are indicated for all patients with fractures that can be seen on plain films. CT is especially useful when the lower cervical spine cannot be adequately visualized on plain films because of overlying soft tissues.

MRI is not as sensitive as CT for detecting or delineating bone injuries. MRI is superb at defining neurologic, muscular, and soft tissue injury. It is the diagnostic test of choice for describing the anatomy of nerve injury. Entities such as herniated disks or spinal cord contusions are easily seen on MRI. Many of these require only supportive therapy. However, some require acute surgical intervention. Early identification helps plan therapy. MRI may also be used to identify ligamentous injury. MRI is indicated in patients with neurologic findings with no clear explanation following plain films and CT scanning. CT myelography is an alternative when MRI is unavailable and immediate diagnosis of a neurologic lesion is required. If the patient is neurologically stable and MRI is unavailable, delayed MRI and/or transfer to a tertiary care facility may be appropriate.

The determination of a spinal column injury at one level should prompt imaging of the remainder of the spine. Approximately 10 percent of patients with spine fracture in one segment will have a second fracture in another. Often plain films will suffice, but multilevel CT scanning and/or MRI may be necessary to investigate such patients completely.

TREATMENT

The goals of treatment are to prevent secondary injury, alleviate cord compression, and establish spinal stability. Spinal immobilization must be maintained, and movement kept to a minimum.

Once the patient is stabilized, it should be determined whether the patient has a neurologic deficit and/or the spinal column is unstable. If either of those conditions exists, subspecialty consultation should be requested emergently. The consultant, be it a neurosurgeon or orthopedic surgeon, must have the opportunity to perform a detailed neurologic examination early in the patient's course, so as to optimize outcome. In a few cases, this will be impossible if the patient requires intubation. Patients with progressive neurologic deterioration require urgent surgical intervention. The method of stabilization (collar or traction) must be determined, as must the need for further CT or MRI imaging.

Corticosteroids

Although controversial, the use of high-dose methylprednisolone presently remains the standard of care for the treatment of blunt spinal cord injury in the US. The National Acute Spinal Cord Injury Study (NASCIS) group conducted a series of multi-institutional studies to evaluate the efficacy of methylprednisolone in spinal trauma.¹⁸

Methylprednisolone infusion resulted in improvement of both motor and sensory function in patients with complete and incomplete neurologic lesions. This positive outcome was dependent upon dosage of steroids and time of administration. The current recommended steroid protocol for victims of spinal injury with neurologic deficits is as follows:

1. Treatment must be started within 8 h of injury.
2. Methylprednisolone (30 mg/kg) bolus administered IV over 15 min.
3. This is followed by a 45-min pause.
4. A maintenance infusion of methylprednisolone (5.4 mg/kg per h) is continued for 23 h.

NASCIS evaluated only blunt spinal cord injury. Patients with penetrating injuries were excluded from the study. **Massive steroid therapy has not been shown to be effective in penetrating spinal cord injury**, and in fact may impair recovery of neurologic function.¹⁹

The major neuroprotective mechanism by which high-dose methylprednisolone is believed to work is its inhibition of free radical-induced lipid peroxidation. Other proposed beneficial actions include its ability to increase levels of spinal cord blood flow, increase extracellular calcium, and prevent loss of potassium from injured cord tissue. Methylprednisolone is advocated in preference to other steroids because it crosses cell membranes more rapidly and completely.

Recent studies question the validity of the NASCIS trials and the effectiveness of high-dose steroid therapy in patients with spinal cord injury.^{20,21} Potential complications associated with prolonged, high-dose steroids such as pneumonia, sepsis, wound infection, thromboembolism, gastrointestinal bleeding, and delayed healing are a frequently cited concern; however whether any of these concerns relate to a 23-h protocol has not been investigated to date.

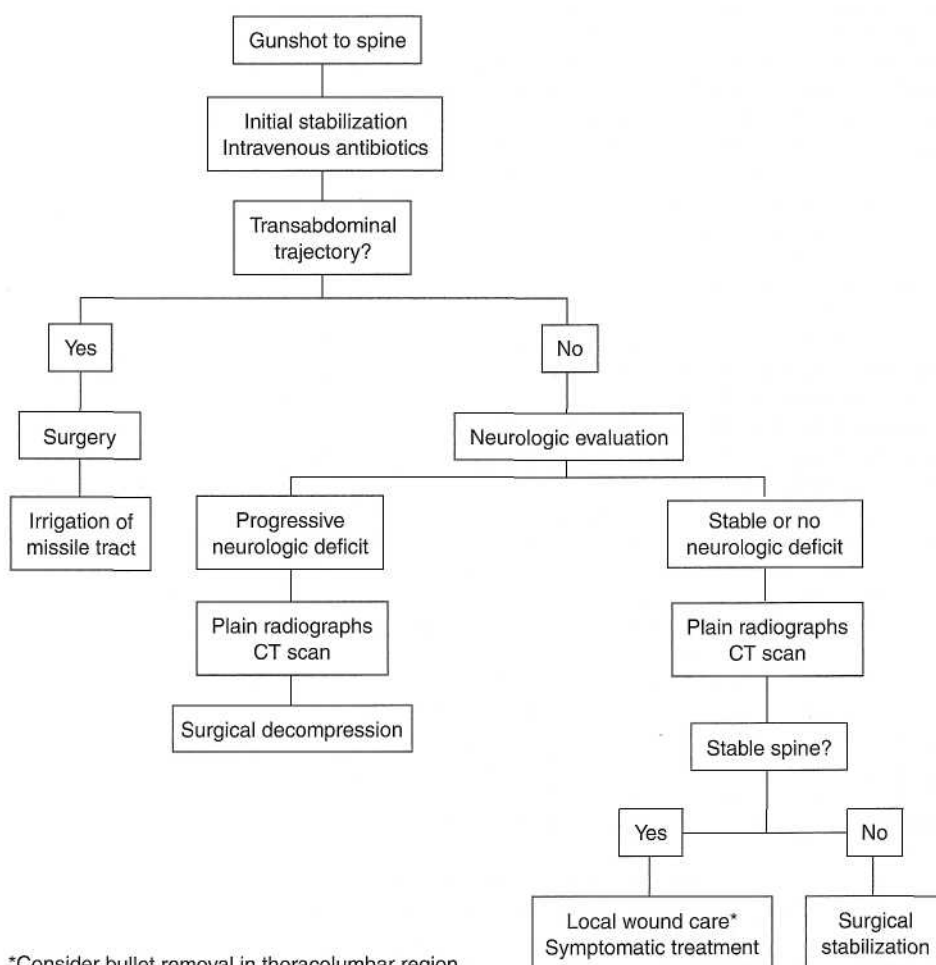

Penetrating Injury

Treatment goals are the same for penetrating and blunt spinal injury. There are, however, additional considerations in penetrating trauma. Figure 256-8 shows an approach for gunshot wounds. Optimal treatment of these injuries has been the subject of debate. One concern is that of infectious complications related to the presence of foreign bodies. Additional contamination is associated with transperitoneal and transintestinal trajectories of gunshot wounds to the spine. Intravenous antibiotics should be given in the ED. Surgical debridement with laminectomy has not proven effective in reducing the incidence of infectious complications, as most are managed nonoperatively. If the patient requires laparotomy for abdominal trauma, irrigation and debridement of the spinal injury through the missile tract may be appropriate.⁸

As with blunt trauma, there is general agreement that progressive neurologic deficits warrant surgical decompression. The indication for removal of bullet and bone fragments in those patients with nonprogressive neurologic deficits is less clear. Wound location may determine the need for surgical intervention. Bullet removal does not significantly improve the neurologic status of patients with stable cervical and thoracic spinal cord lesions. In contrast, bullet removal from the thoracolumbar spine may significantly improve motor recovery in both complete and incomplete injuries.²² Most gunshot wounds to the spine following penetrating trauma are stable and require only symptomatic treatment with a supportive orthosis and analgesics.

Patients who present with stab wounds to the spinal region with no neurologic deficits should receive antibiotics and local wound care. Plain films and/or CT scan may be performed to evaluate for a retained foreign body, but the literature is controversial as to whether or

FIG. 256-8. Algorithm for gunshot to spine.

not to surgically remove the blade if there are no or stable neurologic deficits. If no metallic foreign bodies are present, neurologic deficits are best evaluated with MRI. Progressive neurologic deficits are generally treated surgically.

Chap. 258 details approaches to stab wounds to the neck. Significant spinal injuries are related to direct penetration of spinal cord neural elements, spinal infarction, or, rarely, from a spinal epidural hematoma. Vertebral instability is not an issue per se. Delayed deficits are rare. When they do occur, they are related to retained fragment of blade within the spinal canal.

Nonoperative Spinal Stabilization

The goal of stabilization is to reduce deformities and then restrict motion and maintain alignment. In the cervical spine, it is important to determine the adequacy of cervical bony reduction. Subluxations are generally reduced using Gardner-Wells tongs, which are placed into the soft tissue of the temples under local anesthesia. The location and type of injury determine the amount of weight applied. The upper cervical spine generally requires less weight for traction than the lower cervical spine. Depending upon location, initial weight should be started at 5 to 10 lb. Weight should be increased in 2.5- to 5-lb increments. Ideally, this should be done under fluoroscopic guidance. If fluoroscopy is unavailable, radiographs and neurologic examinations should be performed after each increment of weight. The radiographs should be evaluated for alignment of the spinal column and to ensure that overdistraction has not occurred. Neurologic performance can improve if reduction is achieved. Inability to achieve adequate reduction is an indication for early spinal decompression and fusion.

Spinal orthoses are used to immobilize well-reduced cervical fractures. The cervical spine is the region most effectively stabilized by external splinting devices. There is less soft tissue separating the brace from the spine at this level. In addition, some braces can be solidly secured by fixation points at the cranium and the thoracic cage. Cervical orthoses consist of cervical and cervicothoracic types. Cervical collars fit around the neck and contour to the mandible and occiput. They restrict flexion and extension in the middle and lower cervical spine. Lateral bending and rotational movements, however, are poorly controlled. Examples of cervical orthoses include the hard collar, the Philadelphia collar, and the Miami J collar. Cervicothoracic braces provide additional support. The "gold standard" is the halo cervical immobilizer, which provides the most rigid stabilization. Consisting of a halo ring pinned to the skull, a vest, and upright posts, it can be used for traction and reduction of unstable fractures as well as immobilization.

Immobilization of the upper thoracic spine by orthoses is difficult. Fortunately, an intact rib cage and sternum provide relative stability. Although brace immobilization is not always necessary in the treatment of these fractures, braces can provide additional comfort. Thoracic corsets provide minimal control of motion and are appropriate only for minor injuries. Jewett and Taylor braces provide intermediate control of spinal motion. Maximum limitation of motion is provided by the Risser jacket and the body cast.

The thoracolumbar junction and lower lumbar regions are also difficult to immobilize externally. Splints are limited by lack of an adequate caudal fixation point. The functions of most thoracolumbosacral orthoses are the following: to create an awareness and remind the patient to restrict movements, to support the abdomen and relieve some of the load on the lumbosacral spine, to provide some restriction of motion of the upper lumbar and thoracolumbar spine by three-point fixation, and to reduce lumbar lordosis in order to provide a straighter, more comfortable lower back.

Complications of external immobilization devices include pain, pressure, muscle weakness and disuse atrophy, venous compromise, psychological dependence, ineffective stabilization, and pin-site complications (halo vest) (see Chap. 236 for ED evaluation).

Operative Management of Spine Injuries

The indication for operative stabilization is somewhat controversial and varies from institution to institution. Those favoring an aggressive approach stress the importance of early mobilization of the multiply injured patient as it helps decrease pulmonary problems, skin breakdown, deep venous thrombosis, and pulmonary embolus. Rigid fixation may also decrease time in hospital as well as long-term pain and deformities.

Those advocating a nonoperative approach point out the possibility of worsening neurologic performance by operative manipulation. In addition, the long-term results with operative intervention may not be substantially better than with nonoperative therapy.

All would agree that progressive neurologic deterioration is an indication for urgent surgery. In addition, spinal instability should most often be managed operatively even in the case of a complete spinal cord level. This helps prevent long-term deformity.

MAXILLOFACIAL TRAUMA

Nael Hasan

Stephen A. Colucciello

ETIOLOGY/INCIDENCE

Up to 60 percent of patients with severe facial injuries have multisystem trauma and have potential for airway compromise. The etiology of facial fractures varies between urban and rural environments. Penetrating trauma and assault-related injuries are more common in cities, whereas motor vehicle crash (MVC), sporting, and other recreational injuries are seen frequently in rural hospitals. In community emergency departments, fractures of the nose and mandible are most common; in trauma centers, however, midface and zygomatic injuries are more frequent. Domestic violence and elder and child abuse are important causes of facial trauma. Facial injury accounts for the majority of emergency department visits related to domestic violence. As many as one-fourth of women with facial trauma are victims of domestic violence.¹ **If a woman has an orbital fracture, the likelihood of sexual assault or domestic violence rises to more than 30 percent.**² Falls are also an important cause of facial injury in the very young and the elderly.

Potential injuries associated with facial trauma are those of the head, cervical spine, and eye. As many as 20 to 50 percent of victims of facial trauma sustain concurrent brain injury, especially those with upper face and midface fractures.

Although most series show no increased incidence in cervical spine injury with facial trauma (1-4 percent), this is of statistical interest only. One must consider possible spinal injury in all patients with significant or suspected maxillofacial fractures because it takes considerable force to shatter the midface or upper face. Factors that may increase the likelihood of cervical spine injury in this population are older age, MVCs, and concomitant brain injury.³ Maxillofacial trauma by itself can be a "distracting injury" that masks cervical spine injury. Always exclude cervical spine injury clinically and/or radiographically in such patients. One study has linked carotid artery injury to severe facial trauma.⁴

Periorbital fractures may be associated with globe disruption or blindness. The dangerous triad of limited extraocular movement, limited visual acuity, and limited visual fields should be evaluated in all patients with facial injuries.

Blindness occurs in 0.5 to 3 percent of patients with facial fractures and is most frequent in patients with Le Fort III (2.2 percent), Le Fort II (0.64 percent), and zygomatic fractures (0.45 percent).⁵ MVCs and gunshot injuries are responsible for most cases of visual loss.

In addition to the physical consequences of facial trauma, there are psychological costs as well. More than one-quarter of patients with significant facial trauma may develop posttraumatic stress disorder.⁶

ANATOMY

The facial buttresses, bony arches joined by suture lines, provide vertical and horizontal support. The main purpose of these buttresses is to withstand vertical stresses associated with mastication, accomplished by the strong zygomaticomaxillary buttress laterally and the frontal process of the maxilla medially. In contrast, the horizontal support is weak and consists of the superior orbital rims, orbital floor, and hard palate. Hence frontal, lateral, and oblique forces tend to produce facial fractures. Sutures linking these facial bones rupture in predictable fashion during trauma. Knowledge of their location enables one to palpate these sutures to detect diastasis or tenderness.

Sutures found at borders of the sphenoid wings, pterygoid plate, and the zygomatic arch anchor the face to the skull. These are the structures disrupted in Le Fort injuries (Figure 257-1). The most complex aspect of facial anatomy is the orbit, an elaborate structure com-

prised of seven different bones: maxilla, zygoma, frontal, sphenoid, palatine, ethmoid, and lacrimal. Between these bones lie the orbital foramina, through which course cranial nerves II, III, and VI and branches of cranial nerve V. The weakest portions of the orbit are the floor and medial wall, which are the thickness of an eggshell. Rupture of orbital bones may compress the fissures and cause blindness through traction, rupture, or compression of the optic nerves.

PREHOSPITAL CARE

The major concern in prehospital care is control of the airway. In severe midfacial injuries, loss of bony support may result in both collapse of the pharynx and loss of periorbital stability, making use of the bag-valve mask problematic. A nasal airway or laryngeal mask airway (LMA) can help splint the upper airway, as well as sitting the patient up or leaning the patient forward if needed, always being conscious of potential cervical spine injury. The mouth should be cleared of any foreign body or debris and suctioned of blood. The tongue may block the airway, and a jaw thrust or modified chin lift without neck extension often relieves the obstruction. With severe mandible fractures, these maneuvers may not elevate the tongue, necessitating other techniques (see "Airway," below). Prehospital providers should immobilize the cervical spine using standard indications. If there is copious bleeding and massive facial injury, early notification allows the emergency department to prepare for a difficult airway.

EMERGENCY MANAGEMENT: RESUSCITATION

The compelling and sometimes grotesque nature of facial injuries must not distract physicians from following the routine, sequential trauma protocol. The most urgent complication of facial trauma is not shock but airway compromise, particularly with midfacial and lower facial trauma. Prior to detailed evaluation, some presentations require immediate attention, as detailed below.

Airway

Simple intervention, such as the chin lift without neck extension, jaw thrust, and oropharyngeal suctioning, often clears the airway. In mandibular fractures, however, loss of bony support may result in a *flail mandible*, leaving the tongue to obstruct the airway. In this case, the mouth should be opened and the tongue pulled forward with a gauze pad, towel clip, or a large suture placed through the anterior tongue. When the cervical spine has been cleared, clinically or radiographically, it is best to allow the patient to sit up and lean forward and to give the patient a tonsil-tip suction. This position may be lifesaving in patients with significant mandible fractures. Patients who do not respond to simple maneuvers may require intubation.

Intubation Considerations

Because the cribriform plate may be disrupted, avoid nasotracheal intubation in patients with midface trauma. Nasotracheal intubation can result in nasocranial intubation or dramatic nasal hemorrhage. Admittedly, these complications are rare, and some patients have been intubated successfully using the nasotracheal route. Nonetheless, orotracheal intubation is preferred and is often successful even with severely distorted facial anatomy.

Rapid-sequence intubation carries particular risk in facial trauma. These dangers include the failure to intubate and subsequent failure to ventilate with a bag-valve mask. Before paralyzing any patient, evaluate the degree of difficulty anticipated for mask ventilation. Patients with distortion of the maxilla or mandible may be impossible to bag because the mask will not fit tightly on an unstable face.

In such cases, consider an awake intubation. Options include sedation with a benzodiazepine, ketamine, or other induction agent in a

FIG. 257-1. Coronal and lateral facial bone anatomy. [Reprinted with permission from Isenhour J, Colucciello S: Maxillofacial trauma, in Ferrera P et al (eds): *Trauma Management*. St. Louis: Mosby, 2000.]

dose that minimizes respiratory depression. If a patient with severe maxillofacial trauma is given paralytics, prepare for immediate backup cricothyroidotomy. *Preparation* in this case implies more than locating a surgical tray: It extends to povidone-iodine on the neck, a ready blade, an opened cricothyroidotomy tray, and a tracheostomy tube at the bedside. The LMA has emerged as an excellent bridge to intubation or surgical airway in the operative theater, provided the hypopharynx remains intact. Some authors describe creative approaches to intubation in facial trauma. Fiberoptic intubation with patients in the semiprone position may be useful in penetrating injuries of the face. The traditional supine intubating position may be impossible with a ruined maxilla that falls into the airway. Such airways may clear when a patient lies on his or her side (although this may be both awkward and disconcerting to the physician).

Other alternatives include percutaneous transtracheal ventilation and retrograde intubation as a temporizing measure. Both require considerable preparation, and the most dependable alternative airway is surgical. Emergency cricothyroidotomy, being faster and associated with fewer complications, is preferable to emergency tracheostomy.

Hemorrhage Control

Patients rarely develop shock from facial bleeding.⁷ In hypotensive patients, other sources of blood loss, such as intrathoracic, intra-abdominal, and retroperitoneal hemorrhage, should be sought. Maxillofacial bleeding is controlled with direct pressure. Clamping in wounds is avoided because important structures such as the facial nerve or parotid duct may be injured. Severe pharyngeal bleeding may require packing of the pharynx and hypopharynx around a cuffed endotracheal tube. In patients with Le Fort fractures, manual reduction of the face should stem bleeding. Grasp the anterior hard palate at the maxillary arch, and realign the fragments. Severe nasal bleeding requires direct pressure to the nares or combined posterior and anterior packing, taking care not to inadvertently pack the cranium. In the case of massive nasopharyngeal bleeding, a balloon-tipped urinary catheter placed along the floor of the nose and inflated with saline may be lifesaving. Nasopharyngeal dual-lumen balloons and packs impregnated with procoagulant factors are also available commercially for this purpose.

Once the airway is secure and gross hemorrhage controlled, the potential existence of other life threats in the chest, abdomen, and pelvis are sought.

HISTORY

It is important to determine the mechanism and time of injury and to assess for loss of consciousness. The addition of airbags to automobiles is associated with less severe maxillofacial injuries compared with either seatbelt use alone or no restraint.⁸ Allergies and tetanus status are standard inquiries.

The following essential three face-oriented questions target eye involvement, injury to facial nerves, and alignment of central and lower face:

"How is your vision?"

"Is any part of your face numb?"

"Are your teeth meeting normally?"

Monocular double vision occurs with lens dislocation or with corneal or retinal injury, whereas binocular double vision implies dysfunction of the extraocular muscles or nerves. Pain on eye movement suggests injury to the orbit or globe.

If the mechanism of injury is not an MVC, ask women about domestic violence. Although a victim of domestic violence may tell the triage nurse that she fell or "ran into a door," many patients reveal the true etiology if questioned directly by a physician. Child abuse and elder abuse are important considerations when patients at the extremes of age present with facial trauma. **More than half of all abused children are injured in the head, face, mouth, or neck.**⁹

PHYSICAL EXAMINATION

Inspection

The patient is viewed initially from the front. Facial elongation occurs with high-grade Le Fort fractures (the so-called donkey face). Next, the face is viewed from above looking down (bird's-eye view) and

from below up (worm's-eye view). These perspectives reveal subtle asymmetries. Because posttraumatic Bell palsy occurs with fractures of the temporal bone, particular attention should be paid to the cranial nerve. Ecchymoses around the eyes (raccoon's eyes) and over the mastoid area (Battle sign) are associated with basilar skull fracture. These findings usually develop over several hours and often are absent on admission despite serious facial trauma. Raccoon's eyes can be seen with nasoethmoidal-orbital injuries, Le Fort fractures, and frontal bone fractures, as well as with direct periorbital and nasal trauma.

Palpation

Palpation will disclose the majority of facial fractures. The entire face should be palpated carefully for tenderness, bony crepitus, and subcutaneous air. The presence of subcutaneous air is pathognomonic for fracture of a sinus wall or nose.

Particular attention should be paid to vulnerable sutures such as those on the infraorbital rim and the zygomaticofrontal suture located on the upper lateral aspect of the orbit. Simultaneous palpation of the zygomatic arches will reveal any asymmetry. The best way to distinguish tenderness of the soft tissues of the cheek from bony tenderness is by intraoral palpation. A gloved finger is placed inside the patient's mouth and on the buccal surface of the upper molars (outside the teeth). The examining finger is placed under the zygomatic arch. This method will identify displacement or collapse of the arch.

To assess facial stability, with the patient's mouth open, the maxillary arch is grasped (*not* the central incisors—which might pull out). Le Fort fractures are best diagnosed by rocking the maxillary arch and simultaneously feeling the central face for movement with the opposite hand.

Although anesthesia of the face may be secondary to nerve contusion, it often signifies a fracture. Damage to the infraorbital nerve (often due to blowout or rim fractures) results in anesthesia of the ipsilateral upper lip, nasal mucosa at the vestibule, lower eyelid, and maxillary teeth. Lower lip and lower dental anesthesia can occur with mandibular fractures.

Periorbital and Orbital Examination

The eye examination deserves particular attention, especially when there is periorbital injury. The examination should be performed early during the emergency department encounter, before progressive lid edema prevents appropriate examination. If lids are already swollen, lid retractors help visualize the globe. The bird's-eye and worm's-eye views help detect exophthalmos or enophthalmos.

The pupil is examined for reactivity and whether the pupils line up in the horizontal plane. A teardrop-shaped pupil indicates a ruptured or otherwise penetrated globe in patients without preexisting iridectomy. Hyphema may be apparent only when the patient is sitting. The presence of a hyphema correlates with significant visual loss. The Snellen chart, either standard or hand-held, if feasible to administer, should be used to document visual acuity. If the patient cannot see the chart, record finger counting or, barring that, the presence or absence of light perception. Early recognition of traumatic optic neuropathy should trigger an emergency consultation because timely decompressive surgery may prevent blindness.

The best way to detect damage to the optic nerve or retina (afferent defect) is the swinging-flashlight test. An abnormal pupil (Marcus Gunn) initially dilates (rather than constricts) when first exposed to a light that swings between both eyes.

Subconjunctival hemorrhage is often present with periorbital fractures, and lateral hemorrhage frequently accompanies zygomatic fractures. Soft tissue bruising provides other important clues.

With severe periorbital trauma, it is important to measure the distance between the medial canthi. In average adults, the intercanthal distance should be 35 to 40 mm—or approximately the width of a patient's eye.

Widening of this distance is called *telecanthus* and portends serious orbital injury. In patients with telecanthus, the bridge of the nose appears wide, but the distance between the pupils is unchanged. This is usually seen with nasoethmoidal-orbital trauma. A more serious condition known as *hypertelorism* occurs when the interpupillary distance increases. In this case, the orbits are dislocated and literally "blown apart." This devastating injury usually results in blindness.

Extraocular motions must be evaluated for restriction. Fractures of the zygomatic and infraorbital floor frequently cause diplopia, especially on upward gaze. Significant pain with extraocular motions provides a clue to occult injury.

Palpate the entire orbit for tenderness, subcutaneous air, and deformity. Inexperienced physicians frequently neglect the superior and lateral rims. Despite no palpable external deformity, fractures of the orbit occur quite often as a result of transmission of traumatic forces from the thicker external bone to the thinner and weaker bone of the orbital wall and floor.

Bimanual Palpation Test

One of the most important concerns is the status of the medial orbital area (the nasoethmoidal-orbital complex). Consider this injury if the medial canthus is tender or if the patient has telecanthus. When suspected, the bimanual nasal palpation test is a helpful adjunct (Figure 257-2).

To perform this test, the nose is anesthetized with either cocaine or lidocaine. A clamp or long cotton swab is then inserted into nose. The clamp or swab is pressed intranasally against the medial orbital rim (just inside the medial canthus). Simultaneously, the other hand is pressed against the medial canthus. If the bone moves, the complex is fractured. With telecanthus or severe medial canthal tenderness, this test may be omitted in favor of primary computed tomographic (CT) scanning.

Penetrating Injuries

With periorbital penetrating injuries, consider occult globe penetration. When the orbital septum is violated, fat protrudes from the wound, signaling possible globe perforation. Injuries to the medial third of the eyelids should be considered high risk for damage to the lacrimal apparatus. Lid lacerations should be evaluated for disruption of levator palpebral muscle and tarsal plate.

FIG. 257-2. Intranasal palpation test. [Reprinted with permission from Isenhour J, Colucciello S: Maxillofacial trauma, in Ferrera P et al (eds): *Trauma Management*. St. Louis: Mosby, 2000.]

Nose

The nose is inspected from various angles to detect any deformity. Posttraumatic edema often obscures nasal deviation. The patient can assist in the examination by identifying preexisting nasal deformity. Palpation will detect crepitus, subtle deformity, and subcutaneous air. The two most important potential findings are septal hematoma and cerebrospinal fluid (CSF) rhinorrhea. Septal hematoma appears as a bluish, bulging mass on a widened septum. If there is a doubt, the septum can be palpated with a cotton swab to appreciate the doughy swelling.

CSF mixed with blood forms a double ring or *halo sign* when dropped on a paper towel or a bed sheet. This occurs because blood and CSF have different diffusion properties. This finding is *not* specific for CSF and will occur with trauma-related rhinorrhea. Both CSF and simple rhinorrhea can contain glucose.¹⁰

Ears

The pinna is inspected for subperichondral hematoma. The ear canals should be inspected for lacerations and CSF leak. Hemotympanum appears as a purple (not red), often bulging eardrum. Tympanic membrane ruptures are also seen in conjunction with fractures of the mandibular condyle. In the presence of a basilar skull fracture, the mastoid area may be ecchymotic (Battle sign.)

Oral and Mandibular Examination

During inspection, the jaw is observed for any deviation, which results from either a condylar fracture or dislocation. Malocclusion may indicate Le Fort fractures, and patients may be unable to close the mouth due to premature occlusion of the molars. Zygomatic fractures also prevent jaw closure if the bone fragment either presses against the masseter or impinges on the coronoid process of the mandible. Fracture-associated nerve injury may result in anesthesia of the lips and gingiva.

An intraoral examination may reveal significant pathology. The examination should include manipulation of each tooth, a search for intraoral lacerations, and stress of the mandible. Essentially all fractures can be detected or excluded by both palpating and stressing the jaw. By placing a finger in the external ear canal while a patient opens and closes the mouth, one can palpate the mandibular condyle during jaw motion.

Tongue-Blade Test

The tongue blade, or spatula, test is a useful technique to detect mandibular fractures (Figure 257-3). Although unnecessary in patients with an obvious fracture, it enables physicians to determine the need for x-rays in patients with jaw pain and no obvious instability. The patient should be asked to bite down forcefully on a tongue blade. The physician then twists the tongue blade in an attempt to break the blade. Patients with a broken jaw will reflexively open their mouth, whereas those with an intact mandible will break the blade. In one study, this test was more than 95 percent sensitive and nearly 65 percent specific for mandibular fracture.¹¹

IMAGING

The choice and timing of radiographic studies depend on the clinical stability of the patient. Management of head, chest, and abdominal trauma takes precedence over facial imaging. In the critically injured, diagnostic imaging of the face, including a CT scan, may be deferred for days, until the patient's condition has stabilized.

It is not always clear which patients require facial imaging. In one study, physical examination alone detected 90 percent of clinically significant fractures.¹² However, management was altered in 17 percent of patients based on either CT scan or plain films.¹²

FIG. 257-3. Tongue blade test. [Reprinted with permission from Isenhour J, Colucciello S: Maxillofacial trauma, in Ferrera P, et al (eds): *Trauma Management*. St. Louis: Mosby, 2000.]

Plain Films

Plain films are useful screens for maxillofacial injury and are available in all hospitals. For the uninitiated, the numerous overlapping lines and complex shadows make interpretation challenging. However, becoming adept at reading plain films of the face (in particular the Waters view) can be a time-saving and cost-effective screening tool.¹³

One of the most useful approaches is to assess symmetry. Consider the right and left sides as mirror images. Assymetry is sought for lucencies or shadows, sutures and sinuses. The film is further examined for bony integrity and subcutaneous air. While air-fluid levels in the sinuses may occur with acute sinusitis, in the presence of trauma they are nearly pathognomonic for sinus fracture. Clouding of a sinus may be secondary to soft tissue swelling or due to complete filling of the sinus with blood. When seen in the superior aspect of the maxillary sinus, a soft tissue density may represent herniation of orbital contents through the orbital floor (Figure 257-4).

Radiographic Views of the Face

The Waters or occipital-mental view is the single most valuable study of the midface. Several recent studies have found a single Waters view to be as sensitive as the entire plain-film facial series.^{13,14} In one prospective study, the Waters view identified all significant facial fractures, and CT scan of the face was used only to further delineate complex injuries.¹⁵ It evaluates continuity of orbital rims, provides an initial diagnosis of blowout fractures, and will demonstrate air/fluid levels in the maxillary sinus.

The posteroanterior (PA or Caldwell) view, which best details the bones of the upper face, confirms ethmoidal and frontal sinus fractures, as well as lateral orbital injuries.

Cross-table or upright lateral views are difficult to read and are not very helpful. On occasion, they suggest elongation of the face in Le Fort injuries or disruption of the posterior sinus wall. Look for air-fluid levels in sphenoid or ethmoidal sinuses.

The submental-vertex view, known colloquially as the "jug handle" or zygomatic arch view, shows the base of the skull and the zygomatic arches. It may be the only film necessary for suspected arch fractures.

The Towne view is useful for evaluating the mandibular ramus and condyles, as well as the base of the skull. Regarding the mandible, if a Panorex view is unavailable, a four-view mandibular plain-film series can serve as an adequate substitute.¹⁶

Computed Tomography

CT scans provide a conclusive diagnosis of complex maxillofacial fractures. Its greatest utility lies in evaluating patients with known or

FIG. 257-4. Orbital tomogram showing classical "teardrop" herniation of orbital tissue into the maxillary sinus (arrows).

suspected periorbital and midface fractures. Scans are especially useful to evaluate the globe and orbital fissures. Specialized views—such as coronal, sagittal, or parasagittal cuts, thin-slice scans, and three-dimensional reconstruction—are useful in particular circumstances. In general, the slices should be in a plane 90 degrees to that of the suspected fracture—not parallel to the fracture line. A three-dimensional CT scan is superior to a two-dimensional CT scan for serious midface fractures, such as tripod and complex maxillary fractures.

Multiply injured patients, who are intubated, unconscious, or sedated, frequently have significant and unsuspected facial fractures. If they require a CT scan of the head, consider adding a scan of the face for clinically stable patients. Slightly more than 10 percent of such patients may have unsuspected facial fractures needing surgical repair. However, an unstable patient with severe concomitant injuries should not receive a facial scan if it delays emergency surgery.

Computed tomography with various manipulations, such as coronal and axial views, is essential for management of particular complex fractures. However, plain films still have an important role in screening for maxillofacial injury. In stable patients, physical examination along with a single Waters view may be enough for identifying maxillofacial fractures, augmented by CT scanning as needed.¹⁵ In the case of clinically obvious, complex facial injuries (in particular, periorbital and midface fractures), plain films may be eliminated and computed tomography performed directly. Coronal films should be ordered for periorbital fractures, and thin-slice scans may be appropriate in this area.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is useful to consultants who wish to visualize the soft tissues of the face, particularly the optic nerve or retrobulbar hemorrhage. MRI does *not* adequately delineate fractures, however. It does not have a defined role in emergency department evaluation.

SPECIFIC FACIAL FRACTURES

Frontal Sinus/Frontal Bone Fractures

This injury commonly results from a direct blow to the frontal bone with a blunt object—classically a lead pipe or brick. This fracture is frequently associated with intracranial injury secondary to disruption of the posterior table of the sinus. Dural tears are frequent, and patients may have associated injuries to the orbital roof (leading to blindness), as well as to the brain.¹⁷ Late complications include cranial empyema or mucopyoceles. Mucopyoceles are collections of pus and mucus that occur when fractures block the nasal frontal duct, preventing sinus drainage.

Physical examination may reveal disruption or crepitation of the supraorbital rims or subcutaneous emphysema. Fractures often are overlooked because of traditional prohibitions against skull films for head trauma. Patients with a suggestive mechanism or examination benefit from skull films or a Caldwell view of the face. If a depressed or posterior wall fracture is seen on plain film, a CT scan is required. Patients with hard signs of a frontal bone fracture (subcutaneous air, bony step-off, etc.) require only a CT scan.

Consultation with an otolaryngologist or a neurosurgeon is advised regarding antibiotic use in patients with frontal sinus fractures. Many specialists recommend antibiotics that cover common sinus pathogens, although the literature lacks definitive evidence on this issue. Frequently prescribed antibiotics include first-generation cephalosporins, amoxicillin-clavulanate, erythromycin, and trimethoprim-sulfamethoxazole. Patients with depressed fractures or those who have posterior wall involvement require intravenous antibiotics, admission, and consultation. Those with isolated fracture of the anterior wall may be treated as outpatients.

Nasoethmoidal-Orbital Injuries

Suspect nasoethmoidal-orbital injuries in those with trauma to the bridge of the nose or medial orbital wall (see Figure 257-1). The mechanism of injury is usually dramatic, and these fractures are frequently associated with lacrimal disruption and dural tears. Patients may complain of pain on eye movement, and physical examination may reveal traumatic telecanthus or epiphora (tears spilling over the lid).

If the medial canthus is tender, the intranasal palpation test is performed (see Figure 257-2) and examined for CSF rhinorrhea. If the examination is suggestive, order a CT scan of the face to include coronal sections and thin axial slices through the medial orbital wall.

If a nasoethmoidal-orbital fracture is present, consultation with a maxillofacial surgeon is in order.

Orbital Fractures

Blowout fractures are the most common orbital fractures. These injuries occur when a blunt object strikes the globe, resulting in expansion of orbital contents and subsequent rupture through the bony floor. A direct blow to the orbital rim also will result in a blowout. Four clinical findings suggest the diagnosis:

Rare patients may have enophthalmos, or sunken globe, when a large section is ruptured.

Infraorbital anesthesia is a more common finding and develops when the infraorbital nerve is contused by the initial trauma or when compressed by bony fragments. Anesthesia of the maxillary teeth and upper lip is more reliable than numbness over the cheek.

Diplopia, particularly on upward gaze that usually indicates inferior rectus muscle entrapment, is another important clinical finding. However, the etiology of diplopia may be multifactorial and does not necessarily imply entrapment of extraocular muscles. Other causes include direct muscle injury, damage to the third nerve, or entrapment of periorbital fat. CT scanning and consultation are necessary for patients with posttraumatic diplopia.

Occasionally, a step-off deformity can be palpated over the intraorbital rim. Subcutaneous emphysema is pathognomonic for fracture into a sinus or nasal antrum.

Plain films are useful in the diagnosis of blowout fractures. The "hanging teardrop" sign is seen with herniation of orbital fat into the maxillary sinus, whereas the "open bomb-bay door" sign results from bone fragments that protrude into the sinus. Air-fluid levels in the maxillary sinus are seen frequently in association with these signs.

Once a blowout fracture is suspected or confirmed either radiographically or clinically (i.e., diplopia or subcutaneous air), obtain a CT scan with coronal sections to determine the surface area of the broken floor.

There is significant controversy as to the timing and necessity of orbital floor repair. All fractures, including those with diplopia and entrapment, may have repair delayed for 1 to 2 weeks.¹⁸ Some specialists use a CT scan to determine the need for surgery, whereas others repair the orbit only if there is enophthalmos or persistent diplopia.

Many consultants recommend antibiotics active against sinus pathogens for patients with subcutaneous emphysema. Patients with fractures into the sinus should avoid blowing their nose to prevent accumulation of subcutaneous and intraorbital air.

In rare circumstances, malignant periorbital emphysema may jeopardize vision by injuring the retina or optic nerve. In such cases, emergency cantholysis may salvage the patient's vision. In patients with massive emphysema and no evidence of an open globe, measure the intraocular pressure. If the pressure is significantly elevated, immediately consult an ophthalmologist and discuss the need for an emergency cantholysis.

Orbital Fissure Syndromes

The oculomotor and ophthalmic divisions of the trigeminal nerve course through the superior orbital fissure. A fracture of the orbit involving this canal compresses these nerves, leading to the superior orbital fissure syndrome. This condition is characterized by paralysis of extraocular motions, ptosis, and periorbital anesthesia.

A more serious variant is the orbital apex syndrome, which involves the optic nerve. Patients with the orbital apex syndrome have all the aspects of the superior orbital fissure syndrome plus blindness or decrease in visual acuity. The swinging-flashlight test and visual acuity testing are crucial to the diagnosis. Patients with these syndromes need emergent ophthalmic intervention to save their vision. Although few emergency practitioners have experience, cantholysis can be considered an emergency department procedure if there is significant retrobulbar hemorrhage and marked increase in intraocular pressure. It involves anesthetizing and then crushing the lateral canthal fold to achieve hemostasis. The lateral canthal ligament is cut, and the lids spring apart, relieving intraocular pressure.

Nasal Fractures

Isolated nasal fractures are discussed in Chap. 240.

Zygomatic Fractures

Zygoma fractures occur in two major patterns. The most serious injury is the tripod fracture, whereas the most common is the arch fracture. The zygoma forms a tripod that abuts the frontal, maxillary, and temporal bones. The classic tripod fracture involves the infraorbital rim, a diastasis of the zygomaticofrontal suture, and disruption of the zygomaticotemporal junction at the arch. The fragment may drop and pull the lateral canthus, causing the eye to "tilt." Later, the cheek will flatten, but edema usually obscures this finding in the emergency department.

A significant percentage of patients with large lateral subconjunctival hematomas have associated zygomatic injury. Either trismus or

an open bite will appear if the zygoma impinges on the masseter or coronoid process. Plain films, consisting of the "jug handle" or arch view, are adequate for suspected arch fractures, and the Waters view can screen for tripod injury. Order CT scans for tripod fractures that are diagnosed or suggested by plain films. In patients in whom tripod fractures are unmistakable on physical examination, plain films are superfluous, and the patients should go directly to CT scan. The scans delineate injury to the orbital floor and guide surgical planning.

Patients with tripod fractures require admission for open reduction and internal fixation of displaced fragments. Those with fractures of the arch may be scheduled for outpatient elevation and repair.

Maxillary Fractures

Fractures of the maxilla are high-energy injuries. An impact 100 times the force of gravity is required to break the midface. Accordingly, these patients often have significant multisystem trauma. Many require resuscitation and admission.

On physical examination, a patient may have malocclusion, an open bite, facial lengthening, CSF rhinorrhea, or periorbital ecchymosis. Le Fort fractures are best diagnosed by grasping and rocking the hard palate. In most cases, parts of the midface will shift with this maneuver, but greenstick and impacted fractures may be immobile. Although the classic fracture patterns are diagrammed in this text (Figure 257-5), in clinical practice, fracture patterns are often mixed, with a low-grade Le Fort on one side and a higher grade on the other.

In Le Fort I, a transverse fracture separates the body of the maxilla from the lower portion of the pterygoid plate and nasal septum. With stress of the maxilla, only the hard palate and upper teeth move. A pyramidal fracture of the central maxilla and the palate defines a Le Fort II injury. Facial tugging moves the nose but not the eyes. Le Fort III, also called *craniofacial disjunction*, occurs when the complete facial

FIG. 257-5. Schematic of midfacial fracture lines: Le Fort I, II, and III are represented by Figures 257-1, 2, and 3 respectively. [Reprinted with permission from Dingman RO, Natvig P: *Surgery of Facial Fractures*. Philadelphia: Saunders, 1964, p 248.]

skeleton separates from the skull. The fracture extends through the frontozygomatic suture lines, across the orbit, and through the base of the nose and ethmoid region. The entire face, including most of both orbits, shifts with mobilization. The Le Fort IV fracture (not initially described by Le Fort) involves the frontal bone as well as the midface. These catastrophic injuries often require aggressive airway control and frequently intubation. Look for associated injuries, especially intracranial, spinal, thoracic, and abdominal. A test of visual acuity is especially important for patients with Le Fort fractures. CT scans of the face may be ordered in conjunction with a brain CT scan in clinically stable patients. Patients with complex maxillary fractures require admission for open reduction and internal fixation. Even if surgery is delayed, admission is prudent to monitor these often multiply injured victims.

Mandibular Fractures

After nasal bone injury, mandibular fractures are the second most common facial fracture. Assaults and falls on the chin are responsible for most injuries. Because of its ring shape, fractures are often multiple. Most injuries are to the body, angle, and condylar process. An impact to the point of the jaw may transmit forces through the condyles that can fracture the temporal bone and rupture the eardrum.

History and physical examination will detect nearly all injuries. Malocclusion and pain on jaw movement are clues. Intraoral lacerations suggest that a fracture is open. Gingival lacerations may be hidden between the teeth. Ecchymosis under the tongue is a sensitive finding for mandibular **fracture**, and fracture-induced injury to the mandibular nerve produces anesthesia of the lower **lip**.

Patients with normal occlusion and a negative tongue-blade test rarely require imaging studies. Radiography may include Panorax, Towne, and lateral oblique views. If the symphysis is involved, occlusal films may be helpful. Sometimes plain films are normal despite a condylar fracture. If films are normal, but clinical suspicion remains high, a CT scan of the condyles may show a **fracture**.

Patients with open fractures require admission and IV antibiotics. Penicillin G (2-4 million units IV) or clindamycin (600 to 900 mg IV) are considered the drugs of choice, but first-generation cephalosporins are a good alternative. Patients may be made more comfortable with a Barton bandage, which is an Ace bandage wrapped around the jaw and head. This prevents excessive jaw movement. Many patients with closed fractures may be managed as outpatients after consultation with an oral surgeon.

Temporomandibular Joint Dislocation

Temporomandibular joint dislocation and reduction are discussed in Chap. 240, "Face and Jaw Emergencies."

PEDIATRIC INJURIES

Etiology

Suspicion of nonaccidental trauma in cases of pediatric maxillofacial injury should be high. Associated skull fractures, a torn frenulum, and facial bruising may signify child abuse. Children with facial injuries should be undressed completely and examined for other stigmata of nonaccidental trauma. Some may require a radiographic skeletal survey to detect occult or prior trauma.

Fracture Patterns

Fracture patterns relate to developmental anatomy. Young children have a higher incidence of frontal bone injury due to its prominence. Infants and toddlers almost never suffer midface fractures. The dearth

of maxillary fractures under age 6 is due to the lack of sinuses in the midface. It is these sinuses that weaken the facial buttresses and predispose adults and adolescents to Le Fort injury. As the child grows, the sinuses pneumatize, and fractures shift to the midface and lower face. By ages 12 to 15, the fracture pattern resembles that in adults.

Associated Injuries

Children with facial trauma also have dissimilar associated injuries than adults. Because the pediatric skull is more prominent, children have a higher incidence of intracranial injuries. In addition, the dynamics of cervical injury vary between children and adults. Children are more likely to suffer an upper, rather than lower, cervical spine injury and are also prone to spinal cord injury without radiographic abnormality (SCIWORA).

Airway Management

A young child's airway is subject to subglottic stenosis and tracheomalacia. For this reason, avoid cricothyroidotomy in children younger than age 12. Intubation is the definitive airway of choice in children who need emergency airway management. If intubation is impossible, appropriately sized LMA or percutaneous transtracheal jet ventilation provides temporary airway control until a formal tracheotomy is feasible. See Chap. 15 for a discussion of pediatric airway management.

Complications and Timing of Follow-Up

Because subsequent facial growth may be asymmetrical, pediatric facial fractures can lead to serious cosmetic deformities. Subcondylar fractures of the jaw and displaced nasal fractures are of particular concern in children under age 5. Condylar fractures in this age group predispose children to facial deformity, micrognathia, and ankylosis of the TMJ. Consultation is essential.

Early follow-up is important in all pediatric facial fractures because a child's facial skeleton heals faster than that of an adult. Within a week, early callous formation makes delayed reduction troublesome.

PENETRATING AND BLUNT NECK TRAUMA

Bonny J. Baron

The optimal management of patients with blunt or penetrating neck injuries is challenging. Seemingly minor injuries can quickly become life-threatening. Missed injuries and delayed diagnosis can result in serious complications and death. While ultimate management goals are the same, each mechanism has its own special considerations.

EPIDEMIOLOGY

There are a paucity of data regarding the epidemiology of blunt and penetrating neck trauma. The demographics are expected to mirror those of other trauma victims, particularly in urban settings. There is a predominance of young males, especially those in the 21- to 30-year-old age group. The incidence of gunshot versus stab wounds varies from study to study. Penetrating neck trauma is associated with a high incidence of simultaneous injuries to other systems. Multiple injuries occur approximately half the time.¹ Serious injuries following blunt trauma are not as common and probably are underreported because many are not recognized initially. About half of blunt neck trauma is related to motor vehicle crashes.

ANATOMY

The neck contains a high concentration of vascular, aerodigestive, and spinal structures in a relatively confined space. Other susceptible structures include the thyroid and parathyroid glands, the lower cranial nerves, the brachial plexus, and the thoracic duct. Many of these structures are in close proximity to the skin and therefore are vulnerable to injury. Only the spinal cord has bony protection.

There are several anatomic classifications of the neck. Traditionally, anatomists have defined the neck in terms of anterior and posterior triangles, as divided by the sternocleidomastoid muscle (Figure 258-1). The anterior triangle is bounded by the midline of the neck, the lower border of the mandible, and the anterior border of the sternocleidomastoid muscle. Within this anterior triangle are most major vascular and aerodigestive structures: carotid artery, internal jugular vein, vagus nerve, thyroid gland, larynx, trachea, and esophagus. The boundaries of the posterior triangle are the middle third of the clavicle, the anterior border of the trapezius muscle, and the posterior border of the sternocleidomastoid muscle. The posterior triangle has few vital structures, except at its base, where the subclavian artery and brachial plexus are located.

An alternative anatomic classification divides the neck into three zones (Figure 258-2). This classification was established to guide the clinician in the diagnostic and therapeutic management of penetrating injuries. Various authors have defined the zones differently. The most widely used classification is that of Roon and Christensen.² By their definition, zone I extends from the clavicles to the cricoid cartilage. Zone I includes the vertebral and proximal carotid arteries, major thoracic ves-

FIG. 258-1. Triangles of the neck.

sels, superior mediastinum, lungs, esophagus, trachea, thoracic duct, and spinal cord. Zone II extends from the inferior margin of the cricoid cartilage cephalad to the angle of the mandible. Injuries in zone II may involve the carotid and vertebral arteries, jugular veins, esophagus, trachea, larynx, and spinal cord. Zone III is located between the angle of the mandible and the base of the skull. The distal carotid and vertebral arteries, pharynx, and spinal cord are all at risk of injury in zone III.

The structures of the neck are supported by a series of fascial layers (Figure 258-3). The superficial fascia surrounds the platysma muscle. This thin muscle covers the entire anterior triangle and the anteroinferior aspect of the posterior triangle. The platysma is the most superficial structure beneath the skin and subcutaneous tissue, and it serves as an important planar landmark when evaluating penetrating neck injuries. Beneath the platysma is the deep cervical fascia, a series of fascial compartments that support the muscles, vessels, and viscera of the neck. The deep cervical fascia divides into the investing, pretracheal, and prevertebral layers. The investing layer splits to enclose the sternocleidomastoid and trapezius muscles. The pretracheal layer attaches to the thyroid and cricoid cartilage and blends with the pericardium in the thoracic cavity. The prevertebral layer covers the prevertebral muscles and blends with the axillary sheath, which encloses the subclavian vessels. All three layers of the deep cervical fascia combine to form the carotid sheath. The tight facial compartments provide a tamponade effect, which limits potential for external bleeding from vascular injuries. Bleeding within these narrow compartments, however, can result in extrinsic airway compression and compromise.

INITIAL MANAGEMENT

The initial approach to patients with neck injury is performed according to Advanced Trauma Life Support (ATLS) protocols.³ A directed

FIG. 258-2. Zones of the neck.

FIG. 258-3. Fascial layers of the neck.

primary survey, resuscitation, and secondary survey should be performed expeditiously. Once the initial evaluation is completed, decisions concerning optimal diagnostic studies and definitive care are made.

Airway

Neck injuries can create some of the greatest challenges to airway management. All clinicians agree that any patient with acute respiratory distress, airway compromise from blood or secretions, massive subcutaneous emphysema, tracheal shift, or severe alteration in mental status should have early airway intervention. Controversy arises when presented with patients who have significant injury mechanisms without any immediate evidence of vascular injury or airway compromise. There are no published data that definitively outline the optimal approach in such patients. It is important to realize how quickly blood or air dissecting into fascial compartments can distort normal anatomy. Once this occurs, airway management becomes difficult, if not impossible. *In experienced hands, the risk of performing an unnecessary intubation is minimal compared with the potential morbidity of a difficult intubation with respiratory distress and a distorted airway.* It is particularly important to establish a definitive airway before a patient leaves the monitored setting of the emergency department for diagnostic studies. In most cases, orotracheal intubation with rapid-sequence induction can be used. If unsuccessful, the cricothyroidotomy is generally the next procedure of choice in adults. When performing a cricothyroidotomy, care must be taken to avoid dislodging a contained hematoma. The integrity of the larynx should be evaluated prior to any intubation attempts, particularly in cases of blunt trauma. Intubation of a patient with a fractured larynx may result in complete transection or create a false passage, necessitating a tracheostomy. If there is any doubt regarding the integrity of the larynx, proceeding directly to a tracheostomy may be the best option. Occasionally, a tracheostomy site will be created by the injury itself. An existing tracheostomy may be intubated as a life-saving means of securing the airway.⁴ In all cases of blunt or penetrating neck trauma in which a cervical spine fracture is suspected, the cervical spine should be immobilized in the neutral position.

Breathing

All patients should receive high-flow oxygen and be monitored continuously by pulse oximetry. Proximity of the base of the neck and the

thorax predisposes simultaneous injury to both regions. Difficulty ventilating a patient is indicative of either upper airway or thoracic injuries. Unequal breath sounds and asymmetric chest movement are signs of inadequate ventilation. These signs are associated with a pneumo- or hemothorax. Tracheal deviation may accompany a tension pneumothorax.

Circulation

Active bleeding is controlled by direct pressure at the site of injury. Do not clamp bleeding vessels because additional damage to vascular or nervous structures may result. One should avoid placing intravenous access at a location where the intravenous fluid would flow toward the site of injury (e.g., internal jugular or subclavian vein injury) and extravasate. Nasogastric tubes should be avoided during the initial resuscitation. Gagging and retching induced during nasogastric tube insertion could dislodge a clot and cause hemorrhage from a vascular injury.

Disability

Neurologic deficits may indicate direct nerve or spinal cord injury, or they may result from cerebral ischemia caused by vascular injury. Early evaluation determining the presence or absence of deficits is important, particularly because patients are rapidly sedated and paralyzed for airway control.

Initial Radiographic Evaluation

The first radiographic study should be a lateral C-spine view. This should be followed by an anteroposterior (AP) view, if possible, which may help to quickly determine whether the trajectory of a penetrating injury is transcervical. In cases of penetrating trauma, radiographs are evaluated for fractures and retained foreign bodies. Although the path of a missile is never known with certainty, localizing a bullet may suggest a transcervical trajectory. In both blunt and penetrating trauma, the soft tissues should be examined for hematomas, air-column obstruction or deviation, subcutaneous emphysema, or retropharyngeal thickening. A chest radiograph must be obtained to evaluate for the presence of a pneumothorax, hemothorax, or air in the mediastinum.

Complete Evaluation

A complete history and thorough physical examination should be completed as time allows. Information obtained from prehospital personnel should include mechanism of injury, symptoms, hemodynamic stability, and amount of blood loss at the scene. Once in the emergency department, if possible, the patient should be questioned about neck pain, difficulty breathing, dysphagia, odynophagia, hoarseness, hematemesis, hemoptysis, and any neurologic deficits. Examination of the neck requires a search for clinical signs of vascular, aerodigestive, and neurologic injuries. These include arterial bleeding, large or expanding hematomas, diminished pulses or bruits, lateralizing signs, tracheal deviation, air bubbling through the wound, saliva in the wound, subcutaneous emphysema, and evidence of cranial nerve injuries. These clinical signs can be divided into hard and soft signs of injury⁵ (Table 258-1). All signs require diagnostic investigation, but hard signs are more often associated with significant injury.

PENETRATING INJURY

Mechanisms of penetrating injury can be categorized as stab, gunshot, shotgun, or miscellaneous sharp implements. All mechanisms have potential for causing serious injury. Seemingly innocuous wounds may involve multiple structures. Gunshot wounds cause damage both from the bullet itself and from the blast effect. In addition, the path of a bullet is unpredictable. Localizing a bullet will not delineate which structures it has traversed or disrupted. If the bullet has crossed the midline of the neck, however, there is a higher probability of injury. Transcervical gunshot wounds are twice as likely to cause injuries to vital structures in the neck as are gunshot wounds that do not cross the midline.⁶ Damage caused by shotguns depends largely on weapon-victim range and type of weapon and shot used. Multiple pellets scattered across all three zones of the neck characterize these wounds. Although the course of stab wounds is more limited than that of gunshot wounds, there is still clear potential for major injury.

Despite differences in mechanism, treatment principles are the same. Initial stabilization is always the primary concern. Once this is accomplished, attention is turned to examination of the wound itself. *If the platysma muscle is clearly intact, local wound repair is all that is required.* If the platysma has been violated, it must be assumed that significant injury has occurred. *Neck wounds must never be probed beneath the platysma so as to avoid disrupting hemostasis.* The next priority is establishing wound location and determining which zones are involved. Vital structures at risk for injury can then be identified. Careful physical examination may reveal hard and soft signs of injury.

TABLE 258-1 Signs and Symptoms of Neck Injury

Hard Signs	Soft Signs
Hypotension in Emergency Department	Hypotension in field
Active arterial bleeding	History of arterial bleeding
Diminished carotid pulse	Tracheal deviation
Expanding hematoma	Nonexpanding large hematoma
Thrill/bruit	Apical capping on chest radiograph
Lateralizing signs	Stridor
Hemothorax >1000 mL	Hoarseness
Air or bubbling in wound	Vocal cord paralysis
Hemoptysis	Subcutaneous emphysema
Hematemesis	Seventh cranial nerve injury
	Unexplained bradycardia (without CNS injury)

A diagnostic plan that will evaluate vulnerable structures is then implemented.

Consultation

If the platysma is violated, immediate surgical consultation is indicated. Similarly, early involvement of radiologists will facilitate a non-operative diagnostic workup. A team approach will expedite stabilization, diagnosis, and definitive treatment. If the treating facility is unable to provide adequate diagnostic and surgical support, transfer should occur expeditiously after initial stabilization.

Diagnosis and Management

There is general agreement that patients who are hemodynamically unstable or have obvious aerodigestive injury require immediate surgical intervention. In those who are stable, the diagnostic approach is determined by the location of the wound. Nonoperative studies are used to identify injuries in zones I and III. Vascular control is often difficult to obtain in these zones. Zone I injuries requiring operative repair need a thoracic surgical approach to gain proximal vascular control, especially for arterial injuries. Both proximal and distal vascular control is obtained easily in zone II. For zone III, proximal control of arterial injury actually is gained in zone II. More distal injury presents a difficult problem in zone III. Disarticulation of the mandible may be required for adequate exposure. Given these technical difficulties, routine exploration of zones I and III is not indicated. Both these zones should be studied with angiography because physical examination is not always reliable in identifying vascular injuries.⁷ Zone I also requires diagnostic evaluation of the esophagus because early injuries are often asymptomatic. The operative difficulties encountered in zones I and III usually are not a problem in zone II.

Controversy surrounds the management of stable patients with zone II injuries. Literature supports both mandatory exploration of all injuries that penetrate the platysma and selective operation based on diagnostic studies. Mandatory exploration was popularized during World War II because this intervention led to markedly reduced morbidity and mortality. Advocates of mandatory exploration describe low complication rates following negative operations, as well as significant morbidity associated with missed injuries. There is also concern that diagnostic modalities that are used to detect aerodigestive injuries are inaccurate. Opponents of mandatory exploration cite its high negative exploration rate. In addition, an injury may be missed during surgical exploration. Alternatively, an injury may be discovered that is difficult to control surgically, such as a vertebral artery injury. Surgical exploration alone is often technically difficult with these injuries, particularly if the vascular anatomy and possible vertebral artery anomalies are not identified first by angiogram. Angiography helps clarify management. Complete occlusion of a vertebral artery in an asymptomatic patient with a normal contralateral vertebral artery and no evidence of a distal arteriovenous (AV) fistula usually is managed conservatively. The patient with active arterial bleeding, AV fistula, or pseudoaneurysm of the vertebral artery is preferably treated by percutaneous transcatheter embolization of the proximal and distal vertebral artery. On occasion, angiographic procedures are used during surgery to aid in obtaining vascular control. Obviously, if angiography is unavailable or unsuccessful, surgical exploration and repair are performed. Selective management results in minimal nontherapeutic operations and spares the patient a surgical scar. No definitive evidence exists to establish one treatment paradigm as being more cost-effective than the other.

Further controversy in the management of zone II injuries focuses on the diagnostic role of physical examination. Some advocate observation alone in asymptomatic patients with zone II injuries.^{8,9} Studies supporting this management have mostly been retrospective or had small sample sizes. Missed arterial and esophageal injuries have been

demonstrated in asymptomatic patients.^{3,7} Clinical signs and symptoms have low sensitivity, specificity, and predictive value.^{5,7,10} In addition, multiply injured patients may have associated injuries that make physical examination of the neck less reliable. Selective exploration should be based on the results of diagnostic studies. This will decrease the rate of negative explorations yet avoid missing injuries. Evaluation of zone II injuries routinely should include vascular and esophageal evaluation.

Angiography is currently the "gold standard" for evaluating vascular injury and also can be therapeutic. Duplex sonography is being used with increasing frequency. It is noninvasive, but it is operator-dependent, and its sensitivity at detecting small lesions or intimal flaps is not yet established.

Esophageal evaluation must be performed in all patients because esophageal injuries with trauma in zones I and II are notoriously asymptomatic initially. Delayed treatment of esophageal perforations will result in neck space infections and mediastinitis. Ideally, evaluation should include both an esophagram and esophagoscopy. Using this combination of studies, the sensitivity of detecting injury is increased to nearly 100 percent.¹¹ Flexible, rather than rigid, esophagoscopy is the current procedure of choice.

Laryngotracheal injuries are of concern in zones I and II. Significant laryngotracheal injuries are rarely occult. Diagnosis is usually easy due to the anterior and superficial position of the trachea. Air bubbling through the wound, dyspnea, stridor, hemoptysis, and subcutaneous emphysema are the most common signs and symptoms. Although optimal management is controversial, diagnostic evaluation with laryngoscopy and bronchoscopy generally is reserved for those who are symptomatic.

In summary, stable patients with zone I injuries should undergo angiography and esophagram and/or esophagoscopy. Those with zone III injuries should undergo angiography. Patients with zone II injuries can undergo mandatory exploration or be evaluated with angiography and esophagram and/or esophagoscopy. Patients with symptoms suggestive of laryngotracheal injury require laryngoscopy and bronchoscopy (Figure 258-4). Despite the presence of a single wound, multiple zones may be involved. This happens most often when the injury is caused by a gunshot. Diagnostic evaluation should be liberal and account for all structures that may have been in the pathway of a trajectory.

Preliminary studies suggest that helical computed tomographic (CT) scan will have an important future role in the diagnostic algorithm for penetrating neck injuries. Helical CT scan can be used in selected, stable patients as a screening test to visualize the trajectory of the penetrating injury and its proximity to vital structures. If objective evidence suggests proximity to vital structures, only then would more invasive tests be performed to fully define the injury.¹² In addition, Munera and colleagues¹³ prospectively compared helical CT angiogram (HCTA) with conventional angiography for the evaluation of penetrating vascular injuries of the neck. This group found HCTA to have 90 percent sensitivity and 100 percent specificity for detection of

major carotid and vertebral arterial injuries. There are some technical limitations to HCTA. HCTA is limited in detecting low zone I and high zone III injuries. A suboptimal bolus of contrast dye can limit vascular evaluation and obscure small lesions. Studies may be limited by streak artifact caused by metallic foreign bodies. Future prospective studies will help to define the optimal use for helical CT in the diagnosis of penetrating neck injuries.

It is important to recognize that diagnostic evaluation depends to a large extent on the institution and its personnel. Available resources often determine the optimal diagnostic regimen.

Pediatric Considerations

Initial management of children is identical to that of adults. In children, however, certain predisposing factors may alter the diagnostic evaluation. The diagnostic process itself may be associated with significant morbidity. Young children often must be anesthetized to undergo diagnostic procedures. Angiography is technically more difficult due to the smaller vessel size. Hall and colleagues¹⁴ have suggested observation alone in asymptomatic children with zone II penetrating injuries. Hall cautions that this practice should only be followed if close, active observation by skilled consultants can be performed and operative facilities are immediately available.

BLUNT INJURY

Blunt neck trauma is rare. The head, shoulders, and chest offer protection to the neck when it is in the neutral position. Hyperextension, hyperflexion, rotation, and direct blows contribute to blunt injuries. Most commonly, injury results from motor vehicle collisions in which the extended neck strikes the steering wheel or dashboard.¹⁵ Shearing forces from shoulder safety belts are also responsible for injury. Motorcycles, snowmobiles, and all-terrain vehicles have been implicated in "clothesline injuries." These occur when the exposed neck strikes a stationary cord. They are associated with severe laryngotracheal and esophageal injuries. Other mechanisms include direct blows sustained during sports (e.g., football, karate, or hockey), handlebar injuries from bicycles, assaults, and strangulation.¹⁶

Although uncommon, blunt cervical trauma can be lethal or can result in significant morbidity. Symptoms are often minimal or delayed, and the diagnosis can easily be overlooked. Head, facial, and cervical spine injuries frequently accompany blunt neck trauma. Symptoms of vascular or aerodigestive injuries may be misinterpreted in the context of these associated injuries. Signs and symptoms or a significant injury mechanism mandate aggressive diagnostic evaluation and admission for observation. As with penetrating trauma, surgical consultants should be involved in the initial assessment and management of all patients.

Laryngotracheal Injury

Laryngotracheal injury can range from soft tissue edema and ecchymosis to mucosal lacerations, vocal cord avulsion, fractures of the thyroid and cricoid cartilage, recurrent laryngeal nerve laceration, or complete laryngotracheal disruption. Classic symptoms include dysphonia, hoarseness, dysphagia, odynophagia, dyspnea, pain, hemoptysis, and stridor. Signs of injury include tenderness, subcutaneous emphysema, deformities, contusions, and tracheal deviation. Unfortunately, in contrast to penetrating tracheal trauma, which is frequently associated with signs and symptoms, blunt injury may present with few or no signs.

Establishing an airway is the initial focus in management. Opinions vary as to the optimal method of achieving airway control. Some advocate endotracheal intubation by the most experienced personnel. Others recommend immediate tracheostomy. Those advocating tracheostomy believe that attempts at intubation may result in a false passage, adding further injury to an already compromised airway.

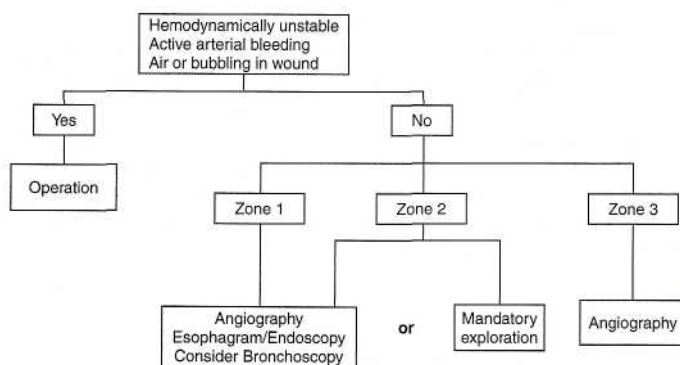

FIG. 258-4. Management of penetrating neck injury.

Cricothyroidotomy should be avoided because this may worsen laryngeal injury. Any patient with suspected laryngotracheal injury should undergo chest, cervical spine, and soft tissue lateral neck radiographs. Subcutaneous emphysema, narrowing of the subglottic airway, and hyoid bone fractures may be seen on radiographs. Diagnostic workup will then focus on identification of specific injuries. Laryngoscopy and bronchoscopy will evaluate vocal cord function, luminal integrity, and level of injury. A CT scan is indicated in hemodynamically stable patients with secure airways. CT scan delineates the type and degree of injury and is helpful in deciding which injuries can be managed conservatively and which require immediate operative intervention.

Pharyngoesophageal Injury

Blunt pharyngoesophageal injuries generally present with few or no symptoms. As with penetrating trauma, untreated, these perforations lead to life-threatening infections. Pharyngoesophageal injuries usually are associated with laryngotracheal injuries. Laryngotracheal injuries should prompt diagnostic evaluation of the esophagus with esophagram and esophagoscopy.

Vascular Injury

High suspicion of injury, coupled with early diagnosis and treatment of carotid injuries, improves outcome. Injuries are often missed because there is a delay in the onset of signs and symptoms, and when these signs do develop, they are often attributed to an associated head injury rather than a vascular injury. Any movement that distracts or compresses the artery can create injury. Five mechanisms of injury have been described:

- Hyperextension with compression of the artery against the transverse process of the cervical spine
- Hyperflexion, with compression of the artery between the mandible and the spine
- Direct blows
- Intraoral trauma
- Basilar skull fracture causing tearing of the intracranial portion of the carotid artery¹⁷

Two different lesions may occur following blunt trauma. A pseudoaneurysm may form,¹⁸ or the vessel wall may dissect and cause secondary thrombosis, resulting in distal emboli or occlusion.¹⁹ Clinical findings associated with closed carotid injury include neck hematomas, bruits, pulse deficits, ipsilateral Horner syndrome, transient ischemic attacks, and contralateral motor or sensory deficits. Neurologic symptoms may develop immediately, or they may be delayed for several weeks. Outcome may be compromised once a deficit develops. The first step in diagnosis is a head CT scan to eliminate closed-head injury as the cause of symptoms. This should be followed by angiographic evaluation of the carotid arteries. Once the diagnosis of carotid injury is confirmed, the first line of treatment is anticoagulation. The rationale for systemic anticoagulation is to minimize clot formation at the site of intimal injury, decrease further propagation of the clot that has formed, and prevent embolization of clot from any pseudoaneurysm sac.²⁰ Medical management has been shown to provide good results in patients with minimal neurologic deficits. Patients with severe neurologic deficits on initial examination may benefit from surgical intervention.

There are several cases in the literature of vertebral injury following chiropractic neck manipulation. Cases of severe neurologic deficit following vertebral artery injury also have been reported with Yoga exercises, calisthenics, archery, and painting a ceiling.^{21,22} All mechanisms of injury involve either cervical hyperextension, excessive contralateral rotation, or most commonly, both. The vertebral arteries are susceptible to mechanical injury because of their relationship to neighboring bony structures and ligaments. Traumatic intimal disruption

may lead to complete thrombotic occlusion, subintimal hematoma, dissection, or pseudoaneurysm formation. Distal branch occlusions may result from dissecting aneurysms, thrombus propagation from the neck, or thromboembolism. Patients may be asymptomatic, or they may have transitory or delayed neurologic symptoms. Symptoms vary from neck pain and occipital headache to Wallenberg syndrome and lethal stroke. Wallenberg syndrome (lateral medullary infarction syndrome) may include ipsilateral facial loss of pain and temperature; isolated loss of cranial nerves V, IX, X, and XI; cerebellar ataxia; Horner syndrome; and (body) contralateral loss of pain and temperature sensation. Sudden death, quadriplegia, and "locked-in syndrome" (quadriplegia with loss of all lower cranial nerves) also have been described. Cerebral arteriography should be performed for any suspicion of vertebral artery injury. Anticoagulation and platelet aggregation inhibition are recommended, but the efficacy of this therapy has not been clearly established.

STRANGULATION

Significant external pressure applied to the neck results in strangulation. This is caused by hanging, ligature strangulation, manual strangulation, and postural strangulation. Circumstances surrounding strangulation injuries include homicides or assaults, suicides, accidents, and judicial executions. Depending on the method used, death from strangulation may occur by one of three mechanisms: injury to the spinal cord and brainstem, mechanical constriction of the neck structures, and cardiac arrest.²³ These are explained below.

Pathophysiology

Hanging occurs when pressure is exerted on the neck and then tightened by the weight of the victim's body. Hangings in which the body is suspended and the feet do not touch the ground are termed *complete*. These generally occur with judicial hangings. All other positions of the body, when the feet are in contact with the ground, are referred to as *incomplete*. The mechanism of death may differ depending on the method of hanging. If a victim drops a distance equal to his or her height, death usually results from fracture of the upper cervical spine (hangman's fracture) and transection of the spinal cord. If a hanging is incomplete or the victim drops a distance less than his or her height, the cervical spine is spared. Constriction causes jugular venous obstruction, stagnant cerebral blood flow, and brain ischemia. Loss of consciousness results. Muscle tone decreases, and compression of vital structures increases. Complete arterial occlusion and/or airway compromise result in death. Alternatively, cardiac arrest may occur due to carotid sinus stimulation and increased vagal tone.

In ligature and manual strangulation, the constricting force is external, but the weight of the body and head play no part. Postural strangulation is seen in infants. This results when the victim's neck is placed over an object, and the weight of the body adds pressure to the neck. In all these methods of strangulation, death probably results from airway obstruction (suffocation) or vascular occlusion, as described previously in incomplete hangings.

Fracture of the thyroid cartilage, hyoid bone, and larynx is associated with strangulation. Traumatic edema of the larynx and supraglottic tissue leads to airway compromise. Delayed mortality is often due to neurogenic pulmonary edema and aspiration pneumonia. Cerebral anoxia may cause neurologic damage. Neurologic deficits are not always immediately apparent and may develop over time. Long-term psychiatric manifestations include psychosis, Korsakoff syndrome, amnesia, and progressive dementia.

Clinical Presentation

Abrasions, ecchymosis, and a brownish compression groove may be apparent. A rise in venous pressure above the ligature can lead to the

formation of Tardieu spots. These petechial hemorrhages can best be seen in the skin and subconjunctival areas. Patients may complain of painful swallowing. Severe hoarseness and stridor are suggestive of an impending airway obstruction.

Treatment

Treatment is directed at airway, respiratory, cardiac, neurologic, and psychiatric complications. Endotracheal intubation should be performed if airway problems or respiratory abnormalities are evident. As noted earlier, *cervical spine fracture or instability is all but impossible except in judicial-style hangings*, where a significant free-fall drop is designed to cause a death resulting in vertebral fracture. Thus, *for most suicidal and accidental hangings, cervical spine immobilization is unnecessary*. Neurogenic pulmonary complications are best treated with controlled ventilation and positive end-expiratory pressure (PEEP). Cardiac monitoring is essential for the identification and management of dysrhythmias. Cerebral edema and increased intracranial pressure can be difficult to treat and often require intracranial pressure monitoring to direct the use of hyperventilation, diuretics, and fluid restriction. Psychiatric support is often necessary in long-term survivors.

A high level of suspicion must be maintained in all patients who sustain compression injuries to the neck. Admission for 24 h is warranted to observe for delayed airway obstruction.

THORACIC TRAUMA

Timothy G. Buchman
Bruce L. Hall William M.
Bowling Gabor D. Kelen

INTRODUCTION

Thoracic trauma accounts for up to a quarter of civilian trauma deaths. Recent advances may reduce the deaths attributable to misdiagnosis, late diagnosis, and the secondary stress of highly invasive therapies. Hospital mortality is quite low (<5 percent) for isolated chest injuries and rises to about 33 percent in severe multisystem injuries.

Mechanism of injury predicts clinical course and outcome. In most cases, penetrating injuries that do not violate the pleura can be managed as simple lacerations or punctures. Penetrating injuries that violate the pleura typically result in a pneumothorax. Hemothorax accompanies pneumothorax in 75 percent of such cases. With the exception of very small pneumothoraces, tube thoracostomy is indicated and is nearly always sufficient therapy. Fewer than one in twenty will require thoracotomy. If the trajectory appears to traverse the diaphragm, suspicion of intra-abdominal injury prompts laparotomy or at least laparoscopy.

Blunt trauma causes injury by several mechanisms: compression (organ rupture), direct trauma (e.g., fracture), and acceleration/deceleration forces (vessel shear and tear). The severity of the injury predicts clinical course and outcome.¹ Patients with blunt injury may or may not require thoracostomy to drain a hemopneumothorax, but many will require intubation and mechanical ventilation and will sustain complications of injury and therapy such as pneumonia. In general, victims of penetrating injuries who survive to reach hospital often have smoother, shorter courses than those who have sustained blunt injuries.

CHEST WALL, BRONCHI, LUNGS, AND DIAPHRAGM

Patients with chest trauma who develop acute, severe respiratory distress have a high mortality rate. In our level I trauma center, about 10 percent of patients admitted with chest trauma require endotracheal intubation soon after entrance to the ED. If shock is also present in addition to the respiratory distress, 75 percent will die. In patients with blunt chest trauma, the most frequent factors associated with acute respiratory distress include shock, coma, multiple rib fractures, and hemopneumothorax (Table 259-1). In patients with penetrating trauma, respiratory distress is usually associated with severe shock or hemopneumothorax (Table 259-2), but the latter is quickly relieved by tube thoracostomy.

Initial Resuscitation, Airway Control, and Ventilation

Initial resuscitation and airway management are discussed in detail in Chaps. 19 and 251. If the patient is making little or no effort to breathe, central nervous system dysfunction due to head trauma, drugs, or spinal cord injury is the most likely problem. If the patient is attempting to breathe but is moving little or no air, upper airway obstruction should be suspected. Auscultation of the neck to detect abnormal or absent air movement can be diagnostic.

TABLE 259-1 Injuries in Patients with Respiratory Failure after Blunt Chest Trauma

Injury	Incidence, %	Mortality Rate, %
Flail chest/multiple rib fracture	75	52
Hemopneumothorax	55	39
Lung contusion	39	45
Extremity fracture	30	53
Intra-abdominal	23	46
Intracranial	23	46
Myocardial contusion	13	57
Diaphragm	9	20
Paraplegia	4	100
Other	7	100

Source: Wilson RF, Gibson DEB, Antonenko D: Shock and acute respiratory failure after chest trauma. *J Trauma* 17:167, 1977.

If the patient is attempting to breathe and the upper airway appears to be intact but the breath sounds are poor, thoracic problems such as flail chest, hemopneumothorax, diaphragmatic injury, or parenchymal lung damage are more likely. Each of these has specific therapies. However, respiratory distress that is not immediately relieved (within a minute or two) by specific intervention should prompt the physician to secure the airway (intubation or surgical airway) and mechanically ventilate the patient with pure oxygen.

CARDIAC ARREST DURING OR JUST AFTER ENDOTRACHEAL INTUBATION Although Rotondo and associates² have pointed out that urgent paralysis and intubation of trauma patients who are combative or have complex injuries is relatively safe, cardiac decompensation can occur. Table 259-3 lists common causes for cardiac arrest during intubation. If the patient has poor venous return because of hypovolemia, ventilation with excessive pressures can further reduce venous return and cause cardiac arrest. Hypovolemic patients should probably be ventilated with tidal volumes of only 5 to 8 mL/kg at 10 to 14 times per min until venous return is improved.

If there is a lung injury or if there are fragile subpleural blebs, overzealous insufflation can cause a tension pneumothorax, further reducing venous return. Ventilatory pressure exceeding 50 to 60 cm H₂O damages normal lungs. Excessive hyperventilation can also cause severe alkalosis, shifting the oxyhemoglobin saturation curve to the left, a state that impairs unloading of oxygen at the tissue level. Any patient with a lung injury, especially with hemoptysis, is at risk for developing a systemic air embolus, particularly if high ventilatory pressures are used.

TABLE 259-2 Injuries in Patients with Respiratory Failure after Penetrating Chest Trauma

Injury	Incidence, %	Mortality Rate, %
Lung	55	69
Intra-abdominal	36	83
Heart	29	63
Hemopneumothorax	18	42
Diaphragm	17	64
Chest wall	8	60
Extremity vessels	8	20
Other	41	63

TABLE 259-3 Causes of Cardiac Arrest with Endotracheal Intubation Complicating Trauma Evaluation

Inadequate preintubation oxygenation and ventilation
Esophageal intubation
Intubation of the right (or left) main bronchus
Excess ventilation, further reducing venous return
Development of a tension pneumothorax
Systemic air embolism (especially with lung injury)
Vasovagal response (rare)
Sudden development of severe respiratory alkalosis (from aggressive manual ventilation)

Vasovagal responses are rare in injured patients. Bag-valve-mask ventilation can distend the stomach. Unexplained bradycardia temporally associated either with bag-assisted ventilation or temporary malposition of a tube intended for the trachea into the esophagus should prompt immediate gastric decompression with a nasogastric tube, verification that oxygen is being delivered to the lungs, and exclusion of a tension pneumothorax.

Initial Survey

Specific life-threatening thoracic injuries should be suspected, diagnosed, and treated during the initial survey. These are airway obstruction (noted above), tension pneumothorax, cardiac tamponade, massive hemothorax, open pneumothorax, and flail chest. In the past, cardiac tamponade and massive hemothorax were difficult to recognize. Today, immediate ultrasound examination facilitates making these two important diagnoses.^{3,4}

Although skilled operators may diagnose simple pneumothorax with ultrasound, most depend on a chest radiograph.

TENSION PNEUMOTHORAX The diagnosis of tension pneumothorax should be suspected based on physical examination alone. The presentation includes dyspnea, hypoperfusion, distended neck veins, diminished or absent breath sounds on the affected side, a hyperresonant percussion note on the affected side, and tracheal deviation to the opposite side. Hyperexpansion of the chest wall with poor respiratory excursion may be present on the affected side. Not all elements of the presentation need be present to suspect the diagnosis. Noise in the resuscitation area makes the percussion note difficult to hear. Distention of the neck veins may be absent in the face of hypovolemia.

If a tension pneumothorax is suspected, the next intervention must be the insertion of a small cannula (typically a 14-gauge IV catheter) through the chest wall into the pleural space to convert the tension pneumothorax into an open pneumothorax. Any point in the superior, anterior, or lateral chest wall may be selected. Once the tension pneumothorax is decompressed (a hiss of gas exiting the pleural space may be audible), the patient's perfusion often improves within seconds. The initial survey should be completed and a chest tube (tube thoracostomy) inserted on the side of the tension pneumothorax as soon as practicable, prior to the first chest radiograph. Lack of improvement following decompression means that another cause of hypoperfusion should be sought immediately. If the neck veins of a patient in shock remain distended once tension pneumothorax has been excluded, cardiac tamponade from pericardial blood (pericardial tamponade) must be suspected, diagnosed, and treated immediately.

PERICARDIAL TAMPONADE (CARDIAC TAMPONADE) Both blunt and penetrating thoracic injuries have the potential to cause blood to accumulate in the pericardium. Although stab wounds to the mid-chest are the most common cause, blunt compressive forces to the anterior heart can rupture the right atrium or its appendage while maintaining enough filling of the right ventricle to sustain life for a short interval. In either case, blood fills the poorly compliant pericar-

dial sac, with pressure increasing sharply as each small increment of fluid accumulates.

The presentation of tamponade is similar to that of tension pneumothorax: both lesions cause obstruction of venous return to the heart. In addition to hypoperfusion and distended neck veins, the patient with tamponade may have muffled heart tones. Breath sounds should be audible bilaterally and the trachea should lie in the midline. ECG amplitude may be diminished.

While the initial treatment of tamponade is emergency pericardiocentesis (described later), immediate surgical intervention will be required to control the bleeding. An intravenous bolus of fluid to transiently increase the pressure filling the right atrium is helpful to increase cardiac output for a minute or two. If there is any ambiguity about the diagnosis, immediate bedside ultrasound will readily identify fluid in the pericardial sac and often can identify paradoxical septal motion. Ultrasound visualization can be conducted while preparations are being made for the pericardiocentesis and/or immediate surgical intervention. The poorly compliant pericardium, although full and under pressure from the blood within, casts a rather ordinary shadow on the chest x-ray. As little as 150 to 200 mL of blood may result in cardiac tamponade. Therefore, chest radiographs cannot be used to exclude this life-threatening diagnosis.

If surgery cannot be performed immediately, a cannula can be placed within the pericardial sac for serial aspirations as surgical preparations are being made. Aspiration of only 5 to 10 mL of fluid can substantially improve cardiac performance—again a consequence of the rigidity of the pericardium.

MASSIVE Hemothorax Each hemithorax can potentially hold about 40 to 50 percent of the circulating blood volume. While the hemithorax is ordinarily filled with air, a small amount of blood, and the tissues of the lung, blood can accumulate rapidly in the pleural space. A massive hemothorax in an adult is defined as 1500 mL or more—i.e., about two-thirds of the available space in the hemithorax is occupied by blood.

Massive hemothorax is life threatening by three mechanisms. First, the acute hypovolemia renders preload inadequate to sustain effective left ventricular function. Second, the collapsed lung promotes hypoxia by disturbing ventilation-perfusion matching. Third, the pressure of the hemothorax compresses the vena cava (further impairing preload) and the pulmonary parenchyma, raising pulmonary vascular resistance.

If a radiograph of the chest has been obtained, the diagnosis of a massive hemothorax can be made if the aerated lung is completely surrounded by fluid (blood). However, these patients are often in deep shock and a radiograph may unnecessarily delay therapy. Here again, quick bedside ultrasound can reveal a layer of fluid between the chest wall and the lung. If a radiograph has been obtained, care should be taken to verify that the opaque hemithorax is not the consequence of intubation of the contralateral main stem bronchus. In the latter case, repositioning of the endotracheal tube above the carina will often reveal that the diagnosis of massive hemothorax was in error.

Immediate tube thoracostomy is required to initially manage the massive hemothorax. Surgical repair must be performed emergently; delay can be fatal. Common causes of massive hemothorax include injury to the lung parenchyma, to an intercostal artery, and to the internal mammary artery.

Patients with "ordinary" hemothorax will occasionally drain a moderate amount of blood, but then rebleed or continue to bleed. If there is evidence of ongoing hemorrhage after initial drainage exceeding 600 mL/6 h (i.e., 100 mL/h for 6 h, 300 mL/h for 2 h, or 600 mL/h for 1 h), a "massive hemothorax equivalent" is diagnosed. In such cases of rebleeding/ongoing bleeding, "conservative" management suggests thoracotomy, although occasional patients may be managed nonoperatively.

Since massive hemothorax is by definition associated with accumulation and subsequent drainage of large volumes of potentially

"clean" blood, it is desirable to at least collect the effluent into an autotransfusion-prepared device. The decision to proceed with autotransfusion must be based on the patient's condition and the probability that the blood is free from contamination by enteral pathogens from an occult injury to the gastrointestinal tract.

OPEN PNEUMOTHORAX Open pneumothorax (discussed in detail later) is an open communication between the outer chest wall and the pleural space. Respiratory distress is due to inability to ventilate the affected side. The injury is sometimes referred to as a "sucking chest wound" because of the sound produced as air moves through the wound. Air entry is diminished on the affected side, and chest wall motion is less dynamic. The injury is very often associated with a hemothorax. The initial maneuver in the field or the ED is to cover the wound with a three-sided dressing so that air can escape but not enter through the wound. Complete occlusion may convert the injury into a tension pneumothorax.

FLAIL CHEST The term *flail chest* refers to a free-floating segment of ribs that are no longer connected to the rest of the thorax. This entity is also described in detail later in this chapter. During the initial survey, the examiner must search for segmental paradoxical chest wall motion, which is easy to miss if not specifically sought. Air entry will be diminished on the affected side. Jugular venous pressure may be intermittently increased in rhythm with respirations due to *pendelluft* (see below).

Ventilatory Support

In patients with chest trauma, impaired ventilation that persists in spite of measures to ensure an open airway, relief of chest wall pain, and drainage of hemopneumothorax is an indication for ventilatory support. Respiratory failure associated with a flail chest is best treated by early endotracheal intubation and ventilatory assistance, particularly if there are associated injuries, and even if the patient's breathing initially seems adequate. Ventilatory assistance should also be strongly considered if the patient is in shock, has had multiple injuries, is comatose, requires multiple transfusions, is elderly, or has preexisting pulmonary disease. A respiratory rate greater than 30 to 35 breaths per min, a vital capacity less than 10 to 15 mL/kg, and/or a negative inspiratory force (NIF) less than 25 to 30 cm H₂O can also be considered early indications for ventilatory support.

All trauma patients should be monitored by pulse oximetry. In patients with severe chest trauma, an arterial blood gas should be drawn soon after admission and at regular intervals thereafter. Metabolic acidosis with insufficient respiratory compensation is another indication for ventilatory support. Although there are several formulas relating the expected change in Pco₂ to the magnitude of the decrease in HCO₃⁻, the simplest approach is to expect a 1:1 relationship. For each milliequivalent per liter decrease in HCO₃⁻, ventilatory response should result in a decrease of Pco₂ of 1 mm Hg. Thus in the face of metabolic acidosis, "Pco₂ less than 40 mm Hg" may still be inappropriately high (see Chap. 25 for a detailed discussion).

When used properly, pulse oximetry can also reduce the need for arterial blood gas (ABG) determinations; however, since the Sao₂ indicated by the pulse oximeter is often 2 to 3 percent higher than that seen with ABG, one should try to keep the saturation above 92 to 93 percent.

Shock

At the same time that one is ensuring adequate ventilation, efforts should be directed toward rapidly restoring a more than adequate tissue perfusion. Resuscitation to physiologic endpoints such as splanchnic perfusion is necessary for optimal outcomes and may require extraordinary resuscitative measures.⁵

Other preliminary studies indicate that capnometry to determine the end-tidal P_{CO_2} ($PETCO_2$), particularly if combined with P_{aCO_2} determinations so one can determine the arterial-end tidal CO_2 difference [$P(a - ET) CO_2$] can also help monitor the adequacy of tissue perfusion ventilation. In general, a persistent $PETCO_2 < 28$ mm Hg or $P(a - ET) CO_2 > 10$ mm Hg is an indication of a poor prognosis.

If hypovolemic hypotension is present in patients with blunt chest trauma, it is most likely due to pelvic or extremity fractures, intra-abdominal injuries, and/or intrathoracic bleeding. In patients with penetrating chest trauma, the cause of shock will most often be the intrathoracic injury. The most frequent sources of intrathoracic bleeding are lung, heart, great vessels, and intercostal or internal mammary arteries. Up to one-half may have extrathoracic injuries contributing to the shock. **When** this occurs, it is most likely due to intra-abdominal bleeding, which often has a delayed diagnosis. The delay is due to the fact that blood flows down the pressure gradient from the abdomen to the pleural space. Thus abdominal bleeding can present as a hemothorax.

TREATMENT

Fluids Failure to correct hypotension within 15 to 30 min greatly increases the mortality rate. In previously healthy patients requiring massive transfusions but having hypotension for less than 30 min, the mortality rate has averaged about 10 percent. However, if the hypotension is present for more than 30 min, the mortality rises to almost 50 percent. If the patient has preexisting disease or is over 65 years of age, the mortality with massive transfusions plus prolonged hypotension exceeds 90 percent.

To provide fluids rapidly in hypotensive patients, one usually needs at least two large-gauge intravenous catheters. If peripheral veins are not readily available, one may be forced to cannulate the subclavian or internal jugular veins. **If subclavian venous cannulation is required, it should be performed on the side of the injury.** If one side of a chest is injured and the other lung is collapsed during insertion of a central intravenous line, impaired function of both lungs could be rapidly fatal. Many prefer to cannulate the right internal jugular vein regardless of the side of injury, due to the much more favorable geometry and the relatively lower risk of pneumothorax. A corollary to this observation is that failure to cannulate a central vein of one hemithorax requires an intervening chest radiograph to exclude hemopneumothorax prior to attempting venous cannulation on the other side.

Peripheral veins may be collapsed, unavailable, or inadequate. Especially in patients with thoracic trauma (and because of the activity required at the chest to deal with the direct consequence of that trauma), femoral venous cannulation is a preferred route of access for infusion of fluids. Seldinger technique (i.e., catheter over a guidewire) is usually used to insert a short, fat cannula, such as an **introducer** of the kind otherwise used in conjunction with pulmonary artery catheters.

The goal is to stabilize the intravascular volume long enough to definitively manage the bleeding, and only then to volume replete the patient. Rapid resuscitation prior to control of the source can increase the rate and volume of blood loss, worsening hypothermia, immune suppression, and even mortality. Stopping the bleeding is the ultimate priority.

Chest Tube and Thoracotomy A large hemothorax or hemopneumothorax can seriously interfere with ventilation and venous return; consequently, it should be evacuated as rapidly as possible. If the vital signs deteriorate as the blood is being evacuated, in spite of the rapid infusion of IV fluids, the patient may be exsanguinating via the chest tube because the tamponading effect of the hemothorax has been lost. In this unique circumstance, the chest tube should be clamped and the patient taken directly to the operating room for an emergency thoracotomy.

Cardiac Arrest

EXTERNAL MASSAGE In patients with cardiac arrest due to chest trauma, **external cardiac massage is generally of no value and may in fact be harmful.** Since the trauma patient suffering cardiac arrest is generally hypovolemic, external massage is usually ineffective and may actually cause significant additional injury to the heart, liver, lungs, or great vessels. In addition, forced ventilation and external cardiac compression may result in air emboli in the coronary arteries.

THORACOTOMY AND INTERNAL [OPEN] MASSAGE Resuscitative thoracotomy can be helpful in carefully selected patients (see below). Patients with blunt thoracic injuries who arrive in the ED without signs of life should be declared dead.

The decision to perform a thoracotomy or alternately determine that resuscitation is futile, must of course be made in short order under highly stressful circumstances. Fortunately, data based on the presence of vital signs⁶ or signs of life (SOL)^{6,7} are available to guide the decision. Unfortunately, different studies use different definitions of these terms. Branney and colleagues⁶ use the presence of a palpable pulse (at least carotid) and measurable/palpable blood pressure as evidence of vital signs. Rhec and associates use pupillary response and spontaneous ventilatory effort as evidence of SOL,⁷ while the American College of Surgeons Committee on Trauma contain all elements of the former two as indications of SOL.⁸ Others have included electrical cardiac activity, respiratory effort, corneal reflex, gag reflex, and extremity motion within the definition of SOL, making comparison of studies difficult. The Committee on Trauma's practice guidelines are based on a 24-year review (1966-1999) of 167,000 references.⁸ The final recommendations are based on a review of more than 8300 emergency department resuscitations. There were no class I (prospective, randomized) trials.

Essentially for all blunt injuries (thoracic, abdominal, or multiple), thoracotomy is indicated only if there were SOL at least on patient arrival (even if they were subsequently lost in the ED). There is no chance of survival in the absence of SOL at the scene.^{6,8} Survival among those who lose SOL at the scene or in transit is approximately 2.5 percent (presumably due to effective CPR and prehospital resuscitation measures). Slightly more (4.0 percent) of those who are hemodynamically unstable or lose SOL in the ED survive. Results in children and adults are similar. There is no difference whether the injuries are thoracic, abdominal, or multiple. These data may even be optimistic as publications likely reflect best experiences.

Patients with penetrating wounds have a significantly better chance of surviving with benefit of thoracotomy.^{6,8} Overall, patients with stab wounds (15 percent survival)⁶ are more likely to benefit than those with gunshot wounds (GSWs) (4 percent survival).^{6,7} The American College of Surgeons Committee on Trauma also has practice guidelines regarding indications for thoracotomy for penetrating wounds. **If there were no vital signs at the scene, thoracotomy is not indicated** unless basic resuscitative measures are effective. Survival rates in such patients with GSWs are exceedingly poor (about 1 percent), but fair for those with stab wounds (9 percent).⁶ Patients who lose their vital signs at the scene or in transit should have a thoracotomy performed, particularly for cardiac chest wounds, and as an adjunct in treating abdominal vascular injuries, as a reasonable rate of survival for both GSWs (16 percent) and stab wounds (23 percent) can be expected.⁶ Among these patients cardiac injuries, especially stab wounds associated with tamponade, have the best prognosis, with survival as high as 29 percent.¹⁵ In this group, thoracotomy can be employed to differentiate cardiac from other injuries. As in blunt trauma, those who arrive with SOL, even if later lost in the ED, should have a thoracotomy. Survival rates in this group are as high as 38 percent for stab wounds, but remain low (14 percent) for GSWs.⁷ Pediatric experience is similar.⁸

A high rate of good neurologic outcomes (76 to 92 percent) can be expected among those who survive thoracotomy, with uniformly better prognosis for those with penetrating injuries.^{6,8} A detailed description of thoracotomy is beyond the scope of this chapter.

Open cardiac massage is usually performed through an anterolateral incision in the fifth intercostal space on the side of the injury (Figures 259-1 and 259-2). The pericardium is opened vertically 1 to 2 cm anterior to the phrenic nerve. The thoracic incision allows direct inspection of the heart, control of bleeding sites in the chest, and complete evacuation of any pericardial tamponade or hemothorax. In addition, a left thoracotomy allows the physician to compress or clamp the descending thoracic aorta.

Since about 60 percent of the cardiac output normally goes to the tissues below the diaphragm, clamping of the descending thoracic aorta can increase coronary and carotid blood flow almost threefold. If the arterial systolic blood pressure does not rise to 90 mm Hg within 5 to 10 min of aortic cross-clamping, further resuscitation will probably be of no avail. On the other hand, if the proximal aortic pressure rises above 160 to 180 mm Hg in a previously normotensive individual, both the brain and left ventricle are at risk.

Diagnosis of Thoracic Injuries

SYMPTOMS The most frequent symptoms of thoracic trauma are chest pain and shortness of breath. The pain is usually well localized to the involved area of the chest wall, but sometimes it is referred to the abdomen, neck, shoulder, or arms. Dyspnea and tachypnea are nonspecific and may also be caused by anxiety or pain from other injuries.

PHYSICAL EXAMINATION A thorough physical examination, directed toward detecting the potential presence of the six major conditions to be sought during the primary survey, can be performed rapidly. There should not be an excessive reliance on chest x-rays. In particular, tension pneumothorax should be diagnosed and treated before obtaining a chest x-ray.

FIG. 259-1. Emergency thoracotomy to treat a stab wound of the heart or to perform open cardiac massage is usually done through an anterolateral thoracotomy approach. The incision extends along the fifth intercostal space with the skin incision placed in the inframammary crease. It extends from just lateral to the sternum to the midaxillary line. (Reproduced with permission from Geller ER: *Shock and Resuscitation*. New York: McGraw-Hill, 1993.)

FIG. 259-2. If the descending thoracic aorta is to be cross-clamped, it is best done under direct vision. To accomplish this, the anterior thoracotomy must be large and the incision opened as widely as possible. The left lung is pulled up anteriorly as far as possible by an assistant standing at the right side of the table. The pleura and fascia anterior to the aorta are thin, but the tissue between the aorta and the vertebral column is often rather tough and must be incised to get around the aorta properly. A straight clamp is often easier to put around the aorta than a curved clamp, and is less likely to rupture the intercostal vessels. (Reproduced with permission from Geller ER: *Shock and Resuscitation*. New York: McGraw-Hill, 1993.)

Inspection

CHEST WALL The chest wall is inspected for contusions, abrasions, and other signs of trauma such as a seat belt imprint sign. In addition, signs of paradoxical segments (flail chest), intrathoracic bleeding, and open (sucking) chest wounds are sought. The paradoxical motion of a flail chest may be minimal when the patient is first seen, especially if it involves the lateral or posterior thorax.

However, some penetrating wounds are open only intermittently and may not be discovered until or unless the patient makes increased ventilatory efforts.

NECK Distended neck veins, especially when the patient is sitting upright, may indicate the presence of pericardial tamponade, tension pneumothorax, cardiac failure, or air embolism. However, distended neck veins may not appear until hypovolemia has been at least partially corrected. If the face and neck are cyanotic and swollen, severe damage to the superior mediastinum with occlusion or compression of the superior vena cava should be suspected. Subcutaneous emphysema from a torn bronchus or laceration of the lung can cause severe swelling of the neck and face.

ABDOMEN A scaphoid abdomen may indicate a diaphragmatic injury with herniation of abdominal contents into the chest. Excessive abdominal movement during breathing may indicate chest wall damage that might not otherwise be apparent. A rocking-horse type of ventilation may indicate a high spinal cord injury with paralysis of intercostal muscles.

PALPATION Palpation of the chest should begin with determining whether the trachea is midline or displaced. Palpation of the chest wall may reveal areas of localized tenderness or crepitus from fractured ribs or subcutaneous emphysema. Well-localized and consistent tenderness over ribs should be considered to be due to rib fractures, even if the initial x-rays appear to be normal.

SECTION 22 • TRAUMA

Motion of a portion of the sternum or severe localized tenderness may be the only objective evidence of a fractured sternum. When a patient is coughing or straining, palpation can sometimes detect abnormal motion of an unstable portion of the chest wall better than visual inspection.

Percussion Percussion of the chest wall can be of some help in differentiating between a hemothorax and pneumothorax. Dullness to percussion over one side of the chest following trauma may be the first evidence that a hemothorax is present, which may be missed if the chest x-ray is taken while the patient is lying supine. Hyperresonance may indicate the presence of a pneumothorax.

If the pericardial cavity is greatly distended by an effusion or tamponade, the area of cardiac dullness may extend beyond the midclavicular line on the left or the sternal border on the right. This sign is especially helpful if the point of maximal impulse is located more than an inch inside the left border of cardiac dullness. However, lack of extended cardiac dullness does not exclude tamponade.

Auscultation Initial auscultation should always focus on the axillae, where the distance from the skin to pulmonary parenchyma is least and therefore breath sounds are most readily heard. Later the chest may be auscultated systematically and thoroughly. If the breath sounds are equal bilaterally, the major bronchi are probably intact.

The presence of bowel sounds high in the chest may be the first indication of a diaphragmatic injury. Decreased breath sounds on one side usually indicate the presence of hemothorax or pneumothorax, but this may also occur if the endotracheal tube is in too far and only one lung is being ventilated. Before inserting a chest tube in such patients, the position of the endotracheal tube should be evaluated, and if appropriate, repositioned so that it is no deeper than 21 cm for adult women and 23 cm for adult men. Occasionally, persistently decreased breath sounds on one side are due to a bronchial foreign body or ruptured bronchus.

Imaging Bedside ultrasound can give early clues to life-threatening diagnoses such as hemothorax and pericardial tamponade. Chest radiographs, especially upright inspiration and expiration views, can verify the presence of pneumothoraces and hemothoraces as well as identifying rib fractures, pulmonary contusions, and diaphragmatic rupture. Computed tomography (CT) of the chest is becoming standard in all major blunt torso trauma.⁹

Injuries to the Chest Wall

SOFT TISSUE INJURIES

Bleeding Probing of a penetrating chest wound to determine its depth or direction can be deceptive and dangerous. If bleeding from chest wall musculature persists after 5 min of local pressure, it is preferred to inspect the depths of the wound in the operating room and use ligatures to control the bleeding and carefully close the wound.

Open (Sucking) Chest Wounds Small open chest wounds can act as one-way valves, allowing air to enter during inspiration, but none to leave during expiration, thereby causing an expanding pneumothorax. This not only reduces tidal volume, but can also interfere with venous return. If the open chest wound exceeds two-thirds the area of the trachea, air will preferentially enter the pleural cavity through the chest wall opening rather than through the tracheobronchial tree into the lungs.

Sucking wounds of the chest should be covered immediately by a sterile petrolatum gauze, and a chest tube should be inserted simultaneously at a separate site to relieve the consequent pneumothorax. Although often advised, **a chest tube should not be inserted through the trauma**

wound, because it is then likely to follow the missile or knife tract into the lung or diaphragm. In the prehospital setting, the occlusive dressing is fastened to the skin on only three sides, in order to allow air to escape during exhalation, but none to enter during inhalation.

Tissue Loss Injuries caused by close-range shotgun blasts or high-powered rifles may destroy such large volumes of chest wall that it may be impossible to close the chest in the usual manner. Intubation and mechanical ventilation are required until the defect is definitively closed.

Subcutaneous Emphysema Subcutaneous emphysema usually develops because air from lung parenchyma or the tracheobronchial tree gains access to the chest wall through an opening in the parietal pleura. The air may also reach the chest wall from an interstitial lung injury by dissecting back along the bronchi into the hilum and mediastinum and then into the extrapleural spaces. Extensive subcutaneous emphysema suggests an injury to the pharynx, larynx, or esophagus.

Patients with subcutaneous emphysema should be presumed to have an underlying pneumothorax, even if it is not visible on the chest x-ray. If the patient requires a general anesthetic or is to be placed on a ventilator, a chest tube should be inserted on the involved side(s). If subcutaneous emphysema is severe, a major bronchial injury should be suspected and sought by bronchoscopy.

Very rarely, linear incisions into the subcutaneous space of the chest wall are used to relieve massive subcutaneous emphysema. Once the initiating cause is controlled, subcutaneous emphysema usually disappears over a period of several days.

BONY INJURIES

Clavicular Fractures Isolated clavicular fractures due to blunt trauma are usually uncomplicated. Occasionally, however, direct trauma produces sharp fragments that may injure the subclavian vein and produce a moderately large hematoma or venous thrombosis. Rarely, excess callus that forms later at the site of a clavicular fracture may press against the subclavian artery or brachial plexus, producing a thoracic outlet syndrome.

Rib Fractures

SIMPLE FRACTURES Rib fractures should be assumed to be present in any patient who has localized pain and tenderness over one or more ribs after chest trauma. Up to 50 percent of rib fractures (especially those involving the anterior and lateral portions of the first five ribs) may not be apparent on x-ray, particularly for the first few days after injury. Furthermore, injuries to the cartilaginous portions of the ribs may never be appreciated on x-ray.

The principal diagnostic goal with clinically suspected rib fractures is the detection of significant complications: hemopneumothorax, pulmonary contusion, or major vascular injury. If there is a suspicion of a pneumothorax that is not seen on the initial chest x-ray, the pneumothorax may be better appreciated on expiratory films, on which a pneumothorax is better visualized. If the patient has severe trauma, if the rib fractures have sharp fragments, or if the patient has other injuries, serial chest roentgenograms (every 6 to 12 h for 24 to 48 h) should be obtained.

The pain of rib fractures can greatly interfere with ventilation. Strapping the chest with adhesive tape or a rib belt is more likely to predispose to atelectasis and pneumonia and is not recommended. Probably the best analgesic for mild to moderate chest wall pain is the combination of an opioid and an NS AID.

If the patient is admitted, an intercostal nerve block with a long-acting agent such as bupivacaine will relieve pain of muscle spasm and ventilation for 6 to 12 h. Intrapleural catheters for administration of local anesthetics can also relieve chest wall pain quite well. Epidural analgesia

usually works even better,¹⁰ but in many hospitals this requires admission to a step-down or intensive care unit (ICU) for monitoring.

FIRST- AND SECOND-RIB FRACTURES With the exception of direct trauma, as from a hammer blow, it takes great force to fracture the first and second ribs. It is frequently associated with significant injuries such as blunt myocardial injury (formerly referred to as myocardial contusion), bronchial tears, or a major vascular injury. There is conflicting evidence in the literature as to whether first- or second-rib fractures are more likely to be associated with mortality. Nevertheless, 15 to 30 percent of cases of either fracture type is associated with poor outcome, usually from head injury or rupture of a major vessel.

MULTIPLE RIB FRACTURES If a patient with fractured ribs, especially ribs 9, 10, and 11, becomes hypotensive and does not have a large hemothorax or tension pneumothorax, intra-abdominal bleeding from the liver or spleen should be suspected. In major trauma, it is wise to image the abdomen with CT if multiple lower ribs are fractured.

In general, it is wise to hospitalize patients with fractured ribs for at least 24 to 48 h if they cannot cough and clear their secretions adequately, especially if they are elderly or have preexisting pulmonary disease. Admitting the patient also provides time to observe the patient for associated injuries that might not be apparent initially. Aspiration pneumonitis and fat embolism often do not become apparent clinically or on chest x-ray for at least 24 to 48 h.

Flail Chest

PATHOPHYSIOLOGY Segmental fractures (i.e., fractures in two or more locations on the same rib) of three or more adjacent ribs anteriorly or laterally often result in an unstable chest wall and the phenomenon known as flail chest. This injury is characterized by a paradoxical inward movement of the involved portion of the chest wall during spontaneous inspiration and outward movement during expiration.

Although the paradoxical motion of the involved chest wall can greatly increase the work of breathing, the main cause of the hypoxemia is the underlying lung contusion. In the past, pendelluft (a ventilatory phenomenon referring to movement of air back and forth between the injured and uninjured lungs with each breath) was considered to be an important cause of the hypoxemia. However, pendelluft is probably significant only when the upper airway is partially obstructed.

Immediately after the injury, little flail may be apparent. Later, as fluid moves into the area of the pulmonary contusion, lung compliance falls, and more pressure is needed to inflate the lungs. The increasing pressure differential between intrathoracic and atmospheric pressure may then overcome the resistance of the muscles attached to the fractured ribs, thereby allowing the involved chest wall to develop increasing paradox. In addition, the patient may fatigue rapidly because of the decreased efficiency of ventilation and increased muscular effort. Thus a vicious cycle of decreasing efficiency of ventilation, increasing fatigue, and hypoxemia may develop. In some instances, the increasing ventilatory fatigue can result in a sudden respiratory arrest.

TREATMENT OF FLAIL CHEST Historically, belts and adhesive tape were applied to strap and stabilize the chest. These interventions actually inhibit expansion of the chest and thereby aggravate the atelectasis of the underlying lung. The preferred intervention is analgesia adequate to allow the patient to fully expand the underlying lung, with a goal of improving ventilation and pulmonary toilet.

Patients with mild to moderate flail chest and little or no underlying pulmonary contusion or associated injuries can often be managed without a ventilator, by 1) relief of pain by analgesics or intercostal nerve block, 2) frequent coughing and chest physiotherapy, and 3) restriction of IV fluids to prevent volume overload. However, ventilatory support should be provided if, in spite of this regimen, the arterial P_{O_2} remains less than 80 mm Hg on supplemental oxygen.

Indications for early ventilatory support of patients with flail chest include shock, three or more associated injuries, severe head injury, comorbid pulmonary disease, fracture of eight or more ribs, or age greater than 65 years. Early (prophylactic) ventilatory assistance in patients with flail chest and one or two additional injuries may reduce mortality to about 7 percent. This is in sharp contrast to a mortality rate of 69 percent in similar patients in whom ventilatory assistance is delayed until there is clinical evidence of respiratory failure. Demand-based ventilatory support such as pressure-support ventilation can be used in most simple cases. Where there is underlying pulmonary contusion, bronchopleural fistula, or a combination, high-frequency oscillation (using, for example, the SensorMedics 3100 series ventilators) may splint the alveoli open while minimizing air leakage.

A controversial area in the management of flail chest is the role of surgical fixation of the fractured ribs or the sternum. The aim is to reduce the need for ventilatory assistance. However, this same objective can often be achieved with improved pain relief and ventilatory support. Although some European and Asian surgeons have claimed significant reductions in mortality and morbidity with surgical fixation of the flail chest, it is performed only infrequently in the United States.^{11,12}

STERNAL FRACTURES Historically, fracture of the sternum had long been considered associated with motor vehicle collisions (MVCs) and a marker of serious and life-threatening injury, particularly cardiovascular injury. Mortality rates as high as 45 percent were reported. However, a large study of patients with sternal fractures collected over 6M years found that the incidence of sternal fracture as a result of MVCs was only 3 percent.¹³ This series had a very low incidence of cardiac dysrhythmias requiring treatment (1.5 percent), and a low mortality rate (0.7 percent).

The variability in the data likely reflect diverse definitions of blunt myocardial injury (BMI). Accumulating evidence suggests that sternal fracture is not an indicator of significant blunt myocardial injury.^{14,15} Authors of a small retrospective study have offered an algorithm to use in the consideration of BMI.¹⁵ Patients with blunt chest trauma without sternal fractures whose vital signs and ECG are normal require no further consideration of BMI. Patients with normal vital signs and ECG with sternal fractures should have repeat ECG in 6 h. If unchanged, then no further work-up for BMI is required.¹⁵

TRAUMATIC ASPHYXIA Sudden, severe crushing of the chest may cause subconjunctival hemorrhage or petechiae together with vascular engorgement; edema; and cyanosis of the head, neck, and upper extremities. This clinical picture appears to be due to an abrupt sustained rise in superior vena caval pressure and concurrent closure of the airway after deep inspiration. Although these patients often look moribund initially, neurologic impairment is usually only temporary, and long-term morbidity is due primarily to associated injuries.¹⁶

Injury to the Lungs

PULMONARY CONTUSION Pulmonary contusions, defined as direct damage to the lung resulting in both hemorrhage and edema in the absence of a pulmonary laceration, are a significant source of severe morbidity and mortality following penetrating and blunt trauma. While such trauma has long been recognized to be a source of deranged physiology, new diagnostic techniques, including CT, have made recognition of this common problem much more frequent. Prompt recognition and therapy can be life-saving. The most typical cause of pulmonary contusion is a compression-decompression injury to the chest. In high-speed automobile crashes, airbags can attenuate but do not entirely prevent this injury.

Pathophysiology There appear to be two significant stages in the pathophysiology of pulmonary contusion. The first is related to the

direct injury, while the second is related to the resuscitative measures directed at associated injuries that ultimately prove harmful to the lung, in particular the administration of IV fluid. Administration of fluid in the setting of unilateral pulmonary contusion can cause extravasation of fluid into the contralateral (uninjured) lung, probably in association with reflex attempts to increase blood flow through this uninjured lung. The mechanism appears to be a fall in pulmonary vascular resistance in the uninjured lung, causing pressures exerted by the right heart to increase hydrostatic pressure in the capillaries, high enough to force both blood and fluid out of those capillaries into the interstitium and alveoli. Unfortunately, the process is self-perpetuating because as each proximate segment of lung sees the full force of the right heart activity, it becomes functionally congested and contused, and the process continues to the next uninjured segment of lung.

Intrapulmonary shunting is increased, resistance to airflow is increased, the elasticity of the lungs is reduced, and respiratory work is markedly increased. Thus the patient becomes hypoxic, hypercarbic, and acidotic. Adaptive increases in cardiac output are usually insufficient to overcome the hypoxic process and cardiopulmonary decompensation can occur very quickly.

Diagnosis Areas of opacification of the lung seen on the chest x-ray within 6 h of blunt trauma are usually considered to be pulmonary contusions. The lung changes with aspiration pneumonia and fat embolism are not usually seen on chest x-rays for at least 12 to 24 h. The extent of the lung injury seen at thoracotomy or autopsy or on CT scan is usually much greater than suspected from chest x-rays.

Treatment Treatment primarily involves maintenance of adequate ventilation. Chest physiotherapy, intercostal nerve blocks, epidural analgesia, and nasotracheal suction are used as needed to ensure that the patient takes deep breaths and coughs adequately. If ventilatory assistance is required, care should be taken not to overstretch the normal alveoli, which are preferentially inflated. Patients with extensive pulmonary contusion who may need mechanical stenting of most alveoli throughout the ventilatory cycle may be well-served with high-frequency oscillation. An important determinant of the need for mechanical ventilation is the volume of contused lung. Patients with involvement of less than 18 percent of total lung volume (about one lobe) do not require such support, whereas patients with more than 28 percent of total lung volume involved in the contusion predictably require such support. Pre-morbid health status and associated injuries can, of course, affect the threshold for mechanical ventilation in either direction.

Patients who have a severe unilateral lung injury and are responding poorly to conventional mechanical ventilation may benefit from synchronous independent lung ventilation (SILV) provided through a double-lumen endobronchial catheter. This rarely used technique helps prevent overinflation of the normal lung and underinflation of the damaged, poorly compliant lung.

In severe pulmonary contusion, ordinary mechanical ventilation may be insufficient to reverse the hypoxemia. The first maneuver should be to place the good lung "down" by turning the patient to the decubitus position to improve ventilation/perfusion matching. Failing this, consideration should be given to chemical paralysis and institution either of pressure-controlled inverse-ratio ventilation, or (if available) high-frequency oscillation. Both modes cause hemodynamic changes that require experience and invasive monitoring for effective management. However, the airway pressures sustained in effective high-frequency oscillation are typically lower than those required to perform pressure-controlled inverse-ratio ventilation. For this reason, high-frequency oscillation may be favored.

HEMOTHORAX

Etiology Hemothorax requiring a thoracotomy is most frequently caused by bleeding from lung injuries, but is required in fewer than

5 percent of patients admitted with chest trauma. The compressing effect of the shed blood, the high concentration of thromboplastin in the lungs, and the low pulmonary arterial pressure combine to help reduce bleeding from torn lung parenchyma. The other causes of severe and/or continuing intrathoracic bleeding include damage to the great vessels of the chest or intercostal or internal mammary arteries.

Pathophysiology If there is more than 300 to 500 mL of blood in the pleural cavity, it should be removed as completely and rapidly as possible. Large clots can act as a local anticoagulant by releasing fibrinolysins and fibrinogenolysins from their surface. A large hemothorax also restricts ventilation and venous return. Bleeding from multiple small intrathoracic vessels often stops fairly rapidly after the hemothorax is completely evacuated.

Diagnosis A hemothorax should be suspected following trauma if the breath sounds are reduced and the chest is dull to percussion on the involved side. Fluid collections greater than 200 to 300 mL can usually be seen on good upright or decubitus radiographs of the chest. However, if the patient is supine, more than 1000 mL of blood may easily be missed because it may only produce a mild to moderate diffuse haziness on that side. Use of ultrasound trauma to detect hemothorax is increasingly accepted. Even so, plain chest x-rays give much more additional information.

Treatment If the hemothorax is judged large enough to drain, a chest tube should be used. Needle aspiration of a hemothorax is usually incomplete and may cause a pneumothorax or infection of the hemothorax. Tube thoracostomy remains the mainstay of care.

CHEST TUBE (TUBE THORACOSTOMY) TECHNIQUE Detailed description of thoracostomy tube placement is beyond the scope of this chapter. A few important aspects are provided here. Chest tubes for treatment of traumatic pneumothorax or hemothorax are usually inserted in the anterior axillary line just behind the lateral edge of the pectoralis major muscle. For a pneumothorax the tube should be directed as high and anteriorly as possible without the tip pressing on the mediastinum. For a hemothorax, the tube is usually inserted at the level of the nipple and directed posteriorly and laterally.

We prefer the skin incision to be at least 1 to 2 cm below the interspace through which the tube will be placed. A large clamp is then inserted through the intercostal muscles in the next higher intercostal space, with care taken to prevent the tip of the clamp from penetrating the lung (Figure 259-3A). The resulting oblique tunnel through the subcutaneous tissue and intercostal muscles usually closes promptly after the chest tube is removed, thereby reducing the chances of recurrent pneumothorax.

Once the clamp is pushed through the internal intercostal fascia, it is opened to enlarge the hole to approximately 1.5 to 2 cm. A finger is inserted along the top of the clamp through the hole to verify the position within the thorax and to make sure the lung is not adherent to the chest wall (Figure 259-3B). This is particularly important if a chest x-ray has not been taken or if the x-ray does not clearly show that the lung is away from the chest wall.

For a simple pneumothorax, a 24F or 28F chest tube can be inserted. For a hemothorax, a 32F to 40F chest tube is preferred. When in doubt, the larger tube should be chosen for trauma situations. Smaller tubes may not drain blood adequately. The tube is advanced at least until the last side hole is 2.5 to 5 cm (1 to 2 in.) inside the chest wall.

The open end of the tube is attached to a combination fluid-collection water-seal suction device, such as the Pleur-evac, with 20- to 30-cm H₂O suction. If a significant hemothorax is known to be present or if a large amount of blood starts to drain immediately, consideration should be given to collection of blood in a heparinized autotransfusion device so that it can be returned to the patient either directly or after washing the red blood cells in saline.

FIG. 259-3A. The clamp is inserted through the incision and is tunneled up to the next intercostal space. (Reproduced with permission from Roberts JR, Hedges JR: *Clinical Procedures in Emergency Medicine*, 2d ed. Philadelphia, PA: WB Saunders, 1991.)

FIG. 259-3B. Using the finger as a guide, one places the tip into the pleural cavity. The pleura is punctured just above the rib to avoid intercostal vessels and nerves. (Reproduced with permission from Roberts JR, Hedges JR: *Clinical Procedures in Emergency Medicine*, 2d ed. Philadelphia, PA: WB Saunders, 1991.)

The intrathoracic position of the chest tube and its last hole and the amount of air or fluid remaining in the pleural cavity should be checked with a chest x-ray as soon as possible after the tube is inserted. If there is a significant air leak, the chest films are best done as portables at the patient's bedside so as not to risk the development of a tension pneumothorax while the patient is off suction en route to the x-ray department.

If the patient is sent to the radiology department, the chest tube should not be clamped because any continuing air leakage can rapidly collapse the lung and/or cause a tension pneumothorax. While the tube is undamped, the water-seal bottle should be kept 1 to 2 ft lower than the patient's chest.

Serial chest auscultation, chest x-rays, and careful recording of the volume of blood loss and the amount of air leakage are important guides to the functioning of chest tubes. If a chest tube becomes blocked and a significant pneumothorax or hemothorax is still present, the tube should be replaced. This can often be done easily through the same incision. Irrigating an occluded chest tube or passing a Fogarty catheter through it in an effort to reestablish its patency is seldom effective and almost certainly increases the risk of infection. If the chest tube is functional and well placed but a decubitus film shows a shift of some of the pleural fluid, the hemothorax is partially clotted; another chest tube placed with ultrasound guidance may be helpful. If a significant hemothorax persists, early evacuation of the clotted blood via thoracoscopy can prevent atelectasis.

If a chest tube is inserted for pneumothorax, is left in place on suction for at least 24 h after all air leaks have stopped. If it is inserted for bleeding, it is left in place until the drainage is serous and less than 200 mL/24 h.¹⁷ However, if the patient is mechanically ventilated, many physicians prefer to keep the chest tubes in place in case a new pneumothorax suddenly develops.

When the tube is to be removed, the patient is asked to take a deep breath and bear down, as in a Valsalva maneuver, to produce maximum intrathoracic pressure and lung volume. The patient should be in full inspiration when the tube is pulled. An involuntary reflex due to pleu-

ral pain while the tube is being pulled may rapidly suck in several hundred milliliters of air just as the tube is being removed, necessitating reinsertion of another tube. Following removal of the chest tube, a chest x-ray should be obtained to rule out a recurrent pneumothorax. Another chest x-ray should be obtained 12 to 24 h later to confirm continued complete expansion of the lungs.

Although there continues to be controversy about the need for prophylactic antibiotics in patients requiring a chest tube for a traumatic hemothorax and/or pneumothorax, a recent study showed a reduction in the incidence of pneumonia and/or empyema when antibiotics were given until the chest tubes were removed.¹⁸ Studies suggest that giving antibiotics for just 24 h is adequate,¹⁹ and one study suggests that only one dose of antibiotic need be given when thoracostomy tubes are required following penetrating trauma.²⁰ More important than antibiotics, however, is adherence to a protocol for placement, maintenance, and early removal of chest tubes placed for simple thoracic trauma when there is no other indication for antibiotics. Where such protocols exist and are followed, a single dose of an antibiotic at the time of tube placement may well suffice to limit subsequent infections to an irreducible minimum.

THORACOTOMY Most patients with intrathoracic bleeding can be treated adequately by intravenous administration of fluids and evacuation of the hemothorax with a chest tube. Fewer than 5 percent will require operative management. Massive hemothorax mandates operation (see earlier discussion). Selection of management approach must be made by the most qualified surgeon in the context of available resources.

Occasionally, when the chest tube is initially inserted, blood emerges at an alarmingly rapid rate. If the patient's condition improves as the blood is being removed, continuing drainage of the blood and observation of the patient are in order. However, if the patient's vital signs deteriorate as the blood is being removed, loss of the tamponading effect of the hemothorax has probably allowed serious bleeding from the lung to recur. Consequently, the patient should be taken directly to surgery.

PNEUMOTHORAX

Pathophysiology Collections of air or blood within the pleural cavity reduce vital capacity and increase intrathoracic pressure, thereby decreasing minute ventilation and venous return to the heart. During inspiration, the negative intrapleural pressure increases the tendency for air or blood to leak into the pleural cavity through any wound in the lung or chest wall. If there is any obstruction of the upper airway or if the patient has chronic obstructive lung disease, additional air may be forced into the pleural cavity during expiration, increasing the likelihood of tension pneumothorax with intrapleural pressures exceeding atmospheric pressure.

Diagnosis Failure to obtain a chest x-ray soon after admission and again in 4 to 8 h may result in missing significant intrathoracic injuries. The presence of a chest injury is usually readily apparent from the history and physical examination; however, accurate assessment of the damage, especially to intrathoracic organs, often requires serial chest x-rays and/or a CT scan.

A pneumothorax is not likely to cause severe symptoms unless it 1) is a tension pneumothorax, 2) occupies more than 40 percent of one hemithorax—about 2.5 cm from the chest wall in an adult, or 3) occurs in a patient with shock or preexisting cardiopulmonary disease. If there is a suspicion of a pneumothorax but it is not clearly seen on the first chest roentgenogram, repeat films during exhalation may be helpful. Apical-lordotic films may allow better visualization of an apical pneumothorax. Occasionally, a pneumothorax after a stab wound is delayed for more than 12 h. Consequently, serial chest x-rays every 6 h for 12 to 24 h are indicated in selected patients. In a recent study of 4106 patients with initially asymptomatic stab wounds of the chest, Ordog and associates found that 12 percent of the patients required a tube thoracostomy for a delayed hemothorax or pneumothorax.²¹ Current accepted practice is to observe the patient and repeat the film in 6 h. If no pneumothorax is noted on the repeat film, and there are no other concerns, the patient can be discharged.

One should assume that a tension pneumothorax is present and begin treatment without waiting for a chest x-ray if the patient has 1) severe respiratory distress, 2) decreased breath sounds and hyperresonance on one side of the chest, 3) distended neck veins, and 4) deviation of the trachea away from the involved side. Insertion of a large needle into the involved side through the second intercostal space in the midclavicular line is indicated and may help confirm the diagnosis and provide temporary relief while a chest tube is inserted.

A small pneumothorax (less than 1.0 cm wide and confined to the upper third of the chest) that is unchanged on two chest roentgenograms taken 4 to 6 h apart in an otherwise healthy individual can usually be treated by observation alone. However, in most instances after trauma, a chest tube or small catheter should be inserted as a precautionary measure, especially if the patient cannot continue to be observed closely or requires intubation and mechanical ventilation.

Occasionally a small pneumothorax is not apparent on chest x-rays but is seen on a CT scan of the chest or abdomen. This is referred to as an *occult pneumothorax*. Chest tube drainage of an occult pneumothorax is not required unless the patient requires mechanical ventilation.^{22,23}

If only a pneumothorax is present, a small (24F or smaller) chest tube may be inserted anteriorly in the second intercostal space in the midclavicular line. However, a high midaxillary tube is generally preferable. We believe it is safest to avoid trocar techniques and insert chest tubes using a large hemostat. Catheter aspiration of a simple pneumothorax (CASP) is most suitable for the treatment of iatrogenic pneumothoraces caused by needles or catheters. It has no role in trauma care.

Complications In general, a small- or moderate-sized pneumothorax does not cause problems unless there is a continuing air leak or the patient has other trauma or preexisting cardiopulmonary disease. Also,

a continuing air leak does not usually result in complications provided the lung is completely expanded. However, if a combination of a pneumothorax and continued air leak is allowed to exist for more than 24 to 48 h, the incidence of empyema and bronchopleural fistula is greatly increased.

The most frequent reasons for failure to evacuate a pneumothorax rapidly and to completely expand the lungs are 1) improper connections or leaks in the external tubing or water-seal collection apparatus, 2) improper position of the chest tube(s), 3) occlusion of bronchial by secretions or a foreign body, 4) a tear of one of the large bronchi, or 5) a large tear of the lung parenchyma. If a pneumothorax persists in spite of one or two well-placed chest tubes and there is a large leak, emergency bronchoscopy should be performed to clear the bronchi and identify any damage to the tracheobronchial tree that may need repair. High-frequency oscillation is indicated for bronchopleural fistula and may substantially slow the leak. Continued large air leakage and failure of the lung to expand adequately in spite of these measures is an indication for early thoracotomy to control the air leak.

PNEUMOMEDIASTINUM Subcutaneous emphysema in the neck or the presence of a crunching sound (Hamman sign) over the heart during systole suggests the presence of a pneumomediastinum. The diagnosis is usually readily apparent on CT scans. It can easily be missed on chest x-rays. Traumatic pneumomediastinum is of itself usually asymptomatic, but one must look closely for an injury to the larynx, trachea, major bronchi, pharynx, or esophagus. Although foreign body aspiration has occasionally been linked to pneumomediastinum in children, and although severe trauma can potentially cause both aspiration and pneumomediastinum, pneumomediastinum in the setting of thoracic injury is much more likely to be due to the other causes listed.

PULMONARY HEMATOMAS Pulmonary hematomas are parenchymal tears filled with blood. These generally resolve spontaneously over a few weeks; however, if they become infected, they can form lung abscesses that may be very difficult to manage. These hematomas are more likely to become infected if a thoracotomy is performed, if there is prolonged chest tube drainage of the pleural cavity, and/or if prolonged ventilatory assistance is required.

PULMONARY LACERATIONS WITH HEMOPNEUMOTHORAX Major hemorrhage from lacerations of the lung following blunt trauma are usually caused by the sharp ends of fractured ribs. Occasionally they may be caused by tearing of the lung at pleural adhesions during rapid deceleration injuries. Very rarely the adhesions themselves are quite vascular, and a torn adhesion will bleed enough to cause shock.

SYSTEMIC AIR EMBOLISM In patients with penetrating chest wounds, and particularly those with hemoptysis, positive-pressure ventilation must be used with great care. High ventilatory pressures, especially over 50 cm H₂O, may force air from an injured bronchus into an adjacent injured vessel, producing systemic air emboli. This may account for many of the severe dysrhythmias or central nervous system (CNS) changes that occur when patients with penetrating chest wounds are intubated and ventilated. One should be particularly concerned about causing systemic air emboli if the patient has hemoptysis.

If systemic air embolism occurs, the head should be lowered, and an immediate thoracotomy should be performed to clamp the injured area of lung and then aspirate air from the heart and ascending aorta. Open cardiac massage with clamping of the ascending aorta may help push air through the coronary arteries. Cardiopulmonary bypass should be instituted promptly if available.

INTRABRONCHIAL BLEEDING Intrabronchial bleeding is poorly tolerated and can rapidly cause death from severe hypoxemia by flooding dependent alveoli. Patients with intrabronchial blood tend to die from "drowning" rather than from hypovolemia.

In patients with hemoptysis due to trauma, the uninvolved lung should be kept as free of blood as possible and nasotracheal suction and bronchoscopy used as often as necessary. If the bleeding is severe, a double-lumen endotracheal (Carlen) tube can sometimes be used to confine the bleeding to one lung. If a Carlen or similar split-function tube is not available or cannot be inserted, one may insert an endotracheal tube over a flexible bronchoscope into the unaffected main-stem bronchus.

ASPIRATION Aspiration of gastric contents is quite common after severe trauma, especially if the patient is unconscious. If it is recognized promptly, immediate bronchoscopy should be performed to remove any residual food particles. Immediate irrigation of the tracheobronchial tree with buffered saline or a bicarbonate solution may also help reduce the severity of the chemical pneumonitis, but the value of such irrigation is controversial.

Radiologic changes are usually delayed for more than 12 to 24 h. If an opaque foreign body is aspirated into the tracheobronchial tree, it is usually readily diagnosed on x-ray. However, radiolucent foreign bodies are easily missed. Inspiratory and expiratory chest films may help diagnosis of a one-way valve effect due to a foreign body by demonstrating failure of one lung to empty properly during expiration. Occasionally, a foreign body can remain lodged in various bronchi, causing repeated pulmonary infections or hemoptysis for years before being discovered. Persistent or recurrent cough, atelectasis, or pneumonia after trauma should be indications for bronchoscopy and/or bronchography.

Tracheobronchial Injury

LOWER TRACHEA AND MAJOR BRONCHI Most injuries to major bronchi are due to rapid deceleration and shearing of more mobile bronchi from relatively fixed proximal structures. However, forced expiration against a closed glottis and/or compression against the vertebral column may cause bursting of these structures.

The most common presenting signs and symptoms are dyspnea, hemoptysis, subcutaneous emphysema, Hamman sign, and sternal tenderness. A large pneumothorax, pneumomediastinum, deep cervical emphysema, and an endotracheal tube balloon with a round appearance on chest roentgenograms may suggest tracheobronchial injury. Approximately 10 percent are almost completely asymptomatic.

Most tracheobronchial injuries occur within 2 cm of the carina or at the origin of lobar bronchi. The air leak (bronchopleural fistula) following tube thoracostomy is continuous and massive. Either rigid or fiberoptic bronchoscopy can be used to make the diagnosis. High-frequency oscillation is the ventilator modality of choice to maintain gas exchange and expand the alveoli in the face of the massive gas leak.

Lacerations of the bronchi involving more than a third of the circumference should be surgically repaired because they tend to eventually cause severe bronchial stenosis with repeated pulmonary infections or complete atelectasis. Untreated tracheal tears may result in severe mediastinitis.

Those patients who survive a tracheal transection generally have their injury in the cervical trachea and have no associated injuries. Intrathoracic tracheal transection is usually associated with two or more major injuries and is almost invariably fatal. Concurrent esophageal injuries occur in almost 25 percent of penetrating tracheobronchial injuries and are easily missed unless esophagoscopy or contrast studies are also performed.

CERVICAL TRACHEAL INJURIES Injuries to the cervical trachea from blunt trauma usually occur at the junction of the trachea and cricoid cartilage. This is most frequently caused when the anterior neck strikes the dashboard in an automobile accident. Evidence of trauma to the neck with subcutaneous emphysema should arouse sus-

picion of this injury. Inspiratory stridor usually indicates a 70 to 80 percent upper airway obstruction. However, cricotracheal separation is often only suspected when an endotracheal tube or bronchoscope cannot be inserted past the cricoid cartilage.

If the patient has a laceration of the trachea that is small and high, it may be managed simply by performing a tracheostomy below the injury. All lacerations of the trachea should be repaired.

Diaphragmatic Injury

ETIOLOGY In urban centers, diaphragmatic injuries are caused most frequently by penetrating trauma, particularly gunshot wounds of the lower chest or upper abdomen. Rupture due to blunt trauma is much less frequent and occurs in less than 5 percent of patients hospitalized with chest trauma. If there is a fracture of the pelvis, the incidence increases. Because of the protective effect of the liver on the right and the possible increased weakness of the left posterolateral diaphragm, it was previously believed that 80 to 90 percent of the diaphragmatic injuries following blunt trauma occur in that area. However, in the series of Brown and Richardson,²⁴ the incidence of right- and left-sided diaphragmatic rupture was almost equal. The discrepancy can be explained by the fact that some right-sided injuries are overlooked owing to the liver blocking herniation of abdominal contents.

NATURAL HISTORY The initial signs and symptoms are often masked by other injuries and occur late unless the diaphragmatic lesion is large. Over time, sometimes even years, a large amount of viscera can gradually work up into the chest through small diaphragmatic tears. The intrathoracic bowel may then become obstructed or strangulated or cause severe compression of the adjacent lung, a phenomenon we have referred to as *tension enterothorax*.

DIAGNOSIS With penetrating trauma, the diagnosis of diaphragmatic injury is often made only intraoperatively. However, if the entrance wound is in the abdomen and there is evidence of an intrathoracic injury or foreign body, one can assume that the missile or knife has traversed the diaphragm. In the series just mentioned, 59 percent of the patients with diaphragmatic injuries had diagnostic chest x-rays. However, eight of nine peritoneal lavages done in these patients were negative.²⁴ In the only positive lavage, the lavage fluid drained out through a previously placed chest tube.

With blunt trauma, any abnormality of the diaphragm or lower lung fields on chest x-ray should arouse suspicion of a diaphragmatic tear. Often, a nasogastric tube is seen to go into the abdomen and then back up into the chest because the stomach has passed through a diaphragmatic tear.

Techniques for diagnosing the less obvious diaphragmatic injuries include upper gastrointestinal (GI) series, looking for displacement of viscera into the chest, and CT scan with contrast. Still, many diaphragmatic injuries are diagnosed only during a thoracotomy or laparotomy. Subtle diaphragmatic injuries can be difficult to diagnose, particularly on the right.

THERAPY Laparotomy is necessary to repair the diaphragm. Thoracotomy may be necessary for associated chest injury, resuscitation, delayed repair of the diaphragm, or management of thoracic complications. Recently there have been several reports of repair using thorascopy techniques.

HEART

Penetrating Injury to the Heart

The many factors affecting survival from penetrating injury to the heart include the weapon used, the size of the myocardial injury, the injured

cardiac chamber, coronary artery damage, the presence of tamponade, associated injuries, and the time taken to reach the hospital. Every patient with penetrating chest injury anywhere near the heart and shock on admission should be considered as having a cardiac injury until proven otherwise. The converse is not true, since about one-third of patients who arrive in an ED alive and are subsequently proven to have a penetrating cardiac wound have near-normal vital signs. With early aggressive resuscitation and surgery, up to one-third of patients arriving in a trauma center in extremis with a cardiac injury can be saved. In patients brought to the operating room with signs of life and a recordable blood pressure, the survival rate is about 75 percent.²⁵

Prognosis in penetrating cardiac injury correlates with cardiovascular status on presentation. Those patients who reach the ED with near-normal vital signs typically have good outcomes, while few who lose signs of life during transport or on arrival to the ED survive with intact neurologic function. Patients who have no signs of life in the field are not candidates for resuscitative efforts.

PATHOPHYSIOLOGY Penetrating wounds of the heart are usually rapidly fatal, generally because of massive hemorrhage; fewer than one-fourth of the patients with this injury reach the hospital alive. Patients surviving more than 15 to 30 min usually have either a small wound or some component of pericardial tamponade. In a sense, pericardial tamponade is a two-edged sword; although it may prolong life by reducing the initial blood loss, the tamponade itself can be fatal by interfering with diastolic filling of the heart.

DIAGNOSIS

Clinical Features All patients in shock with a penetrating wound of the chest between the midclavicular line on the right and the anterior axillary line on the left should be considered to have a cardiac injury until proven otherwise. If the only problem is tamponade and the patient is not hypovolemic, Beck triad may be present: distended neck veins, hypotension, and muffled heart tones. The last is the least reliable sign, even with a large acute pericardial tamponade, which seldom is more than 200 mL.

Since patients with penetrating heart wounds are usually hypotensive, the neck veins will generally not distend until the blood volume is at least partially restored. On the other hand, chest injuries can cause the patient to breathe abnormally or strain, thereby causing neck vein distention in the normovolemic patient even in the absence of tamponade. Other causes of Beck triad include tension pneumothorax, myocardial dysfunction, and systemic air embolism.

Tamponade may also cause two Kussmaul signs. One is increased distention of neck veins during inspiration and the other is pulsus paradoxus. Paradoxical pulse is characterized by a drop in systolic blood pressure of more than 10 to 15 mm Hg during normal spontaneous inspiration. The amount of paradox may be further increased by hypovolemia.

Invasive Monitoring While the obstruction to cardiac venous return is usually evident on physical examination and by the finding of distended neck veins, occasionally a central venous catheter may be required to confirm the elevated central venous pressure in the setting of hypoperfusion. Patients in extremis should undergo diagnostic pericardiocentesis in lieu of central venous pressure following insertion of a central venous catheter.

X-Rays The pericardium is noncompliant. Whereas an obviously globular cardiac silhouette may suggest tamponade as the cause of hypoperfusion, the converse is not true; **most patients with acute tamponade have very ordinary-appearing cardiac silhouettes.**

Electrocardiography Electrocardiography (ECG) changes following cardiac injury are usually nonspecific. ST-T wave changes may indicate pericardial irritation or may reflect associated ischemia or hypoxia.

Echocardiography Transthoracic echocardiography (TTE) is now the diagnostic procedure of choice. TTE performed by both emergency physicians and trauma surgeons has been shown to be successful in the detection of pericardial fluid. Performed in the ED, TTE results in more rapid diagnosis and faster time to surgical intervention, as well as improved survival and neurologic outcome.²⁶ The presence of a hemothorax may limit the ability of TTE to detect occult cardiac injuries;²⁷ however, there are simple methods to distinguish hemothorax from pericardial fluid by using different views.

In experienced hands, transesophageal echocardiography (TEE) is an efficient diagnostic tool, provided that the patient is already intubated and ventilated, the probe can be inserted quickly, and an experienced operator is immediately available.

Diagnostic Pericardiocentesis

ACCURACY Pericardiocentesis is useful as a diagnostic tool only in cases in which the patient is in extremis and the possibility of tamponade must be excluded within seconds. In Demetriades' series, the incidence of false-negative pericardiocentesis was 80 percent and the incidence of false-positives was 33 percent.²⁰ In addition to its inaccuracy, attempts at pericardiocentesis may injure the heart or cause dangerous delays in needed surgery.

TECHNIQUE Again, the scope of this chapter allows discussion of only a few details. The paraxiphoid approach is commonly used. An 18-gauge, 10-cm spinal needle attached to a stopcock and then to a 20-mL syringe is usually used. Continuous ECG monitoring should be used if possible. Use of ultrasound guidance of the needle increases accuracy,²⁸ and is a class IACC/AHA recommendation for critically injured patients.²⁹ If this technique is not available or the operator is experienced, the V lead of the ECG can be attached to the metal pericardiocentesis needle using an insulated wire with alligator clips on both ends.

Most authors direct the needle toward the left scapula tip; however, directing the needle toward the right scapula is more likely to parallel the right border of the heart and is less likely to penetrate the right ventricle (Figure 259-4).

One should aspirate every 1 to 2 mm as the needle is advanced. One can insert a stylet or inject 0.5 to 1.0 mL of saline solution at intervals to be certain that the needle is not plugged. The needle is then carefully advanced until 1) ultrasound indicates correct placement, 2) blood is obtained, 3) cardiac pulsations are felt, or 4) the ECG shows an abrupt change.

Generally, a large portion of the blood in the pericardial cavity is clotted. Consequently, one can usually remove only a few milliliters of blood without manipulating the needle. If 20 mL of blood can be drawn out easily and rapidly, it usually indicates that the blood is being aspirated from the right ventricle.

If an immediate thoracotomy is not possible in a patient with a positive pericardiocentesis, a plastic catheter (inserted over a needle or Seldinger wire) can be left in place for continuous drainage of intrapericardial blood until the cardiac wound can be surgically repaired.

COMPLICATIONS The pericardiocentesis needle can perforate the right ventricle or a coronary artery and cause tamponade as a consequence of the procedure itself. Dysrhythmias may also occur. A falsely negative pericardiocentesis may delay needed surgery.

Pericardial Windows If the patient has been hemodynamically stable and echocardiography is either not available or equivocal, an alternative method for diagnosing pericardial tamponade is a subxiphoid pericardial window. This should be performed in the operating room under general anesthesia.

TREATMENT

Fluid Replacement It is essential that patients with penetrating wounds of the chest have two or more large intravenous lines in place,

FIG. 259-4. The paraxiphoid technique for pericardiocentesis is usually performed with the needle directed toward the left shoulder or left scapula tip. However, if one aims toward the tip of the right scapula, the needle tends to go parallel to the lateral border of the right heart and is less apt to penetrate the coronary artery or myocardium. [Reproduced with permission from Wilson RF: Injury to the heart and great vessels, in Henning RS (ed): *Critical Care Cardiology*. New York, NY: Churchill Livingstone, 1989.]

with at least one line in a groin or leg vein in the event that the superior vena cava or one of its major branches is injured. It is particularly important to have an adequate or increased blood volume if hypovolemia or tamponade is present. If tamponade is present with an elevated central venous pressure, one should administer further fluid and blood to improve venous return to the heart while moving the patient to an operating room.

Pericardiocentesis Pericardiocentesis in diagnosed tamponade is therapeutic. Patients who are in shock and may have a cardiac injury should have an emergency thoracotomy as soon as possible. If it is not possible to perform an emergency thoracotomy promptly, continuing pericardiocentesis to relieve the suspected tamponade should be attempted.

Removal of as little as 5 to 10 mL of blood from the pericardial sac may increase stroke volume by 25 to 50 percent, with a dramatic improvement in cardiac output and blood pressure.

Thoracotomy Conservative management of penetrating heart injury requires prompt surgical exploration and repair. Only in the rarest circumstance, a highly selected, stable patient with a tiny penetrating cardiac injury, as by a needle or ice pick, may be successfully treated without surgery. However, all patients with hemodynamic instability and a suspected injury to the heart should have an immediate resuscitative thoracotomy.

Blunt Injury to the Heart

ETIOLOGY AND MECHANISMS OF INJURY The most common cause of blunt cardiac trauma is a high-speed motor vehicle accident. However, myocardial injury has been documented in accidents involving vehicles going less than 20 mph. Other causes include direct blows to the chest, industrial crush injuries, falls from heights, blast injuries, and athletic trauma.

The heart is suspended relatively freely from the great vessels within the chest cavity, and this mobility plus its location between the

sternum and the thoracic vertebrae make it susceptible to injury as a result of several mechanisms: 1) sudden horizontal acceleration and/or deceleration, causing the heart to impact against the sternum and vertebrae; 2) a compression between the sternum and vertebrae following a direct forceful blow to the chest; 3) a sudden increase in intrathoracic and intracardiac pressures, causing disruption of the myocardium or cardiac valves; 4) a "hydraulic ram effect," with compression of the abdomen forcibly displacing abdominal viscera against the heart with sudden great force; and 5) strenuous or prolonged cardiac massage, particularly if done through the intact chest wall.

TYPES OF INJURIES Blunt trauma to the heart can cause a wide spectrum of injuries, including 1) rupture of an outer chamber wall, with resulting death from tamponade or bleeding; 2) septal rupture; 3) valvular injuries (aortic valve is the most common); 4) direct myocardial injury (contusion); 5) laceration or thrombosis of coronary arteries; and 6) pericardial injury.

DIAGNOSTIC PROBLEMS Blunt cardiac trauma can be very difficult to detect. The victim may have experienced severe multiple-system trauma, overshadowing the presence of a cardiac injury. In addition, the forces that produce blunt cardiac trauma may cause little or no external evidence of injury. Therefore, a history of moderate to severe chest or upper abdominal injury, even without abnormalities on physical examination, should make one suspect cardiac injury (Table 259-4).

BLUNT MYOCARDIAL INJURY (BMI)

Terminology There has been great confusion regarding the appropriate appellation for cardiac injuries related to blunt trauma. The terms *cardiac* (or *myocardial*) *contusion*, *cardiac* (or *myocardial*) *concussion*, *blunt myocardial injury*, and *blunt cardiac injury* have all been proposed. Certainly there is a spectrum of injuries to the heart for which the term *blunt cardiac injury* would be appropriate, if not very specific. *Myocardial concussion*, sometimes referred to as *commotio cordis*, suggests no obvious gross or microscopic pathology to explain the phenomenon. However, sudden death from dysrhythmia can occur. The initiating mechanism is usually from a sudden direct force to the chest, while an individual is participating in contact sports (e.g., karate, hockey, etc.).³⁰ The term *myocardial contusion*, although somewhat out of favor currently, may in fact have a pathologic definition indicating

TABLE 259-4 Clues to Diagnosis of Blunt Cardiac Injury

History	High-speed motor vehicle accident
	Crush steering wheel
	Angina-like chest pain
Physical examination	Tachycardia out of proportion to other findings
	Any dysrhythmia
	Any part of Beck triad
	Evidence of severe anterior chest injury
	Any evidence of heart failure
Radiography	Fractured sternum or first two ribs
	Widened pericardial silhouette
Laboratory	Elevated CPK-MB levels
ECG	Dysrhythmias or conduction disturbance
	Elevated ST segments
Other studies	Impaired motion of anterior heart on two-dimensional echocardiogram or radionuclide angiography
	Pulmonary artery catheter monitoring showing elevated pulmonary artery wedge pressure, low cardiac output, and/or poor response to fluid

anatomic injury. The term BMI, a more encompassing term although not universally accepted, has come into vogue, since *myocardial contusion* rarely exists in the strictest sense, but is often associated with other injuries (e.g., coronary artery thrombosis, infarction related to hypotension). Also, the underlying pathologic definition is less important than determining the cardiac risk profile of patients with blunt chest trauma.

Pathologic Changes The pathologic changes seen in the myocardium typically include subendocardial hemorrhage and a much larger area of focal myocardial edema, interstitial hemorrhage, and myocytolysis with infiltrates of polymorphonuclear leukocytes. The areas most frequently involved are 1) the anterior right ventricular wall, 2) the anterior interventricular septum, and 3) the anterior-apical left ventricle.

Additional myocardial injury may occur if there are concomitant intimal tears or compression from adjacent hemorrhage and edema. Indeed, some feel that much of the myocardial injury seen is due to redistribution of coronary blood flow. Very occasionally, transient hypotension may cause complete occlusion of a previously diseased coronary artery.

Usually there is complete clinical recovery with minimal residual scarring within 3 to 6 weeks of a myocardial contusion. However, in rare cases with severe transmural injury, a ventricular aneurysm may develop.

Physiologic Changes In addition to rhythm and conduction disturbances, some reduction in cardiac output can be found in most victims studied. The degree of cardiac depression is directly related to the mass of contused myocardium. Screening tests, such as the ECG and CK-MB isoenzymes, usually do not accurately indicate the severity of the injury, nor are they predictive of major morbidity or mortality.

Most patients with myocardial contusions have relatively little problem. However, occasionally there is a problem with a dysrhythmia, especially premature ventricular contractions (PVCs), atrial fibrillation, or a conduction defect, or there is clinical evidence of heart failure. Such problems are most apt to occur in patients with preexisting cardiac disease, prolonged general anesthetics, or hypotension because of other injuries.

Diagnosis Overall, significant BMI is an unlikely injury. A recent meta-analysis of studies of blunt cardiac trauma revealed that fewer than 3 percent of over 2200 patients in 25 prospective studies developed a cardiac complication (defined as requiring treatment or intervention).³¹ Most of these were ECG abnormalities (ventricular ectopy, supraventricular dysrhythmias, symptomatic bradycardia). The most frequent cardiac rhythm finding, sinus tachycardia, was not considered, as it did not require specific treatment. ECG abnormalities requiring treatment were independently associated with cardiac complications.³¹

Methods to diagnose myocardial injury have long been controversial. The variation in sensitivity reported for the various diagnostic tests has two origins. First, the tests require subjective interpretation. Second, there is no gold standard for comparison. Since diagnostic criteria (and even terminology) have not been agreed upon, the focus has appropriately become predicting the likelihood of adverse events.

CLINICAL FEATURES Any patient involved in a motor vehicle crash involving speeds exceeding 35 mph and having any chest symptoms or signs should be suspected of having a BMI. Rarely, a patient with BMI will have angina-like pain that is not relieved by nitroglycerin.

Tachycardia disproportionate to the degree of trauma or blood loss may be the first sign of a BMI. Occasionally, an irregular rhythm due to atrial fibrillation or multiple premature atrial or ventricular contractions may be noted. Differentiation from an acute myocardial infarction in older individuals may be difficult in the ED.

RADIOLOGIC EXAMINATION The chest x-ray has its greatest value in the recognition of associated injuries. The closest x-ray correlates of

BMI include pulmonary contusion and fractures (of the first two ribs, the clavicles, or the sternum). Sternal fractures are no longer considered to have specific importance.^{14,15}

Cardiac tamponade usually does not cause an enlarged cardiac silhouette, but a widened azygos vein is suggestive of this diagnosis.

ELECTROCARDIOGRAPHY As with other tests applied in suspected BMI, the value of the ECG is controversial. Suggestions have ranged from a single ED-based ECG to 72 h of continuous ECG monitoring. A recent study of 71 patients with blunt chest trauma (not requiring admission to an intensive care unit) revealed that the initial ECG was predictive of subsequent clinically significant ECG events.³² Still, an initially normal ECG does not exclude the development of a clinically significant cardiac event, since most abnormalities will develop over 24 h.³² The most frequent ECG abnormality is sinus tachycardia, although this finding does not suggest increased risk in and of itself. Significant ECG findings include injury pattern, tachydysrhythmias, ST-T wave abnormalities, and ectopy—particularly premature ventricular contractions.

One reasonable approach is to obtain an initial 12-lead ECG. If normal, then the patient must be monitored for 4 to 6 h. If there are no untoward events, patients can be safely discharged.³³ If the ECG is abnormal but there is no hemodynamic instability, the patient should be admitted to a monitored setting, with the 12-lead ECG repeated in 24 h. Some authorities suggest an intervening ECG at 6 and 12 h. Hemodynamic instability suggests the need for an aggressive diagnostic approach (see below). If at any time the ECG is abnormal (or changed) or if there is ectopy or dysrhythmia, cardiac monitoring should be continued and a cardiology consult obtained.

CARDIAC ENZYMES Initially there was considerable controversy regarding the value of CK-MB determination. Its certainly appeared that CK-MB determinations were of questionable value and likely only to confuse, as they appeared to be of insufficient specificity and sensitivity.³⁴ Further, elevated MB fractions in this setting do not correlate with the clinical course.

Determination of cardiac troponins has been advocated as a laboratory criterion,³⁵ and has even been proposed as the gold standard for the diagnosis of BMI. In particular, troponin I may have greater specificity for myocardial injury than troponin T, CK-MB or myoglobin. Experimental animal data appear to show that troponin I and T release kinetics are associated with the degree of blunt trauma force. Significant myocardial injury can occur without significant troponin release.³⁶ Also, due to the complex kinetics of troponin release, serial assessment may be required.³⁷ Finally, troponin release could be related to ischemic consequences of hemorrhage and shock in severely injured patients.³⁸

ECHOCARDIOGRAPHY A recent detailed review concludes that echocardiography does not appear to be useful as a primary screening modality in the identification of patients likely to develop complications from myocardial injury. It may well be the most sensitive test, but observed wall motion abnormalities often resolve and are usually clinically insignificant. However, patients who do develop cardiac complications may benefit from echocardiographic evaluation. Thus the current recommendation is to use echocardiography in selected patients who demonstrate cardiac dysrhythmias or dysfunction.³⁸ While myocardial wall motion abnormalities may be present in stable patients with blunt chest trauma, this finding alone does not seem to predict the likelihood of a complication.

Treatment Although occasional patients will require treatment of heart failure or rhythm or conduction disturbances, specific treatment interventions are seldom required.

Supplemental oxygen should be administered as needed to maintain PaO₂ above 80 mm Hg, and analgesics should be given as needed to reduce excessive pain. Coronary vasodilators should not be used unless the patient has suspected preexisting coronary artery disease. Car-

diac dysrhythmias should be diagnosed and treated appropriately. Prophylaxis against dysrhythmias is not indicated. Low cardiac output or hypotension should be treated with fluids or inotropic agents as indicated, with prompt ultrasound evaluation to exclude tamponade.

In the absence of dysrhythmias or hemodynamic instability, patients with BMI can safely undergo surgical procedures so long as continuous hemodynamic monitoring (invasive or sonographic) is used. If the patient remains in a low-output state despite adequate fluid resuscitation, inotropic support, and correction of any mechanical problems such as tamponade, use of an intra-aortic balloon counterpulsation device should be considered.

There is some question as to whether patients with a myocardial contusion and an intramural thrombus seen on two-dimensional echocardiography should have prophylactic anticoagulation if not otherwise contraindicated. In limited studies, patients with echocardiographically proven right ventricular thrombi did not develop subsequent systemic or pulmonary embolization. Furthermore, anticoagulation is contraindicated in most cases of multiple trauma because of the potential for severe hemorrhage.

OTHER BLUNT CARDIAC INJURIES The underlying etiology for other significant blunt cardiac injuries will rarely be apparent in the ED. Ninety percent of those with cardiac rupture die at the scene. The few that arrive stable will deteriorate suddenly and resuscitation will be unsuccessful. If recognized, immediate thoracotomy is the only hope. Similarly, patients with septal defects (may be evidenced on typical ECG pattern) are unlikely to survive. Other injuries include valvular rupture and mitral papillary muscle rupture. The latter usually results in death within a few days. Direct injury to the coronary arteries is rare, but may cause tamponade or intrathoracic bleeding. Immediate repair is required. Delayed development of hemopericardium or effusion can occur even without evidence of BMI. Small infusions are usually asymptomatic and resolve.

FOLLOW-UP It is important that patients with proven or suspected cardiac injury be closely observed, not only throughout their hospital stay but also later, for undiagnosed injuries or complications. One should consider posttraumatic pericarditis, ventricular septal defect, valvular defects, and ventricular aneurysms.

PERICARDIAL INFLAMMATION SYNDROME

Etiology and Pathogenesis The cause of pericardial inflammation following unplanned or planned (surgical) injury remains obscure. It may be a delayed hypersensitivity reaction to the presence of damaged myocardium in the pericardial cavity.

Diagnosis This syndrome should be considered in individuals who develop chest pain, fever, and pleural or pericardial effusions 2 to 4 weeks after cardiac trauma (or surgery). Patients may also have friction rubs, arthralgia, and pulmonary infiltrates. The blood count often shows a leukocytosis, and the ECG will often show ST-T wave changes consistent with pericarditis.

Treatment Treatment is primarily symptomatic. Nonsteroidal anti-inflammatory medications and rest can often reduce symptoms dramatically within 12 to 24 h, but glucocorticoids are occasionally required. Rarely, drainage of pleural or pericardial fluid may be required to relieve symptoms or rule out other problems.

GREAT VESSELS OF THE CHEST

Penetrating Trauma

Of the patients who reach the hospital with penetrating chest wounds and require admission, only 5 to 15 percent require a thoracotomy, but

up to 25 percent of the patients having such surgery have an injury to a great vessel. The survival rate with stab wounds is generally much higher than with gunshot wounds. Small knife wounds are often rapidly sealed off by surrounding tissue, especially vascular adventitia. This limits the amount of blood loss, particularly after hypotension develops. If the knife stays in place, it may temporarily seal the involved vessel.

The factors that determine the amount of tissue destruction caused by a bullet are discussed in Chap. 264.

TYPES OF VASCULAR INJURIES Simple lacerations are the most common injuries of the great arteries of the chest. They cause exsanguination, tamponade, hemothorax, and/or air embolism. Other vascular injuries include AV fistulas and false aneurysms, which may not be apparent for days or even months. Pulmonary AV fistulas after penetrating chest trauma are said to be extremely rare.

DIAGNOSIS

History Unless the patient had signs of life in the field or in the ED, resuscitative efforts are not indicated. As previously discussed, the decision is based on history alone.

The size of a knife, its length, and the angle of penetration may suggest the vessels or organs most likely to be injured. If there are two skin wounds, it is helpful to know whether they represent two entrance wounds or an exit and an entrance wound. In some instances, a bullet that entered the chest without exiting is not evident on chest or abdominal x-rays because it is in lateral subcutaneous tissues or has entered a major vessel and has embolized. It is also helpful to know, if possible, the caliber of the bullet and whether it was a high-velocity missile (>1000 ft/s). In the case of shotgun wounds, the size and spread of the projectiles can be helpful in predicting injury—small shot (e.g., birdshot) that is dispersed with wounds several centimeters apart tend to be low-energy projectiles that do not penetrate deeply. Conversely, a single large wound containing a few larger projectiles (e.g., 00 buckshot) signals massive tissue destruction within.

Physical Examination Close inspection including lifting the skin edge with a forceps may be useful to determine the general trajectory. **Under no circumstances should the wound be deeply probed to determine depth.**

A large upper mediastinal hematoma may cause an acute superior vena caval syndrome, tracheal compression, and/or respiratory distress. Occasionally, a decreased upper extremity pulse may be noted. Unfortunately patients with injuries to major vessels at the thoracic inlet may have none of the usual diagnostic signs of significant vascular injury.

One should auscultate the entire chest for bruits after a penetrating injury. A systolic bruit, particularly over the back or upper chest, should make one suspect a false aneurysm involving one of the great vessels. A continuous bruit suggests an AV fistula. A millwheel murmur, thought to be due to the churning of air in the heart, may be diagnostic of air embolism. Loss of a peripheral pulse caused by an embolization of a bullet from a thoracic vascular injury is rarely but occasionally seen.

Radiography

PLAIN RADIOGRAPHS The surface wounds should be marked. Evidence of cervical or supraclavicular swelling or widening of the upper mediastinal silhouette or chest x-ray is often present in patients with injury to brachiocephalic vessels. A "fuzzy" foreign body (bullet) can be an important radiologic sign, and is not due to poor radiologic technique. Because foreign bodies tend to pulsate when they lie next to major vessels, their margins may appear indistinct on chest films. Therefore a fuzzy foreign body contiguous with clear mediastinal

SECTION 22 • TRAUMA

structures on chest films can be an important x-ray clue to a vascular injury.

TRAJECTORY VS. EMBOLIZATION Bullets entering large systemic veins or the right heart can embolize to the lungs, whereas bullets entering the pulmonary veins or left heart can embolize to major systemic arteries. Some of these emboli cause no symptoms or signs and cannot be found except with multiple x-rays. If the missile appears distant from the anticipated trajectory, embolization should be suspected. The other explanation for missiles off trajectory is gravity: low-velocity bullets that violate the pleural space but are not trapped in lung parenchyma often fall to the "lowest" place in the hemithorax, namely the posterior costophrenic recess. In AP radiographic projection, the missile appears to be intra-abdominal, but triangulation with the lateral projection discloses the true location and can avoid needless laparotomy.

COMPUTED TOMOGRAPHY SCAN Newer multidetector CT scans acquire data so rapidly that breath-holding is possible, greatly increasing the quality of the image. In combination with computer-controlled contrast injection, low pitch spiral data acquisition, and multiplanar subtractive reconstruction, CT angiography is used increasingly as a rapid screening tool. Caution and high-level supervision should be exercised in transporting marginal patients to the CT scanner, where management of decompensation is difficult and rarely successful.

ARTERIOGRAM Indeed, before exploring penetrating injuries of the thoracic inlet in hemodynamically stable patients, one should obtain a preoperative image to visualize the arch of the aorta and its major branches. Aortography is still considered by some to be the definitive study for evaluating injury to the aorta.

VENOGRAMS Venograms to identify major vascular injuries in the chest are seldom performed. A patient who is actively bleeding from a major venous injury is usually explored emergently because of unstable vital signs or continued blood loss through chest tubes.

CONTRAST SWALLOWS A contrast swallow may be performed on a stable patient if there is concern about an associated esophageal injury. Water-soluble contrast is used first, but may miss up to half of esophageal leaks. Barium swallows have fewer false-negatives but can cause a worse mediastinitis if a perforation is present.

Endoscopy With penetrating wounds of the chest or lower neck in hemodynamically stable patients, it may be prudent to perform bronchoscopy and esophagoscopy to rule out an injury to the aerodigestive tract. Such studies should be deferred until the patient is hemodynamically stable.

Ultrasound Controversy persists regarding the evaluation of hemodynamically stable patients with transmediastinal gunshot wounds. The goal is the determination of trajectory to identify or exclude wounds to the heart, esophagus, and trachea. The combination of CT scan, contrast swallow, and transesophageal echocardiography to evaluate trajectory probably represents the current choice of many trauma surgeons.

TREATMENT

Initial Resuscitation The standard ABCs (airway, breathing, circulation) of initial resuscitation should be followed aggressively if the patient is in shock. One of the problems occasionally seen with injuries to vessels in the thoracic outlet is massive mediastinal hematoma formation with resulting tracheal compression. Consequently, **early endotracheal intubation should be performed.** Tracheostomy should be avoided in patients with injuries at the thoracic inlet, at least initially, because of the possibility of precipitating massive bleeding from an otherwise controlled hematoma.

If the patient is in severe shock (systolic blood pressure <60 mm Hg), surgery should be performed promptly and aggressive fluid replacement should not be employed to a target blood pressure around 90 mm Hg. If the shock is persistent, the patient is rushed to the operating room. If cardiac arrest appears imminent, an immediate resuscitative thoracotomy should be performed there to control bleeding, provide internal cardiac massage, and cross-clamp the descending thoracic aorta as needed.

If rapid control of the bleeding sites and cross-clamping of the descending thoracic aortic arch do not raise the systolic blood pressure to at least 90 mm Hg within 5 min, terminal cardiovascular failure is present; almost all of these patients will die in the operating room regardless of effort.

Blunt Trauma to the Great Vessels of the Chest

The mechanical factors responsible for traumatic rupture of the thoracic aorta and its major branches are probably somewhat different for each anatomic area, but include shearing stress, bending stress, and torsion stress.

The aortic injury tends to progress from the intima out toward the adventitia. The adventitia, which has the lowest elastic limit, seems to withstand these stresses better than the intima or media.

Of the patients who reach a hospital and survive for 1 h, about half die within 24 h, and three-quarters die within 7 days. Of the remainder, most die within the next 1 to 3 months. Diagnosis and treatment can therefore be lifesaving.

At least 90 percent of blunt aortic injuries in patients who reach the hospital alive occur in the isthmus of the aorta, between the left subclavian artery and the ligamentum arteriosum.

DIAGNOSIS

History The single most important factor in establishing the diagnosis of acute traumatic rupture of the aorta (TRA) is a high index of suspicion (Table 259-5), particularly in anyone who has sustained sudden severe deceleration or a high-speed impact from the side.

Patients with TRA usually complain primarily of their associated injuries and generally have no symptoms related to the aortic injury itself. The most common complaint that may be due to the aortic injury itself is retrosternal or interscapular pain. Recurrence or exacerbation of the pain, particularly if associated with a rise in blood pressure (which may be due to excess fluid administration or inadequate pain control), may herald an impending rupture of the pseudoaneurysm. Less frequent symptoms, due primarily to pressure from the associated hematoma, include dysphagia, stridor, dyspnea, or hoarseness.

Physical Examination In many reports, at least one-third of the patients with blunt trauma to the aorta have no external evidence of thoracic injury at the time of the initial physical examination.

Physical findings that suggest aortic injury include 1) an acute onset of upper extremity hypertension, 2) difference in pulse amplitude between the upper and lower extremities, and 3) the presence of a harsh systolic murmur over the precordium or posterior interscapular

TABLE 259-5 Clinical Factors Suggesting Possible Traumatic Rupture of the Aorta

High-speed deceleration injury or side impact

Hoarseness without laryngeal injury
Superior vena caval syndrome

area. Upper extremity hypertension has occurred in 31 to 43 percent of the patients reported in the literature, and has been attributed to compression of the aortic lumen by a periaortic hematoma. However, the hypertension may also be secondary to stretching or stimulation of special receptors located in the vicinity of the aortic isthmus. If the torn intima and media form a flap that acts as a ball valve, partial or complete aortic obstruction can occur. With partial obstruction, an "acute coarctation syndrome" can develop, with hypertension in the upper extremities and weak pulses or hypotension in the lower extremities. A systolic murmur, thought to be caused by turbulent blood flow across the area of transection, is found in fewer than 30 percent of the patients. If complete aortic obstruction occurs, anuria and paraplegia can develop almost immediately. Other, less frequently encountered physical findings include hoarseness, voice change, superior vena cava syndrome, swelling at the base of the neck, and paraplegia.

Plain Chest X-Ray The original report by Gundry and colleagues, of radiographic findings in traumatic rupture of the aorta (TRA)³⁹ (Table 259-6), is still helpful. Widened mediastinum visualized on an upright chest radiograph remains the most sensitive and specific finding in patients subsequently shown to have TRA. Secondary signs, which are less predictive, include: esophageal deviation, obscuration of the aortic knob, and loss of the paraspinal stripe.

One of the main reasons that many unnecessary aortograms are performed is a technically poor chest x-ray. The upper mediastinum tends to appear wider than normal if the chest x-ray is taken: 1) anteroposteriorly (AP) rather than posteroanteriorly (PA), 2) with the patient less than 3.25 ft (100 cm) from the origin of the x-ray beam, 3) with the patient lying flat, and 4) with poor inspiration.

The most accurate radiographic sign of TRA is usually deviation of the esophagus more than 1 to 2 cm to the right of the spinous process of T4. Patients in whom the esophagus is deviated less than 1.0 cm from the midline are unlikely to have a TRA. A nasogastric tube in a normal position virtually excludes TRA. Blurring or obscuration of the aortic knob or descending aorta is almost as accurate an indication of TRA. Studies have shown that patients with a normal aortic contour and no evidence of deviation of the trachea or nasogastric tube to the right on the chest x-ray do not have TRA.

Other chest x-ray signs include displacement of the left main stem bronchus more than 40° below the horizontal, obliteration of the usual clear space between the aortic knob and the left pulmonary artery (apical cap), widening of the right paratracheal stripe, and displacement of the right paraspinal interface.

The paratracheal stripe is a linear structure just to the right of the tracheal air column. It extends from the thoracic inlet to the proximal right bronchus and normally measures less than 5 mm in thickness at a level 2 cm above the azygos vein. If the paratracheal stripe is more than 5 mm wide and/or is deviated to the right, this may be another sign of mediastinal hemorrhage.

The paraspinal lines lie between the pleura and the lung, projected away from the lateral margin of the thoracic spine. The right paraspinal line is usually not visible on routine chest x-rays, but if it is seen and if it is displaced to the right in the absence of spinal or sternal fractures, it may be of some diagnostic value.

The left paraspinal line may be distinguished from the image of the descending aorta by the fact that it is not continuous with the aortic knob. When displaced more than one-half the distance from the spine to the left margin of the descending aorta without spinal or sternal fractures, the displacement is almost certainly due to a periaortic hematoma.

It is now very controversial whether fractures of the first or second ribs are associated with a significantly increased incidence of TRA.

One should not assume that a TRA has been ruled out if the initial chest x-ray is normal, because in up to one-third of cases, characteristic x-ray changes may not be apparent until several hours after the injury. Two-thirds of patients above 65 years of age with TRA may not show mediastinal widening. Consequently, serial chest films should be taken in any patient with severe chest trauma at 6- to 12-h intervals during the first day and then daily for at least the next 3 days. Indeed, the circumstances of the trauma in such individuals should be the main indication for ordering an aortogram.

Transesophageal Ultrasound Unlike aortography, CT, or magnetic resonance imaging (MRI), transesophageal echocardiography (TEE) can be safely performed in hemodynamically unstable patients.

The thoracic aorta is not readily imaged by transthoracic ultrasound. However, the entire thoracic aorta can be imaged by TEE. TEE can be performed in less than 30 min compared to aortography, which requires over 75 min on average. Data on sensitivity and specificity of TEE is study-dependent on local factors such as patient population, limited study enrollment, operator type (cardiologists, surgeons, and radiologists), and experience. However, in at least one study, TEE and CT were equivalent in detecting blunt aortic injury requiring surgical repair, but had the advantage of diagnosing associated injuries such as to the innominate artery, and could identify lesions to the intima and media not identifiable on CT.⁴⁰

The complication rate from TEE is very low, with esophageal perforation (perhaps the most feared complication) being on the order of 2 to 3 per 10,000.

CT Scans Technical advances in instrumentation and technique are so rapid that an ongoing dialogue between emergency physicians and radiologists at the facility is necessary to understand local capabilities. Reports in the literature more than 2 to 3 years old tend to underestimate the sensitivity and specificity of current CT diagnosis. The sole contraindication to CT evaluation is hemodynamic instability. CT has become the predominant screening tool in many trauma centers.

TABLE 259-6 Reliability of Selected Clinical and Radiographic Criteria in the Detection of Traumatic Rupture of the Aorta*f

Radiographic or Clinical Finding	Correlation with TRA	Sensitivity	Specificity	Accuracy
Widened mediastinum (under 65 years old)	$p = .001$	0.95	0.82	0.84
Widened mediastinum (all ages)	$p = .001$	0.80	0.82	0.82
Murmur	$p = .002$	0.32	0.93	0.84
Pneumothorax/pulmonary contusion	$p = .07$	0.22	0.67	0.51
Hemothorax	$p = .21$	0.25	0.88	0.81
First/second rib fracture	$p = .39$	0.36	0.73	0.68

*A11 other clinical and radiographic criteria were less useful in detecting TRA.

tSensitivity = TP/(TP + FN); Specificity = TN/(TN + FP); Accuracy = (TP + TN)/A11 tests.

Source: From Gundry,³⁹ with permission.

Magnetic Resonance Imaging MRI is a technically seductive method for investigating injuries to the aorta and great vessels. MRI has certainly emerged as the preferred tool for the evaluation of dissecting aneurysms of the thoracic aorta. Given the conditions required for current-generation imaging, the role of MRI in the evaluation of blunt thoracic injuries remains indeterminate at best.

Aortography Although aortography is still considered by some to be the gold standard for the diagnosis of TRA, it is positive in only about 10 percent of patients in whom injuries are suspected based on plain films. Further, it is an invasive procedure that requires 1 to 2 h.

A patient who is in shock from a suspected TRA or who has a rapidly expanding mediastinal hematoma should be taken directly to the operating room without undergoing aortography.

Although it is often thought that there is relatively little risk to angiography, the overall complication rate has remained steady at about 25 percent,^{41,42} although the rates of amputation (0.1 percent) or death (0.3 percent) resulting from transfemoral studies is relatively low. If angiography is done in a hospital where relatively few cases are done each year, the incidence of complications can be increased up to 32-fold. It should be remembered that occasional false-negatives occur with aortography.

TREATMENT Although it is essential to resuscitate severely injured patients aggressively and to correct hypotension and hypoxemia rapidly, **the patient with a TRA should not be allowed to develop a systolic blood pressure over 120 mm Hg or to perform a Valsalva maneuver.** Endotracheal intubation can likewise cause gagging and coughing. In addition to the standard paralytic and sedative drugs administered during rapid-sequence intubation, preemptive intravenous administration of lidocaine (1 mg/kg) to attenuate the vascular and bronchial responses prior to laryngoscopy may be advisable in patients with suspected or proven TRA. Fluid administration should be watched carefully, and administration of sedatives, analgesics, vasodilators, and beta-adrenergic blockers may be required to keep the patient's systolic blood pressure at safe levels. Nasogastric intubation should be undertaken with caution owing to the transient spikes in blood pressure should the patient cough and gag during insertion.

Since 1958, emergency repair has become the accepted standard for care. More recently, three alternatives have emerged: endovascular stenting; initial aggressive medical control of blood pressure, with delayed repair; and prolonged observation with careful BP control in some patients with small unsuspected injuries seen only on high-resolution CT scan.

Special Considerations in Less Frequent Great Vessel Injuries

ASCENDING AORTA Very few patients with ascending aortic injury survive long enough for the diagnosis to be established and repair to be carried out. These injuries are frequently associated with cardiac rupture or severe myocardial contusion, and the aortic tears are multiple in up to 15 to 20 percent. Most victims have been hit by or thrown from moving vehicles or have fallen from great heights.

Thoracic aortic injuries distal to the isthmus should be suspected with severe chest trauma in which a lower thoracic vertebra is severely crushed.

DESCENDING AORTA Injuries to the descending aorta are uncommon. The presentations include paraplegia (owing to injuries to vessels supplying the spinal cord), mesenteric ischemia, anuria, or lower extremity ischemia. Contrast-enhanced CT scans may show a false channel, pseudoaneurysm, or extravasation into perivascular tissues. Cardiopulmonary bypass may be required for surgical management. The more distal the injury, the better the anticipated outcome-provided that the patient does not exsanguinate prior to repair. If the injury lies be-

tween the renal arteries and the aortic bifurcation, endovascular stenting may be considered. Otherwise, traditional open repair should be performed immediately.

INNOMINATE ARTERY In patients reaching the hospital alive, blunt injuries of the innominate artery are second in frequency only to rupture of the aorta at the isthmus.

Making a diagnosis of blunt injury to the innominate artery can be very difficult because there are no characteristic physical findings except for some diminution of the right radial or brachial pulse, which occurs in about 50 percent of the patients. Signs and symptoms of distal ischemia are uncommon. Occasionally, a systolic murmur may draw attention to a possible lesion in this area.

The chest x-ray findings are somewhat similar to those seen with TRA, but the mediastinal hematoma tends to be higher and the trachea and esophagus may be pushed to the left. Although aortography remains the standard diagnostic technique, CT angiography is now widely used, at least as a screening tool.

Subclavian Artery Although a subclavian artery is occasionally avulsed at its origin because of sudden deceleration, direct trauma to the distal artery with intimal damage and occlusion associated with fractures of the first rib or clavicle are more likely. Shoulder restraints that are loose may be a major factor in causing this injury.

The most important sign of a subclavian occlusion is absence of a radial pulse. In the patient with only a partial laceration and no occlusion, the radial pulse may be preserved. Other physical findings that are highly suggestive of subclavian artery rupture are a pulsatile mass or a bruit in the root of the neck. Occasionally a patient may develop an acute subclavian steal syndrome if the subclavian artery occludes proximal to the origin of the vertebral artery.

Up to 60 percent of patients with blunt injury to the subclavian artery, especially from motor vehicle accidents, will also have some damage to the brachial plexus. Horner syndrome often indicates avulsion of nerve roots from the spinal cord.

The chest x-ray with subclavian artery injuries may show the presence of a widened superior mediastinum without obscuration of the aortic knob. CT angiography can be diagnostic. An angiogram usually shows occlusion, but a pseudoaneurysm is occasionally found.

The treatment of acute subclavian artery injury is usually immediate repair. However, in certain high-risk patients who are doing poorly, occlusion by an interventional radiologist may be the treatment of choice. If the artery is already occluded, observation may be all that is required. The collateral circulation to the distal portions of the vessel is usually very good. However, if there has been severe blunt trauma to the shoulder girdle, many of the collateral vessels may be damaged, resulting in critical ischemia of the hand or upper extremity gangrene in about 30 percent.

ESOPHAGEAL AND THORACIC DUCT INJURIES

Esophageal Injuries

Lacerations of the esophagus occur most frequently during endoscopic biopsy or dilatation of a narrowed or obstructed esophagus. The esophagus can also be injured by swallowed foreign bodies. Injury to the thoracic esophagus is seen only rarely in patients who reach the hospital alive.

If esophageal injury is suspected, an esophagogram should be obtained. **The initial study should be performed using water-soluble contrast,** since extravasation of barium into the mediastinum can complicate mediastinitis. However, a negative water-soluble contrast study should always be confirmed with a barium study owing to the former's relatively high false-negative rate. Small leaks of water-soluble contrast may be better visualized on CT scan, which should be performed prior to a barium study.

Flexible esophagoscopy is being performed increasingly for diagnosis but may miss occasional injuries, even if combined with an esophagogram. **Neither barium nor water-soluble contrast will interfere with a subsequent esophagoscopy.** Some prefer rigid esophagoscopy in combination with bronchoscopy to rule out associated tracheobronchial injuries.

In spite of all our technical and nutritional advances in recent years, the mortality rate for esophageal injuries ranges from 5 to 25 percent for those treated definitively within 12 h, and 25 to 66 percent for those treated after 24 h.

Thoracic Duct Injuries

Thoracic duct injuries should be suspected in patients with penetrating trauma to near the left proximal subclavian vein. The diagnosis is unlikely to be made in the ED and usually discovered at time of surgical exploration and repair.

ABDOMINAL INJURIES

Thomas M. Scalea
Sharon A. Boswell

PATHOPHYSIOLOGY OF INJURY

Abdominal trauma generally is divided into two types: blunt and penetrating. This is somewhat simplistic. For instance, patients can suffer both blunt and penetrating trauma simultaneously. Patients involved in motor vehicle crashes may be impaled on objects at the same time. In addition, people who are shot or stabbed may also be assaulted at the same time.

Blunt Trauma

Blunt trauma is the most common mechanism of injury seen in the United States. This diffuse injury pattern puts all abdominal organs at risk for injury. The biomechanics of blunt injury involve a compression or crashing by direct energy transmission. If the compressive, shearing, or stretching forces exceed tissue tolerance limits, they are disrupted. This may result in injury to solid viscera (i.e., liver or spleen) or rupture of hollow viscera (i.e., the gastrointestinal tract).

Injury also can result from the movement of organs within the body. Some organs are rigidly fixed, whereas others are more mobile. Injury is particularly common in areas of transition before fixed and mobile organs. Examples include mesenteric or small-bowel injuries, particularly at the ligament of Treitz or at the junction of the distal small bowel and right colon.

Falls from a height produce a unique pattern of injury. Injury severity is a function of distance, the surface on which the victim lands, and whether the fall is broken. Intraabdominal injuries are uncommon and hollow visceral rupture is most common.¹ Retroperitoneal injuries with significant blood loss, however, are common because force is transmitted up the axial skeleton.

Pedestrians struck by cars are completely unprotected and all force is applied directly to the patient's body. Motorcyclists or bicyclists generally are protected only by a helmet.

Penetrating Trauma

Stab wounds directly injure tissue as the blade passes through the body. External examination of the wound may underestimate internal damage and cannot define the trajectory of the blade. Any stab wound in the lower chest, pelvis, flank, or back has caused abdominal injury until proven otherwise.

Gunshot wounds injure in several ways. Bullets may injure organs directly, via secondary missiles such as bone or bullet fragments or from energy transmitted from the bullet. Bullets designed to break apart once they enter a victim cause much more tissue destruction than a bullet that remains intact.

Entrance and exit wounds can approximate the missile trajectory. Plain radiographs help to localize the foreign body, allowing prediction of organs at risk. Unfortunately, bullets may not travel in a straight line. Thus all structures in any proximity to the presumed trajectory must be considered injured (see Chap. 264).

DIAGNOSING ABDOMINAL INJURY

Solid Visceral Injuries

Solid visceral injuries usually produce symptoms by blood loss. Patients often develop hypotension.² Some patients develop tachycardia, skin changes, and mental confusion with blood loss.² These signs are highly nonspecific. Young patients may lose 50 to 60 percent of their blood volume and be asymptomatic.³ Thus, assuming that a stable patient does not have an intraabdominal injury is hazardous.

Abdominal tenderness, distention, and/or tympany may not be present until patients have nearly exsanguinated into their abdomen. Some patients develop tenderness early with hemoperitoneum. Others, however, remain asymptomatic for many hours or days. Use of physical examination alone will lead to an unacceptable rate of missed injuries.

Gastrointestinal Injuries

Hollow visceral injuries produce symptoms by the combination of blood loss and peritoneal contamination. Perforation of the stomach, small bowel, or colon is often accompanied by some blood loss such as from a concomitant mesenteric injury. Gastrointestinal contamination will produce physical findings over a period of time. Patients with trau-

matic brain injuries or intoxication may not demonstrate physical findings initially. In addition, patients with substantial injuries elsewhere may be distracted from their abdominal pain for a number of hours.

Gastric injuries produce symptoms by chemical irritation when acidic contents are spilled into the abdominal cavity. This often occurs early in the treatment course but may take more time if patients are on H₂ blockers. Small-bowel and colonic injuries elicit symptoms because bacterial content produces suppurative peritonitis. Inflammation may take 6 to 8 h to develop.

Retroperitoneal Injuries

As with intraabdominal injuries, symptoms and physical findings of retroperitoneal injuries may be subtle or completely absent initially. Occasionally, retroperitoneal injuries do produce abdominal pain, even if they are relatively insignificant, such as a small retroperitoneal hematoma.

Duodenal injuries also can be asymptomatic at the time of presentation. Duodenal wall hematomas can produce relative gastric outlet obstruction with abdominal pain, nausea, and vomiting (Figure 260-1). Duodenal rupture is usually contained within the retroperitoneum. This may present with abdominal pain, fever, and tenderness, though they may take hours or even days to become clinically obvious. Duodenal rupture often occurs from rapid increases in intraluminal pressure when both the pylorus and the proximal small bowel develop spasm, most often occur after high-speed vertical or horizontal decelerating trauma.

Pancreatic injuries often accompany rapid decelerating injury. Pancreatic transection usually occurs in the midbody as the pancreas is displaced against the vertebral column. Thus, unrestrained drivers who hit the steering column or bicyclists who hit the handlebars are at special risk for pancreatic injury.

The diagnosis of pancreatic injury can be elusive. Patients can have few symptoms initially. There are no biochemical or radiographic markers pathognomonic for the diagnosis. Elevations in serum amylase are nonspecific. Computed tomography (CT) scanning may be normal initially. Relatively small pancreatic injuries can become symptomatic days later. Leakage of activated pancreatic enzymes from the pancreas can produce retroperitoneal autodigestion. These also can become superinfected with bacteria, producing a retroperitoneal abscess.

Urologic injuries may occur with abdominal trauma, but are discussed in detail in Chap. 262.

FIG. 260-1. Duodenal injury. Computed tomography (CT) scan demonstrating duodenal hematoma. Note the partial obstruction of the duodenum with an intramural hematoma. The injury resolved with nasogastric decompression and a short period of intravenous nutrition.

Diaphragmatic Injuries

A plain film of the chest demonstrating viscera in the chest or a nasogastric tube coiled in the thorax definitively diagnoses a diaphragm injury. More often, chest x-ray findings are subtle or absent. Diagnostic peritoneal lavage (DPL) can be helpful, particularly if the DPL fluid exits via a concomitantly placed chest tube or if follow-up chest x-ray demonstrates a new pleural effusion. Both helical CT and magnetic resonance imaging (MRI) can be helpful in diagnosing a diaphragmatic injury.⁴ Occasionally, cavity endoscopy or laparotomy are necessary to make the diagnosis.

ABDOMINAL EVALUATION AFTER BLUNT TRAUMA

A multiplicity of diagnostic modalities exist to evaluate the abdomen. No test is foolproof, and each must be used in conjunction with an assessment of stability, associated injuries, and physical findings.

Who Needs Evaluation?

All patients undergo initial physical examination. Unfortunately, this is often inadequate to make the diagnosis of abdominal injury. As a minimum, the following category of patients should undergo evaluation:

1. Presence of abdominal pain, tenderness, or distention
2. Mechanism of injury and prehospital details suggest potential for injury
3. Lower chest or pelvic injury
4. High-speed collisions or collisions where there has been substantial deformity to the vehicle (particularly if the patient was unrestrained)
5. Motor vehicle crashes with fatalities or those in which there were others with substantial injuries
6. Unprotected injury (i.e., motorcycle crashes)
7. Inability to tolerate a delayed diagnosis (e.g., the elderly, those with significant comorbid diseases)
8. Presence of distracting injuries (e.g., long-bone fractures)
9. Decreased level of consciousness/altered sensorium
10. Pain-masking drugs (e.g., ethanol, opiates)

Techniques of Evaluation

In the past, diagnostics were designed merely to document that an abdominal injury existed. Organ-specific diagnosis was made at the time of surgery, and all patients with abdominal injury underwent laparotomy. A large number of patients are now managed nonoperatively. Table 260-1 details the available diagnostic testing used for blunt abdominal trauma. Some specific comments, however, are necessary.

Physical Examination

The abdomen should be examined for signs of injury such as abrasions or contusions. This should include the flank, back, and lower chest, as well as the anterior abdomen.

A single physical examination is insensitive. Serial physical examinations increase the utility in identifying intraabdominal injury. These must be performed by the same senior-level clinician and should span a

period of time of at least 16 to 24 h. The patient must be awake, alert, and reliable. While there is little science describing this technique, we suggest that physical examination must be performed at least every 30 min for the first 4 h, hourly for an additional 4 to 6 h, and every 2 to 4 h for the remainder of the 24-h observation period. This should be accompanied by frequent hematocrit determinations and measurement of vital signs.

Plain Radiographs

Plain radiographs have an extremely limited use in patients with blunt abdominal trauma. They are incapable of making the diagnosis of hemoperitoneum. Even patients with hollow visceral injury often have normal radiographs. Occasionally, a chest x-ray will show free air under the diaphragm. However, routine use of plain films of the abdomen is not cost-effective.

Pelvic films, on the other hand, are standard in the evaluation process. Patients with pelvic fractures have a high-energy mechanism. This mandates rapid abdominal evaluation to avoid confusing retroperitoneal bleeding, common with pelvic fracture, with intra-abdominal blood loss. In addition, patients with thoracolumbar spine fractures must have abdominal evaluation. Intravenous pyelography (IVP) has been replaced by CT. Retrograde urethrography is useful in males with pelvic fractures to exclude urethral injury.

Screening Examinations for Abdominal Injury

Both DPL and ultrasonic abdominal evaluation can screen for hemoperitoneum after blunt trauma. Both examinations identify the presence or absence of blood in the abdomen but can make no determination as to the etiology of the hemoperitoneum. DPL is rapid, safe, and inexpensive. There is approximately a 1 percent incidence of major complication. DPL can be performed using either an open or a closed technique (Figures 260-2 and 260-3). We prefer closed percutaneous DPL because the complication rate is no different from the more cumbersome open technique. An immediately positive tap is defined as the aspiration of 10 mL of free-flowing blood. If the tap is negative, 1 L of saline is instilled and the abdomen drained by gravity. Some authors recommend that 250 mL of return is necessary.⁵ One hundred thousand red blood cells per fL is considered a positive lavage in blunt trauma. Thus, only 25 mL of blood must accumulate in the abdomen (assuming complete mixing) for DPL to be positive.

Laparotomy based solely on a positive DPL for red cells results in a nontherapeutic procedure approximately 30 percent of the time.⁶ Minimal injury can easily produce a hemoperitoneum sufficient to render DPL positive. Determining white cell count in the DPL effluent is nonspecific.⁷ In addition, biochemical assays such as liver function tests or amylase determination are nonspecific. Decision on laparotomy should be made based on the patient's hemodynamics and associated injuries in concert with the DPL. A patient with a positive DPL who is stable and does not have peritonitis is still a candidate for nonoperative management.

Focused assessment with sonography for trauma (FAST) is a rapid screen for intraabdominal injury and can be performed in less than 3 min. Like DPL, it can determine the presence of hemoperitoneum.

TABLE 260-1 Diagnostic Testing

Techniques	Easy	Rapid	Sensitive	Specific	Retroperitoneum	Expensive	Repeatable	Invasive	Transport from ED
Physical examination	Yes	Yes	No	No	No	No	Yes	No	No
DPL	Yes	Yes	Yes	Not at all	No	No	No	Yes	No
FAST	Yes	Yes	Yes	Not at all	No	No	Yes	No	No
CT	No	No	Yes	Yes	Yes	Yes	Yes	IV contrast	Yes

Abbreviations: CT = computed tomography; DPL = diagnostic peritoneal lavage; FAST = focused assessment with sonography for trauma.

FIG. 260-2. Closed diagnostic peritoneal lavage (DPL). Closed percutaneous DPL is an effective manner of evaluating the abdomen for hemoperitoneum. A needle is inserted two finger breadths below the umbilicus after infiltration with local lidocaine with epinephrine. A guidewire can be then inserted into the abdomen and the peritoneal lavage catheter inserted over the guidewire. One liter of fluid is instilled and the abdomen is then drained.

FAST is clearly operator-dependent and requires true expertise for reliable use. Like DPL, FAST is ineffective for imaging the retroperitoneum.

The amount of fluid necessary for a positive FAST remains unclear. In general, several hundred cubic centimeters of fluid/blood are necessary to be clearly visible using FAST.⁸ Like DPL, FAST cannot determine the etiology of the fluid.

FAST is generally performed in four areas: perisplenic, perihepatic, pelvic, and pericardial. No matter which organ is injured, the perihepatic view is most commonly positive. Blood pools in Morison pouch, the most dependent portion of the abdomen. The pericardial views can be extremely helpful, although pericardial tamponade is rare after blunt abdominal injury.

The ability of FAST to determine the need for laparotomy is questionable. McKinney et al. have encouraging data that suggest that their scoring system can predict the need for laparotomy.⁹ Unlike DPL, FAST can be repeated.

Clearly, FAST has limitations. Its ability to detect small amounts of fluid is questionable, even in skilled hands. In addition, a single FAST cannot absolutely exclude intraabdominal injury. A recent international consensus conference concluded that **prudent evaluation would involve two FAST exams performed at least 6 h apart** supplemented with serial physical exams to avoid missing an injury.¹⁰

ORGAN-SPECIFIC DIAGNOSIS

Only CT scanning can make the diagnosis of organ-specific abdominal injury. CT scanning images both the abdomen and the retroperitoneum. It is the diagnostic test of choice to investigate the duodenum and pancreas. It can diagnose urinary extravasation and images the ureters. CT can quantitate the amount of blood in the abdomen.

The disadvantages of CT are the expense and time required to perform the scan. In some centers, the CT scanner is some distance away

FIG. 260-3. Open diagnostic peritoneal lavage. Open diagnostic peritoneal lavage (DPL) is a surgical procedure requiring some expertise. An incision is made under local anesthetic and can be performed in an infraumbilical or supraumbilical location. **Patients with pelvic fractures must have their DPL performed open and above the umbilicus.** An incision is made through the skin and subcutaneous tissue under local anesthesia. The fascia is opened and a purse-string suture placed in the peritoneum. The peritoneum is then opened within the purse-string suture and the catheter passed into the peritoneal cavity. Fluid is infused and returned as with a closed DPL.

from the ED. This limits its use, particularly in critically ill patients. The oral contrast material often produces nausea and vomiting and must be administered while the spine remains immobilized. The intravenous contrast material has a small incidence of allergic reactions. Some advocate that oral contrast is unnecessary for abdominal CT during the initial assessment.¹¹ This requires further study before it is likely to gain widespread acceptance.

There are some patients who require CT scanning despite a normal FAST. Chiu et al. have shown that 28 percent of selected patients may have intraabdominal solid visceral injury without hemoperitoneum.¹² These include those with abrasions or tenderness in the lower chest, abdomen, or pelvis. Other findings mandating CT are pelvic fractures or thoracolumbar spine fractures.

EVALUATION OF THE ABDOMEN AFTER PENETRATING TRAUMA

Stab Wounds

Mandatory exploration, a policy used in the 1960s and early 1970s, has largely been abandoned, as it yields unacceptably high rates of nontherapeutic laparotomy. Feliciano and Renz described significant complication rates for nontherapeutic trauma laparotomy.¹³

Diagnostic modalities available for the evaluation of patients with stab wounds to the anterior abdomen include physical examination, DPL, and local wound exploration.

Physical examination may fail to suggest injury for the reasons stated for blunt trauma. Serial physical exams, on the other hand, are accurate in the evaluation of patients with abdominal stab wounds.¹⁴ This must be considered with all the provisos mentioned above.

Closed percutaneous DPL is an excellent technique for evaluating patients with anterior abdominal stab wounds. It is performed exactly as used for blunt trauma. There is some controversy as to the amount of red cells required for a positive DPL for stab wounds. The lower the threshold for a positive cell count, the higher is the rate of nontherapeutic laparotomy, but the lower is the rate of missed injury. The converse is also true. Most centers set between 10,000 and 20,000 red blood cells/xL as a threshold for laparotomy. The accuracy increases from approximately 78 to 90 percent as the threshold for positivity decreases. Any patient who undergoes DPL must be observed in the hospital for at least 12 to 24 h.

Local wound exploration accurately evaluates the abdomen after a stab wound (Figure 260-4). This is a surgical procedure that requires proper lighting, instruments, and local anesthesia. **Digital probing of the wound or radiographic tractograms with contrast material are unwise.** Both are inaccurate and lead to both nontherapeutic laparotomy and missed injuries.

If local wound exploration demonstrates no violation of the anterior fascia, the patient can be discharged home. If local wound exploration demonstrates fascial violation, several options exist. Diagnostic exploration is reasonable as the rate of nontherapeutic laparotomy will be relatively low. Positive local wound explorations can also be followed by DPL. If DPL fluid does not exit the wound or is negative by cell count, the patient can be observed.

It is often difficult to follow the trajectory of a stab wound. If the clinician is not completely comfortable that this has been a technically satisfactory procedure, one must abandon the use of local wound exploration and use another form of evaluation. Our preference would be to use DPL in this setting.

Gunshot Wounds

The most important consideration with anterior abdominal gunshot wounds is to determine whether the missile traversed the peritoneal cavity. Patients with transabdominal gunshot wounds virtually all have

FIG. 260-4. Local wound exploration. Local wound exploration is the appropriate way to evaluate the abdomen after a stab wound. This is a surgical procedure requiring expertise, proper instrumentation, and lights. It is an appropriate diagnostic technique only for patients with anterior abdominal stab wounds. The stab wound is widened and explored down to the level of the fascia. A determination can be made whether the anterior fascia and/or posterior fascia has been violated.

intraabdominal injury requiring surgery. Most often, this can be determined by estimating trajectory. Thus, a hole both in the anterior and posterior abdomen clearly defines a transabdominal trajectory. In the event of a single entrance, a plain film of the chest, pelvis, and/or abdomen often can determine trajectory. A lateral film may be helpful.

Occasionally, in the case of tangential injuries or multiple gunshot wounds, it may be impossible to clearly determine trajectory. It often may be safest to simply explore these patients. While not perfect, surgical exploration at least ensures that a potentially life-threatening injury will not be missed. The second option is to carefully observe the patient with frequent physical examinations and laboratory values. The last option is to perform a peritoneal lavage. There are virtually no data that determine the correct threshold for red blood cell positivity in patients with gunshot wounds. The only purpose is to determine whether the missile traversed the abdominal cavity. Thus, we generally set the threshold very low and explore patients if there is even a pink tinge to the effluent or the red blood cell count is 5000/xL or greater.

Penetrating trauma to the flank and back can be investigated with contrast-enhanced CT enema using oral, intravenous, and rectal contrast agents and managed nonoperatively (see Chap. 261 for details).

CT scanning is now being used to evaluate injuries to the anterior abdomen as well. It can easily make the diagnosis of transabdominal trajectory by demonstrating free air or fluid,¹⁵ but cannot accurately define the organs injured. Patients with a positive CT scan should have diagnostic laparotomy.

Likewise, FAST is now being used for penetrating trauma. A positive FAST has a positive predictive value of >90 percent.¹⁶ A negative FAST, however, cannot exclude injury. Further investigation is necessary.

MANAGEMENT OF ABDOMINAL INJURY

Laparotomy

Laparotomy is the "gold standard" therapy for intraabdominal injuries. It is definitive, rarely misses an injury, and allows for complete evaluation of the abdomen and retroperitoneum. Table 260-2 describes generally accepted indications for exploratory laparotomy. Certainly all patients with hypotension, abdominal wall disruption, or peritonitis mandate surgical exploration. In addition, the presence of extraluminal, intraabdominal, or retroperitoneal air either on plain film or CT should prompt surgical exploration. Finally, organ-specific diagnosis on CT often will mandate exploration. Examples include pancreatic injury, duodenal injury, renal injury with urine leak outside Gerota fascia, or a bowel injury.

Some patients have the diagnosis of injury made but are hemodynamically stable with a normal physical examination. Examples include patients with a positive DPL or FAST or patients with a CT-diagnosed splenic or hepatic injury. Clearly, some of these patients can be managed nonoperatively. In smaller centers or community hospitals, these patients may be best served by surgical exploration. In tertiary care centers, some of these patients can be managed nonoperatively.

Many patients with fluid seen on CT scan without a solid visceral injury have a trivial liver or splenic injury that is missed on CT. Unfortunately, others will have mesenteric injuries and/or small-bowel injuries. Often the safest course is exploration to avoid late diagnosis of GI perforation or ischemia. Careful observation and/or repeat CT can also be used.

NONOPERATIVE MANAGEMENT OF BLUNT TRAUMA

The evolution of nonoperative therapy has been greatly advanced by the evolution of CT. CT makes the diagnosis of solid visceral injury and often can rule out other injuries requiring surgery. Solid visceral injuries can be graded as to severity.

TABLE 260-2 Indications for Laparotomy

	Blunt	Penetrating
Absolute	Anterior abdominal injury and hypotension Abdominal wall disruption Peritonitis Free air on chest x-ray CT-diagnosed injury requiring surgery, i.e., pancreatic transection; duodenal rupture	Injury to abdomen, back, and flank with hypotension Abdominal tenderness GI evisceration Positive DPL (GSW) High suspicion for transabdominal trajectory CT-diagnosed injury requiring surgery, i.e., ureter or pancreas
Relative	Positive DPL or FAST in stable patient Solid visceral injury in stable patient Hemoperitoneum on CT without clear source	Positive local wound exploration (SW)

Unfortunately, CT grading may not agree with intraoperative observation and does not always predict the success of nonoperative therapy.^{17,18} CT precisely reveals the status of the internal parenchyma but not three-dimensional injury anatomy. Operative grading provides an excellent three-dimensional view of the organ, but may underestimate internal damage. CT is a single snapshot in time, not a dynamic assessment.

As patients age, the capsule of the spleen and liver weakens. Parenchymal changes may occur as well. Accordingly, nonoperative management of even very severe injuries is the norm in children. Failure rates are much higher in adults. As patients age, the consequences of rebleeding increase.

Over the last several years, several technologic advances have increased the sophistication of nonoperative management. The increased resolution of helical CT can identify vascular injuries (i.e., pseudoaneurysms or atrioventricular fistulas) or active extravasation of contrast. Angiography can also diagnose intraparenchymal vascular injury and evaluate the possibility of ongoing blood loss. Patients without vascular injury usually can be managed nonoperatively. In patients in whom vascular injury is diagnosed, percutaneous transcatheter embolization with either stainless steel coils or Gelfoam pledgets can arrest hemorrhage with a high degree of reliability.

Nonoperative Management of Hepatic Injury

Several recent large series have documented successful nonoperative treatment in 90 percent of patients who are hemodynamically stable at

TABLE 260-3 American Association for the Surgery of Trauma (AAST) Liver Injury Scale

Grade*	Injury Description
I. Hematoma Laceration	Subcapsular, nonexpanding, <10 cm surface area Capsular tear, nonbleeding, <1 cm parenchymal depth
II. Hematoma Laceration	Subcapsular, nonexpanding, 10–50 percent surface area; intraparenchymal, nonexpanding, <10 cm in diameter Capsular tear, active bleeding; 1–3 cm parenchymal depth, <10 cm in length
III. Hematoma Laceration	Subcapsular, >50 percent surface area or expanding; ruptured subcapsular hematoma with active bleeding; intraparenchymal hematoma, >10 cm or expanding >3 cm parenchymal depth
IV. Hematoma Laceration	Ruptured intraparenchymal hematoma with active bleeding Parenchymal disruption involving 25–75 percent of hepatic lobe or 1–3 Couinaud's segments within a single lobe

presentation.¹⁹ Liver injuries are most commonly classified according to the system described by the American Association for the Surgery of Trauma (AAST) (Table 260-3). Complications of nonoperative management of hepatic injuries include delayed bleeding, bile leak, intraabdominal sepsis, and missed intraabdominal injuries. These are relatively rare and occurred in only 5 percent of the largest series of nonoperative management of liver injuries.¹⁹ However, the vast majority of complications occurred in higher-grade injuries.

Today, many of these complications can be managed nonoperatively as well. Angiography with selective embolization can treat delayed blood loss from hepatic injuries. Percutaneous drainage can treat "bilomas" or hepatic abscesses. Endoscopic retrograde cholangiopancreatography (ERCP) can decompress clots from the biliary tree and stent intraparenchymal hepatic ductal injury. Recently, Carrillo et al. reviewed 135 patients managed nonoperatively.²⁰ Thirty-two patients developed complications requiring intervention, with most of these patients having high-grade injuries. A combination of these techniques successfully managed these complications nonoperatively 85 percent of the time.

Nonoperative Management of Splenic Injury

Nonoperative management of splenic injuries in adults has a failure rate as high as 20 percent. This relatively high failure rate has prompted some authors to advocate limiting nonoperative management to patients under 55 years of age and those with a CT injury grade no higher than 3 (Table 260-4).

The addition of angiography to the treatment algorithm has radically changed the nature of nonoperative management for splenic injury. First reported by Sclafani et al., sequential DPL, CT, and angi-

TABLE 260-4 American Association for the Surgery of Trauma (AAST) Spleen Injury Scale (1994 Revision)

Grade*	Injury Description
I. Hematoma Laceration	Subcapsular, nonexpanding, <10 percent surface area Capsular tear, nonbleeding, <1 cm parenchymal depth
II. Hematoma Laceration	Subcapsular, nonexpanding, 10–50 percent surface area; intraparenchymal, nonexpanding, <5 cm in diameter Capsular tear, active bleeding; 1–3 cm parenchymal depth, which does not involve a trabecular vessel
III. Hematoma Laceration	Subcapsular, >50 percent surface area or expanding; ruptured subcapsular hematoma with active bleeding; intraparenchymal hematoma, >5 cm or expanding >3 cm parenchymal depth or involving trabecular vessels
IV. Hematoma Laceration	Ruptured intraparenchymal hematoma with active bleeding Laceration involving segmental or hilar vessels producing major devascularization (>25 percent of spleen)
V. Laceration Vascular	Completely shattered spleen Hilar vascular injury that devascularizes spleen

* Advance one grade for multiple injuries up to grade III.

raphy was used as a management algorithm in the care of patients with blunt trauma.¹⁷ Stable patients with a positive DPL underwent CT. All patients with CT-diagnosed splenic injury were then treated angiographically. All vascular injuries identified at the time of angiography were treated with proximal coil embolization. Proximal embolization, similarly to splenic artery ligation, decreases the pressure head to the spleen, allowing for spontaneous hemostasis. Splenic viability and immune function are preserved by collateral vessels via the pancreatic branches of the splenic artery, the short gastric vessels, and collaterals from the superior mesenteric artery. In 150 patients, splenic salvage rate was 98 percent.¹⁷ Most important, a negative splenic arteriogram predicted successful nonoperative management.

Initial CT scan may miss a splenic pseudoaneurysm in 75 percent of the patients with this pathology. Thus, follow-up CT even in asymptomatic patients is important.

While higher-grade injuries have an increased likelihood of vascular injury identified,^{17,21} more than 10 percent of patients with grade 1 injuries have vascular injuries identified and embolized at the time of angiography.¹⁷ Thus, reliance on CT grading to predict the success of nonoperative therapy may be insufficient. Alternatively, early, liberal use of angiography should help to identify patients with vascular injuries. Either of these techniques (i.e., follow-up CT, early angiography) appears to decrease the incidence of delayed splenic rupture. This often presents at 7 to 10 days in patients who were stable initially following the diagnosis of splenic injury.

FIG. 260-5. Nonoperative management of splenic injuries. A. FAST (focused assessment with sonography for trauma) in this 21-year-old female with blunt abdominal trauma clearly demonstrates hemoperitoneum. B. The patient remains hemodynamically stable and CT scan demonstrates a grade 4 splenic injury.

The early series cited above^{17,21} did not have a large proportion of high-grade splenic injuries contained within them. Recently, the authors prospectively evaluated a series of 120 patients with a large proportion of CT grade 3 and 4 injuries.²² All patients diagnosed with splenic injuries underwent early angiography. The presence of a vascular abnormality correlated with grading. The higher the grade, the more likely the patient was to have vascular injury at the time of angiography. These were treated with a combination of proximal coil and subselective embolotechniques (Figure 260-5). Nonoperative management was successful more than 90 percent of the time, although some patients required repeat angiography and/or embolization.

Nonoperative management for splenic injuries is certainly a safe and effective technique. However, this must involve a committed team of emergency physicians, surgeons, and invasive radiologists to safely manage patients with high-grade injuries nonoperatively. Coil embolization is a safe technique and an effective method of hemostasis. These innovative techniques should be performed in a tertiary care center under strict protocol in order to be managed safely.

PENETRATING TRAUMA TO THE FLANK AND BUTTOCK

Alasdair K. T. Conn

Penetrating injuries to the flank and buttock challenge the physician because of the possibility of missed injuries to retroperitoneal structures. Gunshot and stab wounds in these areas must be evaluated carefully to determine whether there is retroperitoneal injury with intraperitoneal or vascular injury that might mandate immediate surgical intervention. Evaluation is difficult; the retroperitoneal structures are well protected by dense layers of musculature and the spine. There is significant risk of missed injury and delay in diagnosis. Fortunately, an increased armamentarium of diagnostic testing assists in timely diagnosis and allows for selective conservative management. The choice of management, conservative or operative, is determined based on the emergency evaluation, making the emergency physician's input essential to a correct decision and a clinically successful outcome. Penetrating injuries to the buttock are relatively uncommon, and some trauma centers report as few as three to five patients with this type of injury per year. Trauma centers in urban settings have reported 50 to 80 patients per year. With appropriate management, the mortality is low, but case reports indicate that there is a potential for a missed injury to the bowel or major vessels, especially with shotgun or high-velocity gunshot wounds, unless the clinician is vigilant in the emergency evaluation. This chapter outlines the evaluation of patients who present to the emergency department with penetrating trauma to the flank or to the buttock.

PENETRATING TRAUMA TO THE FLANK

Pathophysiology

The flank is the area between the anterior and posterior axillary lines, superiorly bordered by the sixth rib and inferiorly bordered by the iliac crest. Although a penetrating wound to the flank can produce intraperitoneal injury with the associated physical findings of peritonitis or hemoperitoneum with shock, it is possible that a penetrating flank wound only injures the retroperitoneal organs. A delay in diagnosis of duodenal, colonic, rectal, renal, pancreatic, or major vascular injuries may result in the late appearance of septic or hemorrhagic shock.

The path of a gunshot or stab wound to the flank may track superiorly. Bullets may ricochet off the bony structures of the spine and produce a unique bullet path and injury pattern. Other intra-abdominal organs may be injured, such as the stomach or pancreas, the diaphragm, and intrathoracic organs. Inferior tracking will jeopardize the lower gastrointestinal (GI) tract and colon. Treatment of these specific organ injuries is covered elsewhere in this text.

Clinical Features

Patients with penetrating trauma to the flank should be resuscitated and evaluated according to standard resuscitative protocols. Initial resuscitative efforts should be directed toward the primary survey (see Chap. 251). Information regarding the mechanism of injury, how

much time has passed since the traumatic event, and the nature of the weapon should be obtained and recorded. In the case of a gunshot wound, the nature of the gun (e.g., shotgun, handgun, BB gun) and the range between the gun and the patient at time of the gun's discharge should be ascertained and noted in the emergency record. Following stabilization, an attempt should be made to find an exit wound, and a bullet path should be reconstructed. Baseline laboratory and radiologic data, including a hemogram, chest radiograph, urinalysis, and rectal examination with testing for occult blood, should be performed on all patients. In the presence of peritonitis, IV fluid and broad-spectrum antibiotics (e.g., ampicillin 0.5-2 g IV every 6 h, gentamycin 1.0-1.7 mg/kg IV every 8 h, metronidazole 15 mg/kg IV X 1 and then 7.5 mg/kg IV every 6 h) should be administered and urgent surgical consultation obtained. Multiple regimens are available, but coverage for gram-negative aerobic and anaerobic organisms is required. A suitable regime of antibiotics is ampicillin, gentamycin, and metronidazole initiated in the emergency department. Most patients are stable and will require additional diagnostic modalities.

Diagnosis

BEDSIDE ULTRASOUND In a patient with a penetrating wound to the flank, portable bedside ultrasonography can be used to determine if there is fluid in the abdominal cavity. In the absence of a preexisting medical condition (such as cirrhosis with ascites), such information may be invaluable. Although the sensitivity and specificity vary with the type of equipment used and the experience of the operator, fluid collections of 600 mL should be detected easily by the emergency physician.¹ For a patient with a gunshot wound, this may be sufficient to recommend an operative approach. For a patient with a stab wound, this indicates a significant intra-abdominal injury, even if the patient is hemodynamically stable. Operative intervention is sometimes delayed pending further adjunctive diagnostic measures. A recent study indicates that this should be a screening study only—the positive predictive value being 90 percent, but the negative predictive value being only 60 percent.²

WOUND EXPLORATION Although local wound exploration under adequate local anesthesia using sterile technique is of value in anterior abdominal wounds, it is only of limited value in wounds of the flank. If local exploration demonstrates that the injury does not penetrate beyond fascia or muscle, the wound may be closed safely and the patient discharged from the emergency department with appropriate follow-up instructions. With deeper penetrating injuries, it is difficult to determine the extent of injury with local wound exploration. More information usually can be obtained by computed tomographic (CT) scanning. Deep wound exploration often leads to further hemorrhage and tissue damage and is of limited value. It is difficult, if not impossible, to ascertain the exact depth of a stab wound from deep wound exploration.

DIAGNOSTIC PERITONEAL LAVAGE Appropriately performed, diagnostic peritoneal lavage (DPL) is highly accurate in determining the presence of intraperitoneal injury, but it does not detect injuries restricted to the retroperitoneum. (For details of the technique and criteria, see Chap. 260.) In most institutions, the use of DPL for a stable patient has been replaced by CT scanning, but in an unstable patient, DPL can be performed (especially if portable ultrasound is not immediately available) to rapidly detect the presence (or absence) of hemoperitoneum.

COMPUTED TOMOGRAPHY In many centers, CT has become the diagnostic modality of choice in patients who present hemodynamically stable following a penetrating flank trauma.^{3,4,5} Double (oral Gastrografin and intravenous) contrast or triple (oral, intravenous, and rectal) contrast is used; rectal contrast should be used if there is even a remote likelihood of a rectal or sigmoid injury. Cooperation with the radiologist is essential because fine "cuts" through the site of injury may be required to delineate the injury tract. Particular attention

should be paid to the presence of intraperitoneal fluid and any edema of the bowel wall. The latter may represent bowel perforation, even without evident leakage of the contrast material.⁶

CT scanning is of particular use in stab wounds to the flank in which the patient is hemodynamically stable. The diagnostic accuracy has been reported at 97.9 percent for CT scanning.⁷ Other studies^{8,9} validate this figure with a 97 percent accuracy in predicting the need for laparotomy.

The majority of patients with identified injury will be found to have retroperitoneal hematoma without bowel or solid-organ damage. Rarely, a hematoma around one of the major blood vessels or the pancreas is evident, requiring further diagnostic testing such as angiography, venography, or endoscopic retrograde cholangiopancreatogram (ERCP). Occasionally, a gunshot wound may be observed to pass extraperitoneally, but concerns about blast effect may lead to the decision to perform laparoscopy.

Treatment

The treatment of penetrating trauma to the flank remains somewhat controversial, although there is a tendency toward more conservative management. Celiotomy is generally reserved for patients with hemorrhagic shock, peritonitis, evisceration, transabdominal missile path, and intraperitoneal free air. At the time of surgery, all intraperitoneal and retroperitoneal organ structures should be evaluated according to standard operative procedures.

Although some surgeons still advocate mandatory exploratory laparotomy in an effort to detect all injuries early, most surgeons now advocate selective management with early CT scanning, which allows many injuries to be managed by close observation. Using this conservative approach, celiotomy rates have been decreasing from 100 percent to approximately 30 percent, with the incidence of positive laparotomy rising from 15 percent to approximately 80 percent, without increases in untoward outcome.¹⁰ Using this approach, the risks associated with the negative laparotomy (early: hemorrhage and infection; late: complications and small bowel obstruction) as well as added expense are avoided. Many recent reviews support this selective management approach.

Exploratory laparotomy is performed most commonly for flank gunshot wounds. Many flank stab wounds can be safely managed conservatively. In the case of high-velocity gunshot wounds, blast effect must be considered. Depending on the exact location and type of injury, consideration of the blast effect may lead to exploratory laparotomy if there is concern about bowel, bladder, or vascular integrity. Laparoscopy also may be used to determine the extent of intraperitoneal injury. A surgeon experienced in laparoscopy should perform this procedure because bowel injuries may be difficult to detect.

With CT scanning, the exact depth of a stab wound often can be determined. Decision algorithms based on low-risk flank stab wounds (penetration superficial to the deep fascia) or high-risk flank stab wounds (penetration beyond the deep fascia) have been developed and appear to be justified clinically.¹¹ Hemodynamically stable patients with stab wounds to the flank can be risk-stratified based on these contrast-enhanced CT findings. Low-risk patients may be discharged immediately from the emergency department. High-risk patients require surgical consultation and should be admitted to the hospital, but in many cases a discharge decision can be made within 24 h.

PENETRATING BUTTOCK INJURIES

Pathophysiology

Penetrating trauma to the buttock may be either from gunshot wounds or stab wounds. Gunshot wounds have the greatest potential for injury because the thick musculature and fat over the buttocks normally pro-

tections the gastrointestinal, genitourinary, and neurologic systems from injury in all except the deepest penetrating trauma from stab wounds. With gunshot wounds, the risk of intraperitoneal injury is much higher and may necessitate immediate exploratory celiotomy. Injured systems requiring operative intervention are the lower GI tract, the lower genitourinary (GU) tract, and rarely, a vascular injury. Vascular injury to gluteal or internal iliac arteries has been reported from gluteal-penetrating wounds and may lead to exsanguinating external hemorrhage.¹² An intrapelvic injury also may cause injury to the internal iliac vessels with hypovolemic shock; this will require early operative intervention. A delay in diagnosis of colonic or rectal injury will contribute to increased mortality and morbidity. From the civilian trauma literature, approximately 30 percent of patients who present with gunshot wounds to the buttock require surgery. Factors associated with surgical intervention include findings of peritonitis, a positive finding at sigmoidoscopy, gross blood in the urine, entrance wound above the level of the greater trochanters, and a transpelvic (as opposed to extrapelvic) bullet course.¹³⁻¹⁵ In contradistinction, stab wounds to the buttock infrequently require laparotomy.

Diagnosis and Management

Initial approaches to trauma resuscitation should be followed, as noted earlier. Local wound exploration is of limited value, primarily to detect gross foreign bodies. Attention should be paid to the abdominal examination. If there is indication of peritonitis or of a gunshot wound with a transabdominal missile path, emergent surgical consultation should be obtained, broad spectrum antibiotics given intravenously, and preparations made for an exploratory laparotomy. Baseline hemogram, urinalysis, and rectal examination should be performed on all patients. If there is any concern about injury to the rectum because of blood being noted on rectal examination or because of the trajectory of the bullet, proctosigmoidoscopy should be performed.¹⁵ A cystourethrogram should be obtained on patients when there is blood on urinalysis or the proximity of the wound to the GI tract is a concern. This can be performed either as a separate study or in conjunction with CT scanning with rectal and intravenous contrast material and clamping of the urethral catheter to obtain a CT cystogram. If the CT scan demonstrates a pelvic hematoma, angiography or venography may be indicated to document a significant vascular injury. In all patients, the peripheral pulses in the lower extremities should be examined looking for decreased pulses or pallor as evidence of a proximal injury. Neurologic examination of the lower extremities searching for any injury to the sciatic or femoral nerve also should be performed on all patients. Buttock wounds rarely cause damage to the sciatic plexus or femoral plexus. Injury could include transection, partial transection, or stretch injury secondary to the trauma. The presence of any symptomatic signs requires appropriate consultation. The signs of peritonitis, intrapelvic or transabdominal missile path, and intraperitoneal free air warrant immediate celiotomy.

GENITOURINARY TRAUMA

Frederick Levy Gabor D. Kelen

EPIDEMIOLOGY

Injuries to the genitourinary system occur in approximately 2 to 5 percent of adult trauma victims. The vast majority of these injuries are a result of blunt trauma. More than 80 percent of those with injuries to the kidney have other concurrent injuries; approximately a third of those injuries are life-threatening. Consequently, detection of injury to the genitourinary system may be overlooked.

Approximately 80 percent of the urogenital injuries involve the kidney, and approximately 10 percent involve the bladder. Patients with anatomic anomalies, including tumor and hydronephrosis, appear more susceptible to renal injury. Significant ureteral injuries are relatively rare and are usually associated with penetrating trauma. Significant urethral injuries most often occur in males and are usually associated with pelvic fracture. Accurate overall estimates for children are not available, but it appears that approximately 10 percent of pediatric patients with blunt abdominal trauma have genitourinary system injury. This increased percentage in children may reflect the absence of periadipose tissue and the large size of the kidneys relative to overall body size.¹

CLINICAL APPROACH

Chap. 251 discusses the overall approach to trauma. Only issues specific to genitourinary trauma are discussed here.

Genitourinary system injuries rarely require immediate intervention. Investigation of renal injuries should not supersede evaluation of more life-threatening injuries. For example, with a pelvic fracture, determining the need for pelvic angiography is more important than determining whether a urethral injury exists. The patient may well die from a sheared major artery, whereas an injured urethra will never require immediate attention. The retrograde introduction of dye will render subsequent pelvic angiography very difficult, if not impossible.

During the detailed secondary survey, a concerted effort should be made to closely inspect the perineum. Blood on the underwear is an

important finding. In both male and female patients, the folds of the buttocks should be spread in search of perineal lacerations, which often denote an open pelvic fracture. Such lacerations should not be probed lest a clot be disrupted and exsanguinating hemorrhage result. During the rectal examination, sphincter tone, the position of the prostate gland, and presence of any blood should be noted. If the prostate is riding high or feels boggy, there has been a disruption of the membranous urethra.

In males, the scrotum is palpated and inspected for ecchymoses, laceration, and testicular disruption. Simultaneously, the length of the penis is palpated to inspect for blood at the meatus. In females, the vaginal introitus is inspected for lacerations and hematomas. These findings are often associated with pelvic fractures in which a displaced fracture fragment may cause a vaginal laceration or urethral disruption. If there is any evidence or likelihood of trauma in this area, a bimanual vaginal examination is required. If there is blood in the vagina, a speculum examination is necessary to exclude vaginal laceration.

During the secondary survey, the trauma series x-rays are obtained and often include an anteroposterior view of the pelvis. The presence of a pelvic fracture has important implications in the workup of genitourinary injuries. Patients with pelvic fractures have a higher incidence of mortality and often have concomitant extraperitoneal bladder injuries.

Generally, no urinary catheter should be introduced until the urine can be evaluated for hematuria. However, the placement of a urinary catheter for monitoring of urine output may be required in severely injured patients who cannot void. Often times, catheter placement will reveal the first signs of genitourinary injury. If there is doubt and placement of a catheter is emergent, a suprapubic approach may be the most prudent. In menstruating women, a specimen obtained with a catheter is likely to offer more accurate urinalysis than a spontaneously voided specimen.

The standard hematology and serum chemistry results are generally not helpful in determining the presence or degree of renal injury in the acute setting.

Detection of Specific Injuries

The need to determine the existence of specific injuries is based on the clinical elements obtained in the history, physical examination, and plain films, and to some extent, on the age of the patient. Table 262-1 lists some key elements that should prompt the consideration of further evaluation of renal tract injury. The approach to evaluation is dependent on the following: blunt versus penetrating trauma, the presence of gross or microscopic hematuria, associated injuries, mechanism of injury, hemodynamic stability, and age of the patient.² Renal injuries require staging for appropriate management (Table 262-2).³ Staging is usually accomplished through use of an imaging modality, but sometimes exploration is required (see below).

TABLE 262-1 Key Clinical Findings Associated with Renal System Injury

Acceleration or deceleration injury (renal pedicle)
Lower rib fractures (kidney)
Fracture lower thoracic or upper lumbar spine
Pelvic fracture (urethra)
Abdominal trauma
Flank ecchymosis, tenderness, mass (kidney)
Straddle injuries (urethra)
Penetrating trauma (in vicinity of any part of the renal system)
Penile scrotal or perineal hematoma (urethra)
Gross hematuria
Microscopic hematuria in certain circumstances (see text)
Abnormally positioned prostate (posterior urethra)
Blood at penile meatus (urethra)

TABLE 262-2 Grading of Renal Injuries⁴

Grade	Injury	Treatment
I	Contusion (microscopic or gross hematuria, with normal urologic study results) Subcapsular, nonexpanding hematoma without laceration	Observation, spontaneous resolution
II	Parenchymal laceration <1.0 cm depth limited to cortex, no extravasation Nonexpanding hematoma, confined to retroperitoneum	Observation, spontaneous resolution
III	Parenchymal laceration >1 cm depth with extravasation or collecting system rupture	Observation or surgery
IV	Laceration extending through to collecting system Vascular pedicle injury, hemorrhage contained	Surgery
V	Shattered kidney Avulsed hilum (devascularized kidney)	Surgery

BLUNT TRAUMA

Physical Exam Findings as a Clue to Injury Localization

MEATAL BLOOD Blood at the meatus is associated with urethral injuries. Urethral injuries are almost exclusively seen in males. Posterior urethral injuries are commonly associated with pelvic fractures. A superiorly displaced prostate indicates disruption of the posterior urethra. Anterior urethral injuries are associated with straddle injuries and instrumentation.

When meatal blood is noted, a urinary catheter should not be placed in order to prevent the conversion of a partial urethral laceration into a complete transection. A retrograde urethrogram is virtually mandatory in this setting in order to make the diagnosis and to minimize the chances of long-term complications of a urethral transection (i.e., urethral strictures and urinary incontinence).

HEMATURIA For the purposes of trauma, microscopic hematuria is defined as more than five red blood cells (RBCs) per high-power field (hpf). A 10-mL specimen must be centrifuged for 5 min at 2000 revolutions for an accurate assessment. Gross hematuria is, of course, readily visible blood. Reddish urine, per se, does not necessarily indicate hematuria; several medications and toxic substances may cause discoloration. Results of a dipstick evaluation may be erroneous because myoglobin, a frequent finding in patients with rhabdomyolysis as a consequence of major trauma, reacts with the reagent.

The initially voided urine may provide clues as to the location of injury. When possible, at least two specimens (initial stream and terminal stream) should be obtained. Initial hematuria suggests injury to the distal system (i.e., urethra or prostate). Terminal hematuria suggests bladder neck injury. Continuous hematuria suggests upper renal system (bladder, ureter, or kidney) injury.

Gross hematuria may occur from injury virtually anywhere in the genitourinary renal tract. The finding of gross hematuria mandates a diagnostic imaging study that is chosen based on other findings (Table 262-3). For example, in the presence of pelvic fractures, gross hematuria should raise the possibility of bladder or urethral injury. Almost 95 percent of bladder injuries are associated with gross hematuria.

All patients in whom microscopic hematuria is found with concurrent nonrenal injuries and those with hemodynamic instability should

TABLE 262-3 Selection of Diagnostic Imaging for Suspected Renal System Injury

Imaging Study	Suspected Injury
Retrograde urethrogram or cystogram	Urethral injury
CT (with IV contrast)	Renal injury (staging) Ureteral injury
Cystogram, plain film (retrograde)	Bladder injury
CT cystogram (retrograde)	Bladder injury
"One-shot" IVP	Unstable patients taken to operating room
IVP	Alternative to CT in unstable patients Ureteral injury
Angiogram or venogram	Pedicle injuries, venous disruption
Retrograde pyelogram	Renal pelvis disruption

Abbreviations: CT = computed tomography; IVP = intravenous pyelogram

have a diagnostic imaging study, as discussed below. In such patients, computed tomography (CT) is often impractical. A "one-shot" intravenous pyelogram (IVP) can be obtained in the operating room.

Many studies demonstrate that, **in adult patients with blunt trauma, the degree of hematuria does not correspond to the degree of injury.** Gross hematuria may be seen with relatively minor renal contusions, whereas microscopic hematuria (or even no hematuria) may be seen in renovascular injuries. However, in the absence of significant hemodynamic compromise, isolated microscopic hematuria is unlikely to represent significant blunt injury. While there is no clinically validated or generally accepted upper limit of microscopic hematuria beyond which imaging is done, many physicians do not image patients where the degree of microscopic hematuria is ≤ 50 RBCs/hpf. A review of several major studies addressing this question concluded that isolated microscopic hematuria indicates significant injury in approximately 1 in 500 patients with such a finding.² Thus, the current consensus is that adult patients with isolated microscopic hematuria do not require further imaging studies. There are three exceptions. When the mechanism of trauma involves rapid deceleration, renal pedicle injuries may ensue but can present with minimal (or even no) hematuria. Also, hematuria in a patient with even transient hypotension should not be considered an isolated finding.

Special Considerations

RAPID DECELERATION FORCES Rapid deceleration injuries may result in renal pedicle and vascular injuries. Such injuries result in high mortality rates, but, fortunately, they are quite rare, occurring in less than 1 percent of blunt renal trauma. However, hematuria, the clue to renal injury, may not be present. Accordingly, patients whose mechanism of injury is from forces of rapid deceleration should have a renovascular imaging study. Because pedicle injuries virtually always occur in association with other significant injuries,⁴ other indications for radiographic evaluation are likely. Many such patients have other indications for surgical exploration.

PEDIATRIC BLUNT TRAUMA Hematuria following blunt trauma may have different significance in the pediatric population.^{5,6} Unlike the situation in adults, the degree of hematuria does seem to correlate with the degree of injury.⁴ Many advocate that pediatric patients with any degree of hematuria, even if hemodynamically stable, should undergo imaging studies.^{7,8} However, **pediatric patients with less than 50 RBCs/hpf do not appear to have significant injuries.**^{1,4} Thus, it appears appropriate to perform imaging studies on only those patients

with significant hematuria, as defined above.² The most recent experience suggests that all grades of renal injury in stable children can be managed conservatively.⁶ Other standards for imaging studies for pediatric patients remain similar to those for adults.

Imaging Techniques for Diagnosing Genitourinary Blunt Trauma Injury

The following should be considered when ordering studies in the trauma patient: 1) intravenous contrast agents can cause false-positive scan results for blood; 2) the total quantity of contrast required may limit the number of contrast studies, especially with shock; 3) hypotensive patients are at risk for developing contrast-induced acute renal failure; 4) abdominal CT reveals more information but requires a hemodynamically stable condition; and 5) an intraoperative IVP during an emergency laparotomy may be needed to determine the status of the contralateral kidney. Table 262-3 provides a guideline for the selection of diagnostic imaging modalities.

ULTRASONOGRAPHY Ultrasonographic examination of the right upper quadrant (Morrison pouch) and the left upper quadrant (splenorenal recess) is part of the focused assessment with sonography for trauma (FAST) examination (see Chaps. 251 and 303) but has little accepted role to date in the initial detection (or exclusion) of significant renal injury in the United States. Certain conditions, such as patient position, obesity, fractured ribs, and overlying bowel gas make such examinations difficult to perform. Furthermore, sonography reveals nothing about renal function.

PLAIN FILM Plain films are helpful in determining likelihood of renal trauma when abnormalities such as lower rib fractures, lower thoracic and upper lumbar spinal fractures, and pelvic fractures are seen. Loss of the psoas shadow or scoliosis may suggest injury. However, plain films are inappropriate for evaluating the renal tract.

COMPUTED TOMOGRAPHY Indications for imaging the kidneys following blunt trauma include gross hematuria, hematuria with multiple injuries or hemodynamic instability, and mechanisms that include rapid deceleration (Table 262-4). When renal injury is suspected, CT is considered superior to other imaging modalities, including sonography, angiography, and IVP. CT is most likely to allow appropriate staging of renal injury (see Table 262-2) and has several advantages. CT is a noninvasive modality with superior imaging detail that allows detection of even minor injuries and minimal extravasation, estimation of extent of hematoma, and simultaneous evaluation of other organs. In the last decade, the use of helical (spiral) CT scanning has enhanced the sensitivity of detecting renal injury, primarily by eliminating the phenomenon of respiratory misregistration. In children with hematuria, CT is the radiographic study of choice in evaluating renal injuries because a significant nonrenal intraabdominal injury is more likely than a renal injury.

The major disadvantage of CT scanning is that it can be performed only in a stable patient. Other disadvantages are cost and the difficulty in detecting vascular, particularly venous, injury.

TABLE 262-4 Clinical Indications for Contrast CT of the Upper Urinary Tract

1. Patients with hematuria with/without shock.
2. Hemodynamically stable with microscopic hematuria who have other indications for a CT of the abdomen/pelvis.
3. Hemodynamically stable patients with microscopic hematuria with clinical evidence of major blunt flank trauma.
4. Patients with any degree of hematuria following penetrating flank injuries.

Source: Tze MW, Spencer JA: The role of CT in the management of adult urinary tract trauma. *Clin Radiol* 56:276, 2001.

Certain considerations should be kept in mind. Routine abdominal CT evaluation often stops at the iliac crests. In situations where lower ureter or bladder trauma is under consideration, the examination should be extended to the pelvis. Also, contrast enhancement is usually indicated for appropriate evaluation. Both oral and intravenous contrast material is often given when other intraabdominal trauma is under consideration. However, if enhanced CT is required to image the kidneys and collecting system appropriately, gastrointestinal contrast studies may need to be delayed to allow accurate interpretation.

MAGNETIC RESONANCE IMAGING Magnetic resonance imaging (MRI) is generally not a first-line imaging modality. However, its accuracy appears to be similar to that of CT. It may prove useful in stable patients who have dye allergy or patients with equivocal findings on CT.

ANGIOGRAPHY Angiography has largely been replaced by CT. It still has a role when vascular injury is suspected and remains the gold standard for detecting renal venous injury. Arteriography may be indicated in selected patients when no renal function is evident on IVP or CT. Other indications include penetrating trauma where the likelihood of vascular injury is high, and when embolization is considered for persistent or delayed hemorrhage. It should be kept in mind that the kidney can tolerate only 4 to 6 h of warm ischemia. Arteriographic confirmation may cause an undue delay.

RADIONUCLIDE IMAGING Radionuclide imaging has a very limited role now, given the superiority of CT. It may still be useful in patients with iodinated dye allergy in whom technetium-99m (^{99m}Tc) glucoheptonate can be safely used.

INTRAVENOUS PYELOGRAM Formal IVP with or without tomograms can be used in stable patients if CT is unavailable. However, it is not the ideal study in the trauma setting, given the need for quality imaging. If used, the dose of contrast material needs to be greater than the standard 1 mL/kg to account for hemodilution for intravenous fluid administration and possible impaired renal perfusion. The recommendation is 2 mL/kg up to 150 mL of 60 percent iodinated contrast. In patients with a history of allergy, a nonionic agent, such as iohexol, can be used. Alternatively, noncontrast CT, radionuclide imaging, or MRI may offer satisfactory results.

IVP remains the mainstay of diagnosing ureteral injuries, although it is not infallible.⁹ Extravasation of dye is the classic finding, although on occasion there is absence or delay of contrast in the distal collecting system. However, many are now using spiral CT to diagnose ureteral injuries because it offers the advantage of viewing the entire retroperitoneal space and has the ability to detect urinomas.

A "one-shot" IVP can be obtained in unstable patients in the emergency department or operating room, although there continues to be some controversy surrounding the need for a single-shot study. Certain authors suggest that the single-shot IVP can often give the surgeon valuable information, not only about the presence of a contralateral kidney, but about which renal injuries may be safely observed.¹⁰ Others suggest that the utility of this test is limited to those patients who present with either flank wound or hematuria.¹¹

The technique entails injecting 2 mL/kg intravenous contrast material about 5 min before the film is taken. However, if the patient's blood pressure is 70 mm Hg or less, the kidneys may not concentrate the contrast material and are more susceptible to dye-related injury.

CYSTOGRAPHY For suspected bladder injuries, plain-film cystogram is classically used. Approximately 300 to 500 mL (5 mL/kg in children) of contrast media is instilled retrograde into the bladder under gravity from 2 ft (60 cm) above the patient. At a height of 2 ft, the intravesical pressure generated approximates the physiologic voiding pressure. Unless adequate bladder pressure is generated, the cystogram

may be falsely negative. Ideally, the procedure is performed under fluoroscopy to avoid filling the peritoneal cavity with contrast material in the event of a tear. A film of the distended bladder is taken, and a postdrainage view is obtained to note any extravasation not evident on the initial film. Some authorities suggest that the bladder be "washed out" with saline solution prior to obtaining the post-"wash-out" view.

Although some authors continue to advocate clamping a urinary catheter to allow antegrade filling of the bladder,¹² retrograde cystography is felt to be more accurate in detecting bladder injuries, presumably because retrograde filling is not dependent on progressive dilution of contrast material.¹³ CT cystogram may be preferred in patients who require intravenous contrast-enhanced CT imaging for other indications.¹⁴ However, contrast material must still be injected retrograde. Postvoiding scans are generally not required because CT allows full imaging of the retrovesicular space.

A prospective investigation studying indications for cystography in blunt trauma with hematuria or pelvic fracture concluded that it was appropriate and cost effective to restrict this procedure to patients with gross hematuria only.¹⁵ The authors contend that patients with pelvic fracture and microscopic hematuria do not routinely require cystography.

Urethral injuries are also investigated by retrograde cystography. **An unlubricated urinary catheter is placed** approximately 2 to 3 cm into the navicular fossa of the distal urethra, and the balloon is inflated with 1 to 3 mL water. Approximately 20 to 30 mL of contrast material is injected. An oblique view is obtained. The entire length of the urethra is seen on the plain film when the x-ray is taken as the last 10 mL of the contrast solution is injected. Occasionally, a patient may be transferred from another facility with an indwelling urethral catheter in place. A retrograde urethrogram can still be performed without removing the catheter, by injecting contrast solution into the urethra through a small feeding tube placed adjacent to the urethral catheter.

Urethral injuries should not be investigated in cases of pelvic trauma until it is certain that pelvic angiography or embolization is not required. Also, if the prostate gland was grossly displaced on rectal examination, the urethra is transected, and a retrograde study is not needed, at least not during the initial evaluation.

CONTRAST STUDIES When both upper and lower tract injuries are suspected, imaging needs to be approached with particular attention to order. While the most serious potential injury should guide the order of obtaining images, **oral contrast material should generally not be given before an IVP or cystogram** because gastrointestinal contrast may obscure important findings. Patients with potential bladder injuries may require a retrograde urethrogram to evaluate possible urethral disruption first. If injury is noted, cystography can be accomplished by suprapubic puncture.

Situations in which contrast is best avoided and risk of contrast nephropathy are discussed in Chap. 302.

IMAGING CONSIDERATIONS FOR OTHER CONDITIONS A perinephric hematoma may initially be difficult to distinguish from a urinoma. A delayed CT image may demonstrate contrast, indicating a urinoma. Patients with such perinephric collections can be followed with ultrasonographic studies. A nuclear ^{99m}Tc renal scan can also detect a persistent urine leak.

Significant adrenal injuries are relatively rare. Adrenal hematomas may be found in up to 3 percent of patients with blunt abdominal trauma. They are usually associated with other significant thoracic and abdominal injuries. Adrenal hematomas can be followed by CT or sonography and usually resolve over a few months. Long-term sequelae are unlikely.

PENETRATING TRAUMA

Approximately 10 percent of patients with renal injury related to stab wounds may not manifest hematuria. Thus, appropriate evaluation de-

pends on clinical suspicion, the weapon involved, and patient characteristics. Generally, all stable patients with penetrating trauma with the potential of genitourinary system injury should undergo imaging studies. Hematuria, microscopic or gross, does not correlate with injury from penetrating trauma.¹⁶

The choice of imaging depends on the vicinity of the trauma. The presence of penetrating trauma alone mandates further evaluation.

Penetrating ureteral injuries are usually a result of bullet wounds. Again, hematuria is not a reliable finding in this setting. Imaging is required for penetrating injuries near ureters. Contusions from secondary energy forces related to bullets cannot be detected by imaging. They may come to light during surgical exploration.

Penetrating bladder injuries are usually accompanied by gross hematuria. As with other penetrating trauma, in the absence of hematuria, the need to perform imaging studies is driven by clinical concern.

Choice of Diagnostic Imaging for Penetrating Renal Trauma

CT with intravenous contrast material remains the primary imaging modality for penetrating trauma to the kidneys. It usually shows appropriate detail of injury to inform management decisions. Several studies have shown utility for staging even penetrating injuries, allowing nonoperative management in selected patients (i.e., those with minor injury).^{17,18}

As with blunt trauma, sonography has no accepted role for detection or staging of renal injury in the United States at this time.

Ureteral injuries can be assessed by IVP or CT with contrast. Extravasation indicates injury. CT has the added advantage of being able to evaluate the extent of extravasation and other intraabdominal injuries. As with blunt trauma, cystography (plain film or CT) is required to evaluate penetrating injuries of the bladder. Unstable patients who require emergency laparotomy can undergo a "one-shot" IVP while in the operating room.

SPECIFIC INJURIES

Renal Injuries

The kidneys are well protected in the retroperitoneal location, being surrounded by bulky musculature, fascia, and lower ribs. Considerable force is generally necessary to cause significant renal injury. Fractured ribs, vertebral transverse process fractures, flank bruises or hematomas, and hematuria may indicate injury. Contusions account for most (92 percent) renal injuries, with renal lacerations (5 percent), renal pedicle injuries (2 percent), and renal ruptures or shattered kidneys (1 percent) accounting for the rest.

RENAL CONTUSION This relatively minor injury includes renal parenchymal ecchymosis, minor lacerations, and subcapsular hematomas with an intact renal capsule. Results of the IVP are usually normal. The CT may reveal edema with microextravasation of contrast material within the renal parenchyma. Subcapsular hematoma appears as a flattened portion of the renal cortex compressed by the hematoma under the renal capsule.

RENAL LACERATION Renal lacerations are classified as either minor cortical lacerations that do not involve the medulla or collecting system, or major renal lacerations that extend deep into the corticomedullary junction or collecting system (see Table 262-2). The resulting perirenal hematoma may fill the perirenal space before it is tamponaded by the Gerota fascia. Radiographic studies demonstrate disruption of the renal outline, a perirenal hematoma, and possibly extravasation of contrast material adjacent to the kidney.

RENAL PEDICLE INJURY Renal pedicle injuries include lacerations and thrombosis of the renal artery, renal vein, and their branches. These injuries result from high-velocity deceleration injuries and penetrating trauma. In blunt trauma, the most common renal pedicle injury is thrombosis of the renal artery, which follows tearing of the intima with intact adventitial and medial layers. There is bruising surrounding the renal artery, but no perirenal hematoma is found in renal pedicle lacerations. When the renal artery is occluded or divided, the IVP shows nonfunction, and the arteriogram reveals renal artery occlusion or bleeding. In such injuries, CT demonstrates a thin rim of contrast material just below the renal capsule. This represents blood flow through the capsular arteries to the subcapsular cortex ("rim sign").

Renal vein thrombosis results in delayed renal function and parenchymal swelling in the absence of ureteral obstruction.

RENAL RUPTURE A large expanding perirenal hematoma accompanies renal rupture, and the patient becomes clinically unstable from continued bleeding. Radiographic studies reveal multiple deep lacerations, devitalized kidney fragments, and extravasation of contrast.

RENAL PELVIS RUPTURE Ruptures of the renal pelvis result in extravasation of urine into the perirenal space and along the psoas muscle. Renal pelvis ruptures are rare and are often associated with congenital renal anomalies. Radiographic studies reveal a normally functioning kidney, filling of the calyceal system, and extravasation of contrast without visualization of the ureter. Renal pelvis ruptures are often misdiagnosed as small renal lacerations. If the diagnosis is delayed, the patient may develop high fever, increased abdominal pain, and tenderness as the extravasation of urine continues into the retroperitoneal space. Sepsis may ensue. The diagnosis of renal pelvis rupture is confirmed by retrograde pyelogram.

Ureteral Injuries

Ureteral injuries are the rarest of all genitourinary injuries and are usually the result of penetrating trauma (Figure 262-1). Blunt trauma, however, can induce a rupture at or just below the ureteropelvic junction as a result of hyperextension of the spine with the distal ureter fixed at the trigone of the bladder. Blast effects from gunshot wounds may cause microvascular thrombosis in the ureteral wall, delayed

ureteral necrosis, and urinary fistula formation. Diagnosis is sometimes delayed. If the ureter is completely transected, hematuria may be absent.¹⁰ IVP is likely to miss such injuries.¹⁰ Enhanced CT or a retrograde pyelogram may be required for detection.

Bladder Injuries

The bladder is an intra-abdominal organ in children, but is situated deep in the bony pelvis in adults. It is protected from all but the most severe injuries to the abdomen and pelvis. Bladder injuries are the second most common injury to the genitourinary tract after renal injuries and are usually associated with blunt trauma and pelvic fracture. Penetrating bladder injuries are often associated with injuries to other abdominal and pelvic organs.

BLADDER CONTUSION Bladder contusion is bruising of the bladder wall and resultant hematuria. A cystogram demonstrates an intact bladder outline. With a fractured pelvis, a large hematoma often results inside the bony pelvis, causing displacement of the bladder superiorly and laterally (Figure 262-2). This finding can serve as an indicator of pelvic hemorrhage. Large bladder hematomas also alter the architecture of the bladder, which takes on the shape of an inverted pear, hence the term "pear-shaped" bladder. Hematomas are best detected by CT.

BLADDER RUPTURE There are two types of bladder ruptures. *Intraperitoneal* bladder rupture is usually a burst injury of a full bladder resulting in a 1-in laceration in the dome posteriorly, the only portion of the dome covered by the peritoneum. In this type of injury, urine is spilled into the peritoneal cavity. *Extraperitoneal* bladder rupture is more common. The rupture is usually located at the bladder neck. Associated pelvic ring fractures predominate. The classic triad includes abdominal pain and tenderness, hematuria (usually gross), and inability to void. If the rupture is intraperitoneal, there may be peritonitis. Kehr sign (pain referred to the shoulder), suggesting blood or urine irritating the diaphragm, may be a clue. Patients in whom bladder injury is suspected but who are unable to void spontaneously should have a retrograde or suprapubic catheter placed. Retrograde catheter placement should be avoided until urethral disruption has been ruled out.

Bladder injuries are best diagnosed by cystogram or CT cystogram (see above). Gross extravasation indicates rupture. Intraperitoneal rupture

FIG. 262-1. Rare ureteral injury from a gunshot wound, with extravasation of contrast material on retrograde pyelogram.

FIG. 262-2. Bladder contusion and displacement from pelvic hematoma.

is demonstrated by extravasation of contrast material in the cul-de-sac posterior to the bladder, along the paracolic gutters, and between the loops of intestine above the bladder, hi extraperitoneal bladder rupture, the cystogram shows flamelike extravasation of contrast material streaking into the perivesical tissues. The wash-out film (not necessary with CT cystogram) is helpful when the extravasation is predominantly behind the bladder and obscured by contrast material in the full-bladder film of the cystogram. An irregular outline of an intact bladder may indicate contusion, hematoma, or an incomplete tear. Cystoscopy is not considered useful in this setting due to the gross hematuria and clot formation.

Urethral Injuries

Urethral injuries in males occur in the posterior (prostatomembranous) urethra and in the anterior (bulbous and penile) urethra. Posterior urethral injuries are associated with pelvic fractures. Digital rectal and perineal examinations reveal the presence of a perineal hematoma or high-riding detached prostate, which is associated with complete posterior urethral disruption. Anterior urethral injuries result from direct blows to the urethra (e.g., fall-astride injuries, straddle injuries, or kicks) or from instrumentation, and in conjunction with a penile fracture. Examination reveals the classic "butterfly" perineal hematoma, limited by the attachments of the fascia lata.

In anterior urethral contusions, there is blood at the external urinary meatus, but the retrograde urethrogram findings are normal. In partial anterior urethral lacerations, the retrograde urethrogram reveals contrast extravasation at the site of injury and contrast material outlining the urethra proximal to the site of injury (Figure 262-3). In complete anterior urethral lacerations, the retrograde urethrogram reveals contrast extravasation at the site of injury without contrast proximal to the site of injury.

Female urethral injuries should be suspected in extensive pelvic fractures. Most female urethral injuries present with vaginal bleeding. Careful vaginal and endoscopic examination should be undertaken, even when the patient has menstrual bleeding or an indwelling tampon. Delayed diagnosis has resulted in labial edema, necrotizing fasciitis, and sepsis.

MANAGEMENT OF UPPER GENITOURINARY SYSTEM INJURIES

Patients with isolated microscopic hematuria (5 to 50 RBCs/hpf) in whom imaging was not indicated may be discharged from the emer-

FIG. 262-3. Partial urethral laceration, with contrast extravasation at the site of injury and outlining the prostatic urethra and bladder.

gency department. Strenuous activity should be proscribed. Follow-up urinalysis should be obtained in 1 to 2 weeks.

Renal

Grades I and II renal injuries (see Table 262-2) are usually managed nonoperatively. If there are no other medical considerations, such patients can be treated similarly to those with isolated hematuria. Renal contusions almost always resolve without sequelae unless there is a pre-existing renal lesion, such as hydronephrosis, cyst, or tumor. Almost all minor lacerations heal without sequelae with conservative management.

Patients with grades III and IV injuries should be admitted to the hospital. Most of these patients will have other compelling reasons to be admitted or be taken to the operating room. Many hemodynamically stable adult patients with clearly delineated grade **III** and even grade IV injuries can still be managed nonoperatively.^{19,20} Interestingly, most of these patients have retroperitoneal penetrating renal injuries.

Many centers attempt nonoperative management for all stable children unless the renal injury is particularly severe or the child fails conservative therapy.^{6,21}

Exploration itself is not without consequence, because it may accentuate considerable hemorrhage. Neither the volume of blood replacement nor the degree of extravasation is an indication for exploration in itself.² However, if exploration is undertaken for the evaluation of other injuries, repair of renal injuries is usually undertaken. If conservative management is attempted, frequent reassessment is required, and there should be a low threshold for ordering reimaging studies. Conservative management includes bed rest, hydration, serial hematocrit determinations, monitoring of vital signs, and serial urine specimens to assess the degree of hematuria. Patients with gross hematuria remain at bed rest until the gross hematuria resolves, and remain at limited activity until microscopic hematuria resolves.

Table 262-5 lists indications for operative management.² Renal rupture is usually explored and nephrectomy usually required. Most, but not all, penetrating injuries are explored. The only widely accepted absolute indication for surgical exploration of a renal injury is persistent retroperitoneal bleeding with hemodynamic instability. As noted, CT may allow adequate staging even for penetrating injuries.^{17,18} If the patient has other injuries warranting abdominal exploration, an intraoperative IVP may assist in determining the necessity for retroperitoneal exploration while also giving information regarding function of the contralateral kidney.

Renal pedicle injuries are usually associated with multiple life-threatening injuries, and the safest surgical option is nephrectomy. In a stable patient with an isolated renal pedicle injury, repair should be undertaken within 12 h of the injury if a viable kidney is to result. Thrombosis of segmental arteries is treated conservatively.

Ureter

Ureteral injuries are managed intraoperatively. Unfortunately, not all ureteral injuries are found at the time of injury. Delayed presentations

TABLE 262-5 Indications for Operative Exploration or Intervention in Renal Injury

Uncontrolled renal hemorrhage
Penetrating injuries
Inadequate staging
Multiple kidney lacerations
Shattered (ruptured) kidney
Avulsed major renal vessel
Pulsatile or expanding hematoma found on abdominal exploration
Vascular injuries*
Extensive extravasation

include infection, including sepsis, and urinoma formation. Contusions are missed by imaging studies, but, if noted at the time of exploration, can be managed expectantly or with placement of an internal stent.

MANAGEMENT OF LOWER GENITOURINARY SYSTEM INJURIES

Bladder

Incomplete bladder lacerations can be managed by catheter placement and observation. Contusions require no specific intervention. Intraperitoneal rupture and penetrating injuries require operative intervention. Extraperitoneal bladder ruptures are treated with urethral catheter drainage alone. In such cases, the catheter remains indwelling for 10 to 14 days, and the cystogram is repeated to verify healing before the urethral catheter is removed. Rarely, persistent urinary extravasation is seen, with a bony fragment remaining in the bladder wall or a pelvic fixation impinging upon the bladder.

Urethra

Anterior contusion heals with conservative management, with or without a urethral catheter, depending on whether the patient can void. Partial anterior urethral lacerations are managed with an indwelling urethral catheter (placed coaxially over a guide wire under fluoroscopic control) or with a suprapubic cystostomy. Complete lacerations of the anterior urethra are repaired surgically with debridement and end-to-end anastomosis over a urethral catheter.

Surgical repair is usually deferred for posterior urethral injuries. Suprapubic cystostomy is favored by most for bladder drainage. Partial posterior urethral lacerations are managed with a urethral catheter placed coaxially over a guide wire under fluoroscopic control or with a suprapubic catheter. In complete posterior urethral lacerations, the management remains controversial. The injury is managed with primary realignment of the lacerated urethra or with suprapubic cystostomy alone. Stricture formation occurs with both techniques. However, the subsequent urethral stricture in patients with primary realignment tends to be less extensive. The advantage of suprapubic cystostomy alone, especially in an unstable patient, is its simplicity. The impotence and incontinence rates are thought to be related to the extent of injury and are the same for both techniques.

In women, a layer repair of the urethral and associated vaginal injuries is performed over a urethral catheter. The voiding phase of the repeat cystogram is essential in confirming complete urethral healing.

The Full-Bladder Dilemma

Emergency physicians in nontrauma centers may encounter patients with a urethral injury precluding bladder catheterization but with a full urinary bladder. Such a patient may have to be transferred many miles to reach a center with a urologic service. Spontaneous or conscious bladder contraction may ensue, with spillage of urine into the perivesical space, increasing the risk of infection. Guidewire-aided placement of a temporary suprapubic catheter into the bladder can alleviate this problem. Using the Seldinger-technique, a large-bore central venous catheter or cavity drainage catheter may provide temporary relief. The exploring needle is inserted perpendicularly about two finger breadths above the symphysis pubis. The guidewire is inserted when urine returns. The catheter selected should be long enough to coil within the bladder so that it remains in the lumen of the bladder when it is empty. Because the bladder may be displaced by a large hematoma or extravasated urine, it is advisable to inject a few milliliters of contrast material into the bladder while obtaining an x-ray to confirm that the catheter is actually in the bladder.

Testicular and Scrotal Injuries

The mobility of the testicle, cremaster muscle contraction, and the tough capsule of the testis (tunica albuginea) are responsible for the infrequent rate of injury to the testis. A direct blow to the testis impinging it against the symphysis pubis is the primary cause of blunt testicular injury. Blunt testicular injuries are either contusions or ruptures. Rarely, traumatic dislocation of the testicle to the inguinal canal has been reported. In testicular contusions or ruptures, the tunica vaginalis sac fills with blood (hematocele) and appears as a large, blue, tender scrotal mass. Penetrating injuries to the scrotum through the tunica vaginalis require exploration. Bilateral testicular injuries are often seen in penetrating trauma. Testicular ultrasonography studies with colored Doppler studies can help to delineate the extent of testicular trauma and are quite reliable in diagnosing ruptured testes.

Most testicular injuries can be managed conservatively with non-steroidal anti-inflammatory drugs, ice, elevation, scrotal support, and appropriate urologic follow up.

For more severe injuries, early exploration, evacuation of blood clots, and repair of testicular rupture tend to result in an earlier return to normal activity, decreased hematoma infection, and less testicular atrophy than does conservative management. Testicular salvage following penetrating trauma is on the order of 35 percent.²²

Scrotal skin avulsion is managed by housing the testicle in the remaining scrotal skin even though the reconstruction places the skin under tension. Usually the scrotum returns to nearly normal size within a few months. In complete scrotal skin loss, the testicles are placed in pouches in the inner thighs.

Injuries to the Penis

Injuries to the penis range from small contusions to degloving injuries or amputations. Self-inflicted injuries include vacuum cleaner injuries and blade injuries. Vacuum cleaners cause extensive injury to the glans penis and some loss of the urethra, requiring debridement of devitalized tissue and reconstruction. Amputation of the penis is managed by reimplantation or local repair. Reimplantation is preferable if the distal penis is in satisfactory condition, and the ischemia time is less than 12 to 18 h. Loss of penile skin by avulsion injury or burns is managed by split-thickness skin grafts after the denuded penis is clean and sterile. The avulsed skin should not be reappplied, for it invariably becomes necrotic and infected, and must be subsequently removed.

Traumatic rupture of the corpus cavernosum of the penis or fracture of the penis occurs when the erect penis impacts forcibly on a hard object (sexual partner's pubis or the floor), receives a direct blow, or is subjected to abnormal bending. A cracking sound is heard, followed by penile pain, immediate detumescence, rapid swelling, discoloration, and distention. Urethral injuries may accompany penile ruptures. Penile ruptures are managed by immediate surgical evacuation of blood clot and repair of the torn tunica albuginea of the corpus cavernosum and urethra.

Zipper injury to the penis is caused when the penile skin is trapped in the trouser zipper. Mineral oil and lidocaine infiltration are useful in freeing the penile skin from the zipper. Otherwise, wire-cutting or bone-cutting pliers are used to divide the median bar (or diamond) of the zipper, which causes the zipper to fall apart, freeing the penile skin.

Contusions of the perineum or penis, which can result from straddle or toilet seat injuries, are treated conservatively with cold packs, rest, and elevation. If the patient is unable to void, catheter drainage is elected.

and murders have risen by 59 percent since 1987. Penetrating trauma accounts for up to 82 percent of all vascular injuries to the extremities. Gunshot and shotgun wounds account for nearly 65 percent of penetrating vascular extremity injuries, and stab wounds account for approximately 15 percent. Of patients presenting with gunshot wounds, 20 to 40 percent have extremity involvement, either isolated or in combination with other injuries. In 1950, a patient with a penetrating extremity injury with vascular involvement had a 50 percent chance of leaving the hospital with an amputated limb. With recent advances in emergency care, vascular surgery, invasive radiology, and the science of thrombosis, penetrating extremity injury results in amputation in fewer than 5 percent.¹ Despite this improved diagnosis, there is still a 15 to 40 percent long-term morbidity due to other complications, such as nerve damage, fractures, wound infections, open joint injuries, and compartment syndromes.²

PATHOPHYSIOLOGY

Gunshot and stab wounds account for the largest percentage of penetrating extremity injuries. Gunshot and blast injuries often present a diagnostic and management dilemma. A basic understanding of wound ballistics will enable astute clinicians to better plan the clinical management of patients who sustain a gunshot wound to an extremity. Diagnostic and treatment modalities as well as outcome differ with the type and severity of the injury. Although the damage from a stab wound can be relatively predictable with a good knowledge of clinical anatomy, the tissue damage inflicted by a missile or blast depends on a variety of factors (see Chap. 264).

DIAGNOSIS AND MANAGEMENT

After the initial trauma resuscitation and primary and secondary surveys are complete, specific points of the victim's past medical history should be examined: preexisting vascular and neuromuscular deficits, and the events surrounding the injury, such as the type of gun and number of shots. An extremely careful and thorough physical examination is needed to identify significant injuries rapidly and to determine whether immediate surgical intervention is necessary or which, if any, diagnostic studies are indicated. This may be challenging in the presence of other serious trauma or distracting injuries.

The presentation of penetrating vascular injury varies widely. Prompt recognition of arterial injury is one of the fundamental goals of management. The presence and volume of the distal pulses in the affected extremity should be noted and compared with the unaffected limb. Ankle-brachial indices (ABIs) should be calculated on the affected and unaffected limbs (method described below). The color, temperature, and capillary refill time are important clinical indicators of more subtle injury to underlying vessels. Examination should also look for signs of compartment syndrome. Capillary refill alone is an unpredictable marker of vascular injury but may be useful in conjunction with other modalities. Only a small minority of patients (fewer than 6 percent) will present with classic "hard" signs of arterial injury (Table 263-1). These patients require expeditious operative management or, under certain circumstances, angiography (Figure 263-1). A surgeon should be involved in the management of these patients as soon as possible. Patients with "soft" signs (Table 263-1) of arterial vascular trauma can usually be managed without surgical intervention on an inpatient surgical service. Controversy surrounds the management of the patient with a wound in proximity to a major vascular structure but without clinical evidence of arterial injury. Historically, patients with these types of injuries were all surgically explored, which yielded a large number of negative exploratory surgeries, and thus angiography became popular. Angiography based on proximity alone yields abnormalities in 10 to 20 percent of the cases, with less than 2 percent requiring surgical intervention. Current practice regarding penetrating injuries in proximity to major vessels without any signs of

PENETRATING TRAUMA TO THE EXTREMITIES

Alan M. Kumar
Richard D. Zane

Emergent management of penetrating extremity injuries is an evolving and controversial subject. Recent advances in surgical technique enable arterial repair with an extremely low rate of postoperative thrombosis, making the recognition and rapid treatment of arterial injury of paramount importance. Associated injury to soft tissue, nerve, and bony structures is now the primary determinants of limb salvage. Emergency physicians play a crucial role in the management of penetrating extremity injuries by identifying injuries early and promptly initiating care crucial to limb rescue. Unnecessary delays in treatment can lead to irreversible limb ischemia and subsequent limb loss.

EPIDEMIOLOGY

In the past 10 years, there has been a surge in the number of violent crimes associated with firearm usage. Gun-related assaults, robberies,

vascular injury is to observe patients with clinically silent arterial injury. The natural course in these cases is likely benign, and these patients can be safely observed with serial examinations.

Duplex ultrasound has become a popular modality in the management of proximity injuries without evidence of arterial injury. Recent advances in duplex ultrasonography have shown highly accurate rates of detecting occult arterial injury (see below). Some clinicians use duplex ultrasound to distinguish between patients who require observation and those who can safely be discharged home.

Although patients with venous trauma can bleed profusely, management by either ligation or reanastomosis often yields similar results.⁴ Asymptomatic venous injury rarely results in long-term morbidity. During the initial trauma resuscitation, attempts should not be made to clamp or ligate bleeding vessels in an attempt to control bleeding. Nerves are bundled with vascular structures and can be easily damaged by blind clamping or ligation. Profuse bleeding should be initially controlled with direct pressure.

Although arterial injury is the most dramatic result of penetrating extremity injury and represents the most immediate life threat, injuries

to major nerves are the most likely to lead to long-term disability. Fortunately, 70 percent of peripheral nerve injuries noted during the initial examination recover completely within 6 months of the initial injury. A neuromuscular examination of the extremities should indicate both muscular and sensory function (Table 263-2) and check for evidence of compartment syndrome. Patients with suspected nerve, orthopedic, vascular injury or compartment syndrome should be immediately evaluated by surgical subspecialists.

The size and shape of the wounds, and soft tissue and obvious bony deformities, should be noted and thoroughly examined. Pain on palpation or movement of an extremity is suspicious for an underlying fracture. Penetrating trauma near a joint should be evaluated thoroughly for damage to the joint capsule, as associated long-term morbidity is significant. Radiologic evidence of air in a joint is evidence of joint penetration. Patients with obvious bony or joint capsule injury should be evaluated by an orthopedic surgeon. The majority of orthopedic surgeons will undertake arthroscopic exploration and "wash out" an involved major joint. Joint sepsis and destruction, rapid chondrolysis, and loss of anatomic contours can lead to long-term morbidity in the form of posttraumatic degenerative arthritis and decreased or total loss of flexibility. Metal fragments left in the joint space may dissolve in the synovial fluid, resulting in lead toxicity. Patients with penetrating injury proximal to or overlying a major joint without obvious joint penetration and without fracture can be splinted and discharged with 24 h orthopedic follow-up. Most orthopedic authors recommend discharging these patients on oral antibiotics, although the rationale has not been clearly established. Bony fractures as a result of penetrating injury are treated as open fractures. The injury is surgically debrided and the patient admitted for intravenous antibiotics.

Wound management is of great importance in the proper healing of penetrating injuries. Careful treatment is, however, just one important factor in decreasing the rate of wound infection. Bacterial inoculum, tissue devitalization, blood supply, time to presentation and treatment, presence of foreign bodies, and host immune status all play a role in the final outcome. Irrigation of wounds with either normal saline or

1% povidone-iodine solution at high pressure until removal of all visible contaminants or at least 250 mL is recommended to reduce bacterial counts. More vigorous and lengthy irrigation might be needed for heavily contaminated wounds. In wounds older than 3 to 4 h, host defenses can actually prevent further reduction in bacterial counts and gentle scrubbing of the wound is recommended.

Soft tissue foreign bodies present a special dilemma. If the wound is not completely visualized, radiographic studies are often necessary. Materials such as glass, metal, gravel, or bone are usually visible on plain films and can be localized using this technique. Organic materials such as wood are more difficult to isolate using this method and ultrasound has become an increasingly useful modality in their localization. However, object size, density compared to surrounding tissue, orientation, depth, and the presence of devitalized tissue and air can limit the effectiveness of either of these radiographic techniques. CT scanning is more accurate in finding both radiolucent and opaque foreign bodies. Once localized, the decision to remove a foreign body is dependent on many factors. The exploration of tissue necessary to find the foreign body can further damage tissue and increase risk of infection. The size of the object, along with its composition, should also be considered. Organic materials tend to be more reactive and have a higher risk of causing infection. Inert substances such as bullet fragments and glass are less likely to cause these reactions. The chance that a bullet may migrate into vital structures or the possibility of embolism if it is near a vessel makes removal of the foreign body more important.

The decision to close a wound depends on the presentation and degree of contamination. If it is associated with bony injury, the wound should be considered an open fracture and the patient admitted for surgical debridement. Wounds that have little contamination and

are amenable to irrigation can be closed if close follow-up can be arranged. Patients with delayed presentations, contaminated wounds, soft tissue foreign bodies, or extensive tissue destruction would likely benefit from delayed primary closure after 72 to 96 h if there are no signs of infection at that time. The role of antibiotics remains controversial in penetrating extremity trauma. They are not beneficial in low risk injuries but may have a role in special situations such as hand injuries, patients with compromised immune systems, significant tissue damage or contamination, and joint or bony involvement.⁵

DIAGNOSTIC MODALITIES

Radiographic Studies

Plain films, including anteroposterior and lateral views, of the involved extremities should be obtained in all cases. Oblique views may also offer additional information. **It is important that the joints above and below the suspected injury site be imaged.** Five general types of fracture patterns are created from bullets (Figure 263-2). A drill hole pattern from penetration of cancellous bone is often seen in sites such as the proximal humerus, pelvis, and distal femur. These fractures have less comminution than those in cortical bone because cancellous bone is more porous and less dense. Unicortical fractures of the metaphysis on long bones are often seen with bullet impact on a tangential plane. The majority of gunshot fractures of the diaphysis are comminuted, and the degree of comminution depends on the amount of energy transfer from the penetrating missile. Spiral fractures distant from the site of impact on the bone can occur if the bone is under a degree of torsional stress. There have also been reports of

FIG. 263-2. Types of fracture patterns created by bullets: drill hole, unicortical, distant spiral, comminuted. The fifth type seen is a simple fracture.

simple fractures of long bones caused by indirect damage from the temporary cavity. It is also important to note whether a joint has been penetrated, because this complication changes patient management. **In the case of shotgun or blast injury, it is important to image the extremity distal to the injury** in order to detect any pellets that may have embolized (Figures 263-3A and B).

Computed tomography is considered helpful in selected cases before definitive orthopedic care. It can help diagnose bony pathology and determine if intraarticular fractures, fragments, or foreign bodies are present.

Magnetic resonance imaging is not commonly used for penetrating extremity trauma. Angiography can be used to delineate the extent, nature, and location of vascular injuries with special situations such as shotgun wounds, multiple or severe fractures, chronic vascular disease, thoracic outlet wounds, or extensive soft tissue injury. The widespread availability and accuracy of angiography led it to become the

"gold standard" in the evaluation of patients with wounds in proximity to major neurovascular bundles. Arteriography for the evaluation of proximity injuries in patients without hard signs of injury reveals normal results in 80 to 90 percent, with a complication rate of 1 to 2 percent from the procedure. Recent studies have shown that occult vascular injuries can exist without hard clinical findings in up to 23 percent of patients. Among these, however, fewer than 2 percent have surgically important lesions. Still, with observation and a careful examination, positive findings will eventually be more evident and the wounds subsequently repaired without increased morbidity.^{6,9}

The algorithm presented in Figure 263-1 outlines the approach to vascular injuries. In the presence of hard signs of vascular injury on clinical examination, immediate surgery is indicated in some conditions, without a preoperative angiogram. However, certain injuries are still best evaluated by angiography prior to surgical intervention. The need for angiography in patients with soft signs of vascular injury is still a matter of some debate among surgeons and radiologists. However, current practice in most centers is to observe patients with soft signs and conduct serial examinations. Angiography and surgery are delayed until there is clinical evidence of arterial injury.

Digital subtraction angiography has also been used in evaluation of vascular trauma with accuracy similar to standard techniques but is less reliable in detecting intimal disruption. The test requires a cooperative patient, because it is extremely sensitive to motion artifact.³

Ankle Brachial Indices

Doppler devices are used to determine wrist or ankle brachial indices (ABIs). Diagnostic accuracy has been reported to be as high as 95 percent, but sensitivity and specificity vary depending on whether the classification of abnormal is set at a ratio of 1.0 or 0.9.^{9,10} This test does not reliably detect nonocclusive arterial disease, such as intimal flaps and pseudoaneurysms. It can augment the clinical examination by objectively confirming the subjective impression of a diminished pulse in a patient under observation. To perform accurate ABIs, it is important to place the patient in supine position and measure the systolic blood pressure in all four extremities. To measure an ankle systolic pressure, a standard adult blood pressure cuff should be snugly wrapped around the ankle just above the malleoli. While using the Doppler flowmeter to monitor the signal from the posterior of the anterior tibial artery, distal to the cuff, inflate the cuff to a pressure approximately 30 mm Hg above the systolic pressure to occlude flow temporarily. As the cuff is slowly deflated (2 to 5 mm Hg/s), the pressure at which the Doppler flow signal is heard should be noted and recorded as the ankle systolic pressure. To assure accuracy, the upper extremity systolic blood pressure should be measured by using a Doppler flowmeter, as well. An ABI is then calculated by dividing the ankle systolic blood pressure by the greater of the two systolic upper extremity blood pressures. An ABI of greater than 1.0 is normal. An ABI of 0.5 to 0.9 is indicative of injury to a single arterial segment. An ABI of less than 0.5 is indicative of severe arterial injury or injury to multiple arterial segments. A difference of greater than 20 mm Hg between the upper extremity blood pressures is indicative of upper extremity arterial injury. Underlying conditions, such as preexisting peripheral vascular disease or severe hypothermia, can also affect the accuracy of the ABI.

Duplex Ultrasonography

Duplex ultrasonography has a diagnostic accuracy of 96 to 98 percent and can image extremity vessels with as much resolution as contrast angiography. Advantages over angiography include an increased safety profile and rapid results. However, it is highly operator dependent and has not been tested in patients with severely injured extremities with open wounds or fractures, large hematomas, bulky dressings, or traction devices.^{1,3,10}

FIG. 263-3. A. Gunshot wound to the shoulder and axilla. B. Actual embolization of shotgun pellet, illustrating importance of obtaining images of the extremity distal to such injuries.

DISPOSITION

Patients with hard signs of arterial injury are not a diagnostic dilemma. These patients require surgical intervention or, at the very least, expedient surgical evaluation and angiography. Patients with soft signs of arterial injury require inpatient observation. Patients with penetrating extremity injury, no signs of arterial injury, no bony or nervous injury, minimal soft tissue defect, and no signs of developing compartment syndrome can be safely discharged home with close follow-up after a period of observation and serial examinations. There is no consensus on the ideal observation time, but the current literature describes times from 3 to 12 h. Wound exploration in the emergency department should be reserved for those patients with suspected foreign bodies in the wound, for ligamentous involvement, or for control of minor venous bleeding. Wound exploration to control arterial or major venous bleeding should be done in the operating room. The general principles of wound management, including tetanus prophylaxis, apply here. Although controversial, there is no proven rule for prophylactic antibiotics unless a wound is contaminated or patients have an underlying preexisting condition that would predispose to infection.

WOUND BALLISTICS

Jeremy J. Hollerman
Martin L. Fackler

GENERAL CONCEPTS

The medical literature is full of erroneous articles classifying gunshot wounds based on bullet velocity. Other bullet and tissue characteristics are at least as important as velocity.^{1,3} Bullet *mass*, which is related to diameter and length, is a major determinant of how deeply the bullet will penetrate tissue. Bullet *construction* (such as whether the bullet is solid lead with no bullet jacket, is partially jacketed, or has a full metal jacket) is a primary determinant of whether the bullet will deform or fragment. Bullet shape and center of mass (which determine how soon it will yaw in its path through tissue), the *thickness of the body part*

wounded (determining whether the bullet has a long enough path through tissue to deform or yaw) (Figure 264-1), *tissue type* struck (e.g., femur versus lung), tissue elasticity, density, specific gravity, and internal cohesiveness [which determine how well the tissue will withstand tissue stretch (temporary cavitation) forces] are all important, in addition to bullet *velocity*, in determining the nature of the wound produced. The amount of kinetic energy "deposited" or "retained" in a victim wounded by a projectile is not a reliable predictor of wound severity,⁴ and muzzle energy is not a reliable indicator of bullet performance.

An understanding of wound ballistics enables physicians to evaluate and treat missile wounds without repeating the errors of conventional wisdom. Based on common misconceptions about wound ballistics, many papers have suggested harmful and unnecessary treatment for gunshot wounds. An example of such an unnecessary and harmful recommendation is that for mandatory surgical excision of the tissue surrounding the bullet track (the path of the projectile through tissue) whenever an extremity wound is caused by a high-velocity bullet. This is based on the belief that these tissues will become necrotic. Clinical experience and research show this to be false.⁵

WOUNDING POTENTIAL

Every moving bullet has a maximum wounding potential determined by its mass and velocity. Bullets of equal wounding potential may produce wounds of very different severity depending on bullet shape, internal and external construction, and which tissues they traverse.

Bullets with equal wounding potential often do not produce similar wounds. A heavier, slower bullet crushes more tissue but induces less temporary cavitation; most of the wounding potential of a lighter, faster bullet is likely to be used up forming a larger temporary cavity, but this bullet leaves a smaller permanent cavity (crushes less tissue).^{4,6} The heavier, slower bullet causes a more severe wound in elastic tissue than the lighter, faster bullet, which uses up much of its wounding potential producing tissue stretch (temporary cavitation). This tissue stretch may be absorbed with little or no ill effect by elastic tissue such as lung or muscle. In less elastic tissue such as liver or brain, the temporary cavity produced by the lighter, faster bullet can produce a more severe wound. Penetration depth will be less with the lighter, faster bullet, and critical structures such as the heart may not be reached.

MECHANISMS OF WOUNDING

Both missile and tissue characteristics determine the nature of the wound. Missile characteristics are partly inherent (mass, shape, and construction) and are partly conferred by the weapon (longitudinal and rotational velocity). Tissue characteristics (elasticity, density, and anatomic relationships) also strongly affect the nature of the wound. The severity of a bullet wound is influenced by the bullet's orientation during its flight through tissue and by whether the bullet fragments⁴ and/or deforms (into the typical mushroom shape of expanding hollow-point or soft-point bullets).

Two major mechanisms of wounding occur: the *crushing* of the tissue struck by the projectile (forming the permanent cavity) and the radial *stretching* of the projectile path walls (forming a temporary cavity) (see Figure 264-1). In addition, a sonic pressure wave precedes the projectile through tissue. The sonic pressure wave plays no part in wounding.⁷

Crushing of Tissue

A missile crushes the tissue it strikes, thereby creating a permanent wound channel (permanent cavity). If the bullet is traveling with its pointed end forward and its long axis parallel to the longitudinal axis

SECTION 22 • TRAUMA

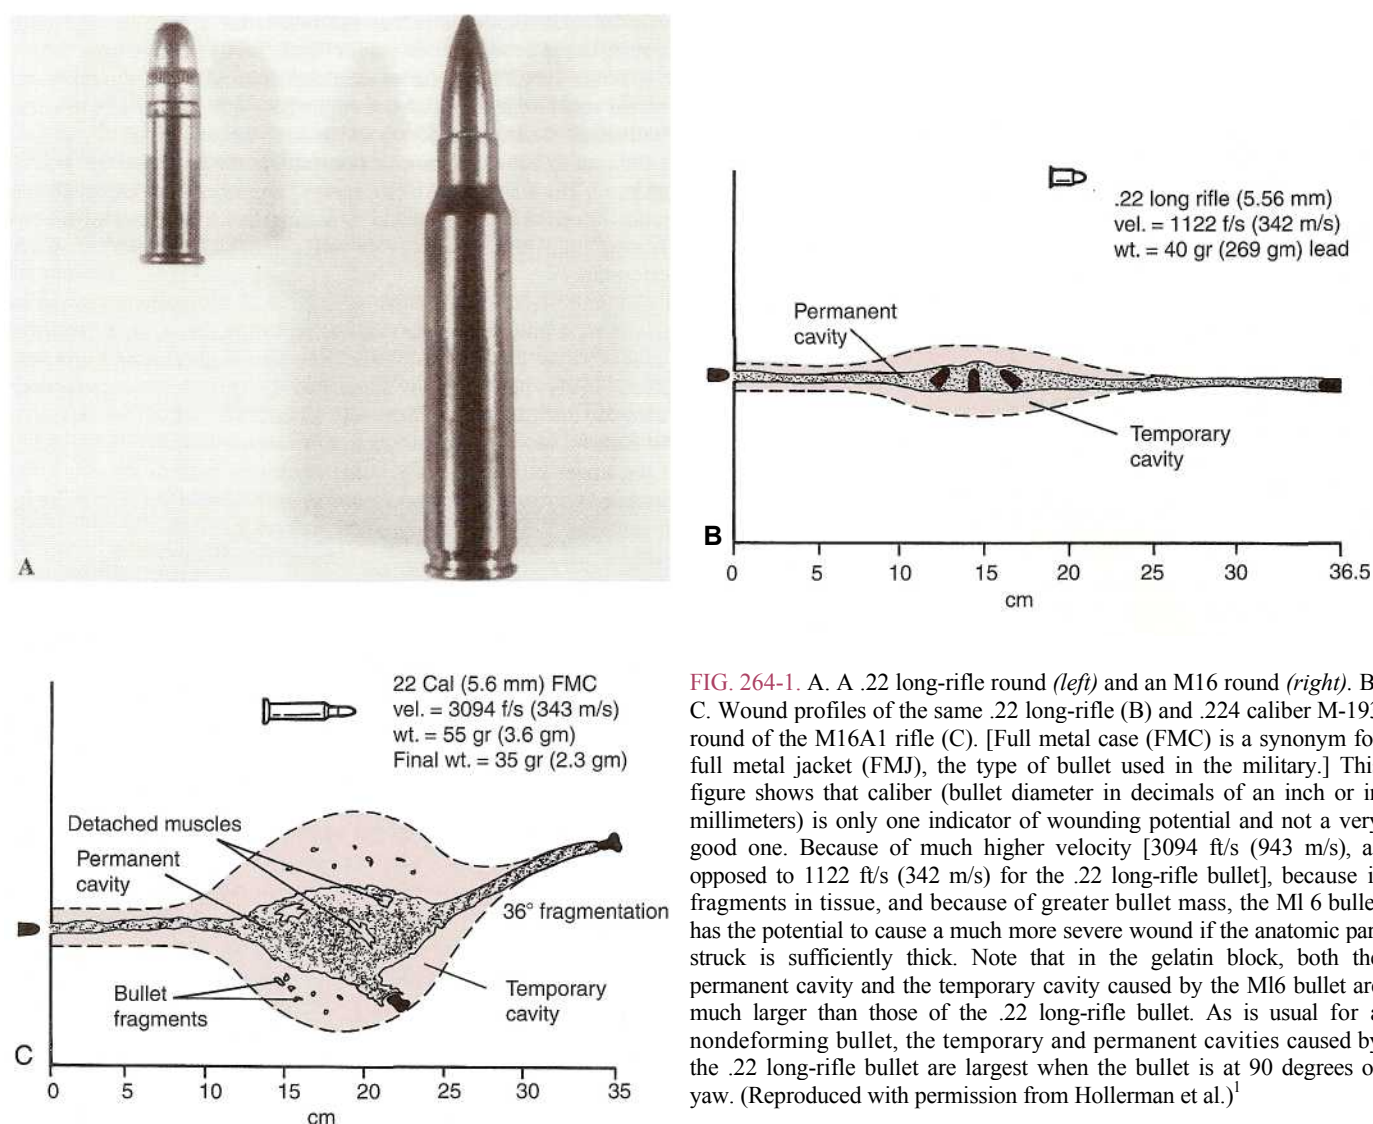

FIG. 264-1. A. A .22 long-rifle round (left) and an M16 round (right). B, C. Wound profiles of the same .22 long-rifle (B) and .224 caliber M193 round of the M16A1 rifle (C). [Full metal case (FMC) is a synonym for full metal jacket (FMJ), the type of bullet used in the military.] This figure shows that caliber (bullet diameter in decimals of an inch or in millimeters) is only one indicator of wounding potential and not a very good one. Because of much higher velocity [3094 ft/s (943 m/s), as opposed to 1122 ft/s (342 m/s) for the .22 long-rifle bullet], because it fragments in tissue, and because of greater bullet mass, the M16 bullet has the potential to cause a much more severe wound if the anatomic part struck is sufficiently thick. Note that in the gelatin block, both the permanent cavity and the temporary cavity caused by the M16 bullet are much larger than those of the .22 long-rifle bullet. As is usual for a nondeforming bullet, the temporary and permanent cavities caused by the .22 long-rifle bullet are largest when the bullet is at 90 degrees of yaw. (Reproduced with permission from Hollerman et al.)¹

of flight (0 degrees of yaw, the angle between the long axis of the bullet and its path of flight), it crushes a tube of tissue approximately equal to its diameter. When the bullet yaws to 90 degrees, the entire long axis of the bullet strikes tissue. The amount of tissue crushed may be three times greater than at 0 degrees of yaw.

When striking soft tissue with sufficient velocity, soft-point and hollow-point bullets deform into a mushroom shape. This increases surface area and the amount of tissue crushed. For most big-game hunting, such bullets are mandated by law. This is to increase the probability of prompt lethality rather than the creation of a disabling but nonlethal wound causing an animal prolonged suffering. If the mushroomed diameter is 2.5 times greater than the initial diameter of the bullet, the area of tissue crushed by the bullet is 6.25 times greater than the amount that would have been crushed by the undeformed bullet.

Bullet fragmentation also increases the volume of tissue crushed.^{1,4} After bullet fragmentation, bullet surface area is increased, and much more tissue is crushed. For large handgun (e.g., .44 magnum) and rifle bullets, the striking of bone is one of the causes of early bullet fragmentation.

Comminuted fracture may be created by rifle and large handgun bullets striking bone. Bone fragments can become secondary missiles, crushing tissue. Many handgun bullets are unable to fragment bone

significantly. When a large bone is struck, it is likely that the bullet will expend its wounding potential in the victim and will not exit.

Bullet fragments and secondary missiles, such as bone fragments, teeth, or coins propelled by contact with the bullet are likely to increase the severity of the wound. Multiple perforations weaken tissue and create focal points for stress (stress risers). Tissue tears are particularly likely to occur at stress risers during temporary cavitation stretch.⁴

Unjacketed lead bullets cannot be driven faster than about 2000 ft/s (610 m/s) without some of the lead stripping off in the barrel. This is avoided if a jacket made of a harder metal (such as copper or a copper alloy) is used to surround the lead. The jacket of a military bullet completely covers the bullet tip (a full metal jacket). Civilians often use hollow-point or soft-point bullets. Hollow-point bullets have a hole in the jacket at the bullet tip, and soft-point bullets have some of the lead core of the bullet exposed at the bullet tip. These constructions weaken the bullet tip, causing it to flatten on impact. This flattening often greatly exceeds bullet diameter, resulting in a mushroom-shaped projectile.

The hollow-point and soft-point bullets used by civilians are often more damaging to tissue than are military bullets fired from rounds otherwise configured identically.^{1,4,8} Because of this, wounds pro-

duced by civilian hunting rifles, shotguns, and large-caliber handguns are usually more severe than wounds produced by military-rifle bullets of the same mass and velocity.⁸

Hollow-point and soft-point bullets either deform into a mushroom shape or stay undeformed. Up to one-third of hollow-point and soft-point handgun bullets fail to deform into a mushroom shape, usually due to insufficient bullet velocity or an excessively stiff or thick bullet jacket that prevents deformation.

When the tip of a hollow-point bullet is plugged with material such as clothing or drywall, bullet expansion into a mushroom shape in tissue is usually delayed and sometimes prevented. This causes deeper penetration of tissue, sometimes resulting in a perforating wound (having both an entrance and an exit). This may result in the injury of bystanders. Some recent handgun bullets have designs attempting to overcome this problem.

Projectiles penetrate more deeply as projectile velocity is increased, but only up to the point where velocity becomes sufficiently high to deform the projectile. Penetration decreases markedly from that point on. The greater the bullet diameter expansion from mushrooming, the less is the depth of penetration.⁹

There is a critical range of velocity for each handgun hollow-point and soft-point bullet within which the bullet may perform as expected. Below this velocity range, the bullet will have insufficient velocity to mushroom on impact, and at velocities above this range, the bullet may fragment after impact, resulting in many light bullet pieces crushing tissue at a superficial depth.

Military full metal jacket bullets do not flatten at the bullet tip; i.e., they do not mushroom. Sometimes they can break and fragment as a result of yawing to 90 degrees. The stress on the bullet as its long axis strikes tissue causes the sides of the bullet to flatten as if the bullet had been squeezed in a vise. If the bullet breaks, it usually will do so at the cannelure, a circular groove around the bullet where it is crimped into the cartridge case. Although the M-193 military bullet of the M16 rifle fragments in soft tissue wounds with a characteristic pattern depending on range,¹⁰ most other full metal jacket military bullets, such as those fired from the AK-47, AK-74, and the NATO 7.62-mm rifle (U.S. version), do not fragment unless they strike a large bone.

If a bullet is jacketed, the bullet jacket usually cannot be distinguished from the lead core on standard radiographs because the entire bullet is metallic density. Sometimes, as the bullet deforms or fragments, the bullet jacket separates from the bullet and is visible on a radiograph. It is often less dense than the bullet fragments and may have a distinctive shape.

In extremity wounds, when a radiograph reveals an undeformed bullet lying in the soft tissues and no fracture is present, tissue disruption is usually minor. If a major vessel or nerve is divided, however, even a simple wound can have a severe effect on the patient.

Wounding is like real estate: Location is the most important factor. A bullet of low wounding potential can cause a severe wound if it passes through a vital structure such as the spinal cord.

Temporary Cavitation (Tissue Stretch)

Fired from an appropriate, well-designed weapon, a bullet flies in air with its nose pointed forward; it yaws only 1 to 3 degrees. Yaw occurs around the bullet's center of mass. In pointed rifle bullets, the center of mass is behind the midpoint of the bullet's long axis. Although the bullet's most naturally stable in-flight orientation would be with its heaviest part (its base) forward, for aerodynamically efficient flight, it must fly point forward.

During flight, a bullet is stabilized against yaw by the spin imparted to it by the spiral grooves (rifling) in the gun barrel. The longer (and heavier) the bullet in relation to its diameter, the more rapidly it must be rotated to avoid significant yaw in flight. A gun barrel in-

tended to fire a heavier bullet has rifling that makes a full turn in fewer inches of barrel length than the rifling in a barrel intended for a shorter, lighter bullet of the same caliber. This will cause a faster rate of bullet spin.

A gun with a shorter barrel generally will produce a bullet of lower velocity than would a weapon with a longer barrel when firing the same round. With shorter barrel length, the expanding gasses of the burning gunpowder have less time to accelerate the bullet before they are discharged into the atmosphere. A .22 long-rifle round fired in a rifle will produce a bullet with up to 300 ft/s more velocity than would the same round fired in a handgun.

Although the bullet's spin is adequate to stabilize it against yaw in its flight through air, it is not adequate to stabilize it in its path through tissue because of the higher density of the medium. If it does not deform, a pointed bullet eventually yaws to a base-forward position (180 degrees of yaw). Expanding bullets lose the physical stimulus to yaw because, after mushrooming, their heaviest part is forward.

As a bullet passes through 90 degrees of yaw or after it deforms into a mushroom shape, it is crushing its maximal amount of tissue (unless it fragments, which will crush more). It is slowed down rapidly as its wounding potential is used up. The bullet creates a splash-type force in tissue, which spreads out radially. This force creates the temporary cavity. This aspect of the wounding process is analogous to the splash of a diver entering the water.

If a diver enters the water very straight and pointed forward (similar to a bullet at 0 degrees of yaw), the splash may be minimal. If the diver does a belly-flop (similar to a bullet at 90 degrees of yaw), a large splash is induced. In tissue, this splash, the temporary cavity, produces localized blunt trauma.⁶

The maximal size of the temporary cavity occurs several milliseconds after the bullet has passed through the tissue. Because forces follow paths of least resistance, temporary cavitation is likely to be asymmetric and spread out through tissue planes.

The temporary cavity caused by common handgun bullets is generally too small to be a significant wounding factor in all but the most sensitive tissues (brain and liver). Center-fire rifle bullets and large handgun bullets (e.g., .44 magnum) often induce a large temporary cavity [10- to 25-cm (4- to 10-in.) diameter] in tissue. This can be a significant wounding factor depending on the characteristics of the tissue in which it forms.

Near-water-density, less elastic tissue (such as brain, liver, or spleen), fluid-filled organs (including the heart, bladder, and gastrointestinal tract), and dense tissue (such as bone) may be damaged severely when a large temporary cavity displaces them or forms within them. More elastic tissue (such as skeletal muscle) and lower-density elastic tissue (such as lung) are less affected by the formation of a temporary cavity. Because of these tissue differences, transmitted blunt trauma from temporary cavitation caused by a bullet traveling 800 to 950 m/s can cause a more severe pulmonary contusion when the bullet traverses the chest wall musculature than the pulmonary contusion it would have caused if it passed through the lung.

Although the formation of a large temporary cavity often has devastating effects in the brain or liver, its effect in wounds of the extremities frequently has been exaggerated.¹¹ Fracture of large bones not hit by the bullet and tearing of major vessels or nerves by the temporary cavity are mentioned often in the literature but are rare in clinical experience. This includes a systematic review of 1400 rifle wounds sustained in the Vietnam conflict and analyzed in the Wound Data and Munitions Effectiveness Team (WDMET) study (R. F. Belamy, personal communication). Most of the permanent damage done in wounds of the extremities is the result of structures being hit by the intact bullet, bullet fragments, or secondary missiles. As in all blunt trauma, shear forces develop and tear structures at points where one side is fixed and the other side is free to move. The temporary cavity is no exception.⁶ In the unlikely event that the blunt trauma caused by

SECTION 22 • TRAUMA

the temporary cavity tears a vessel wall, this is particularly likely to occur at the vessel origin.

BALLISTIC PROPERTIES AND THE WOUND PRODUCED

Animal experiments using military-rifle bullets⁵ have clearly disproved the assertion that all tissue exposed to temporary cavitation is destroyed. Not only does the 14-cm-diameter temporary cavity produced by an AK-74 bullet not destroy a great amount of muscle, but the sizable stellate exit wound it causes in the uncomplicated thigh wound ensures excellent wound drainage, which assists healing.⁵ A history that the wound was caused by a high-velocity bullet does not mandate radical excision of the wound path."

The characteristics of the wounded tissue; the thickness of the body part; the point in the path of the bullet at which deformation into a mushroom shape or yaw or fragmentation occurs; and other factors strongly influence the wound produced.

Experiments with ballistic gelatin (which reproduces the projectile deformation and penetration depth of living animal muscle) have shown that most full metal jacket rifle bullets yaw significantly only at tissue depths greater than the diameter of human extremities.

In the first 12 cm (the average thickness of an adult human thigh) of a soft tissue wound path, there is often little or no difference between the wounding effect of low- and high-velocity bullets when the high-velocity bullet is of the military full metal jacket type. This is particularly true of the relatively heavier military-rifle bullets such as those fired by the AK-47 and NATO 7.62-mm (U.S. version) rifle. A wound of an extremity caused by an AK-47 bullet that does not hit bone is often similar to a handgun bullet wound. No matter how high its velocity, if a nondeforming, heavy bullet does not break, fragment, or hit a large bone, it may exit an extremity with much of its wounding potential unspent. These same bullets are often lethal in chest or abdominal wounds because the trunk is thicker than an extremity and allows the bullet a sufficiently long path through tissue to yaw. Maximal temporary cavitation induced by the AK-47 bullet usually occurs at a tissue depth of 28 cm, much greater than the diameter of a human extremity.

A soft-point or hollow-point bullet fired from a civilian center-fire rifle deforms soon after entering tissue and produces a much more severe extremity wound than will a military full metal jacket bullet that does not break and fragment.

The more recently developed, smaller-caliber AK-74 fires a bullet that is lighter than the AK-47 bullet and yaws earlier.¹² Its maximal temporary cavity occurs at a tissue depth of 11 cm. Extremity wounds from the AK-74 can be expected to be more severe than those from the AK-47.¹² The lighter, smaller AK-74 round allows a soldier to carry many more rounds of ammunition. This was the primary motivation for development of the M16 and the AK-74.

Caliber

Caliber (bullet diameter in decimals of an inch or in millimeters) is only one indicator of wounding potential but not a very good one (see Figure 264-1). Caliber indicates bullet diameter but not bullet length and therefore does not disclose bullet mass. Caliber also is independent of bullet velocity and bullet construction.

Unfortunately, commonly used weapon and bullet designations are often misleading. As an example, the .38 special and the .357 magnum use bullets that have the same diameter [.357 in. (9.07 mm)] (Table 264-1). The longer cartridge case of the magnum can hold more powder, giving the bullet higher velocity and greater wounding potential.

Gunshot Fractures

Handgun wounds of the extremities yield characteristic fracture patterns. Frequently seen are divot fractures of cortical bone, drill-hole

fractures, butterfly fractures, and double butterfly fractures.³ Nondisplaced fracture lines sometimes radiate from these defects. These usually heal well. The bullet hole itself can act as a stress riser. Spiral fractures extending proximally or distally from the bullet hole may result from the dissipation of stress forces at the bullet hole. Occasionally, remote spiral fractures at some distance proximal or distal to the bony gunshot wound also occur, probably because of the presence of stress risers, such as vascular channels in the bone, and the fact that the bone was under load and often torsional stress at the time of impact.¹³

In gunshot fractures from rifles and large handguns, a greater extent of comminution may be seen. These fractures often have complications because of the soft tissue damage these bullets cause.³ The vascular compromise associated with these comminuted gunshot fractures increases the likelihood of delayed union or nonunion of the fracture. Wound infections are more common in this group. Early fasciotomy to prevent compartment syndrome is important, when needed.

At some hospitals, outpatient treatment is being used successfully for extremity fractures caused by handguns if no significant neurologic or vascular compromise has occurred.

Trunk Wounds

Bullets are not sterilized by the heat of firing. They can carry bacteria from the body surface or body organs, such as a perforated colon, deep into the wound.

In trunk wounds, an analysis of the bullet path is mandatory to determine whether a laparotomy is needed. Two radiographs in planes separated by 90 degrees, computed tomography (CT), clinical examination, and peritoneal lavage are all useful. Abdominal CT is more accurate if performed before peritoneal lavage. If peritoneal penetration by a bullet is suspected, laparotomy is indicated. The morbidity and mortality rates of an exploratory laparotomy that shows no significant intra-abdominal injury are low compared with those of missed intestinal injury. CT is useful, especially when an exclusively body wall or retroperitoneal path is suspected. CT has largely replaced excretory urography as the preferred means of evaluating the urinary tract after penetrating trauma.

Any bullet wound below the nipple line should raise the question of whether the diaphragm or abdomen has been penetrated. CT sometimes can be used to make this determination. Laparotomy is required if peritoneal penetration cannot be excluded.

Whenever a gunshot wound traverses the midline of the neck or the mediastinum, perforation of the esophagus should be suspected. Esophageal evaluation should not be overlooked after angiographic evaluation of the neck or chest.

Head Wounds

In skull wounds, as elsewhere in bone gunshot fractures, inward beveling of the calvarial defect at the bullet entrance and outward beveling of the skull at the exit wound are typical.^{2,14} This is due partly to the geometry of the skull and partly to the bullet-bone interaction. Characteristic fracture patterns of the skull can be used to identify entrance and exit wounds.¹⁴ When there is a cranial exit wound, skull fractures propagate across the calvarium faster than the bullet travels through the brain, producing characteristic patterns of fracture. These fracture patterns sometimes allow differentiation of entrance and exit wounds.¹⁴ Radial fractures often spread out in a star pattern from the entrance and to a lesser extent from the exit holes in the skull. Concentric heaving fractures may occur, connecting the arcs of the radial fractures around both the entrance and exit holes, if sufficient temporary cavitation forces are generated inside the brain to cause significant outwardly directed tissue splash forces inside the skull, pushing

Note: Often, both the numerical designation associated with the bullet and the cartridge case do not reflect exact measurements. As an example, the 44 Remington Magnum Pistol cartridge is 0.456 inch in diameter at its distal end and uses a bullet with a 0.43-inch diameter.²⁵ Both the .38 special and the .357 magnum use bullets that have the same diameter [0.357 in (9.07 mm)]. These bullets are often exactly the same weight. When trying to determine bullet type from a radiograph, in addition to correcting for magnification or deformation, one must look up actual bullet diameter rather than relying on the bullet name for its size. *Abbreviation:* ACP = Automatic Colt Pistol. *Sources:* Adapted from refs. 24 and 25.

out the calvarium.¹⁴ Because a fracture will not cross a preexisting fracture line, the temporal sequence of the occurrence of the fractures sometimes can be determined from the pattern of the fractures.

Brain, whose tissue properties include near-water density, very little elasticity, and poor tissue cohesiveness, is extremely sensitive to

temporary cavitation forces. When disrupted by such forces, severe brain injury often results. In addition to the relative lack of elasticity of brain tissue, its enclosure in the rigid cranial vault magnifies brain disruption by temporary cavitation forces.

Pellet Wounds

Compared with a pointed rifle bullet, spherical pellets slow rapidly in their flight through air or tissue. The entire wounding potential of a shot pellet at its entrance velocity is likely to be delivered to the target tissue, often with no exit wound. At close range (less than 3 m), shotgun pellets remain tightly clustered. Therefore, shot pellet size makes little difference because the entire load of the pellets functions as a unit, with a velocity virtually equal to muzzle velocity. Shotgun wounds at ranges of less than 5 m consist of multiple parallel wound channels. This grossly disrupts the blood supply to tissue between the wound channels.

The most severe civilian firearm wounds typically seen are those inflicted by a shotgun from close range. After a close-range or contact shotgun wound to the trunk, external examination of the patient, particularly after adequate volume resuscitation, often does not disclose the severity of the internal injuries present.

Major neural injury after shotgun wounding of the extremities may be more important than fracture or major vascular injury in determining the final outcome.¹⁵

During surgical exploration of a close-range shotgun wound, it is important to search for wadding, casing debris, the plastic shot cup, and surface materials carried into the wound (e.g., clothing, glass, or wood). Many of these are radiolucent.³

Diagnosing long-range injury based on the pattern of pellet spread is sometimes problematic. When shotgun pellets are tightly clustered or widely spread out, close-range injury or long-range injury (respectively) is usually suspected. However, in close-range injuries, the *billiard-ball effect* may cause considerable pellet spread.¹⁶ When the tightly clustered group of shot at close range contacts the skin, the pellets at the front of the group are slowed. The pellets behind them in the group strike the pellets in front, with an effect like a billiard-ball break. This causes much more pellet spread in tissue than would be expected at close range. On radiographs, particularly in trunk wounds, this effect can simulate the pellet spread of a longer-range injury.¹⁶ This pitfall can be avoided if the skin physical examination is correlated with the radiologic findings. If there is only one entrance wound hole, it is a close-range injury. If the distribution of the multiple skin entrance wounds is the same as the pellet spread on the radiograph, the injury occurred at longer range.

Recently manufactured BB guns and air guns that fire small pellets have considerably higher muzzle velocity [600 ft/s (183 m/s) or more] than older guns of this type. Penetrating injuries from these weapons are sometimes fatal. These air guns should not be considered toys. It is possible for a patient who has been shot with a BB pellet that has penetrated the scalp, skull, and brain to think that only a scalp wound is present.¹⁷

ASSESSMENT OF MISSILE TYPE AND LOCATION IN THE BODY

As in all of radiology, localization requires two views at 90 degrees or a tomographic image. CT of the head and body is often useful for analysis of bullet path.³

The CT digital scout radiograph, which can be used for missile localization, usually can be taken in anteroposterior and lateral projections without moving the patient. The ability to manipulate the display window and center enables visualization of bullets seen through dense structures such as the shoulders and pelvis.

Assessment of Missile Type

On a radiograph, assessment of missile caliber is difficult because of magnification and missile deformation. If an undeformed bullet is seen in two views at 90 degrees and its degree of magnification is known, the approximate caliber of the bullet can be determined. Some bullets are difficult to distinguish because their diameter is similar to others (see Table 264-1). Sometimes deformed bullets can be characterized accurately radiologically for intact bullet caliber and weight.¹⁸ Many radiographs show only fragments of the bullet and do not enable determination of the type of weapon and projectile that caused the wound. However, certain bullets deform or fragment in a characteristic pattern (such as the M16 military bullet, the Winchester Black Talon or S&W handgun bullets, and the .357 magnum 125-grain Remington semijacketed soft-point bullet) that can be used to identify them. Deformation of large lead shotgun pellets (e.g., 00 buckshot) after contact with bone can cause these to be confused with deformed bullet fragments.

MISSILE EMBOLIZATION

It always must be ascertained that the path from the entrance wound is consistent with the bullet's current location because a bullet may have reached its present location by embolization. Arterial and venous embolization of bullets and shotgun pellets, as well as bullet movement within the subarachnoid space in the head and spine, have been reported. It is generally accepted that a missile freely floating within a cardiac chamber should be removed to prevent embolization. Missiles clearly embedded in chamber walls are relatively safe.¹⁹ Missile size does not seem to be especially important because all sizes can produce morbidity after embolization. Two-dimensional echocardiography may be useful in determining whether a missile is embedded in a chamber wall. CT (particularly high-speed CT) and magnetic resonance imaging for nonmagnetic missiles also have a role. On chest radiographs, blurring of the margins of a pericardiac missile or fragment is a reason to suspect that the missile is in or next to the heart.¹⁶ Bullets and pellets have embolized from the heart to the head during CPR, causing stroke.

Whenever a bullet is not found on radiographs of the body part predicted based on the entrance wound, the bullet's location is not currently known, and there is no exit wound, additional radiographs or fluoroscopy to find the bullet are mandatory. Immediately before surgery for missile removal, repeat radiographic confirmation of the exact location of the missile is usually indicated.

Interventional radiologic techniques are useful in bullet removal, including the removal of intravascular and intrarenal bullets. Significant deformation of an intravascular bullet is a relative contraindication to retrieval using a transarterial catheter because of potential damage to the vessel intima. Arthroscopy sometimes can be used for removing bullets from joints, especially the knee.

Most bullets follow straight paths through the body, but sometimes, even in the absence of embolization, a bullet, particularly a handgun bullet, will not. It may ricochet off body structures, especially bone, or may follow fascial or tissue planes. Bullets traveling less than 1100 ft/s (335 m/s) are the ones most likely to be deflected by anatomic structures or to follow tissue planes. Bullet shape also influences the tendency to be deflected.

Far more common than bullet displacement by embolization from where it came to rest in the body at the end of its path is bullet movement due to the effect of gravity on a bullet that ends up free in the pleural space or peritoneal cavity.

LEAD FRAGMENTS AND LEAD POISONING

Lead fragments in soft tissue usually become encapsulated with fibrous tissue and do not cause problems. Bullet-induced lead poisoning is most common with intra-articular, disk space, and bursal locations

of bullet fragments because of the solubility of lead in synovial fluid.^{20,21} Lead fragments in the brain are usually relatively benign unless they are copper-plated (as are many civilian .22 caliber bullets).²² Copper-plated lead pellets produced a sterile abscess or granuloma in the brain of cats surgically implanted with missiles of this type.²² This can be associated with downward migration of the missile, resorption of copper from the surface of the missile, progressive neurologic deficit, and sometimes death of the cat. These findings were absent in cats whose brains were implanted with uncoated lead pellets.

Intra-articular fragments should be removed to avoid both the mechanical trauma and the destructive synovitis lead can cause.²⁰ Significant damage to the articular cartilage visible at surgery may be present as a result of lead synovitis, even when radiographs remain normal except for bullet fragments.²⁰ If large fragments are present in the joint, they can cause severe mechanical trauma during motion. This motion can lead to further lead fragmentation.

Whether lead poisoning occurs depends largely on the surface area of the retained lead particles and their location in the body.²¹ Sometimes the onset of clinical lead poisoning can be quite rapid, but usually it takes years.

Patients with retained lead pellets or lead bullet fragments should be advised that, on rare occasions, a fragment may erode into a bursa or joint space and cause lead poisoning. They should be assured that lead poisoning poses a threat *only if unrecognized and untreated*. They should be cautioned to inform their physician of the retained lead any time they seek treatment for problems such as headache, abdominal pain, personality change, or bizarre neurologic symptoms. Once the possibility of lead poisoning is considered, it can be easily confirmed or excluded simply by determining the blood lead level.

EVIDENTIARY CONCERNS

Physicians must be aware of the importance of preserving evidence in patients being resuscitated after penetrating trauma. Do not cut through bullet holes or knife holes in clothing when removing it. Do not incise through skin wounds unless absolutely necessary. To preserve powder marks, do not scrub wounds unless necessary. Take photographs, when possible, prior to initiating wound treatment.

Emergency departments must have a protocol for collecting clothing and other evidence so that it can be documented that it was always under surveillance or otherwise kept in such a way that tampering could not occur. Do not describe wounds as entry or exit wounds; instead, describe the appearance of wounds in detail, without interpretation. Describe the location, size, and shape of all gunshot wounds. Include the presence or absence of a soot ring, skin or subcutaneous tissue tattooing with gunpowder, or the presence of subcutaneous gas (such as from a contact wound with injection into the subcutaneous tissues of gases from burning gunpowder). When a bullet or fragment is encountered, do not pick it up with a metallic clamp so that ballistic markings can be interpreted without the possibility that marks were made later with a surgical instrument. Prehospital personnel should receive similar instruction relative to preserving evidence at the scene. The history of the episode can be useful if the number of shots fired or the position of the victim relative to the assailant was observed.

The sharp bullet jacket edges that some soft-point and hollow-point handgun bullets have when they are deformed into a mushroom shape should be avoided. Infectious diseases such as hepatitis and HIV can pass from the victim to the health care provider as a result of skin punctures from these sharp edges.

Some emergency medicine residency programs now include a course in forensic medicine.²³

FORENSICS David
R. Fowler John E.
Smialek

Good medical practice obligates physician/health care providers in EDs to serve as an interface between patients and the state within the context of the public health, legal, and justice systems. To comply with these additional responsibilities, physicians must be aware of local public health and legal obligations, for example infectious reporting requirements in Maryland,¹ and must be able to recognize patterns of injury. Observations must be appropriately documented and evidence must be processed in a manner consistent with legal standards.²

Each ED should provide its physicians with a standard protocol for responding to state-imposed legal and public health¹ requirements. As

an example, all states impose an obligation to report certain infectious diseases¹ (also see Chap. 153) and many states also require reporting of certain injuries to state social services or law enforcement agencies. Generally, these reporting requirements are centered on the vulnerable patients such as children,³ the elderly, and victims of domestic violence. Reporting laws for other types of injuries vary from state to state. There may be obligations to report gunshot wounds, knife wounds, assaults, and burns.

It is important that the physician also take a proper history from the patient and other reporting witnesses, which must include a statement regarding the origin of the injury. These statements must be documented verbatim for several reasons. First, they may be self-serving and the explanation may change upon subsequent reflection. Second, such statements are of legal significance and are admissible in subsequent legal proceedings where they will be analyzed in minute detail.

In addition to obtaining this initial history, the physician must also provide a physical examination of the injury and documentation of that examination before the injury is altered by healing or medical treatment. It is critical that this be documented in detail, because in those surviving their injuries, this becomes the only medicolegal information collected. Other diagnostic and documentary tools, such as x-ray, should supplement the physical examination. The legal significance of injury assessment also warrants documentation of the injury by photograph. Therefore, an autofocus, Polaroid, or digital camera should be standard equipment in every ED.

SURVEILLANCE

ED physicians must also recognize their pivotal role in emerging diseases surveillance for bioterrorist events. Persons who present first to emergency departments might fall under medical examiner jurisdiction if they die suddenly and unexpectedly without a clear diagnosis. Examples include West Nile encephalitis in New York⁴ and the recent anthrax deaths.⁵ Any death that results from the deliberate dissemination of an otherwise natural disease is also a homicide and must be reported to the medical examiner/coroner. Other examples of unexplained deaths include the series of cyanide-laced acetaminophen deaths. Syndromic surveillance is likely to become a primary tool in early identification of emerging diseases and bioterrorism.

PATTERNS OF INJURY

Classification

Injuries may be classified in a variety of ways. Mode of production is one classification that includes blunt force, sharp force, missile, heat, electricity, and chemicals. Injuries may also be categorized according to the circumstances in which they were inflicted. Such circumstances are accidental, suicidal, or homicidal. Wounds may also be characterized as surgical or ritual, depending on the setting in which these wounds are sustained. However, the most useful classification is based on the components of the injury pattern. Injuries consist of one or a combination of several types of tissue damage (Table 265-1).

TABLE 265-1 Types of Tissue Damage from Injury

Abrasion

Abrasion

An *abrasion* is the damage inflicted on the superficial layers of the skin (epidermis) by friction or pressure. An abrasion may be sustained by sliding on a rough carpet, producing what is commonly called a *rug burn*. A much more extreme version of an abrasion is the injury produced when a pedestrian is knocked to the pavement by an automobile, sustaining extensive friction injuries to the skin on various parts of the body. These injuries are commonly called *road burn* or *road rash*. While abrasions may be lacking in specific detail to allow an instrument of causation to be identified, some abrasion patterns may be very specific (imprint abrasions). These may include the abrasions resulting from a rope used as a ligature around the neck or extremities and rubbed against the skin, called *ligature marks*. Abrasions can also be caused by the irregular surface of the shoe sole or by an electrical cord used as a whip (Figure 265-1).

Bruise (Ecchymosis)

An *external bruise* represents bleeding beneath the skin. If sufficient bleeding occurs to create a lump, this is called a *hematoma*. Such injuries result from direct force applied to the skin surface, resulting in the tearing of subcutaneous blood vessels. The pattern of bleeding may be circular, surrounding a central bleeding point where the blow has stretched and torn a blood vessel wall. When multiple blood vessels are torn because of the use of a specific instrument, the bleeding pattern may conform to the outline of that instrument. For example, a blow inflicted with a human fist can produce multiple circular bruises in a pattern that conforms to the tips of the knuckles (Figure 265-2). Similarly, pressure from fingertips, such as occurs when someone grabs another by the arm, may produce several circular to oval bruises.

FIG. 265-1. Abrasion caused by electric cord.

FIG. 265-2. Bruise pattern from knuckles.

In contrast, a strike with a police baton can produce parallel linear bruises conforming to the diameter of the baton (Figure 265-3).

Contusion

When sufficient force is applied to the surface of the body, the combination of friction or pressure and tearing of underlying blood vessels produces a bruise with an overlying abrasion. The term commonly used for this injury pattern is *contusion*, although some individuals use it interchangeably with bruise. Contusions and bruises have different appearances, depending on the pigmentation of the person's skin and the age of the injury. A bruise or contusion that is dark red or purple with well-defined margins is consistent with having been inflicted less than 48 h prior to examination. In contrast, a bruise or contusion that is yellow or brown or whose margins have begun to fade is certainly older than 48 h.

Laceration/Tear

A *laceration* is a tear of the skin caused by blunt force and not a sharp instrument. Depending on the amount of force used, the tear may be confined to the dermis or may extend through the full thickness of the skin. An example of an injury confined to the dermis is overstretching (Figure 265-4). A full-thickness laceration extends into the subcutaneous tissue. When the injury is examined, *bridging* by intact blood vessels may be evident (Figure 265-5). The resilience of elastic walled structures, such as arteries, allows them to maintain their integrity despite a blunt-force impact that tears the adjacent skin.

Because a laceration is usually the result of a crushing force, the margins of the laceration will show the effects of the pressure crush-

FIG. 265-3. Parallel linear bruises from police baton.

FIG. 265-5. Full-thickness laceration with "bridging" by intact blood vessels.

and recovery of particles of concrete, brick, or sand may be very helpful in the determination of whether an injury resulted from impact with an object such as a rock or the butt of a handgun (Figure 265-6). This information should be included in the description of the injury.

Stab/Cut

A *stab* or *cut* is an injury inflicted on the skin by contact with a sharp object. Laceration (see above) is not the correct term to use when describing cuts, as it specifically means tearing of the skin. Knife blades, shards of glass, and fragments of metal can penetrate the skin and leave a cutting pattern that will vary depending on the movement of the injured party and the object causing the injury. The sharp edge

ing the epidermal layer or skin surface. Depending on the instrument causing the injury, a specific imprint may be evident when the margins of the laceration are reapposed. A laceration can also be called a tear but should never be called a cut, which implies the application of something other than blunt force. A common type of laceration occurs in protuberant areas of the body such as the elbow, knee, or eyebrow, where a fall against a hard surface such as a floor or pavement may result in the crushing of the skin against the underlying bone. Because the crushed skin margins may be nonviable, simple suturing of such a laceration without debridement may not result in healing by first intention.

Because lacerations often result from contact with a foreign object, residue from this object may be left within the wound. Recognition

SECTION 22 • TRAUMA

of these objects severs structures in the skin, leaving no evidence of bridging such as that seen in lacerations. Depending on the shape of the sharp object, the cut edges will be abraded accordingly while the ends of the wound may be squared or pointed (Figure 265-7). Unique abrasions found around a stab wound may represent the effect of the hilt of a knife blade striking the skin (see Figure 265-7). Examination of the stab-wound track may reveal particles of the offending weapon, and such particles should be retained as evidence to assist in the identification of a weapon. The location of specific stabs or cutting wounds may suggest the manner in which they were inflicted. For example, cuts or stabs on the inner (volar) side of the wrist or forearm are consistent with efforts of individuals trying to protect themselves from an assailant by raising their arm in front of their body in a defensive posture. Forensic pathologists call these defense wounds.

To properly evaluate the wound characteristics of cutting or stabbing wounds, the wound edges must be reapposed. The reapposition counteracts the effect of elastofibro-retraction and allows the physician to observe the wound as it occurred. It also enables the physician to identify abraded margins, as well as patterns of squared ends or pointed ends. A *squared end* results from the noncutting or blunt edge of a knife blade, whereas a *pointed end* results from contact with the sharp edge of a blade. The physician should use transparent tape to hold the edges of the wound together while the wound is photographed. This practice can be extremely valuable in the comparison of the wound with a suspected weapon (Figure 265-8).

Another example of a patterned abrasion injury is the one caused by fragments of automobile glass. These characteristic wound patterns in human skin can enable the physician to identify whether the glass causing the injury is from a windshield or side auto window. The side window consists of tempered glass that breaks into 5-mm cubes, causing right-angle cuts to the left side of the face of the driver of the vehicle sustaining a driver-side impact. They may also be found on the right side of the face of passenger of a vehicle sustaining a passenger-side impact (Figure 265-9A). Recognizing these patterns and their location can be useful in establishing who was driving the vehicle at the time of the collision. Cuts from windshield glass are distinguishable from side-impact injuries. Windshield glass, which consists of thin layers of laminated glass, breaks into tiny splinters that produce superficial, parallel, linear cuts (Figure 265-9B).

FIG. 265-7. Abrasion and bruise around periphery of stab wound suggesting cause is blunt trauma from hilt of a knife blade.

FIG. 265-8. Transparent tape applied over wound may aid in reconstruction and identification or verification of weapon.

Bite

Contact between human mouth and/or teeth and skin will leave evidence of the amount of force used in the contact as well as material (saliva) and/or teeth marks that can lead to the identification of the biter. Love bites or hickeys (suction injuries) result when there is extended oral contact with the skin of a partner involving sucking or biting. Hickeys are typically seen on the neck but may occur on any part of the body and usually exhibit no evidence of damage to the subepidermal layers, although discoloration from tissue fluid leakage may occur. On the other hand, *love bites*, and bites inflicted during a struggle, usually damage the dermis, leaving a partial or complete pattern of the dentition of the biter (Figure 265-10). Not only can this bite pattern be used for comparison with the dental pattern of the suspect, but also the recognition of the bite mark sustained during an attack should alert a physician to protect the skin surrounded by the bite pattern so that it can be swabbed to obtain saliva containing DNA material. A DNA profile can be compared with that of a suspect, providing almost 100 percent accuracy of identification. The most severe form of human bite is one that extends through the dermis into the subcutaneous tissue and results in the loss of blood. Thus, one can grade bite marks as first degree (mild), second degree (moderate), or third degree (severe). Using this grading system, a love bite would be considered in the mild category, whereas one similar to that occurring during a recent notorious boxing match as third degree (severe).

Burn

Injuries of the skin resulting from contact with electrical energy, extreme heat, heated objects, or certain chemicals often exhibit characteristic patterns. For example, immersion of a child's buttock in 60°C (140°F) water will result in second-degree burns to the immersed skin. The resulting burn pattern will show a characteristic line of demarcation that represents the amount of skin immersed in the hot water (Figure 265-11). Similarly, contact of the skin with electrical current can result in a central area of necrosis characteristically seen as black, charred tissue surrounded by a pale zone with a bright-red peripheral margin.

Tremendous electrical force contained in a lightning strike may produce relatively little in the way of external evidence and may include only singeing of hair or slight charring of skin where contact occurs. An arborization or fernlike pattern of redness may be seen on the skin of fatally injured victims. A possible result of contact with a lightning strike is magnetization of certain metal articles on the victim's body.

FIG. 265-9. A. Right-angle lacerations from side window glass of car made of tempered glass that brakes into 5-mm cubes. B. Linear lacerations and abrasions from windshield glass that brakes into tiny splinters.

Missile Penetration

The entrance wound of a skin penetration caused by a high-speed missile (such as a bullet) or a low-speed missile (such as an arrow) is circular, oval, or triangular, with a circumferential rim of abrasion. This abrasion pattern, produced by the friction sustained by the skin margins in contact with the missile, enables a physician to identify which hole is the exit and which is the entrance in a through-and-through gunshot wound. The outer skin edges of an exit wound do not come in contact with the missile and therefore do not sustain friction damage

FIG. 265-10. Human bite revealing pattern of dentition.

and do not exhibit this rim of abrasion. However, if a person is wearing tight clothing or the skin is resting against a hard, firm surface when the missile exits, the skin around the exit wound may be abraded from contact with this material. This produces a pattern called a *shored exit wound* (Figure 265-12).

The presence of gunpowder residue surrounding a gunshot wound of the skin is a critical finding that needs to be described and documented with photographs before cleansing. The description of the distribution of the gunpowder residue, whether it consists of black smudging (soot) or stippling by particles of gunpowder, should include measurements with photographs. Wound photographs should always have a measurement scale in the field (see Figure 265-2). Clothing soiled with gunpowder residue must be protected and retained for collection by law enforcement agencies for analysis in the crime lab. This type of evidence is used for determining the distance between the muzzle of the weapon firing the bullet and the injured party. Establishing this distance provides one parameter for evaluating the validity of accounts given by each of the parties as to the circumstances of the shooting. For example, one person may allege that there was a struggle and the gun was fired in self-defense, while the other person may say he or she was shot without threatening the shooter in any way.

Identification of the site of the entrance and exit of a gunshot wound path is an important step in the reconstruction of the shooting incident. When these incidents are not fatal, legal action often results, leading to a dispute over the accuracy of accounts given by each of the two parties: the injured party and the shooter.

Physicians without forensic training should avoid giving any opinion regarding a wound being an entrance or exit, or whether firing at close

readers who wish to become more familiar with the variety and details of injury are referred to several informative forensic medicine texts available in the medical library.

MEDICAL RECORDS

When an injury becomes the subject of a legal proceeding, the medical record documenting that injury and its subsequent treatment becomes a central part of the court deliberations, which may include obtaining testimony from the physician that created that record. The defendant or the accused is entitled to cross-examine that physician to establish or refute the validity of the medical information presented to the court. Physicians must recognize the legal responsibility that society places on them and be prepared to provide competent, professional testimony when required. The proper documentation of injuries includes the description of the details previously specified under *wound pattern*. The use of anatomic diagrams, together with photographs, makes the record more representative of the injuries as a physician saw them and more understandable by the lay members of a court. These items (charts, diagrams, and cameras) should be essential equipment in an ED, and photographs should become part of the permanent medical record.

PRESERVATION AND COLLECTION OF EVIDENCE

Preservation of blood samples, missiles, and debris found in wounds may be extremely valuable in identifying a particular weapon and in tying this weapon to an assailant. However, this evidence is useful only if a proper chain of custody is established. In handling such evidence, EDs should follow a protocol developed in consultation with the local law enforcement agency. The use of a simple envelope that enables a physician to identify the patient, the date the evidence was recovered, where it was recovered from, and to whom it was given, and signed by the physician is adequate for establishing the chain of custody. Use of an appropriate receipt form documenting the transfer of this evidence should be an essential part of the medical record.

range or a distance caused it, or whether any type of activity or movement occurred during the shooting or what type of ammunition was used. Rather, physicians should document in as much detail as possible the information set out above for evaluation by those expert in this area.

Strangulation

Attempts to injure or kill a person by strangulation using one's hands, a ligature, or forearm, in a chokehold, may result in skin damage to the neck. For example, in manual strangulation, multiple bruises and scratches typical of contact with hands and fingernails will be seen on a victim's neck. On the other hand, if a ligature is forcefully wrapped around a victim's neck, a band of abrasion approximating the diameter of the ligature will be seen on the skin. Pinpoint hemorrhages, or petechiae, which are dramatically evident in the translucent conjunctival lining of the eyes, are important evidence of strangulation. These hemorrhages, which are the result of ruptured capillaries, occur when the buildup in pressure occurring when venous return from the head and face is obstructed. Because a period of 4 min is required for compression of the blood supply of the brain to result in irreversible neuronal damage and death, it is not surprising that so many attackers let go of their victim before death has occurred. If other forces, such as shooting, stabbing, or beating, are not used, a victim may survive strangulation and appear in the ED, with evidence of neck injury and petechial hemorrhages in the eyes. Such victims should be examined for evidence of sexual assault, and vaginal swabs should be taken for identification with semen and DNA analysis.

The foregoing categories of injuries represent those most commonly seen in a trauma unit or a medical examiner office. However,

REPORT OF DEATH

This chapter is confined to those issues relevant to the assessment of living patients. However, another important responsibility of the emergency physicians is that of notifying the local law enforcement agency, medical examiner, or coroner of a death that constitutes a medical examiner or coroner case.

Statutory language identifies those deaths that require an investigation by a medical examiner/coroner of the circumstances of the death. This enables one to determine whether an autopsy is necessary, which can then be carried out under the same statutory authority. Such deaths are generally those of individuals who die suddenly while not under the immediate care of a physician and any death associated with some type of injury, and usually include a category of any suspicious or unusual death. It should be emphasized that the length of time a patient has been in hospital, or the age of an injury associated with the underlying cause of death, is not a factor in determining whether the death should be reported to the medical examiner/coroner.

For example, the death of a person who sustained paraplegia from a gunshot wound of the back remains a medical examiner case despite the many medical procedures and complications that result from such an injury—even when many years have passed and the victim has died of a complication of paraplegia, such as a chronic urinary tract infection. The evidence of gunshot injury together with the medical treatment and any other intervening events leading up to the eventual death need to be assessed by the medical examiner/coroner. If a chain of events exists, leading from the gunshot wound to the immediate cause of death, then the manner of death would be determined to be homicide.

Death Certification

A death certificate is an important legal document. The information on the document forms the basis of public health data and provides essential documentation of the cause and manner of death to insurance companies, the legal profession, and family to name but a few. Inaccurate information has many serious consequences, including affecting insurance payments. The information on the document should reflect the sequence of abnormalities that resulted in the death of the individual. This should be done by following the national guidelines.⁶ The terminal cause of death is placed on the top line, and then each subsequent line contains the preceding process until the bottom line contains the primary underlying cause of death. This is the disease or injury that started the cascade of events that directly lead to the death. Death certificates also have fields for information on how injuries occurred and these must be completed if the death was due to an injury.

The death certificate must be filled out by the physician who last attended the deceased and must be completed within 24 h of the death. For deaths occurring in the ED, the obligation rests with the attending physician. The certificate usually accompanies the remains to the funeral home. If the case is a medical examiner/coroner case, it is usually appropriate to contact that office immediately after death to obtain a decision on whether or not medical examiner/coroner intends to accept the case. If the case is going to the medical examiner/coroner, that office can inform the physician of local statutes, regulations, and protocols. In most medical examiner/coroner cases, the medical examiner/coroner will complete the death certificate.

As with most legal documents, death certificates must be filed out in black ink only, abbreviations, erasures, alterations, white-out, and the like are unacceptable and a certificate with such marks will be returned to the physician.

Certain terms, such as asystole, cardiac arrest, brain death, and arrhythmia, are mechanisms of death that are final physiologic common pathways. These are usually not accepted by the various departments of vital records and will result in a rejected certificate. Other terms such as "_____ failure" (i.e., heart failure, respiratory failure, etc.) will also cause inquiries and must be qualified with the cause of the failure.

INJURY CONTROL

Arthur L. Kellermann
Debra E. Houry

Injuries account for about one-fourth of emergency department visits nationwide, and they are the most common cause of death for Americans ages 1 to 44.¹ Because injuries disproportionately affect the young, they account for more years of potential life lost before age 65 than all causes of cancer and heart disease combined.

Epidemiologic research shows that injuries, like diseases, tend to affect identifiable high-risk groups, follow a predictable chain of events, and therefore are preventable. After an injury occurs, morbidity can be minimized by providing optimal acute care and, subsequently, rehabilitation. This combination of strategies—prevention, acute care, and rehabilitation—is termed *injury control*.

A PUBLIC HEALTH APPROACH

William Haddon developed the classic approach to injury control by identifying the three principal factors of injury (host, vehicle, and environment) and considering each factor in the three temporal phases of an injury-causing event: prior to the event, the event itself, and the postevent phase. This can be portrayed graphically in a *phase-factor matrix* of nine discrete cells.² Examining each cell can suggest a variety of strategies to prevent or control injuries. Since its introduction in 1972, the *Haddon matrix*, as it is now known, has proven to be an invaluable tool for injury control.

Haddon also outlined 10 generic injury-control strategies that can be used to break the chain of injury causation³ (Table 266-1). Examining this list to identify promising approaches to injury control is known as *options analysis*. Certain options lend themselves more easily to one class of injuries than others. The best injury-control strategy is not always the most obvious one. Often a combination of approaches is superior to any single strategy.

The Injury-Control Model

More than a century after yellow fever was controlled by targeting the vector of transmission to prevent the disease, Haddon's work demonstrated

TABLE 266-1 Options Analysis: Strategies with Examples for Injury Control

1. Prevent creation of hazard
Ban production and sale of assault weapons to civilians
2. Reduce the amount of hazard
Limit water heater temperature to 47.25°C (125°F)
3. Prevent the release of a hazard that already exists
Put dangerous medications in "childproof" containers
4. Modify the rate of distribution of release of the hazard from its source
Require fire-safe cigarettes that cannot easily ignite furniture or bedding
5. Separate, by time or space, the hazard from that which is to be protected
Construct overpasses or underpasses to eliminate crossing streams of traffic
6. Physically separate, by barriers, the hazard from that which is to be protected.
Equip cabs with bullet- and knifeproof partitions
7. Modify surfaces and basic structures to minimize injury
Equip all new cars with driver- and passenger-side air bags
8. Make that which is to be protected more resistant to damage
Issue bulletproof vests to law enforcement officers and security guards
9. Begin to counter damage already done
Promote citizen training in first aid and CPR
10. Stabilize, repair, and rehabilitate the injured person
Implement trauma care systems throughout the United States

Source: From Haddon,² with permission.

that many injuries can be controlled by broadening our traditional emphasis on acute care and rehabilitation to include *prevention*. Injury control draws on the expertise of many disciplines, including epidemiology, prevention, biomechanics, acute care, rehabilitation, law, and public administration. Whenever it is practical, prevention should be tried first. If and when prevention is not enough, acute care can minimize further damage from trauma. After a victim is stabilized and his or her injuries have been treated, long-term outcomes can be enhanced by optimal rehabilitation.

Haddon's approach was first applied with great effect to reduce deaths and injuries from car crashes. Prior to his involvement, the federal government poured millions of dollars into costly and largely ineffective media campaigns directed at drivers. Little progress occurred until the National Highway Traffic Safety Administration mandated changes in the design of motor vehicles, as well as the development of safer roadways and driving environments (see "Engineering" below).⁴

These efforts produced one of the greatest public health achievements of the twentieth century. While the number of vehicle miles traveled in the United States has risen annually, today's crash fatality rate is less than one-third that of 1950. If the United States had not launched and maintained its highway traffic safety initiative, the annual toll of motor vehicle crash-related deaths, injuries, and costs would be thousands of lives and billions of dollars higher than it is today.

PREVENTION STRATEGIES

Active and Passive Countermeasures

Preventive countermeasures can be divided into two basic strategies—active and passive. *Active* countermeasures require the conscious cooperation of the individual to be effective. Examples include use of manual safety belts, motorcycle helmets, and child safety seats. *Passive* countermeasures, on the other hand, require little or no cooperation by the person being protected. Examples include automatic air bags, sprinkler systems, floatation hulls on watercraft, and spring-loaded kill switches on lawn mowers. In general, the less a countermeasure relies on the user, the more likely it will provide protection when needed. For example, manual safety belts reduce the risk of death in a car crash by 45 to 55 percent. However, they are effective

only when buckled by the user. In contrast, air bags deploy in serious crashes virtually 100 percent of the time.

The Three E's of Injury Control

Whether active or passive in nature, most injury-prevention efforts fall under one of the three E's of injury control—education, enforcement of safety regulations, and engineering to make products or environments safer.

EDUCATION Education is often the first approach taken to encourage the public to accept an active countermeasure of proven efficacy. Implicit in its approach is the belief that once people are taught what to do, they will change their behavior to reduce their risk of injury. Driver's education programs, child pedestrian training, and bicycle helmet campaigns are examples of this strategy.

Although public education campaigns are popular and often attract large numbers of volunteers, they rarely result in sustained behavior change. One study evaluated the impact of a campaign to promote bicycle helmet use by children. Although the campaign was launched in several communities, subsequent surveys revealed that the helmet use went up only 1 percent compared with communities without the educational campaigns.⁵

Not all public education efforts have yielded such dismal results. A multistate community action campaign promoting responsible alcohol consumption found that self-reported rates of "having had too much to drink" declined 49 percent and driving when "over the legal limit" decreased 51 percent. More important, assault injuries declined by 43 percent and motor vehicle collisions declined by 10 percent.⁶ A hospital-led bicycle helmet-promotion campaign for children reported a 20 percent increase in helmet use and a 10 percent decline in bicycle-related head injuries.⁷

The impact of public education campaigns is blunted by *attenuation of effect*. No matter how powerful, pervasive, and repetitive a safety message may be, there will always be people who never encounter it. Among those who see or hear the message, some will actively reject it. Others will receive the message but be insufficiently motivated to change their behavior. Among those changing their behavior, some will relapse into old habits over time. Others will fail to follow the message on a consistent basis. Finally, not everyone who conscientiously adopts a protective strategy escapes injury.

Educational interventions may be enhanced by incorporating theoretical models that include important determinants of individual behavior.⁸ These include a number of personal, community, and political factors. The PRECEDE health-promotion model has been used with some success in planning injury-prevention programs.^{9,10} PRECEDE is an acronym for *predisposing, reinforcing, and enabling causes* in *educational diagnosis and evaluation*. Predisposing factors are characteristics of a patient, consumer, or community that motivate behavior. Reinforcing factors are rewards or punishments that are anticipated or follow as a consequence of these specific behaviors. Enabling factors are environmental characteristics that facilitate or hinder injury-prevention behaviors. This framework has been used successfully to assess educational needs and select appropriate strategies to encourage bicycle helmet use and prevent child pedestrian injuries

^{9,10}

ENFORCEMENT Unfortunately, **the group most prone to risk-taking behaviors (e.g., adolescent males) is precisely the group least likely to respond to a public education campaigns.** When voluntary acceptance of an effective countermeasure is poor, compliance can be increased by adding the force of law. The impact of "mandatory use" laws can be impressive. Although an educational campaign to promote bicycle helmet use only boosted use by 1 percent in a Maryland county, helmet use went up 26 percent after the state enacted a mandatory helmet law.⁵ Motorists in Texas increased restraint use by

15 percent after law enforcement began issuing traffic citations and fines.¹¹ In comparison, 6 months after Florida repealed its motorcycle helmet law, the number of brain-injured motorcyclists presenting to one trauma center increased from 18 to 35, the number of fatalities increased from 2 to 8, and self-reported helmet use by patients decreased from 83 to 56 percent.¹²

Community education and high-visibility enforcement are needed to obtain maximal benefit from a mandatory use law. In Elmira, New York, an enforcement and publicity campaign promoting the state's seat belt law boosted rates of belt use from 49 to 77 percent. Four months later, use sagged to 66 percent, but it rebounded to 80 percent during a reminder campaign.¹³ Mandatory use laws are effective, but they are difficult to enact. People are often quite willing to support measures limiting the ability of others to injure them, but they resist measures that limit their own actions. Speed limits, drunk driving laws, and measures to ban the carrying of weapons on commercial aircraft enjoy broad-based support, but mandatory use of seat belts, motorcycle helmets, and restrictions on the purchase of firearms are less popular. Mandatory use laws often engender spirited resistance from those who perceive these laws as an infringement on "personal freedom."

Political backlash can block promising legislation or ultimately lead to the repeal of a successful law. A survey of Colorado legislators revealed that 96 percent knew that safety belts reduce the risk of death and 87 percent believed that a safety belt law would save lives, but the strongest predictor of a "yes" vote on a mandatory use bill was the impression that their constituents favored the law.¹⁴ Despite overwhelming evidence that motorcycle helmet laws save lives, 26 states repealed their statutes when federal incentives were relaxed in 1976. In these states, motorcycle crash fatality rates subsequently increased 40 percent.¹⁵ As of 2000, only 22 states had universal helmet laws, 28 mandate helmets for young riders, and 3 lack any requirement.¹⁶

Opponents of mandatory use laws argue that individuals should be permitted to ignore mandatory use laws if they consider the level of risk acceptable to them. Unfortunately, the circle of harm extends far beyond the victim. For example, a motorcyclist or a bicyclist who rides without a helmet faces an increased risk of serious head injury or death. When such individuals are killed or disabled in a crash, their family and loved ones lose companionship, their dependents lose an important source of financial support, their employers lose productivity, and society is required to cover the cost of their care. All of us, either directly or indirectly, pay the costs of preventable injury.

ENGINEERING Many injuries can be prevented by building safer vehicles or modifying the physical environment in which injuries occur. The up-front cost to design and implement an engineering countermeasure often exceeds the up-front cost of educational or an enforcement campaign, but the downstream effect is often greater as well. Engineering is usually more effective than behavioral strategies because it does not require users to permanently and consistently change what they do.

Consider, for example, the lessons learned in highway safety. In contrast to the consistently disappointing results of driver's education, federal standards for motor vehicle construction saved an estimated 37,000 lives between 1975 and 1978 alone. These standards addressed such issues as passenger restraint systems, windshields, fuel tank integrity, and the flammability of interior fabric. Introduction of air bags cut the nation's toll of deaths and injuries due to car crashes even further. Construction of the interstate highway system saved lives as well. Modifications to the driving environment, such as banked curves, divided lanes of traffic, controlled ramps for ingress and egress, elimination of crossing streams of traffic, and the positioning of energy-absorbing pilings in front of fixed obstructions cut the interstate highway death rate to less than half that for other similarly sized roads.

These lessons could be applied to other hazardous products as well. Cigarettes cause more than half of U.S. house fire fatalities. Most fires

occur when the smoker falls asleep in bed or leaves a burning cigarette on the arm of a sofa or chair. Television, radio, and print advertisements warning of the dangers of smoking in bed have had little or no impact on this problem. Smoke detectors save lives by warning of an impending catastrophe in time to permit the occupants to evacuate the house but require a concerted effort to encourage people to install and maintain them. Passive engineering of the home environment by installing a residential sprinkler system could be a very effective strategy. Unfortunately, such systems are expensive, rarely available, and often cannot be retrofitted into older homes. A more promising option is to modify the cigarette itself to diminish its potential to ignite furniture or bedding.

Laws that require products to be designed so that their potential to cause harm is diminished can be highly effective. Unfortunately, they are difficult to enact. Manufacturers often oppose such regulations because they fear that they will raise the price of their product and discourage sales. In addition to the issue of personal freedom, concerns are often raised about cost, government interference, and reduced competitiveness with nonregulated manufacturers. If efforts to regulate a hazardous product fail, product liability lawsuits may be the only way to force needed changes in product design.

PRACTICE OF INJURY CONTROL

Step 1: Define the Problem

Population-based data of the incidence and impact of injury are essential to define the scope of the problem and mobilize the resources necessary to achieve change. Public health surveillance is needed to monitor patterns and trends and to evaluate the impact of countermeasures.

Several sources of information can be used for this purpose. Vital records or death certificates are useful to document the impact of injuries on overall rates of mortality, but they do not provide information about nonfatal injuries. Hospital discharge data and trauma registries can provide essential information about cases of major trauma, but population-based data are needed to calculate rates of injury. Furthermore, hospital admission statistics and trauma registry data do not capture patients who are treated and released from the emergency department.

Although injuries that are managed on an outpatient basis generally are assumed to be minor, they can result in significant long-term disability. This is particularly true of head, back, and hand injuries. Patients visiting an emergency department for injury have an increased risk for recurrent injury, especially if their index visit is related to alcohol abuse or violence.

Assignment of external cause-of-injury codes (*E-codes*) to every injury-related emergency department visit can substantially enhance community-based surveillance efforts. Several states mandate E-coding of all hospital admissions, but very few require hospitals to E-code emergency department visits.

Step 2: Identify Causes and Risk Factors

Descriptive studies usually are conducted to determine *who* is injured, *what* kinds of injuries are involved, and *where*, *when*, and *why* those injuries occur. These data provide essential clues to injury causation and often generate hypotheses that can be investigated with analytical methods.

In some cases, the link between a risk factor and an injury is so strong that no additional research is needed. For example, early studies of automobile injury showed that 50 percent of all fatal crashes and 60 percent of all fatal single-vehicle crashes involved alcohol.¹⁷ In most cases, however, it is necessary to compare the rate of injury among those *with* a risk factor with the rate of injury in an otherwise similar group *without* a risk factor. Cohort, quasi-experimental, or

SECTION 22 • TRAUMA

classic experimental studies may be employed to reach a definitive conclusion. When the outcome of interest is rare and exposure to the risk factor(s) of interest can be shown to precede the injury, case-control studies may be employed. Meticulous attention to methodology is essential to generate valid results and control for the effects of confounding variables.

Step 3: Develop and Test Interventions

Once the magnitude of the problem and its associated risk factors are identified, a variety of countermeasures may be considered for implementation. Careful attention must be given to the characteristics of the target population, the feasibility of the countermeasure(s), their acceptability to the target population, and cost. Pilot intervention programs often are helpful to test various strategies. The most promising program can then be selected for widespread implementation.

Community education programs are often tried first because they are relatively easy to initiate, attract motivated volunteers, and are invaluable for raising public awareness. They also can help build public support for legislative changes at a later date. It is essential to take the views and values of the community into consideration at every step of the process. Citizen involvement is crucial to any program's success.

Most programs set milestones and predefined measures of success. For example, a campaign to prevent deaths and injuries in residential fires may identify selected measures of *structure* (number of staff hired, office space, cooperative agreements reached), *process* (number of pamphlets distributed, number of home visits made, total smoke detectors installed), or *outcome* (reductions in the rate of deaths, decline in hospital admissions).

It is not always feasible to demonstrate major impacts on rates of morbidity or mortality with small-scale demonstration projects. When this is the case, surrogate measures may be used to demonstrate program impact. For example, preintervention rates of smoke detector use in a target neighborhood can be compared with rates noted after an educational campaign. Telephone surveys can seek evidence of changes in knowledge, attitudes, and self-reported behavior. Self-reports do not guarantee long-term behavior change, but they confirm that a program is reaching the target group.

Step 4: Implement Effective Interventions and Evaluate Their Impact

Once a program is initiated on a large-scale basis, evaluation data should be collected to demonstrate its impact. Measures of cost-effectiveness (e.g., dollars spent per life saved or injury prevented) are particularly important. It is easy to tabulate the cost of a prevention program, but it is harder to document the savings from "tragedies that did not happen." Program support tends to wane over time, especially when no specific group champions its continuation. During difficult economic times, prevention programs are often the first to go. Without documented evidence of clinical or economic impact, worthy programs can fade into extinction.

THE ROLE OF THE EMERGENCY PHYSICIAN IN INJURY CONTROL

Patient Education

Injury-control measures need not be implemented on a grand scale to make a difference. Emergency physicians can incorporate injury-prevention principles into their clinical practice, although long-term benefit has never been shown.¹⁸

Special efforts should be made to correct factors that precipitated the injury or contributed to its severity. Otherwise, a patient is likely to return with a more serious injury in the future. A child sustaining a mi-

nor head injury while bike riding should be told to wear his or her bicycle helmet. The unbelted adult who sustained minor injuries in a low-velocity motor vehicle crash deserves a short lecture on the importance of safety belts. An elder who has fallen should be counseled about checking his or her home for loose rugs and other tripping hazards.

However, emergency physicians should consider every emergency department encounter a *teachable moment*.¹⁹ Due to the nature of their work, emergency physicians are more likely to provide acute care to injured patients than any other group of physicians. Therefore, they have a special stake in preventing and controlling injuries. The mother who brings her child to the emergency department for evaluation of an ear infection should leave the department with information about the importance of child safety seats, bicycle helmets, and four-sided fencing around her swimming pool. Emergency physicians have the opportunity to motivate patients to change high-risk behaviors and modify their home environment to decrease injury risk.

Data Collection and Program Evaluation

If current trends toward capitated care continue, the emergency department will become an increasingly important arena for prevention efforts. Until now, the financial incentives of health care have encouraged hospitalization and provision of services. The move toward capitated payment substantially increases the incentive to prevent rather than treat illness and injuries. As the portal of entry for 40 percent of U.S. inpatient admissions, the emergency department can play a key role in monitoring system performance, identifying high-risk groups, reducing the need for expensive inpatient care, and evaluating the impact of community-based prevention programs.

Research

Emergency physicians are ideally positioned to conduct injury surveillance and evaluate countermeasures. They should take the lead in community-based epidemiologic research. Priority areas for research include prevention of pediatric injuries and alcohol-related trauma; evaluation of drunk driving enforcement efforts; reduction of firearm-related injuries, intimate partner violence, and residential fires; and studies of the biomechanics of trauma.

Advocacy

Sometimes evaluation data indicate that a countermeasure is effective but rarely used. When education is not enough to motivate behavioral change, legislation may have a major impact, particularly when coupled with ongoing education efforts and visible enforcement. For example, states with mandatory motorcycle helmet laws report compliance rates as high as 98 percent.

Coalition building is essential in assembling a broad base of support. Physician leadership ensures the success of these efforts. The testimonies of health care providers, surviving family members, and disabled individuals are needed to give the statistics an emotional context and deliver the message in a personal manner. Information on the economic impact of injuries and the cost-effectiveness of countermeasures is also helpful.

Academic emergency physicians have an important role to play in training the next generation of injury-control experts. Research suggests that many medical students lack a fundamental understanding of the principles and practice of injury control.²⁰ In addition, although 90 percent of emergency medicine residents believe that injury prevention is pertinent to our specialty, the majority do not feel that they received adequate training in injury prevention during residency.²¹ Academic emergency physicians can play an important role by emphasizing the importance of injury control to their trainees.

INJURIES TO THE BONES, JOINTS, AND SOFT TISSUE

INITIAL EVALUATION AND MANAGEMENT OF ORTHOPEDIC INJURIES

Jeffrey S. Menkes

CLINICAL PHYSIOLOGY OF FRACTURES

The ability to properly assess and treat skeletal injuries in the emergency department depends to a large extent on understanding the physiologic processes by which fractures are created and by which they heal. Practical knowledge of fracture physiology may provide the index of suspicion needed to diagnose an injury that might otherwise be missed. It also might help prevent or minimize complications and may form the basis for advising the patient regarding the outlook for recovery of function.

How Fractures Occur

Although fractures are sometimes described in terms of the external mechanism creating them, they also may be considered in terms of the physiology involved.

"TYPICAL" FRACTURES Most fractures are the result of significant trauma to healthy bone. The bony cortex may be disrupted by a variety of forces, including a direct blow, axial loading, angular (bending) forces, torque (twisting) stress, or a combination of these.

PATHOLOGIC FRACTURES Fractures that occur from relatively minor trauma to diseased or otherwise abnormal bone are termed *pathologic fractures*. This term implies that a preexisting pathologic process has weakened the bone and rendered it susceptible to fracture by forces that, under normal circumstances, would not disrupt the cortex. Common examples of such injuries are fractures through metastatic lytic lesions, fractures through benign bone cysts (as in the humerus of Little League pitchers), and vertebral compression fractures in patients with advanced osteoporosis. Numerous other disease processes may render patients susceptible to pathologic fracture.

Because these injuries often are not associated with a history of significant trauma, subtle pathologic fractures may go undetected unless there is a preexisting index of suspicion based on the knowledge that such injuries can occur.

STRESS FRACTURES In some cases, bone may undergo a "fatigue" fracture as a result of being subject to uncustomary repetitive forces before the bone and its supporting tissues have had adequate time to accommodate to such forces. An example is the insidious occurrence of a metatarsal shaft fracture in unconditioned foot soldiers (the so-called march fracture). The physiologic principle of stress fracture can be easily envisioned by anyone who has "cut" an aluminum finger splint to the desired length by bending it back and forth. The pliable metal, too hard to cut with ordinary scissors, ultimately gives way in the face of repeated stresses requiring relatively little force.

The processes that render bone susceptible to stress fracture are not generally agreed upon. The important point is that diagnosis depends on a familiarity with the entity, because **x-rays are typically negative early in the patient's course**. Initial diagnosis may be presumptive, based solely on the history and physical findings. Days or weeks may pass before the fracture line or new bone formation becomes visible on x-ray, ultimately confirming the suspicions of the clinician who, hav-

ing made the correct clinical diagnosis, will have treated the patient appropriately from the outset.

SALTER (EPIPHYSEAL) FRACTURES Fractures involving the physis, the cartilaginous epiphyseal plate near the ends of the long bones of growing children, are called *Salter fractures* after Salter and Harris, the physicians who devised the most popular method of classifying these injuries.¹ The supply of new bone material needed for the elongation of bones during growth is provided by specialized cells within the physis. When growth is completed, the physis transforms into bone, ultimately fusing with the surrounding bone and disappearing as a distinct entity. By definition, Salter fractures cannot occur in fully grown adults.

Any damage to the epiphyseal plate during a child's growth may destroy part or all of its ability to produce new bone substance, resulting in aborted or deformed growth of the bone thereafter. The potential for growth disturbance from an epiphyseal injury is related to the number of years the child has yet to grow (the older the child, the less time remains for deformity to develop) and to the pattern of the fracture line through the epiphyseal area. Classification of Salter fractures and their clinical implications are discussed later in this chapter.

Fracture Healing

The physiology of fracture healing constitutes the basis for many decisions in the emergency department. The judgment as to whether an angulated fracture requires reduction, the choice of treatment modality in relation to the patient's age, and the prognosis for regaining function or being left with residual deformity require familiarity with the short- and long-term aspects of the healing process.

Fracture healing can be described in terms of three phases—**inflammatory, reparative, and remodeling**—each of which gradually blends into the next.²

When a fracture occurs, the microvessels crossing the fracture line are severed, depriving the damaged bone ends of their blood supply. As a result, the bone ends necrose during the ensuing days, triggering a classic inflammatory response. This early phase is brief but creates the tissue environment for the most predominant aspect of fracture healing: the reparative phase.

Granulation tissue soon begins to infiltrate the area. Within this tissue are specialized cells capable of forming collagen, cartilage, and bone, the ingredients of callus, which gradually surrounds the fractured ends and stabilizes them. With time, the callus becomes more densely mineralized.

Meanwhile, the necrotic edges of the fragments are removed by osteoclasts, cells whose specific function is to resorb bone. That is the reason some "hairline" fractures do not appear on x-ray until days after injury. Initially invisible, the diagnostic fracture line appears only after necrotic bone has been resorbed from the area.

The final phase of bone healing, the remodeling phase, is the longest, often lasting years. Remodeling is the tendency of bone to gradually regain its original shape and contour. During this phase, the superfluous portions of callus are resorbed, and new bone is laid down along natural lines of stress. These internal layers, easily visible in x-rays of normal bone, are the bony trabeculae. Formation of trabecular bone is a physiologically efficient process providing maximum strength relative to the amount of bone material used.

The anticipated degree of successful remodeling is related to a number of factors. Young children have a greater capacity for remodeling than adults do. Accordingly, their potential for residual deformity

is less, other circumstances being equal. Remodeling is also related to the magnitude and direction of unreduced angulation and to the fracture's location along the bone. Specific predictors of satisfactory remodeling include youth, proximity of the fracture to the end of the bone (but not involving the epiphyseal plate), and direction of angulation coinciding with the plane of natural joint motion.

Clinical decisions regarding the aggressiveness of fracture reduction are directly linked to a knowledge of this physiology. Angulation near the end of a long bone, for example, is more acceptable than angulation near the midshaft. Dorsal or volar angulation at the wrist has a better prognosis than does ulnar or radial angulation, because the natural plane of wrist motion is dorsal to volar. Mild angulation in a 2-year-old child may be left to remodel on its own, whereas the same angulation in an adult may require correction.

ORTHOPEDIC EMERGENCIES

Some types of musculoskeletal trauma deserve special mention, because a delay in their diagnosis or treatment can increase the chance of significant complications or a negative outcome.

Open Fracture

An open fracture (or compound fracture, in older terminology) is a fracture associated with overlying soft tissue injury, creating communication between the fracture site and the external surface of the body. Although *open fracture* may convey the image of grossly exposed bone, the term is equally applicable to a simple puncture wound extending to the depth of an underlying fracture. Such puncture wounds may be created by external forces or by a sharp bone fragment transiently protruding through the skin before receding back beneath the surface.

The most dreaded complication of open fracture is osteomyelitis. Once established, osteomyelitis may result in months or years of pain, disability, medical therapy, surgical procedures, and ultimately, amputation. Although osteomyelitis may be unavoidable in some cases, it becomes less likely when treatment is prompt and meticulous.

Open fractures are sometimes classified by severity, based on the length of the overlying laceration, extent of tissue damage, kinetic energy of the injuring force, and evidence or likelihood of significant contamination. Irrespective of these factors, any open fracture should be promptly and carefully treated. Elements in the care of open fractures are described later in this chapter.

Dislocation and Subluxation

A joint is dislocated when the articular surfaces of the bones that normally meet at the joint have been displaced completely out of contact with one another. This is the most extreme form of subluxation, a condition in which the articular surfaces are nonconcentric to any degree.

The urgency of treating dislocated joints is based on several factors. One is the potential for neurologic or circulatory compromise. The neurovascular bundle passing close to the affected joint is typically "kinked" around the deformity associated with the dislocation. Persistence of this condition can result in a neurologic or vascular deficit that may be temporary if the deformity is reduced promptly but irreversible if treatment is delayed.

Another consideration is that, the longer a joint has been dislocated, the more difficult it may be to reduce and the more likely it is to be unstable after reduction. This is probably due, at least in part, to edema, muscle spasm, and other tissue changes that increase over time.

Dislocation of the hip carries its own particular urgency in addition to those mentioned above: the danger of avascular necrosis of the femoral head. Avascular necrosis occurs because much of the blood supply to the femoral head is delivered through vessels that emerge

from the acetabulum. When the joint is dislocated, circulation to the femoral head is disrupted. At some point, the vascular insult becomes irreversible, and bony necrosis is the ultimate result. Although aseptic necrosis may occur despite the clinician's best efforts, its likelihood increases with the time delay until reduction.

Neurovascular Deficit

Naturally, any injury associated with neurologic or vascular compromise, such as may result from a severely deformed fracture, should be addressed as soon as possible. The longer a deficit goes untreated, the longer it is likely to persist and the greater the possibility that it will be irreversible. In some cases, simply reducing a deformity by means of longitudinal traction may restore circulation or nerve function, allowing the remainder of the patient's evaluation and treatment to proceed at a calmer pace.

PREHOSPITAL CARE

With the growing sophistication of emergency medical service (EMS) programs in many areas of the United States, important aspects of early care are more likely to be implemented in a timely manner.

Preliminary Splinting

Effective splinting of the injured extremity is crucial for several reasons: (1) it reduces the patient's pain; (2) it reduces damage to nerves and vessels by preventing them from being repeatedly ground between the fragments or being stretched by increased angulation at the fracture site; (3) it reduces the chance of inadvertently converting a closed fracture to an open one as a sharp bone fragment pokes its way through the skin (considered a mishap of severe consequence, because of the potential for osteomyelitis); and (4) it facilitates patient transport and the taking of x-rays by reducing the pain and manipulation associated with moving the patient from ground to ambulance to emergency department stretcher to x-ray table.

Prehospital Splinting Devices

Many splinting devices are available to EMS systems. For injuries of the wrist or forearm, a foam-padded intravenous board can be wrapped in place, supplemented by a sling. The sling is important, because optimal immobilization includes the joint above and the joint below the fracture. The sling keeps the elbow (the joint above) at rest.

For suspected injuries to the elbow or humerus, a sling-and-swathe arrangement works well. This method involves applying a sling and then binding the affected arm to the thorax with a gauze wrap. An exception to this principle is immobilization of patients with suspected anterior dislocation of the shoulder. Such patients have difficulty adducting the forearm against the thorax, and forcibly binding it there is painful and not recommended. A simple sling is adequate. Injuries to the ankle can be immobilized in a pillow or well-padded cardboard splint. If fracture of the tibial shaft or knee is suspected, the device should extend well above the knee (to immobilize the joint above and the joint below).

Some injuries warrant specialized splints, such as winch-mechanism traction devices for femoral shaft fractures. Although such devices do not immobilize the hip (the joint above), the added element of traction makes this component unnecessary. If a traction device is unavailable, the hip needs to be immobilized, which can be accomplished with military antishock trousers, with all compartments inflated or, less elegantly, by binding the legs together and then binding the patient to a backboard from ankles to thorax.

Other types of splints exist, but their use is controversial. Inflatable plastic splints, for example, are acceptable for injuries to the ankle or wrist but sometimes are used inappropriately for fractures of the

humerus or femur. Because these devices normally do not extend above the elbow or knee, they provide inadequate immobilization for such injuries. Also, overinflation of plastic splints may seriously impair circulation. (If the splint cannot be dented by moderate thumb pressure, it is probably overinflated.) Inflatable splints should not be applied over clothing, because underlying wrinkles in the clothing may cause pressure sores in swollen and vulnerable tissue.

Also controversial are nonmalleable aluminum splints, because they are based on the "one size fits all" principle, which some clinicians interpret as "this size fits none." If used, aluminum splints should be very well padded, because their hard surfaces may cause pressure sores. Like any splint, they should immobilize the joint above and the joint below the fracture if they are used for long-bone injuries. For example, an above-knee splint is needed for fracture of the tibial shaft. Aluminum splints should be removed as soon as possible, once a fracture is diagnosed or ruled out. If a fracture is confirmed, the splint should be replaced with another type of immobilization dressing before the patient leaves the emergency department.

Reducing Deformity in the Field

Many EMS programs do not recommend prehospital reduction of deformity of an injured extremity. If the deformity is near a joint (suggesting the possibility of dislocation), this is certainly good advice. Injudicious manipulation may convert a pure dislocation to a fracture-dislocation. Even if a fracture already exists, there will be no way to prove it was not caused by the manipulation.

A circumstance in which prehospital reduction of obvious fractures along the shaft of a long bone can be justified is the absence of a distal pulse. Minutes may count in such cases.

Without a common standard, the indications for reduction of deformity by prehospital personnel ultimately remain at the discretion of the supervising EMS program. If reduction is attempted, it should be performed by means of longitudinal traction.

EMERGENCY DEPARTMENT EVALUATION AND DIFFERENTIAL DIAGNOSIS

The importance of a careful history and physical examination cannot be overstated. Orthopedic diagnosis is sometimes thought of as being as simple as taking an x-ray of the spot where the patient says the pain is. This philosophy is probably more responsible than any other factor for clinicians missing significant injuries.

Although x-ray is an important adjunct, it is not the ultimate diagnostic resource, for the following reasons. The pain of a fracture or even a dislocation may be referred to another area. For example, patients with disruption of the sternoclavicular joint or fracture of the humeral shaft may present complaining of shoulder pain. If the x-ray is based solely on where the patient reports subjective discomfort, then the injury might not be included on the film. The area x-rayed should be determined not only by the patient's chief complaint, but also by systematic palpation looking for subtle deformity or significant point tenderness.

Some fractures or dislocations are apparent only on special x-ray views, which are not part of the standard series for that body part. Such special views will never be ordered unless the clinician has already formulated a presumptive differential diagnosis before x-ray, based on the history and physical findings.

Some injuries may not be radiologically apparent on the first day, regardless of what views are taken. Common examples of such injuries are fracture of the scaphoid (carpal navicular), nondisplaced fracture of the radial head, and stress fracture of a metatarsal. The classic radiologic signs accompanying such injuries, such as the fat-pad sign of the elbow, are not always conveniently present, but suggestive history and findings commonly are. In such cases, the diagnosis of fracture may have to be purely clinical until 7 to 10 days after injury, when

enough bony resorption has occurred at the fracture site to reveal a lucency on x-ray. A bone scan may suggest the fracture even sooner, but on the day of injury, there may be no readily available test capable of demonstrating the pathology. Only the clinician's index of suspicion, arrived at through a systematic history and physical examination, will result in proper and timely treatment of a radiologically undemonstrable fracture.

History

The value of history taking in the case of orthopedic injuries is often underestimated. In fact, knowing the precise mechanism of injury or listening carefully to the patient's symptoms may be the key to diagnosing fractures or dislocations. For example, a history of shoulder injury combined with the complaint of dysphagia may be the only clue to the existence of posterior sternoclavicular dislocation. This entity, which causes pressure on the mediastinal structures, often can be demonstrated only by computed tomography and is associated with severe complications if treatment is delayed. Another example is a history of landing flat on the feet from a significant height, which should prompt the clinician to consider fracture of one or both calcanei, in addition to associated tibial plateau, acetabular, and lumbar vertebral compression fractures.

History is often the only means of correctly assessing and treating young children who "just won't use the arm." Such children, who present with a seemingly paralyzed arm ("pseudoparalysis") after being pulled or yanked, may be incorrectly diagnosed as having a brachial plexus injury, when in fact the history and presentation are classic for subluxed radial head, an entity not discernible on x-ray and easily and quickly remedied by a proper reduction maneuver.

A careful history may enable the clinician to diagnose posterior dislocation of the shoulder, another entity commonly missed on routine films. If the patient has (1) experienced a direct blow to the front of the shoulder, (2) landed forward on an outstretched arm, or (3) had a seizure or undergone violent muscle contraction for any other reason (e.g., contact with high-voltage current) and now complains of excruciating shoulder pain and severely limited motion, the diagnosis of posterior dislocation should be entertained. If the implications of the history are not appreciated, then the specific x-ray views needed to demonstrate the injury may never be ordered.

Table 267-1 provides other examples of mechanisms that might lead the clinician to suspect, or presumptively treat for, specific injuries. This is by no means a definitive or exhaustive list. Some of the mechanisms described may produce injuries other than those mentioned. Conversely, the injuries may be produced by mechanisms other than those listed.

Some musculoskeletal injuries or conditions may not necessarily be associated with a history of trauma. Occult fracture of the hip in an osteoporotic individual, occult stress fracture of a metatarsal in someone who has recently done an unusual amount of walking, and slipped capital femoral epiphysis in a preteenager or young adolescent are examples of injuries whose symptoms may be gradual and insidious in onset, unrelated to an isolated traumatic event. Tenderness to palpation or pain on weight bearing or range of motion suggests the possibility of an occult or easily missed fracture. Depending on the index of suspicion, further studies, such as bone scan or magnetic resonance imaging, may be indicated to rule out significant pathologic conditions before the patient is allowed to resume weight bearing.

History taking should not necessarily be limited to orthopedic issues. Depending on the situation, a general medical history should be obtained, because it may have implications for further workup, the potential for complications, or ultimate prognosis for recovery of function. For example, relevant items may include a history of heart disease, anticoagulant medication, falling due to syncope or transient hemiparesis rather than simply stumbling, or an unsteady baseline gait that cannot withstand further impairment.

TABLE 267-1 Mechanisms Associated with Particular Orthopedic Injuries

Mechanism	Possible Injury
Bilateral compression of shoulders	Anterior or posterior sternoclavicular dislocation
Direct blow to medial clavicle	Posterior sternoclavicular dislocation
Fall, landing on point of shoulder	Acromioclavicular separation
Direct blow to anterior shoulder, fall on outstretched arm, seizure or electroconvulsive muscular activity	Posterior dislocation of shoulder
Yanking of infant's or toddler's arm	Subluxed radial head (sometimes misdiagnosed as brachial plexus injury because of pseudoparalysis of arm)
Fall, landing on outstretched arm or with elbow beneath the body	Fracture of radial head (may be occult on initial x-rays)
Wrist hyperextension (forced dorsiflexion)	Fracture of scaphoid (carpal navicular), lunate or perilunar dislocation, Colles fracture
Striking knee against dashboard in high-speed collision	Posterior dislocation of hip
Landing flat on feet from height	Calcaneus fracture (one or both); tibial plateau fracture (one or more); acetabular fracture (one or both); vertebral compression fracture, usually lumbar (one or more)
Ankle inversion force	Fracture of any of the malleoli, fracture of base of fifth metatarsal
Rotatory ankle force	Fracture of any of the malleoli, disruption of the anterior tibiofibular ligament with proximal fibular fracture (Maisonneuve injury)
Inversion, medial or lateral stress to forefoot; axial load on metatarsal heads with ankle plantarflexed	Midfoot dislocation (Lisfranc injury)

Physical Examination

Essential components of the examination for musculoskeletal trauma are (1) inspection for swelling, discoloration, or deformity; (2) assessment of active and passive range of motion of the joints proximal and distal to the injury; (3) palpation for tenderness or subtle deformity; and (4) verification of neurovascular status.

INSPECTION AND RANGE OF MOTION Gross deformity along the shaft of a long bone is pathognomonic for fracture. The presence of most dislocations or fractures near a joint can be inferred by deformity at the joint, loss of range of motion, and severe pain at rest. An exception is posterior dislocation of the shoulder, which, although intensely painful, may not be accompanied by obvious deformity. Chap. 271 presents a more complete discussion of this entity.

PALPATION When gross deformity is not present, presumptive orthopedic diagnosis strongly depends on the findings noted on palpation. Palpation will disclose areas of bony step-off and the precise location of point tenderness. If films are ordered before performing this phase of the examination, the wrong area may be x-rayed, because pain is commonly referred to a location distant from the injury site.

The palpation examination should be done systematically and consistently from one patient to the next. The area palpated should extend well beyond the location of the patient's subjective pain. For example,

when an injured patient complains of shoulder pain, palpation should begin at the sternoclavicular joint and then proceed along the clavicle, onto the acromioclavicular joint, onto the humeral head, and along the entire humeral shaft. In addition, the scapula should be palpated for tenderness, and the posterior aspect of the shoulder should be palpated for any unnatural prominence that might suggest a posterior dislocation. Injury to any of these areas may be reported by the patient as pain in the shoulder. Only a meticulous palpation examination may protect the clinician from being misled by referred pain and missing a crucial diagnosis.

NEUROVASCULAR ASSESSMENT When injury involves an extremity, as opposed to the vertebral column, sensorimotor testing should be performed on the basis of *peripheral nerve* function, rather than nerve root and dermatomal distribution (Figure 267-1 A, B). In the upper extremity, the radial, median, and ulnar nerves should be tested. When the shoulder is anteriorly dislocated, two additional nerves, the axillary (supplying sensation to the lateral aspect of the shoulder) and the musculocutaneous (supplying sensation to the extensor aspect of the forearm), also should be checked. In the lower extremity, examination of the saphenous (sensory only), peroneal, and tibial nerves should be performed. Neurologic deficit is important to document early, particularly before the patient has undergone any significant manipulation or reduction maneuvers.

FIG. 267-1. A. Peripheral sensory nerve distribution of the hand. B. Peripheral sensory nerve distribution of the foot.

Assessment of vascular status also should be performed early. The sooner circulatory compromise is identified and addressed, the better the chance of avoiding tissue ischemia or necrosis. Injuries such as dislocation of the knee (tibiofemoral joint), fracture-dislocation of the ankle, and displaced supracondylar fracture of the elbow in children are commonly associated with vascular occlusion or disruption, with resulting circulatory impairment.

RADIOLOGIC EVALUATION

The area x-rayed and the particular views ordered should be based on the history and physical examination, rather than on where the patient reports subjective pain. **The joint above and the joint below a fracture should be included on the films**, because injury at the proximal or distal joint may coexist with long-bone fractures.

Injuries that may require special views to be visualized include acromioclavicular separation, fracture of the scaphoid, posterior shoulder dislocation, and sternoclavicular dislocation. **Thus formulation of a presumptive diagnosis before x-ray is crucial. The clinician may never order the specialized views needed to demonstrate a particular injury unless he or she has already anticipated the injury by virtue of the history and physical examination.**

Children who have sustained trauma at or near a joint may need comparison studies of the opposite extremity to differentiate fracture lines from normal epiphyseal plates or ossifying growth centers. This is particularly true for the pediatric elbow, which typically exhibits six separate ossification centers sequentially as the child grows.

Although the clinician may be tempted to base diagnostic and treatment decisions on the radiologist's written report, this is not advisable for at least two reasons. First, a report of negative findings does not rule out significant injury. Fractures of the radial head, scaphoid, or metatarsal shaft, for example, initially may be undetectable on x-ray, even when special views are taken. Second, the terminology used by radiologists to describe malposition of fracture fragments or disrupted joints often differs from the terminology used by orthopedists. Because the emergency physician often will be conferring with an orthopedist regarding the initial management of a patient, and because this interaction commonly involves describing the radiologic appearance of a patient's injury, it is important that the two physicians "speak the same language." This communication might not be achieved by simply relaying the radiologist's written description.

Describing Radiographs

When orthopedic consultation is indicated, proper management of the patient may rest on the emergency physician's accurate description of the x-ray. Often the narrative will influence the orthopedist's decision regarding the need for hospital admission and whether surgical versus nonsurgical management is warranted. In essence, the emergency physician should be able to transmit a virtual copy of the x-ray by means of verbal description.

There are various ways of classifying or categorizing fractures. The method presented in this chapter is intended to be the most practical from the standpoint of effective communication with a consultant who is not physically present.³

OPEN VERSUS CLOSED Although not a radiologic finding per se, this aspect of an injury is among the most important and should be conveyed to the orthopedist before any other. The implications of open fracture are of such significance that this factor alone may determine the patient's immediate care or ultimate disposition.

LOCATION OF THE FRACTURE Typical reference points used by orthopedists to describe the location of a fracture along the shaft of a long bone are the midshaft, the junction of the proximal and middle thirds, and the junction of the middle and distal thirds. Any fracture

more proximal or distal than these locations may be localized in terms of its distance, in centimeters, from the bone end.

When a fracture extends into the adjacent joint, it is termed *intra-articular*. Intra-articular fractures have special significance because disruption of the joint surface may warrant surgery to restore the joint's contour and prevent subsequent traumatic arthritis. This feature of a fracture line, if present, constitutes important information.

Anatomic bony reference points should be cited when applicable. A fracture just above the condyles of the distal humerus or femur, for example, is most precisely called a *supracondylar* fracture. A fracture running from the greater to the lesser trochanter of the proximal femur is an *intertrochanteric* hip fracture, whereas a fracture just below the trochanters is *subtrochanteric*, and a fracture just above is said to involve the femoral *neck*. The area at or proximal to the coronoid process of the ulna is the *olecranon* and should be referred to as such, rather than simply the proximal ulna. Other bony landmarks include the radial head (proximal), radial styloid (distal), and greater tuberosity of the humerus. Numerous additional examples exist.

ORIENTATION OF THE FRACTURE LINE The most common orientations of fracture lines are illustrated in Figure 267-2. Torus and greenstick fractures are seen almost exclusively in young children, whose bones are more pliable than those of adults. Note the segmental fracture, which is commonly described incorrectly as a comminuted fracture. To an orthopedist, the term *comminuted* implies splintering or shattering. A single, large, free-floating segment of bone between two well-defined fracture lines is a *segmental fracture*.

DISPLACEMENT AND SEPARATION *Displacement* refers to the fracture fragments being nonconcentric or offset from each other. It is expressed in terms of direct measurement (4-mm displacement) or in terms of the percentage of the width of the bone (e.g., 50 percent displacement or complete displacement). The direction of displacement is based on the position of the distal fragment in relation to the proximal fragment.

Displacement should not be confused with *separation*, which is the distance two fragments have been pulled apart. Figure 267-3 illustrates principles of displacement and separation.

SHORTENING Shortening is the amount by which the bone's length has been reduced and is expressed in millimeters or centimeters. Shortening may occur by impaction (telescoping of the fragments into one another) or by the overlap of two completely displaced fragments (Figure 267-4). The latter is referred to by some orthopedists as *overriding*. Because an x-ray affords no depth perception, a fracture that appears impacted on one view must be visualized at an angle 90 degrees from the first to differentiate it from a fracture whose ends are completely displaced and overriding.

Depending on the location of the fracture and the age of the patient, shortening may have long-range functional implications and may have to be corrected by closed manipulation or by surgery.

ANGULATION Angulation is expressed in terms of two parameters: direction and amount (Figure 267-5). Quantifying the angulation is relatively simple. One need only estimate the amount of "unbending" (expressed in degrees) that would be required to make the fragments parallel.

Describing the direction of angulation is more difficult, because the terminology is less consistent among clinicians. In general, when a fracture is near the midshaft of a long bone, the direction of angulation is the direction of the *apex* of the angle formed by the two fragments. Figures 267-5 A and 267-5B show 30 degrees of dorsal angulation. When a fracture is near the end of a bone, however, angulation is described in terms of the direction the *terminal fragment* is deviated. Figure 267-5C also shows 30 degrees of dorsal angulation, even though the apex of the angle formed by the fragments is pointing in the

FIG. 267-2. Line orientation. A. Transverse. B. Oblique. C. Spiral. D. Comminuted. E. Segmental. F. Torus. G. Greenstick.

opposite direction from that in the preceding figures. If there is a possibility of ambiguity in the description, specifying the *direction of deviation of the distal fragment* usually can resolve it.

Depending on the anatomic area involved, direction of angulation may be expressed as radial or ulnar, dorsal or volar, anterior or posterior, or lateral or medial.

ROTATIONAL DEFORMITY Rotational deformity, that is, the extent to which the distal fracture fragment is twisted on its own axis relative to the proximal fragment, is generally not measurable on x-ray and sometimes not even radiologically apparent. This element of fracture description depends on physical examination. Its detection is particu-

FIG. 267-3. Fracture displacement and separation. A. No displacement, slight separation. B. Fifty percent dorsal displacement. C. Complete dorsal displacement. D. Nondisplaced, no separation. E. A 4-mm separation.

larly important in the phalanges of the fingers, where, if rotational deformity goes unrecognized and uncorrected, the affected finger will be malaligned when the hand is closed.

FRACTURE COMBINED WITH DISLOCATION OR SUBLUXATION

Injuries near a joint may involve dislocation or subluxation in combination with a proximate fracture. An example is fracture of one or more ankle malleoli, together with partial or complete displacement of the talus from beneath the tibia. Fracture-dislocations are significant injuries, often requiring surgical intervention. If, in describing the injury, the clinician emphasizes the fracture component but expresses the dislocation or subluxation component as mere displacement, then the full severity may not be appreciated by the orthopedist. Such injuries should be described as *fracture-dislocations* or *fracture-subluxations*.

SALTER FRACTURES The physiology of Salter fractures, fractures involving the epiphyseal plate at the end of the long bone of a growing child, has already been discussed. Salter fractures are classified into five types, based on the pattern of the fracture line. Because the type generally correlates with the potential for future growth disturbance (and, consequently, with the aggressiveness of treatment required), the ability to classify such injuries based on their x-ray appearance is important.

FIG. 267-4. Shortening at fracture site. A. Complete displacement with overriding. B. Impaction. In both cases, the width of the shaded area represents the amount of shortening.

Perhaps the easiest way to remember the Salter classification system is to think of these injuries not in terms of where the fracture line runs, but in terms of what has been broken off. Figure 267-6 illustrates the anatomy involved. Table 267-2 lists the five types of Salter fractures, which are illustrated in Figure 267-7. The potential for growth disturbance is least for type I and increases with the classification number, the worst prognosis being associated with type V injuries.

Type I and type V Salter fractures may be radiologically undetectable. Type I injuries usually involve little or no separation of the epiphysis from the rest of the bone, and the lucent fracture line is not visible along the equally lucent epiphyseal plate. If the epiphysis and plate slip transversely along the end of the shaft, or if the epiphysis

FIG. 267-6. Epiphyseal anatomy.

separates appreciably from the shaft, the abnormality will be visible on x-ray, but these rarely occur with type I injuries. Diagnosis of acute Salter type I fractures is usually clinical, based on the presence of swelling and tenderness in the region of the physis.

Type V injuries may be evident only retrospectively, when growth disturbance first begins to appear. At the time of initial presentation, however, a history of a significant axial loading force, coupled with significant tenderness in the area of the epiphyseal plate, should suggest the possibility of a type V injury. Such injuries should be immobilized and referred for orthopedic follow-up.

TREATMENT IN THE EMERGENCY DEPARTMENT

Control of Pain and Swelling

Measures to reduce swelling should be initiated early. Severe swelling not only intensifies the patient's discomfort but also may delay the application of a definitive immobilization dressing and may make the skin more susceptible to pressure sores. Although sometimes regarded as trivial modalities, the application of cold and elevation are effective in keeping swelling to a minimum or at least preventing its progression. When cold is applied, the skin should be protected from direct contact with ice-cold temperatures.

Parenteral analgesics should be administered as necessary. If the patient is relatively comfortable at rest, medication may not be required. **Analgesics have virtually no effect on the pain of movement or manipulation unless combined with hypnotics or other central nervous system active agents.** Jewelry, watches, or rings that may cause compression as an extremity swells should be removed.

Withholding Oral Intake

Any patient who may be a candidate for prompt surgical fixation, manipulation, or any other procedure under general anesthesia or procedural sedation should not be allowed to eat or drink from the moment of arrival until the need for, and timing of, such a procedure has been ascertained. This seemingly obvious point is commonly overlooked, particularly in a busy emergency department, where the process of clinical evaluation may be prolonged and patient hunger or thirst may develop in the interim.

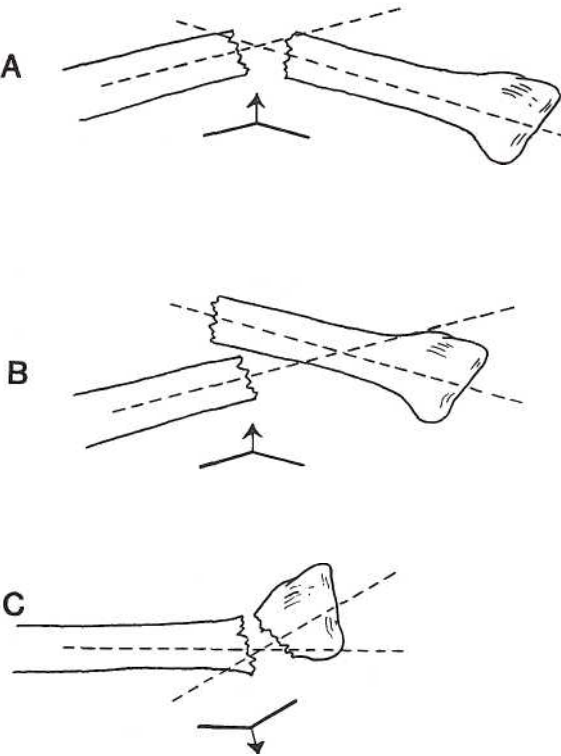

FIG. 267-5. Fracture angulation. All figures depict 30-degree dorsal angulation. A, B. Direction is based on the apex of the angle drawn below the figures. C. Direction is based on the direction of the terminal fragment.

TABLE 267-2 Description of Salter Fractures

Salter Type	What Is Broken Off
I	The entire epiphysis
II	The entire epiphysis with a portion of the metaphysis
III	A portion of the epiphysis
IV	A portion of the epiphysis with a portion of the metaphysis
V	Nothing "broken off"; compression injury of the epiphyseal plate

FIG. 267-7. Epiphyseal fractures based on the classification of Salter and Harris.

Reducing Fracture Deformity

The long-term purpose of reducing significant deformity associated with fractures is restoration of normal appearance and function of the extremity. However, there are short-term reasons for reducing deformity early in the patient's course: (1) alleviating pain, (2) relieving the tension on nerves or vessels that may be stretched as they pass over the deformity, (3) eliminating or significantly minimizing the possibility of inadvertently converting a closed fracture to an open one when the skin is tented by a sharp bony fragment, and (4) restoring circulation to a pulseless distal extremity.

After the patient has been sedated, deformity at or near the mid-shaft of a long bone is usually easy to reduce with gradual, steady, longitudinal traction. Any rotational deformity should be corrected only after the angular component has been addressed and should be performed while traction is maintained. If reduction is performed as a definitive procedure before immobilization, attention to rotational deformity is particularly important, because of its profound effect on ultimate function. Rotational deformity is much easier to appreciate by examining the patient than by examining the x-ray.

The nearer the deformity is to a joint, the more difficult it may be to correct and the more specialized the reduction maneuver may have to be. Who performs the procedure, the emergency physician or the orthopedist, is determined by a variety of circumstances, some of which may be specific to the particular practice environment. When deformity is associated with circulatory deficit, a true emergency exists, and the anticipated delay until reduction should be considered.

Reducing Dislocations

The techniques used to reduce specific dislocations are discussed in subsequent chapters. In general, prerduction x-rays are advisable, unless circulation is threatened and prompt radiologic evaluation is not available. X-rays are needed because dislocations and fracture-dislocations may have a similar appearance on physical examination, but the techniques used to treat them may be markedly different. An example is simple anterior dislocation of the shoulder, as opposed to the same injury associated with complete fracture through the humeral neck. If the fracture is identified at the outset, the patient will be spared the pain of prolonged unsuccessful reduction attempts, and no question will arise as to exactly when the fracture might have occurred. Even "pure" dislocations may be associated with minute fracture fragments. A prerduction film usually will furnish proof of the preexistence of such fragments.

Of course, there are circumstances in which the potential benefits of a prerduction film may be outweighed by the associated expenditure of time and money. For example, a prerduction film may be omitted in a patient with a history of multiple recurrent dislocations of the shoulder who presents with history, signs, and symptoms typical of another recurrence.

The importance of postreduction films is another consideration. Occasionally a joint may feel to the clinician as though it has been reduced, when in fact it has not. Even when a maneuver is successful, the joint may re-dislocate after the patient leaves the emergency department. There is no way to prove that the joint was in anatomic po-

sition at the time of discharge, without a postreduction film. The obtaining of postreduction films is a matter of judgment and ultimately at the clinician's discretion.

Initial Management of Open Fractures

Open fractures, which may be complicated by subsequent osteomyelitis, warrant prompt and meticulous attention. The most important elements in the treatment of open fractures, aside from tetanus prophylaxis that applies generally to any wound, are irrigation, debridement, and antibiotics provided as soon as is practical. Although irrigation and debridement might be performed in the operating room, antibiotics can be administered in the emergency department.

Early administration of antibiotics can help prevent or reduce the clinical manifestations of bacterial contamination in open fractures.^{4,5} The longer the interval between the time of injury and the initiation of antibiotic therapy, the less effective such therapy is likely to be. Exactly what constitutes the ideal antibiotic is controversial. An accepted combination is a first-generation cephalosporin plus an aminoglycoside, but this is by no means the only regimen in use. Aerobic and anaerobic wound cultures can be obtained before antibiotics are administered.

Antibiotics by themselves are not a substitute for irrigation and debridement, both of which have been well demonstrated to be crucial to reducing the incidence of osteomyelitis in open fractures by reducing bacterial contamination and the potential for bacterial colonization.^{6,7} Irrigation should be extensive to (1) make the area more visible to inspection for foreign material, (2) float out nonviable tissue or at least float it into the field of vision so it can be removed, and (3) float out contaminated blood clots and bits of tissue. Pulsatile pumps may increase the effectiveness of irrigation provided the stream is not too forceful. Excessive force may pack debris farther into the recesses of the wound.

Debridement of minor wounds that overlie a fracture sometimes may be performed in the emergency department. When tissue damage is moderate or severe, formal debridement and irrigation are commonly performed in the operating room.

ORTHOPEDIC CONSULTATION IN THE EMERGENCY DEPARTMENT

In many cases, such as fracture of the hip, the need for hospital admission and/or orthopedic consultation in the emergency department is obvious. In some situations, however, differences of opinion may exist among emergency physicians and among orthopedists as to whether the patient needs to be seen by an orthopedist in the emergency department, or whether the patient may be treated in preliminary fashion and referred for subsequent definitive orthopedic management. Even patients with injuries that ultimately may require surgical repair, such as an unstable ankle fracture, sometimes may be immobilized and discharged for prompt orthopedic follow-up.

Some entities or situations that may warrant orthopedic consultation while the patient is still in the emergency department are discussed below.

Compartment Syndrome

The physiology and potentially catastrophic consequences of compartment syndrome are described in Chap. 278. In cases of known or suspected compartment syndrome, orthopedic consultation should be obtained promptly. Emergency surgical intervention may be required to try to avert permanent tissue damage and muscle contracture.

Irreducible Dislocation

The emergency physician sometimes may be unable to reduce a dislocation, even with the aid of nerve block or procedural sedation. Although technique is certainly a factor, there may be other reasons closed reduction cannot be accomplished, such as the interposition of soft tissues or the presence of associated fractures. Orthopedic consultation should be sought in such cases. Timely reduction, which sometimes may be achieved only surgically, may help minimize the complications (and shorten the pain) resulting from a dislocated joint.

Circulatory Compromise

Circulatory deficit resulting from musculoskeletal injury warrants prompt orthopedic consultation. Even if circulation has been restored by the emergency physician through the correction of deformity, the orthopedist may wish to investigate the integrity of the involved vessels and should at least be contacted to discuss the case.

Open Fracture

Some open fractures need to be treated aggressively in the operating room. Other types, such as those involving the phalanges, often may be irrigated in the emergency department and referred for follow-up. If there is any question, a discussion with the follow-up orthopedist may result in a mutually agreeable plan of care.

Injuries Requiring Surgical Repair

Whereas some musculoskeletal injuries require operative intervention as soon as possible, others may be treated on a delayed basis. In many cases, orthopedists differ in their preferred approach to the timing of surgery. Orthopedic consultation, at least by telephone, is indicated in cases of musculoskeletal injury that the emergency physician believes may need operative fixation or repair. The orthopedist may then exercise his or her choice to admit the patient right away, or to see the patient in timely follow-up and schedule surgery at that time.

IMMOBILIZATION TECHNIQUES

Immobilization is indicated not only for fractures but also for dislocated joints that have been reduced. When a joint becomes dislocated, the ligaments that had provided its stability are disrupted, and the joint is susceptible to redislocation until healing has occurred.

Whether plaster or fiberglass is used in the dressing depends on a number of factors, including the emergency physician's preference, the philosophy of the orthopedic community, the needs of the patient, and the hospital's resources. Fiberglass has the advantages of being lightweight, fast setting, and resistant to damage by moisture. Ultimately, the clinician should use the material he or she is most comfortable with and can use most skillfully with the best results.

Principles of Splinting

With the exception of the specific chemical substance involved, references to plaster in the following description are equally applicable to fiberglass.

The chemical reaction that causes plaster of paris (calcium sulfate) to crystallize, or set, is initiated by contact with water. The higher the

water temperature, the faster the hardening process. However, the setting of plaster is an exothermic chemical reaction, which liberates heat. The faster plaster sets, the more heat it generates. This means that the maximum temperature to which the patient's skin is exposed will be the *additive* result of the water temperature plus the heat released by the plaster. For this reason, severe burns can result when plaster has been immersed in hot water, even though the temperature of the water was not sufficient to cause such burns. Although there is no universally prescribed ideal water temperature, a safe practice is to make the water slightly warmer than room temperature. If steam is visible, the water is almost certainly too hot.

To avoid irritation and minimize the potential for pressure sores, plaster dressings need to include several layers of padding between the plaster and the skin. When longitudinal splints are used, the padding need not be circumferential. Longitudinal padding will effectively protect the skin as long as it slightly exceeds the width and length of the splint. The best way to ensure this is to fashion the dry splint first and then measure the padding over it.

The length of a splint should be sufficient to provide ample leverage to immobilize the injured joint. To immobilize the elbow, for example, a splint should begin distal to the wrist and extend high up the lateral arm, to the level of the humeral neck. To effectively immobilize the ankle, a splint should extend from beneath the metatarsal heads to the high calf. If the fracture is along the midshaft of the distal extremity rather than at a joint, the splint should be long enough to immobilize the joint above and the joint below the fracture.

Splints may be fashioned from the plaster rolls normally used for casting or from prepadding material supplied on a continuous roll, which can be cut to length. When using common plaster rolls, determine the necessary length of the splint by measuring out a single layer along the extremity. Then, on a flat surface, unroll the plaster back and forth over itself to make a multilayered splint. For an adult, the splint should be at least 12 layers thick. Even more layers should be used for children, who typically remain as active as possible and have little regard for protecting the dressing.

When the dry splint has been prepared, measure out several layers of padding over it, making the padding longer and wider than the plaster. After setting the padding aside, grip each end of the splint and immerse it in water, keeping it submerged until bubbling stops (indicating that water has been fully absorbed into the interstices of the material). Then withdraw the splint and remove the excess water by sliding the thumb and index finger along the length of the plaster on each side. (Be sure to use a stripping motion, rather than crumpling or wringing out the dressing, or much of the plaster may be lost.)

The next step, frequently overlooked, is to lay the splint on a flat surface and massage the layers into one another so that they fuse. This creates a strong dressing that is solid on cross section. A splint whose separate layers are still visible on cross section is much weaker.

The padding should now be laid on the plaster and the dressing applied to the extremity, with the padded surface against the skin. An assistant can hold the splint against the extremity while it is wrapped in place with gauze bandage. Make sure the assistant uses the palms, rather than fingertips, when holding the plaster. Hardened finger dents can cause irritation or even pressure sores. If a compressive effect is desired, an elastic bandage may be wrapped over the gauze. (If an elastic bandage is wrapped directly onto plaster without an intervening layer of gauze, it will set into the plaster and lose much of its compressive function.)

While the plaster is setting, the affected joint may need to be held in a particular position. The palms, rather than the fingers, should be used. Once the setting process is well under way, the position of a joint should not be changed, or the dressing may crack and become functionally useless. If the joint has gradually migrated from the desired position, the clinician must decide to accept the current position or remove the dressing and start over. There is no need to feel hesitant about the latter course. Patients generally appreciate a desire for perfection by their clinician.

Types of Immobilization Dressings

The more common immobilization dressings used in the emergency department are discussed below and summarized in Table 267-3.

SHOULDER IMMOBILIZER This is a removable, Velcro-fastened device that keeps the arm in "sling position" but allows less mobility than a sling (Figure 267-8). A wide band wraps around the thorax. Two cuffs are attached to the thoracic piece, one on the lateral side, which grasps the upper arm, keeping it adducted against the thorax, and one anterior, which grasps the wrist, keeping the forearm against the abdomen. This dressing is suitable for fractures about the shoulder girdle, including clavicle and well-positioned humeral neck fractures, and for reduced shoulder dislocations.

The shoulder immobilizer is also commonly used for acromioclavicular separations, although the ideal dressing for this injury is one that exerts upward pressure on the elbow and downward pressure on the clavicle. Commercial versions of such dressings exist, but they are cumbersome to apply and uncomfortable to wear, leading to noncompliance. A shoulder immobilizer (or sling and swathe) is an acceptable alternative dressing.

ARM SLING Although it does not provide rigid immobilization, a sling (Figure 267-9) may be used as an adjunct to other splinting techniques for a variety of upper extremity injuries to enhance comfort, reduce motion, and provide some degree of support and elevation to the upper extremity. In some cases, as for nondisplaced fractures of the radial head, it may be used alone, without the need for supplementary immobilization.

TABLE 267-3 Immobilization Devices and Uses

Immobilization Technique	Clinical Application
Shoulder immobilizer	Clavicle fracture Acromioclavicular separation Shoulder dislocation (postreduction) Humeral neck fracture
Sling	A variety of upper extremity injuries, in conjunction with other immobilization techniques; may be used alone for nondisplaced or clinically suspected fracture of the radial head
Long-arm gutter	Elbow fracture or reduced dislocation
Sugar-tong	Wrist or forearm fracture
Short-arm gutter	Metacarpal or proximal phalanx fracture [ulnar gutter for 4th or 5th ray; radial gutter for 2nd (index) or 3rd ray]
Thumb spica	Carpal scaphoid (navicular) fracture (proven or suspected) Thumb metacarpal or proximal thumb phalanx fracture
Knee immobilizer	Patella fracture Knee dislocation, postreduction Tibial plateau fracture Knee ligament injury Suspected meniscal tear (provided the knee can be fully extended)
Posterior ankle mold (consider above-the-knee extension and/or adjunctive use of ankle sugar-tong for unstable ankle injuries)	Ankle dislocation or fracture-dislocation Unstable ankle fracture (high fibula or medial and/or posterior malleolus) Widened medial mortise
Ankle stirrup	Simple ankle sprain Stable lateral malleolus fracture without other ankle involvement

FIG. 267-8. Shoulder immobilizer.

CLAVICLE STRAP (FIGURE-OF-EIGHT BANDAGE) The figure-of-eight clavicle strap is mentioned only as a historical note. This dressing had long been considered the appropriate immobilization method for fracture of the clavicle, but in fact it is fairly ineffective at maintaining alignment of the fracture fragments.⁸ In addition, a clavicle strap may be awkward to apply, may require frequent readjustment, may cause problems related to pressure on the brachial plexus, and is often uncomfortable for the patient. A shoulder immobilizer or a simple sling is a better choice.

LONG-ARM GUTTER SPLINT A long-arm gutter splint maintains the elbow in flexion, usually at 90 degrees (Figure 267-10). The upper extremity is placed in sling position (elbow flexed and palm facing the abdomen). The splint begins on the ulnar surface of the hand at the metacarpal heads and extends along the ulnar surface of the forearm, past the apex of the elbow, to a spot high on the lateral surface of the upper arm just opposite and below the axillary crease. It should be supplemented

FIG. 267-9. Arm sling.

FIG. 267-10. Long-arm ulnar gutter splint.

The most common error associated with fashioning this dressing is insufficient length. If the splint is not carried far enough above the elbow, it will not exert enough leverage to prevent motion of the joint.

The long-arm ulnar gutter is useful for injuries about the elbow, including radial head fractures, nondisplaced supracondylar humeral fractures, and reduced dislocation of the elbow.

SUGAR-TONG SPLINT The sugar-tong is a plaster splint that prevents motion of the wrist and elbow, including pronation-supination (Figure 267-11). The upper extremity is placed in sling position, as described above. The splint begins on the extensor aspect of the hand at the level of the metacarpal heads and runs along the extensor aspect of the forearm, around the elbow and humeral condyles onto the flexor aspect of the forearm, and ultimately to the palmar aspect of the hand, ending at the level of the metacarpal heads. It is wrapped in place with gauze and often topped off with a compression bandage. It should be supplemented with a sling.

FIG. 267-11. Sugar-tong splint.

Proper length of the sugar-tong dressing is important. Too short a splint will fail to immobilize the wrist. If the dressing is too long, it will impair motion of the metacarpophalangeal joints, leaving them stiff and making the fingers more susceptible to swelling due to immobility.

The sugar-tong splint is appropriate for fractures about the wrist or distal forearm. Some orthopedists use it as a definitive dressing after reduction of wrist fractures.

"COCK-UP" WRIST SPLINT (TO BE AVOIDED) A "cock-up" splint is a removable device that extends from the distal forearm to the proximal portion of the hand, and it maintains the wrist in a dorsiflexed position. The splint is fastened with Velcro straps. **Cock-up splints should not be used for fractures of the wrist or carpals**, because such injuries with plaster dressings are usually caused by forceful dorsiflexion, and the splint only reproduces the position of injury, imposing considerable pain in the process. Fractures about the wrist are generally immobilized in neutral position. Colles fractures may even be immobilized in palmar flexion after reduction.

"Cock-up" splints may be useful in some situations unrelated to fractures, such as to immobilize the wrist for tendinitis or to support it in the case of wrist drop due to radial nerve palsy. In such instances, dorsiflexion of the wrist will preserve the patient's grip strength.

SHORT-ARM GUTTER SPLINT A short-arm gutter immobilizes the wrist and the ulnar or radial half of the hand (Figure 267-12). The ulnar gutter, for example, extends along the ulnar surface of the hand and forearm, beginning just proximal to the tip of the fifth finger and ending high onto the forearm. The splint should be wide enough to encompass the fourth and fifth rays (fingers and metacarpals) on the extensor and palmar aspects of the hand. The splint is wrapped in place, with the fourth and fifth fingers bound together but separated by a thin layer of padding to prevent maceration of the skin. The metacarpophalangeal joints and interphalangeal joints should be positioned in gentle flexion. The dressing should be supplemented with a sling.

The short-arm ulnar gutter is useful for fractures of the proximal phalanx of the ring or little finger or for fractures of the fourth or fifth metacarpal (including the common "boxer's fracture"). The counterpart of this splint, the short-arm radial gutter, is designed in similar fashion but extends along the radial surface of the hand and forearm and is used for comparable injuries of the index or middle rays. It is fashioned with a hole that allows the thumb to pass through.

THUMB SPICA A thumb spica immobilizes the wrist and the thumb (Figure 267-13). The term *spica* applies to any dressing that encompasses a main trunk plus one or more of its branches, in this case, the forearm plus the thumb. It is used for fractures of the scaphoid or for fractures of the thumb metacarpal or proximal phalanx.

FIG. 267-12. Short-arm ulnar gutter splint.

FIG. 267-13. Thumb spica splint

A thumb spica can be fashioned from one wide plaster splint, but a more effective and better-looking dressing can be made from two separate splints. The wrist piece runs along the extensor aspect of the hand and forearm, beginning at the metacarpal heads and ending just short of the elbow. The more narrow thumb piece, approximately 2 in. wide, extends from the tip of the thumb (which has been padded separately), along the outer aspect of the thumb metacarpal, and onto the extensor aspect of the forearm, well overlapping the first splint. Along their area of contact, the two splints are molded into each other, with no padding between them, to form a sturdy dressing. The plaster is wrapped in place with gauze, and a compression wrap may be added at the clinician's discretion. The dressing is supplemented with a sling.

While the plaster is setting, optimal position can be achieved by keeping the wrist in *neutral* position and having the patient oppose the tips of the thumb and index fingers in the form of an "OK" sign. This preserves thumb-to-index pinch function, thereby minimizing the patient's incapacitation. It also avoids reproducing the position of injury in the case of scaphoid fractures, which are typically caused by forced dorsiflexion of the wrist.

KNEE IMMOBILIZER The knee immobilizer is a removable circumferential device that extends from the thigh to just above the ankle (Figure 267-14). The splint contains longitudinal metal struts and is fastened with Velcro straps.

A knee immobilizer maintains the knee joint in extension, its position of maximum stability. The device is useful for a variety of injuries, including fracture of the lateral or medial tibial plateau, fracture of the patella, meniscal injuries (provided the patient's knee is not locked in partial flexion), and ligamentous strains or tears.

Use of an immobilizer for days to a week or two may result in painful stiffness of the knee joint. For this reason, orthopedic follow-up should occur within about 7 days. If immobilization is indicated beyond that point, the orthopedist may replace the original device with a cast brace or other orthosis that allows controlled and gradually progressive range of motion.

Motion and Strength Exercises for the Knee Joint stiffness and instability due to quadriceps weakness may occur rapidly when an injured knee is immobilized. Patients wearing an immobilizer should be encouraged to remove the device periodically and perform the following exercises.

1. Passive flexion: While sitting on a flat surface, pull upward on the ends of a towel draped beneath the sole of the foot, creating as much knee flexion as possible without undue pain.
2. "Gravity-assisted" flexion: While sitting on the edge of a bed or chair, support the knee in extension, with the well foot beneath the

FIG. 267-14. Knee immobilizer.

ankle of the injured extremity, then gradually lower the supporting foot so the injured knee "drops" into flexion. When tolerance is reached, bring the knee back into extension.

3. Quadriceps strengthening: While lying supine with a pillow beneath the knee, actively bring the knee to full extension in a straight leg raise and then relax.

Each of these exercises should be performed as multiple repetitions several times a day.

POSTERIOR ANKLE MOLD A posterior mold is a plaster splint that immobilizes the ankle (Figure 267-15). It begins beneath the metatarsal heads, runs along the plantar aspect of the foot, and continues up the back of the lower leg, ending at high calf. The splint is used for severe sprains or fractures of the ankle. Support may be supplemented by a sugar-tong component running down one side of the leg, beneath the heel, and up the other side. Where the two components overlap, they are molded together. The additional component helps minimize inversion and eversion of the ankle. Even more stability is provided by continuing the posterior splint past the back of the knee to the high posterior thigh and using wider plaster for this area. With the knee slightly flexed, rotational motion at the ankle also will be prevented.

While the plaster is setting, the ankle should be maintained in a position as close as possible to neutral, that is, at 90 degrees to the leg. This facilitates regaining range of motion after the dressing is removed. Because most patients with ankle injuries tend to keep the ankle plantar flexed, the clinician usually will have to maintain passive

FIG. 267-15. Posterior ankle mold.

dorsiflexion by exerting gentle pressure with a palm beneath the sole of the foot. An exception to the 90-degree principle is immobilization for rupture of the Achilles tendon. Patients with this injury should be immobilized in plantar flexion to reduce tension on the tendon.

ANKLE STIRRUP Easier to apply and less cumbersome for the patient than a posterior mold, the ankle stirrup (Figure 267-16) is useful for ankle sprains and for stable lateral malleolus fractures. The ankle stirrup is essentially an air-padded "sugar-tong" splint held in place by Velcro straps. Unlike the posterior mold, this device is intended for use in conjunction with weight bearing. It limits inversion more effectively than taping, but allows normal plantarflexion and dorsiflexion. This feature and the graduated compressive effect of the air-filled layers may result in less swelling and edema, less joint stiffness, and a faster return to comfortable ambulation than is typically observed after plaster immobilization.⁹

The stirrup may be removed for purposes of bathing or when not bearing weight. If the patient does remove the splint temporarily, a common error when reapplying it is to fail to unwrap the Velcro straps completely—specifically, to leave the straps attached posteriorly, so that the splint is "hinged" along its posterior aspect, like a "book." This may result in the foot persistently slipping forward and out of the splint. The clinician may wish to instruct the patient that the proper way to reapply the splint is to unwrap the straps *all the way around*, so that the sides fall apart bilaterally, with the foot pad acting as the "hinge" on the plantar aspect (Figure 267-17). The foot can then be positioned on the lower pad, and the sides brought together to adequately

FIG. 267-16. Ankle stirrup.

grasp the medial and lateral aspects of the ankle and lower leg. The final step is to wrap the straps about the posterior and anterior aspects of the dressing.

Motion and Strength Exercises for the Ankle Exercises to restore range of motion, stability, and balance should be started as soon as possible after an ankle injury.

1. Active dorsiflexion and plantarflexion: When done supine with the foot well elevated, this exercise may also enhance lymphatic drainage, thereby reducing swelling.
2. Passive dorsiflexion: One method for performing this exercise is to stand with the palms braced against the wall and then to bend the knee toward the wall while keeping the entire plantar surface of the foot flat on the floor.
3. Eversion, dorsiflexion, and plantarflexion against resistance: This exercise may be achieved by manually applying a counterforce with a stretchable elastic cord (commercially available). Standing on the toes is another means of resistive plantarflexion.

Each of these exercises should be performed as multiple repetitions several times a day.

ADJUNCTS TO AMBULATION

Crutches

Crutches should be used by patients who can bear little or no weight on an injured lower extremity. Ideal crutch height is one hand width

FIG. 267-17. Technique for applying ankle stirrup.

below the axillae. The grip bar should be adjusted to a height at which the elbows are mildly flexed while supporting the body weight. The patient should be instructed to bear the pressure of the pads against the sides of the thorax rather than in the axillae, or brachial plexus injury might result (crutch palsy).

Any of several crutch gaits may be prescribed. With a two-point gait, the patient advances the crutches first and then brings the well leg up to the crutches ("swing-to" gait) or just past the crutches ("swing-through" gait). With a three-point gait, the crutches and the injured extremity are advanced together, and the well extremity is advanced to meet them. The three-point gait results in slower forward progression than does the two-point gait, but it requires less energy. Partial or no weight bearing may be prescribed for the injured extremity, regardless of the gait used.

The method for negotiating stairs is similar for the two- and three-point gaits. To ascend stairs, the patient advances the well extremity up to the next step, followed by the crutches and the injured extremity. To descend stairs, the crutches are lowered first.

Walkers and Canes

Most elderly or infirm patients do not have the strength to use crutches safely. For them, a walker or cane is more suitable. Unfortunately, these devices are more appropriate for partial weight-bearing than for full non-weight-bearing conditions. Elderly patients who can bear no weight on an injured extremity may require initial bedrest and subsequent rehabilitation.

The technique for using a walker is essentially intuitive, with the patient simply lifting it and placing it a short distance ahead and then advancing up to it. In contrast, the technique for using a cane tends to be counterintuitive. Most patients instinctively hold a cane on the same side as the injured extremity. In fact, when the cane is held in the hand on the *well* side, much less strength is required to maintain balance, resulting in an easier and less awkward gait. The patient should be instructed to advance the cane (held on the well side) and the injured extremity simultaneously and then advance the noninjured extremity to meet them.

DISCHARGE INSTRUCTIONS

Continuous elevation of the injured part usually helps minimize swelling and pain. However, most individuals do not realize that, to be effective, elevation must be above the level of the heart. Patients with an injured lower extremity often sit at home or at work with the leg resting on a chair, thinking they are complying with instructions. The patient should understand that the benefits of elevating a lower extremity can be achieved only in a recumbent or near-recumbent position, with the leg supported higher than the rest of the body.

Patients discharged in a lower-extremity plaster dressing should be cautioned not to rest the heel on the floor or any other hard surface. Plaster takes about 24 h to fully set. During this time, prolonged pressure on the heel can gradually create an indentation that may cause significant discomfort or even a pressure sore. This is not a consideration with fiberglass, which sets almost immediately.

If an upper-extremity sugar-tong dressing has been applied, the patient should be instructed to work the fingers (wiggle or wave) as much as possible to minimize stiffness and swelling. The sugar-tong splint should allow full flexion of the metacarpophalangeal joints.

Patients should be advised to monitor the fingers or toes for excessive swelling, decreased sensation, or cyanosis and to be alert for a significant increase in pain. Any of these signs or symptoms warrants a return to the emergency department or prompt evaluation by the follow-up physician.

When crutches, a cane, or a walker is supplied, instruction for use should be provided, and the patient's ability to navigate with such aids should be verified.

FOLLOW-UP

There is no universally prescribed follow-up interval for specific injuries. Orthopedists differ in their opinions as to how soon patients should be seen. In general, patients with unreduced fractures or injuries that may require surgical intervention should be seen within 1 or 2 days.

Sometimes the situation may be discussed with the follow-up physician and an appointment arranged while the patient is still in the emergency department. Alternatively, the emergency physician may instruct the patient to contact the follow-up physician or clinic as soon as possible. If the name of the injury is written on the discharge instruction sheet, the patient can convey it at the time of the call. Based on this information, the follow-up physician can decide when the patient should be seen.

COMPLICATIONS

Complications associated with musculoskeletal injury may be early or delayed and may occur minutes, days, weeks, or even months later.

Neurologic Deficit

Neurologic injury resulting from long-bone fractures or joint dislocations is usually due to traction or pressure on a peripheral nerve or a nerve plexus. Such complications usually manifest themselves early. Recovery may take hours, days, or weeks. Sometimes the injury is irreversible. Prompt reduction of deformity often can prevent, eliminate, or mitigate the effects of neurologic involvement, but it is not a guarantee against permanent deficit.

Vascular Injury

Peripheral vessels that run close to a joint sometimes may be compressed or disrupted when the joint becomes dislocated, as, for example, with dislocation of the ankle or knee (tibiofemoral joint). Loss of peripheral pulse or poor to absent capillary refill calls for expeditious reduction of deformity. Even after reduction, evidence of significant vascular injury may be delayed. Patients who experience tibiofemoral dislocation, for example, often undergo routine postreduction angiography to verify the integrity and patency of the popliteal vessels, regardless of whether a circulatory deficit was noted on initial examination.

Compartment Syndrome

After a fracture or a direct blow to an extremity, there may be extravasation of blood, swelling of muscle tissues, and impairment of venous flow within one or more fascial compartment. The resulting increase in pressure within the limb may lead to circulatory compromise, neurologic damage, and muscle necrosis, known collectively as *compartment syndrome*. This is a true surgical emergency, and early recognition is crucial. Compartment syndrome is discussed in detail in Chap. 278.

Delayed and Late Complications

Patients who have sustained a fracture may be at risk for pulmonary fat embolus, usually originating from the marrow of a large bone, such as the femur. If fat embolism occurs, it is usually within the first few days after injury, rather than in the first hours. This event may have a variable effect on pulmonary function, ranging from mild distress to severe or even fatal respiratory failure.

The most delayed complications of fractures include nonunion, malunion (healing with deformity), joint stiffness, traumatic arthritis of an involved joint, avascular necrosis of one of the bone fragments, and, in the case of open fractures, osteomyelitis.

INJURIES TO THE HAND AND DIGITS

Robert L. Muelleman
Michael C. Wadman

Hand injuries are commonly encountered in the emergency department (ED). The best outcome often depends on an accurate initial evaluation and treatment. This chapter discusses soft tissue injuries distal to the volar wrist crease and fractures distal to the carpal bones.

ANATOMY

The hand consists of 27 bones: 14 phalangeal bones, 5 metacarpal bones, and 8 carpal bones arranged in 5 rays of metacarpals and phalanges having its base at the carpometacarpal (CMC) articulation (Figure 268-1).

The carpal bones are made up of two rows of four bones. They are concave on the volar surface and bridged by flexor retinaculum. This forms the carpal tunnel through which pass the median nerve and the nine long flexor tendons of the fingers. The bases of the second and third CMC articulation are fixed. The thumb, ring, and little finger have mobility at the CMC joint and provide movement that allows for grasp and adaptive movement of the hand.

The soft tissue supporting these bones and joints are the capsular ligamentous structures that give stability, the intrinsic muscles of the hand, and the tendinous structures that generate mobility. The collateral ligaments of the metacarpophalangeal (MP) joints are tightest in flexion (Figure 268-2). The interphalangeal (IP) collaterals are tight throughout the entire range of motion.

The intrinsic muscles of the hand are those that have their origins and insertions within the hand. They consist of the muscle of the thenar and hypothenar eminences, adductor pollicis, the interossei, and the lumbricals (Figure 268-3).

The thenar muscles cover the thumb metacarpal, originate in the flexor retinaculum and carpal bones, and insert at the base of the first

metacarpal and first proximal phalanx. The thenar muscles consist of abductor pollicis brevis, opponens pollicis, and flexor pollicis brevis. The median nerve innervates all three. Adductor pollicis is innervated by the ulnar nerve and originates from the second and third metacarpals and inserts in the first proximal phalanx.

The hypothenar group includes opponens digiti minimi, the flexor digiti minimi, and the abductor digiti minimi. These muscles originate in the flexor retinaculum and carpal bones and insert at the proximal phalanx and metacarpal of the little finger. They are innervated by the ulnar nerve.

There are seven interossei. The three palmar and four dorsal interossei lie between the metacarpal bones and originate from them. The palmar interosseus and the palmar portion of the dorsal interosseus have an insertion into the extensor hood. The palmar interosseus adducts the index, ring, and small finger. The dorsal portion of the dorsal interosseus inserts by tendons into the base of the proximal phalanx. The dorsal interosseous muscles abduct the fingers away from the midline. The interossei are innervated by the ulnar nerve (Figure 268-4).

The lumbricals arise from the flexor digitorum profundus tendons in the palm and course radially to the MP joints and reinforce the interosseous lateral band on the radial side of the digit. The lumbricals contribute little to the flexion of the MP joint; however, they contribute to the extension of the IP joints. The lumbricals play a critical role coordinating the flexor and extensor system of the digits. The median nerve innervates the radial two lumbricals, and the ulnar nerve innervates the ulnar two.

The extensor tendons course over the dorsal side of the forearm, wrist, and hand. Nine extensor tendons pass under the extensor retinaculum and separate into six compartments. In the dorsum of the hand, the extensors digitorum communis are connected by junctura. **Because of this, a complete tendon laceration proximal to the junctura may still result in normal extensor function.** In the finger, the extensor expansion divides into a central slip that attaches to the middle phalanx and into two lateral bands that join with the tendons of the lumbricals and interosseous muscles and that attach to the base of the distal phalanx.

The flexor tendons course over the volar side of the forearm, wrist, and hand. Flexor carpi radialis, flexor carpi ulnaris, and palmaris longus primarily flex the wrist. The remaining nine tendons pass through the carpal tunnel. One tendon goes to the base of the distal phalanx of the thumb. The other four digits have two tendons each. The flexor digitorum superficialis (FDS) inserts into the middle phalanx and flexes all the joints it crosses. The flexor digitorum profundus (FDP) runs deep to FDS until the level of the MP joint where FDS bifurcates. FDP inserts at the base of the distal phalanx and acts primarily to flex the distal interphalangeal (DIP) joint as well as all other joints flexed by FDS (Figure 268-5). Unlike the extensor tendons, the flexor tendons are enclosed in synovial sheaths, making them prone to deep space infections.

The hand and digits have dual blood supplies with contributions from the radial and ulnar arteries. The blood supply of the proximal portion of the hand is composed of a series of deep and superficial arches on the palmar and dorsal side. The blood supply of the fingers is distributed by the digital arteries that arise from the superficial palmar arch (see Figures 268-3 and 268-6).

The radial, ulnar, and median nerves innervate the hand (Figure 268-7). In the hand, the median and ulnar nerves have mixed motor and sensory function. The radial nerve (C5-T1) just has sensory function to the dorsal radial aspect of the hand. The ulnar nerve (C7-T1) supplies sensory function to the ulnar one and one-half fingers and motor function to the hypothenar muscles, ulnar two lumbricals, interossei, adductor pollicis, and the deep head of the flexor pollicis longus. The median nerve (C5-T1) supplies sensory function to the thumb and radial two and one-half fingers and motor function to abductor pollicis brevis, superficial head of flexor pollicis brevis, and

FIG. 268-1. Bones of the hand.

opponens pollicis. As the digital nerves course through the palm, they are superficial structures and are the structures most often injured, so that digital nerve sensation and two-point discrimination should be routinely assessed when evaluating lacerations of the palm (Figure 268-8). The palm is often called "no-man's-land" because penetrating injuries in this area are so difficult to evaluate and treat. Careful neu-

rovascular testing of the hand and digits is necessary for all palmar injuries that involve more than the skin, and hand consultation is advised if the extent of injury is uncertain. In the digits, digital nerves divide into volar and dorsal branches to supply sensation to the fingers. Knowing their location is important to properly perform a digital block (see Figure 268-3).

FIG. 268-2. Ligament attachments of the metacarpophalangeal and interphalangeal joints.

FIG. 268-3. Anterior view of the hand showing relationship of muscles and tendon sheaths.

PRINCIPLES OF EVALUATION

It is important not to let a visually striking hand injury delay the identification and treatment of other potentially life-threatening injuries. After hemorrhage control, assessment involves a detailed history, general hand examination, testing of nerves and tendons, anesthesia, and direct wound inspection. Comparison with the uninjured hand is helpful, especially to identify partial motor or sensory deficits.

History

The history should include the time and cause of injury as well as the possibility of associated crush, burn, or chemical exposure. The position of the hand at the time of injury should be determined. **Injuries with the digits in flexion may result in retraction of the cut end of the tendon when the digit is examined in neutral position.** The patient's occupation, avocations, prior hand injuries, and handedness should be documented because they are important indicators of the functional impact of the injury.

General Hand Examination

The general examination should detail the extent of injury by documenting the amount of devascularization, status of the skin, posture of the fingers, and presence of deformity or active bleeding. Bilateral grip strength should be checked.

Both hands should be compared when assessing motor, sensory, and tendon function to better assess baseline function. Range of motion and strength should be tested against resistance. Have the patient make a

clenched fist to observe the orientation of the middle and distal phalanges. They should be oriented parallel to each other with the nails positioned in the same plane when the fist is clenched. Then, starting with the fingers extended, the patient should draw the fingertips together, so that the tip of the thumb contacts the tips of the other four digits. This is a gross estimation of intact median, ulnar, and radial nerve motor function. Pincer function should also be routinely tested. Have the patient tightly grasp a piece of paper between the thumb and index finger. Weakness suggests median nerve or ulnar collateral ligament disruption, depending on the mechanism of injury being evaluated. Circulation is assessed by regional pulses and capillary refill.¹

NERVE TESTING To test the median nerve, have the patient flex the distal phalanx of the thumb against resistance. Test opposition by touching the tip of the thumb to the tip of the little finger. The patient may be able to accomplish this range of motion with loss of median nerve function due to compensation with muscle groups innervated by the ulnar nerve, but **the patient will be unable to oppose against resistance if median nerve function is lost.** Finally, test thumb abduction by placing the hand palm up and raising the thumb to the perpendicular while palpating the belly of the abductor pollicis muscle to insure it is contracting.

To test the ulnar nerve, spread the fingers apart against resistance and then push them together against resistance. To test the hypothenar muscles (ulnar innervation), extend the fingers and then move the fifth finger away from the others. To test thumb adduction (the ulnar nerve innervates the adductor pollicis muscles), bring the thumb tightly against the side of the index finger. Adductor strength can be further

FIG. 268-4. Origins, insertions, and actions of the palmar and dorsal interossei.

tested by interposing a piece of paper between the thumb and the side of the index finger and then trying to pull the paper away. To test the radial nerve, extend the fingers and wrist. With the thumb in the hitchhiking position, test its resistance to further extension.

Sensation is determined by two-point discrimination. **Normal two-point discrimination is <6 mm at the fingertips and is often <2 mm. Both injured and noninjured fingers must be compared.** Because patients are likely to guess correctly by chance, hand specialists recommend repeating two-point discrimination testing two to four times on each side of the digit. At least 80 percent accuracy is considered acceptable. Less than 80 percent or indeterminate accuracy suggests the possibility of digital nerve injury. A sensory deficit implies a potential digital artery laceration because of the close proximity of the two.

TESTING OF TENDONS In assessing tendon function, full range of motion of each tendon against resistance should be assessed and compared with the uninjured side. It is important to test resistance because **up to 90 percent of a tendon can be lacerated with preservation of range of motion without resistance.** In addition, digit extension is also accomplished by the juncturae tendinum on the dorsum of the hand, so with lacerations of the extensor digitorum communis the

digits can be extended, but not against resistance. Pain along the course of the tendon during resistance testing suggests a partial laceration even if strength appears adequate. Patients can distinguish deep pain of tendon laceration from the superficial pain of lacerated skin. FDP is tested by flexing the DIP against resistance, while the MP and proximal interphalangeal (PIP) are held in extension. Flexing the PIP against resistance while the remaining fingers are held in full extension tests FDS. Each finger must be tested separately. The variable anatomy associated with the FDS to the small finger may lead to a falsely positive result. A modified version of this test, allowing simultaneous ring and small finger flexion, increases the sensitivity of FDS testing.

Anesthesia and Direct Wound Examination

Anesthesia and direct wound inspection is necessary because partial tendon lacerations or intraarticular injuries are not always readily apparent. Sensation and range of motion should be tested before anesthesia. A bloodless field can be facilitated by milking the digit proximally and then applying a local tourniquet or Penrose drain around the base of the digit. The tourniquet should not be stretched to more than 150 percent of its length, and it can be held in place with a hemostat.

FIG. 268-5. Extensor and flexor tendons of the digits.

The digit can be milked by wrapping another Penrose drain circumferentially around the entire digit, going from distal to proximal or by reconfiguring a 4 X 4 in gauze dressing into a narrow band and wrapping that circumferentially around the entire digit. Only moderate compression should be used to avoid compression injury to the digit. The tourniquet should not be left in place for more than 20 min. Contaminated wounds should be copiously irrigated with normal saline, and antibiotics should be administered. Tetanus toxoid should be administered as needed.

Radiographs, Consultation, and Disposition

Radiologic evaluation should include at a minimum a posteroanterior (PA), lateral, and oblique projection. Similar projections are used for the digits, except that the x-ray beam is centered over the digits. Ac-

tual or suspected injuries of tendons and nerves should be referred to a hand specialist. Whether consultation is provided in the emergency department or in follow-up (1 to 3 days) depends on local resources. Injuries requiring immediate and delayed follow-up by a hand surgeon are listed in Tables 268-1 and 268-2, respectively. Table 268-3 provides guidelines for adequate immobilization and follow-up for specific hand injuries referred for delayed hand surgery evaluation. Often the skin can be closed, the hand splinted in the position of function, and at follow-up the wound can be extended, explored, and definitive repair performed by the hand specialist. Most hand specialists prefer to do definitive repair within a 3- to 5-day window after acute injury. While most injuries involving less than 20 percent of the tendon are not surgically repaired, hand specialist follow-up and rehabilitation are still necessary to accurately determine the extent of injury, minimize scarring and tendon contraction, and minimize neuroma formation.

FIG. 268-6. The dual blood supply to the hands and digits.

FIG. 268-7. The cutaneous nerve supply in the hand. DCU = dorsal branch of ulnar nerve; M = median; PCM = palmar branch of median nerve; R = radial; U = ulnar.

For patients with hand or digit lacerations that are sutured in the emergency department, and where there is no suspicion of neurovascular or tendon injury, follow-up evaluation and suture removal in the emergency department should always include repeat hand examination to make sure that significant injuries have not been missed.

TENDON INJURIES

Flexor Tendons

The most common cause of flexor tendon injury is a laceration. Flexor tendon lacerations can be subtle; however, the careful examiner will identify these injuries. A distal-to-proximal five-zone (I-V) classification system for flexor tendon injuries has been developed based on location, treatment considerations, and prognosis.²

ZONE I Extends from the insertion of FDS to the profundus tendon. Patients with these injuries lose flexion at the DIP. Retrieval of the proximal tendon is often difficult.

ZONE II Involves the portion of the digital canal occupied by both FDS and FDP (see Figure 268-5). The close proximity of these tendons makes it essential for exact repair with minimal operative trauma. This region is often referred to as "no-man's-land" because of the frequent poor outcomes prior to the 1960s when improved repair techniques were developed. Lacerations in this zone are common, and partial lacerations are more common than complete.

ZONE III Extends from the distal edge of the carpal tunnel to the proximal edge of the flexor sheath. The lumbrical muscles originate from FDP in this region. Outcomes are generally favorable.

ZONE IV Involves the carpal tunnel and related structures. The area must be explored carefully because so many vital structures go through the carpal tunnel. Isolated injuries are the exception.

ZONE V Involves injuries to tendons proximal to the carpal tunnel. Injuries here tend to be severe and often involve multiple tendons as

well as the median or ulnar nerve. It is essential to search for all major structures.

A hand surgeon should repair flexor tendon lacerations. Primary repair should occur within 12 h. Secondary repair can occur up to 4 weeks after the injury.

Another type of flexor tendon injury is the avulsion of FDP from its insertion in the distal phalanx. This can occur from a grasping motion against high-speed resistance. The patient will be unable to flex the distal phalanx. Prognosis depends on the size of the bony fragment, the length of time from injury to repair, and the blood supply to the tendon.

Extensor Tendons

The extensor tendons are the most common site of tendon injuries because of the superficial nature of the tendons on the dorsum of the hand. A separate zone classification system (I-VIII) has been developed for assessing injury patterns, repair techniques, and rehabilitation.¹³

ZONE I Involves the area over the distal phalanx and DIP. Injury can occur from blunt or sharp trauma. Complete laceration or rupture of the tendon at this level will result in the DIP joint flexed 40 degrees. **This injury after blunt trauma is often referred to as "mallet finger," and it is the most common tendon injury in athletes.** This injury has been classified as type I if there is tendon only rupture, type II if there is a small avulsion fracture, and type III if greater than 25 percent of the articular surface is involved. Types I and II can be treated with the DIP joint immobilized in slight hyperextension continuously for 6 to 10 weeks. Some hand surgeons may prefer operative treatment. Controversy exists whether treatment of type III injuries should be conservative or operative. Chronic untreated mallet finger may develop a **swan-neck deformity** (Figure 268-9). This is caused when the lateral bands are displaced proximally and dorsally, resulting in increased extension forces on the PIP joint.

ZONE II Involves the area over the middle phalanx. Injuries are usually a result of laceration. Treatment is similar to zone I injuries.

FIG. 268-8. Relationship of nerves, arteries, tendons, and muscles in the hand.

ZONE I Involves the area over the PIP. The central tendon is the most commonly injured structure. Complete disruption of the central tendon may result in the volar displacement of the lateral bands, causing them to be flexors, along with the unopposed FDP. Additionally, the extensor hood retracts, causing extension of the MP and the DIP joints, resulting in the **boutonniere deformity** (Figure 268-10). Closed injuries are treated with the PIP joint immobilized in extension for 5 to 6 weeks.

ZONE IV Involves the area over the proximal phalanx. These injuries have clinical findings similar to zone III injuries. Often these injuries are less problematic because the joint is not involved and the tendon at this level is broad and flat.

ZONE V Involves the area over the MP. Open injuries to this area should be considered human bites until proven otherwise. Wounds from human bites should have delayed repair when free from infection. Clean wounds can be repaired primarily.

ZONE VI Involves the area over the dorsum of the hand. Because the tendons in this area are so superficial, even minor-appearing lacerations may be associated with one or more tendon injuries. If the laceration is proximal to the junctura tendineae, the patient may be able to extend the involved MP joint, because weak extensor forces are transmitted to the junctura from adjacent extensor tendons.

ZONE VII Involves the area over the wrist. Repair here can be difficult because of the presence of the extensor retinaculum. This thick, fibrous structure on the dorsum of the wrist contains 12 extensor tendons and 6 retinacular compartments that are lined with synovium.

ZONE VIII Involves the area of the distal forearm. Injuries to this area require a thorough exploration to identify all injured structures. The tendons frequently retract into the forearm and must be retrieved and repaired. As a general principle, lacerations of less than 25 percent don't require repair; 25 to 50 percent need simple suture repair, and greater than 50 percent need repair with a modified Kessler or similar technique. After repairs in zones V through VII, splinting should occur with the wrist in 15-degree extension, the MP joint in 15-degree flexion, and the IP in 15-degree flexion in the involved and adjacent digit.

LIGAMENT AND DISLOCATION INJURIES

Soft tissue injuries to the hand are extremely common. Accurate diagnosis and treatment are important to avoid complications such as joint luxatio, loss of motion, chronic pain, and deformity.

DIP

Dislocations of the DIP joint are uncommon because of the firm attachments of the skin and subcutaneous tissue to the underlying bone

TABLE 268-1 Immediate Hand Surgery Consultation Guidelines

Vascular injury with signs of tissue ischemia or poorly controlled hemorrhage
Irreducible dislocations
Grossly contaminated wounds
Severe crush injury
Compartment syndrome
High pressure injection injury
Hand/finger amputation

Extensor/flexor tendon laceration (if not repaired in ED)
Flexor digitorum profundus rupture (closed)
Nerve injury (proximal to mid middle phalanx)
Fractures
Dislocations
Ligamentous injuries with instability

TABLE 268-3 Immobilization and Follow-Up Guidelines

Injury	Splint	Duration	Referral
Ligamentous injuries			
Thumb MP UCL rupture			
Partial tears	Thumb spica, IP free to flex	2 weeks	1 week
Complete or equivocal	Thumb spica (presurgical repair)	—	2–3 days
Tendon injuries			
Mallet finger	Dorsal splint, full extension at DIP	8 weeks	1 week
Flexor tendon laceration	Dorsal splint, 30-degree wrist flex, 70-degree MCP flexion, 30–45-degree PIP flexion (presurgical repair)	—	1 day
Dislocations			
DIP	Dorsal splint, full extension	2 weeks	1 week
PIP			
Stable/postreduction	Dorsal splint, 30-degree PIP flexion	2 weeks	1 week
Unstable/postreduction	Dorsal splint, 30-degree PIP flexion	2 weeks	2–3 days
MP	Buddy-taping	2 weeks	1 week
CMC	Dorsal–volar splint	2 weeks	2–3 days
Thumb IP	Dorsal splint, full extension	2 weeks	1 week
Thumb MP	Thumb spica	2 weeks	1 week
Fractures			
Distal phalanx	Volar or hairpin splint not immobilizing PIP	2 weeks	2 weeks
Middle/proximal phalanx			
Stable/nondisplaced	Buddy-taping/dynamic splinting	2 weeks	1 week
Nonstable/displaced	Radial/ulnar gutter, 90-degree MP flexion, <15–20-degree PIP flexion, <5–10-degree DIP flexion	2 weeks	1 week
Thumb proximal phalanx	Thumb spica	2 weeks	1 week
Metacarpal			
Index, middle	Radial gutter, 20-degree wrist flexion, 90-degree MP flexion, PIP left mobile	2 weeks	1 week
Ring, small	Ulnar gutter, 20-degree wrist flexion, 90-degree MP flexion, PIP left mobile	2 weeks	1 week
Thumb metacarpal	Thumb spica	2 weeks	1 week
Extraarticular	Thumb spica for initial immobilization (presurgical repair)	—	2–3 days
Intraarticular			

Abbreviations: CMC = carpometacarpal; DIP = distal interphalangeal; IP = interphalangeal; MP = metacarpophalangeal; PIP = proximal interphalangeal; UCL = ulnar collateral ligament.

by osteocutaneous fibers. There is additional stability of the flexor and extensor tendons. When they do occur, they are usually dorsal. Longitudinal traction and hyperextension, followed by direct dorsal pressure to the base of the distal phalanx, accomplish reduction after digital nerve block. Irreducible cases may be due to the entrapment of an avulsion fracture, profundus tendon, or volar plate.

PIP

Dislocations of the PIP joint are one of the most common ligamentous injuries of the hand. The mechanism is usually due to axial load and hyperextension. Dorsal dislocation occurs when the volar plate ruptures. Lateral dislocations occur when one of the collateral ligaments ruptures with at least a partial avulsion of the volar plate from the middle phalanx. The digit is usually ulnarly deviated because the radial collateral ligament is six times more likely than the ulnar collateral ligament to rupture. Volar dislocations are rare. Dorsal dislocations are reduced similarly to DIP dorsal dislocations. After reduction, active motion and strength is tested. If testing is normal, the joint

should be splinted at 30-degree flexion for 3 weeks. If the joint is irreducible or there is evidence of complete ligamentous disruption, operative repair is required.

MP

Dislocations of the MP joint are less common than at the PIP joint. The mechanism is usually due to hyperextension forces that rupture the volar plate causing dorsal dislocation. In simple dislocations (subluxation), the joint appears to be hyperextended 60 to 90 degrees and the articular surfaces are still in contact. Reduction here does not involve hyperextension because it might convert a simple dislocation into a complex one. Reduction is performed with the wrist flexed to relax the flexor tendon and applying pressure over the dorsum of the proximal phalanx in a distal and volar direction. After reduction, the MP joint should be splinted in flexion. Complex dislocations appear

**FIG. 268-9.** Swan-neck deformity.**FIG. 268-10.** Boutonniere deformity.

less deformed. Because the volar plate is interposed in the MP joint space, closed reduction is usually not possible. Volar dislocations are rare and usually require operative reduction.

CMC

Dislocations of the carpometacarpal joint are uncommon because the joint is supported by strong dorsal, volar, and interosseous ligaments and are reinforced by the broad insertions of the wrist flexions and extensors. The cause is usually a result of high-speed mechanisms such as motor vehicle crashes, falls, crushes, or clenched fist trauma. If a dislocation occurs, it is usually dorsal with associated fracture. Reduction of dorsal CMC dislocations can be attempted after regional anesthesia with traction and flexion with simultaneous longitudinal pressure on the metacarpal base. Early referral after reduction is needed to determine if further fixation is needed.

Thumb IP

Dislocations of the thumb IP are rare but, if present, usually open. The mechanism is usually hyperextension with rupture of the volar plate. Reduction is similar to the IP joints of the other digits. After reduction, the joint should be immobilized 3 weeks in mild flexion.

Thumb MP

Dislocations of the MP joint of the thumb are usually dorsal from a hyperextension force causing rupture of the volar plate. The dislocation may be simple or complex. Reduction, after radial nerve block, is accomplished with pressure directed distally on the base of the proximal phalanx with the metacarpal flexed and abducted.

Thumb MP Collateral Ligament Rupture

Rupture of the ulnar collateral ligament (gamekeeper's thumb, skier's thumb) occurs when the mechanism causes radial deviation (abduction) of the MP joint. The tear usually occurs at the insertion into the proximal phalanx. Often significant injury to the dorsal capsule and volar plate occurs. **Hand surgery referral is recommended for all patients with weakness of pincer function and point tenderness at the volar-ulnar aspect of the thumb MCP joint** resulting from a forced abduction mechanism of injury. For patients with normal radiographs, abduction stress testing of the ulnar collateral ligament may be performed to provide additional clinical information. The examiner tests the thumb MCP, both in full extension and 30-degree flexion, by stabilizing the metacarpal with one hand while applying lateral (radial) stress on the proximal phalanx with the other. More than 40 degrees radial angulation indicates complete rupture and requires surgical consultation. Repair is best accomplished within 1 week. Radial collateral ligament rupture is not as common, and the mechanism is forced adduction.

Thumb CMC

Isolated thumb CMC dislocation is rare compared to the more common Bennett fracture dislocation. These are easy to reduce but unstable after reduction. After reduction, a thumb spica splint should be applied. These injuries should have a surgical referral for a decision on operative repair.

FRACTURES

Distal Phalanx

Fractures of the distal phalanx account for 15 to 30 percent of all hand fractures. Mechanisms are usually from crash or shearing forces. The

fractures can be classified as tuft, shaft, or intraarticular. Tuft fractures can be associated with nail bed lacerations. Fractures at the base may be associated with flexor or extensor tendon involvement. Generally, these fractures are treated as soft tissue injuries with protective splinting.

Proximal and Middle Phalanx

The proximal phalanx has no tendinous attachments, therefore fractures frequently have volar angulation from the forces of the extensor and interosseous muscles. The middle phalanx has the FDS insert on the entire volar surface and the extensor tendon insert at the proximal base; therefore, fractures at the base have dorsal angulation and fractures at the neck result in volar angulation. A direct blow mechanism usually causes a transverse or comminuted fracture, while a twisting mechanism will more often result in a spiral fracture. Most often these fractures are stable and nondisplaced and can be treated with early protected motion by buddy taping. Unstable fractures amenable to closed reduction can be splinted from the elbow to the DIP with the wrist at 20-degree extension and the MP joint in 90-degree flexion. Midshaft transverse fractures, spiral fractures, and intraarticular fractures often require internal fixation.

Metacarpal (II to V) Fractures

The second and third metacarpals are relatively immobile, and fractures require anatomic reduction. The fourth and fifth metacarpals have 15- to 20-degree AP motion, which allows for some compensation. Metacarpal fractures are categorized as head, neck, shaft, or base fractures.

HEAD Fractures of the metacarpal head are usually caused by a direct blow, crush, or missile. These fractures are distal to the insertion of the collateral ligaments and are often comminuted. If a laceration is present, a human bite must be considered. Treatment consists of ice, elevation, and immobilization with referral to a hand surgeon.

NECK Fractures of the metacarpal neck are usually caused by a direct impaction force. A fracture of the fifth metacarpal neck is often referred to as a boxer's fracture. These fractures are usually unstable with volar angulation. **Angulation of less than 20 degrees in the fourth and 40 degrees in the fifth metacarpal will not result in functional impairment. If greater angulation in these metacarpals occur, reduction should be attempted. In the second and third metacarpal, angulation of <15 degrees is acceptable.** These fractures should be splinted with the wrist in 20-degree extension and the MP flexed at 90 degrees. Fractures of the second or third metacarpal that are significantly displaced or angulated require anatomic reduction and surgical fixation.

SHAFT A direct blow usually injures fractures in this region. Rotational deformity and shortening are more likely in shaft fractures than in neck fractures. If manipulative reduction is necessary, operative fixation is usually indicated.

BASE Fractures at the base of the metacarpal are usually caused by a direct blow or axial force. They are often associated with carpal bone fractures. Fractures at the base of the fourth and fifth metacarpal can result in paralysis of the motor branch of the ulnar nerve.

Thumb Metacarpal

Because of the mobility of the thumb metacarpal, shaft fractures are uncommon. Fractures usually involve the base.

EXTRAARTICULAR Extraarticular fractures are caused by a direct blow or impaction mechanism. The mobility of the CMC joint can allow for 20-degree angular deformity. Angulation greater than this

requires reduction and thumb spica splint for 4 weeks. Spiral fractures often require fixation.

INTRAARTICULAR Intraarticular fractures are caused by impaction from striking a fixed object. Two fracture types have been described.

Bennett Fracture A Bennett fracture is an intraarticular fracture with associated subluxation or dislocation at the CMC joint. The ulnar portion of the metacarpal usually remains in place. The distal portion usually subluxes radially and dorsally from the pull of abduction pollicis longus and the adductor pollicis. Treatment includes thumb spica splint and surgical referral.

Rolando Fracture A Rolando fracture is an intraarticular comminuted fracture at the base of the metacarpal. The mechanism of injury is similar to the Bennett fracture, but less common. Treatment includes thumb spica splint and surgical consultation.

COMPARTMENT SYNDROME

Crush injury of the hand, with or without associated fracture, may result in compartment syndrome. The involved compartments of the hand include the thenar, hypothenar, adductor pollicis, and four interossei. Edema of tissues or hemorrhage within any of these compartments may lead to elevated pressures that result in tissue necrosis and subsequent loss of hand function due to contracture if not diagnosed and treated in a timely and appropriate manner.³

Signs and symptoms of compartment syndrome typically include pain and paresthesias early, with paralysis and pulselessness occurring later in the course of the ischemia injury. Hand compartment syndromes, however, may lack paresthesias and the extremely subtle motor deficits and difficulty in assessing response to passive stretch on physical examination make the diagnosis more elusive than at other anatomic sites. Pain, the most consistent clinical sign, is often described as deep, constant, poorly localized, and disproportionate to clinical findings. Physical examination findings suggestive of hand compartment syndrome include "intrinsic minus" position at rest (MCP extended with PIP slightly flexed), pain with passive stretch of the involved compartmental muscles (interosseous: performed with MCP extended and PIP fully flexed with slight radial and ulnar deviation; thenar, hypothenar: performed by extension of MCP), and tense swelling of the affected compartment.

Diagnosis is usually confirmed by compartment pressure measurement, but this procedure is more difficult in the relatively small compartments of the hand and may yield misleading results. In the setting of severe crush injury with signs and symptoms suggestive of compartment syndrome, emergent hand surgeon consultation for fasciotomy is mandatory.

HIGH-PRESSURE INJECTION INJURY

A high-risk injury to the hand that initially appears benign is the injection of certain substances under high pressures into the soft tissues of the hand (often 2000 to 10,000 psi). Often occurring in the industrial setting, the operator of the high-pressure device typically attempts to test or clean the nozzle with his nondominant hand and inadvertently injects the substance. The initial dissipation of kinetic energy through the soft tissues of the hand and the subsequent chemical inflammation both produce tissue edema and resultant ischemia of tissue. The most commonly injected substances include grease, paint, hydraulic fluid, diesel fuel, paint thinner, and water. Of the most commonly injected substances, paint, especially oil-based paint, triggers a more intense inflammatory response that contributes to the overall risk for significant ischemic injury and consequent amputation.

The benign appearance of the small injection site puncture wound in the immediate postinjection period may mislead the clinician, and his-

torical information must dictate treatment/disposition decisions. With time, the digit becomes edematous, pale, and severely tender to palpation suggesting the ischemic injury of compartment syndrome. Pressure to areas surrounding the wound may express the injected substance.

Plain radiographs of the injected hand and adjacent forearm provide valuable information as radio-opaque substances, such as lead-based paints or grease, or subcutaneous emphysema may delineate the extent of the injection.

Definitive treatment of high-pressure injection injuries is early surgical decompression and debridement of injected areas. The emergency physician must recognize the injury as a surgical emergency and obtain immediate hand surgery consultation, immobilize and elevate the affected hand, administer tetanus prophylaxis and broad-spectrum antibiotics, and provide adequate analgesia.⁶

WRIST INJURIES

Dennis T. Uehara

Dean Wolanyk Robert

H. Escarza

The wrist comprises the area from the distal radius and ulna to the carpometacarpal joints. It is a complex unit with articulations among the eight carpal bones and the distal radius and ulna. Wrist injuries are common and clinical diagnosis is often difficult. Even subtle injuries may lead to significant impairment if not properly diagnosed and treated. Therefore an understanding of the functional anatomy, mechanisms of injury, and clinical evaluations are needed for proper diagnosis and treatment.

ANATOMY

The distal radius is the only forearm bone that articulates directly with the carpal bones (scaphoid and lunate). The distal radius has three articular surfaces: radiocarpal, distal radioulnar, and the triangular fibrocartilage complex (TFCC). The radiocarpal surface is concave and tilted in two planes. It has an ulnar inclination or tilt of 15 to 25 degrees in the frontal plane and a volar tilt of 10 to 15 degrees in the sagittal plane. The ulna is separated from the carpal bones by the triangular fibrocartilage complex, the main stabilizer of the distal radioulnar joint (DRUJ), on its distal end. The TFCC forms a smooth, continuous, ulnarly directed extension of the distal radial surface and supports the lunate and triquetrum on the distal ulna. The distal radius has a concave sigmoid notch as its ulnar aspect that articulates with the curvature of the ulnar head, permitting rotation of the wrist during pronation/supination of the forearm. The distal radioulnar joint is also supported by dorsal and volar radioulnar ligaments that merge with the TFCC.¹

The eight carpal bones are arranged in two rows (Figure 269-1). The distal row (trapezium, trapezoid, capitate, and hamate) is joined tightly together and to the adjoining metacarpals. This row is quite sta-

FIG. 269-1. Key elements on a normal posteroanterior view. (1) The carpal bones are arranged in two rows forming three smooth arcs. (2) The carpal bones are separated by a uniform 1- to 2-mm space. (3) The scaphoid is elongated. (4) The radius has an ulnar inclination of 13 to 30 degrees. (5) The radial styloid projects 8 to 18 mm, with an average of 13 mm. (6) Half the lunate articulates with the radius, with equal length over the ulna (neutral ulnar variance).

ble, moving together with the metacarpals as a unit in a relatively stable arch. The proximal carpal row (scaphoid, lunate, triquetrum, and pisiform) is also arranged in an arch between the distal radius and distal carpal row. This proximal row functions as a mobile link or "intercalated segment" in this arrangement, and by virtue of this position is potentially unstable. The scaphoid holds a unique position, acting as a stabilizing strut and linking the proximal and distal carpal rows at the radial aspect of the wrist. This position explains the scaphoid's greater propensity for injury.

Wrist motion is produced by forearm muscles that insert onto the bases of the metacarpals. There are no direct tendon insertions on the carpal bones (except for the pisiform, a sesamoid bone of the flexor carpi ulnaris). The carpal bones move passively in response to hand position. Although the radiocarpal joint is often referred to as the "wrist joint," it is important to realize that wrist motion is nearly equally divided between the radiocarpal and midcarpal joints. This is best appreciated when viewing carpal movement from the sagittal view. During flexion and extension of the wrist, each row moves in the same direction with similar degrees of angulation.

The carpal bones are stabilized to one another by intrinsic ligaments and to the bones of the forearm by extrinsic ligaments. The key extrinsic ligaments are arranged in three arcades, two of which are volar and one dorsal. The two volar ligaments are arranged in two inverted-V shaped arches. The apex of one arch inserts on the lunate supporting the proximal carpal row, while the other arch reaches to the distal carpal row, inserting on the capitate. The area between these two palmar arches is inherently weak and is known as the space of Poirier (Figure 269-2). This space lies at the junction of the capitate and lunate and widens upon dorsiflexion of the wrist. Forceful dorsiflexion may tear the capsule here and produce a lunate or perilunate dislocation. The single dorsal arcade has its origins on the rim and styloid of the radius on one side and distal ulna/TFCC on the other. This ligament is less important for wrist stability, acting as a sling across the dorsum of the wrist.²

The intrinsic ligaments are largely responsible for holding the carpal bones together as a kinematic unit in their respective carpal rows. The intrinsic ligaments of the mobile proximal carpal row are particularly

important because of their greater propensity for injury. The intrinsic ligaments of the proximal carpal row are named after the respective carpal bones they connect: the scapholunate and triquetrolunate. The palmar flexed posture of the scaphoid produces a flexion torque on the lunate that is counterbalanced by an extension torque from the triquetrum. Unfortunately, this delicate balance is lost if either ligament is disrupted, producing a dorsal or volar tilt of the proximal carpal row and carpal instability.

CLINICAL ASSESSMENT

Mechanism of injury is an often ignored but helpful aspect of the evaluation of wrist injuries.³ Age affects the maturity of the bones and predisposes patients to certain types of injury. Children are more likely to sustain injuries to the immature, weaker epiphyseal plate or metaphysis of the radius, sparing the still-cartilaginous carpal bones. Young adults, particularly those with active lifestyles, are more likely to be injured with greater force and disrupt either the scaphoid, proximal row intrinsic ligaments, or distal radial metaphysis. In the elderly, the weak point is the brittle distal radial metaphysis, resulting in a Colles' fracture, often with intra-articular involvement.

Most injuries are caused by a fall on an outstretched hand. Impact on the thenar eminence is more likely to injure the scaphoid and its supporting ligaments. An impact on the hypothenar eminence is likely to cause injury to the triquetrum, pisiform, and their supporting ligaments.

Pinpointing areas of tenderness and correlating them to anatomic landmarks of the wrist will help determine what structure may be injured, and the best way to evaluate it is with radiography. The most noteworthy landmark on the dorsum of the wrist is the "anatomic snuffbox." The scaphoid is palpable within this triangle formed by the bony radial styloid at its proximal base, the extensor pollicis brevis tendon at its radial aspect, and the extensor pollicis longus tendon at its ulnar aspect. The extensor pollicis longus tendon wraps around a bony prominence of the distal radius, known as Lister's tubercle. The area immediately distal to this point marks the location of the scapholunate joint. Immediately ulnar to the scapholunate joint is a palpable indentation in the center of the wrist. This is the location of the lunate and capitate, which are palpable as they rise out of this space during wrist flexion. The ulnar styloid is the bony prominence on the ulnar aspect of the wrist. The triquetrum and triangular fibrocartilage complex are located just distal to this prominence.

The crease noted on the volar aspect of the wrist marks the location of the proximal carpal row. The scaphotrapezium joint is palpable at the base of the thenar eminence. The pisiform is the palpable bony prominence at the base of the hypothenar eminence. The hook of the hamate is palpable in the soft tissue distal and radial to the pisiform.

RADIOGRAPHY

Clinical examination should dictate which radiographic views in order to support a diagnosis. Standard views of the wrist include posteroanterior (PA), lateral, and oblique views. These views are adequate in the majority of cases; however, other projections may be necessary to profile specific carpal injuries.^{4,5}

The key to interpreting the radiograph is to first ensure proper positioning, then identify specific features on each projection. On a properly positioned PA view, the distal radius and ulna should not overlap at their distal articulation, and the axis of the third metacarpal should parallel that of the radius. In addition to looking for disruption of the bony cortex, key elements on the PA view are illustrated in Figure 269-1.

On the PA view, three smooth arcs outline the articular surfaces at the radiocarpal and midcarpal joints. Two of these arcs are formed by the proximal and distal surfaces of the scaphoid, lunate, and triquetrum. The third arc is formed by the proximal articular surface of the capitate and hamate in the midcarpal joint. Any distortion of these lines implies a possible fracture, dislocation, or subluxation at the site.

The carpal bones fit together much like a jigsaw puzzle, with the pieces separated by a uniform 1 to 2 mm space. This space is increased or obliterated with ligament disruption, carpal instability patterns, or fracture/dislocations. This occurs most often around the lunate at the scapholunate and capitolunate joints.

The scaphoid has an elongated shape in its normal, palmar flexed position. Fractures or ligament disruption may cause further palmar rotation, causing the scaphoid to appear shortened on the PA view. Injuries to the scaphoid also may obscure the "scaphoid fat stripe," a linear or triangular, radiolucent collection of fat distal to the radial styloid and parallel to the radial border of the scaphoid.⁶

Unfortunately, incorrect positioning can produce overlap patterns that can be misinterpreted as pathologic. For example, radial deviation of the wrist causes normal physiologic rotation of the proximal carpal row, obliterating the capitolunate space. At the same time, the scaphoid that should appear elongated on the PA view appears shorter as it rotates palmarly, and can be confused with a rotary subluxation of the scaphoid.

The radial styloid should project 8 to 18 mm beyond the distal radioulnar joint and create an ulnar inclination of 13 to 30 degrees on the PA view. Distal radius fractures can alter these measurements. At the distal radioulnar joint, the ulna and adjacent portion of the radius should be of equal length, and the distal radius should articulate with at least half the lunate. The extrinsic ligaments along with the TFCC prevent ulnar translocation (migration of the carpal bones down the ulnar tilt of the radiocarpal surface). The lunate would have less contact and support from the radius if ulnar translocation were present. A shorter ulna (negative ulnar variance) also provides less support to the lunate and increases potential shear stress to the lunate, predisposing the lunate to injury.

The lateral radiograph is important for determining carpal alignment and degree of fracture angulation. Again, the first step is assuring that the wrist is properly positioned on the radiograph. The radius and ulna should completely overlap one another, and the radial styloid should be centered over the distal radial articular surface. The key elements are illustrated in Figure 269-3A.

The axis of the radius, lunate, and capitate is collinear on the lateral view. If the articular surfaces of these bones were highlighted, they would appear as three consecutive C's. This provides a simple radiographic assessment of wrist dislocation. Measurement of the capitolunate and scapholunate angles is a more precise assessment of carpal alignment. The axis of the capitate, lunate, and scaphoid runs through the center of their proximal and distal articular surfaces. The axis of the lunate and capitate should nearly overlap and form an angle that is less than 10 to 20 degrees. The scaphoid is normally palmar flexed on the lateral view; its axis should form an angle between 30

FIG. 269-3. A. Normal wrist. (1) Axis of the radius, lunate, and capitate are collinear (three C's sign). (2) The capitolunate (CL) angle is less than 10 to 20 degrees. (3) The scapholunate (SL) angle is between 30 and 60 degrees. (4) The radial volar tilt is 10 to 15 degrees. B. Dorsal intercalated segment instability (DISI). The lunate tilts dorsal and slides palmar, increasing the capitolunate angle. The scaphoid tilts more palmar and increases the scapholunate angle. The axes of the radius, lunate, and capitate take on a zigzag pattern (dark line). C. Volar intercalated segment instability (VISI). The lunate tilts palmar and the capitolunate angle increases, but the scapholunate angle is maintained. The zigzag pattern is in the opposite direction.

and 60 degrees with the lunate. Deviation from either of these angles suggests ligament disruption and carpal instability patterns (Figures 269-3B and 269-3C).

Fracture of the distal radius is the most common fracture in the wrist.⁷ While a displaced fracture is the obvious deformity, the alteration of the normal volar tilt of 10 to 15 degrees of the distal radial articular surface has greater long-term consequences for wrist function. The shape of the distal radius, distal ulna, and TFCC has a significant influence on carpal alignment and movement.

Other radiographic views profile specific areas of the wrist. Oblique views are performed in either partial pronation or supination, and project the scaphotrapezium joint or pisiform away from overlapping adjacent carpal bones. The scaphoid view is a cone-down PA view of the scaphoid in ulnar deviation. This position extends the normal flexed posture of the scaphoid so that the bone is projected length-

wise. This view may assist in detecting subtle fractures and should be used whenever scaphoid injury is suspected. The carpal tunnel view is a tangential view through the carpal tunnel and is helpful in visualizing the pisiform and hook of the hamate. Motion studies are dynamic views in flexion, extension, and radial and ulnar deviation. These views examine carpal movement relative to one another, and stress the intercarpal ligaments for laxity, characterized by widening of the intercarpal space. Likewise, the grip compression or fist view is a stress view in the PA projection of the tightly clenched fist. The capitate is pushed into the proximal carpal row and forces the carpal bones apart if intrinsic ligaments are disrupted.

LIGAMENTOUS INJURIES

The lunate is located in the middle of the wrist, so it is not surprising that the majority of ligamentous injuries are centered on the lunate. These injuries usually result from forceful dorsiflexion of the wrist, most often from a fall on an outstretched hand. The various injuries occur sequentially depending on the degree of force, and range from isolated tears to perilunate and lunate dislocations.⁸

Scapholunate Ligament Instability

The scapholunate ligament is the intrinsic ligament that binds the scaphoid and lunate. Since the scaphoid bridges the proximal and distal carpal rows, it is not surprising that the scapholunate ligament has a marked propensity for injury and is the most commonly injured ligament of the wrist. Injury most often is from a fall on an outstretched hand with impact on the thenar eminence. Patients will complain of pain and swelling on the radial side of the wrist, and often a "clicking" sensation with wrist movement. Examination reveals localized tenderness on the dorsum of the wrist in the area immediately distal to Lister's tubercle. Ballotment of the scaphoid may also produce pain in this area. This injury is often referred to by the various radiographic appearances it may take. There are three different radiographic signs that may occur separately or in combination with one another. Scapholunate dissociation is a widening of the scapholunate joint space of more than 3 mm on the PA view (Figure 269-4). This has been called the "Terry Thomas sign,"⁹ named after a British comedian with a notable dental diastema between his upper front incisors. If it is not apparent on routine views, a grip-compression view or motion study may be necessary to demonstrate the abnormal gap. These maneuvers are particularly helpful in identifying an incomplete tear of the ligament. Rotary subluxation of the scaphoid is another abnormality that often accompanies scapholunate dissociation. A torn scapholunate ligament can cause the scaphoid to tilt more palmar and increase the scapholunate angle to greater than 60 degrees on the lateral view. On the PA view, the scaphoid tilts toward the observer so that it appears shorter as it is viewed more on its end. This causes the circular cortex of the bone to become more prominent and appear as a ring, known as the "cortical ring sign." A third radiographic abnormality is a carpal instability pattern known as dorsal intercalated segment instability (DISI; see Figure 269-3B). The normal flexed posture of the scaphoid produces a flexion torque on the lunate that is counterbalanced by an extension torque from the triquetrum. When the scapholunate ligament is torn, this balance is disrupted. The lunate tilts dorsal from the unopposed extension torque from the triquetrum, while the scaphoid tilts more palmar (rotary subluxation of the scaphoid) because it has lost support from the lunate. The dorsal tilt of the lunate also causes a slight flexion tilt of the capitate. In the lateral view, the normal collinear arrangement of the axes of the capitate, lunate, and radius are replaced by a characteristic zigzag pattern. Both the scapholunate and capitolunate angles are increased. The concept of the proximal carpal row being the middle link or "intercalated segment" in this system, combined with the lunate's pathological dorsal tilt and zigzag pattern, is how this abnormality came to be named "dorsal intercalated segment instability."¹⁰

FIG. 269-4. Scapholunate dissociation with accompanying rotary subluxation of the scaphoid. The scaphoid and lunate are separated by a gap of more than 3 mm (arrowhead) and the scaphoid appears shorter from rotation with a dense ring (cortical ring sign, arrow).

These injuries are treated acutely with a radial gutter splint or short arm volar posterior mold. Appropriate orthopedic referral is necessary because these injuries require either closed reduction with percutaneous pinning, or open reduction and internal repair of the ligament.⁸ Early, severe degenerative arthritis is a possible sequela if left untreated.

Triquetrolunate Ligament Instability

The triquetrolunate ligament binds the triquetrum and lunate on the ulnar aspect of the wrist. Injury to this ligament is the ulnar equivalent of the scapholunate ligament injury. Triquetrolunate ligament injury occurs much less often and is more stable. This injury most often results from falls on the outstretched, dorsiflexed hand with impact on the hypothenar eminence. There will be localized tenderness on the ulnar aspect of the wrist just distal to the ulna. Ballotment of the triquetrum may produce a painful clicking sensation.

Complete disruption of this ligament removes the ability of the triquetrum to counterbalance the flexion torque from the palmar-flexed scaphoid. The lunate hence tilts palmar, and the capitate extends slightly in response. A zigzag pattern in the opposite direction of the scapholunate injury is produced. The capitolunate angle is increased more than 10 to 20 degrees; however, the scapholunate angle is unaffected because the scapholunate ligament is still intact. The lateral radiograph reveals the "volar intercalated segment instability (VISI)" pattern (Figures 269-3C and 269-5). The PA view may reveal a widening of the triquetrolunate joint space and obliteration of the capitolunate joint space because of the volar tilt of the lunate.

These injuries are treated acutely with an ulnar gutter splint or short arm posterior mold and referred to an orthopedist. Immobilization in a cast for 6 to 8 weeks, followed by a protective splint is sufficient in most cases. Open reduction and internal fixation is generally reserved for chronic injuries. Unrecognized injuries can result in early degenerative arthritis and a chronically painful wrist.

FIG. 269-5. Volar intercalated segment instability (VISI).

Perilunate and Lunate Dislocations

Perilunate and lunate dislocations represent the final stages of mid-carpal ligament disruption. Much like the scapholunate and lunatotriquetral injuries, these injuries are also the result of forceful dorsiflexion and impact on the outstretched hand, but usually with much greater force, such as a fall from height or impact from a motor vehicle collision. The injury can begin on either side of the lunate, but typically begins on the radial aspect, tearing the scapholunate ligament. It progresses around the lunate in a semicircular fashion, tearing the volar ligament arcade at the radiocapitate ligament.¹⁷ Remember that the extrinsic ligaments form two strong volar arcades with an inherently weak area between them that widens with dorsiflexion of the wrist (see Figure 269-2). This space of Poirier lies at the junction of the lunate and capitate. This space is opened further as additional loading disrupts the lunatotriquetral ligament. In addition to ligament disruption, any number of carpal bones may fracture along an arc around the lunate (Figure 269-6). If sufficient force is applied, the ligaments and carpal bones around the lunate are stripped away. The capitate is displaced posterior to the lunate, producing a perilunate dislocation. If the capitate rebounds with sufficient force, it can push the lunate off the radius and into the palm, creating a lunate dislocation. These injuries are all part of a continuous spectrum of ligament disruption.

On clinical examination, there is often generalized swelling, pain, and tenderness. However, a gross deformity, typical of many other joint dislocations, is often absent and may be misleading. Radiographic interpretation is the key to diagnosis. The perilunate dislocation is best appreciated on the lateral view. The linear arrangement of the three C's sign is disrupted with the capitate, represented by the third C, displaced posterior to the lunate. The lunate retains its contact with the radius. The scapholunate and capitollunate angles are increased. On the PA view, the three smooth arcs are disrupted and the capitollunate joint space is oblit-

FIG. 269-6. Perilunate and lunate dislocations can fracture any of the carpal bones that surround the lunate in an arc pattern.

erated as the bones overlap one another. The scapholunate and triquetrolunate joint space may either be increased because of torn ligaments, or obliterated by rotation of the fractured carpal fragments. The scaphoid will appear shortened from rotary subluxation or fracture. A perilunate dislocation may also overshadow any associated carpal bone fracture. The scaphoid and capitate are most often involved, so it is prudent to carefully inspect these bones for fractures. These fractures are designated by adding the prefix "trans-" to the carpal bone name (e.g., transscaphoid perilunate dislocation) (Figures 269-1 k and 269-7B).

A lunate dislocation has many similar and several distinct radiographic features when compared to a perilunate dislocation. On the PA view, the lunate has a triangular shape ("piece-of-pie" sign) that is pathognomonic for lunate dislocation (Figure 269-8A). On the lateral view, it also disrupts the three C's sign. The lunate (represented by the middle C) is pushed off the radius into the palm. This has been called the "spilled teacup" sign because it resembles a cup spilling in the direction of the palm (Figure 269-8B). The capitate may rebound back and even rest on the radius. The signs of ligament disruption and the associated carpal bone fractures described with perilunate injuries may also be present.

All patients with perilunate or lunate dislocations require emergency orthopedic consultation. Treatment is determined by the extent of the injury. Closed reduction and long-arm splint immobilization is appropriate for reducible dislocations. Open, unstable, and irreducible dislocations require open reduction and internal fixation, with repair of the ligaments and fractures. Some orthopedists operate on all peri-lunate and lunate dislocations. The complications include development of carpal instability patterns that lead to early degenerative arthritis, delayed union, malunion, nonunion, avascular necrosis, and occasionally, median nerve compression from the volar dislocation of the lunate into the carpal tunnel.

FIG. 269-7. Transscaphoid perilunate dislocation. A. PA view shows subtle overlap of the lunate and capitate. A displaced scaphoid fracture is present (arrows). B. Lateral view shows lunate (L) maintaining contact with the radius while the capitate (C) is positioned posterior to the lunate. CARPAL BONE FRACTURES

Carpal bone fractures account for 7 to 10 percent of all hand injuries. Unfortunately, they are among the most commonly missed wrist injuries. It is important that a high index of suspicion be maintained and a focused examination used to recognize these injuries. The following carpal fractures are listed in descending order of occurrence.

Scaphoid Fracture

The scaphoid is an oblong bone that has the unique role of linking and stabilizing the two rows of carpal bones. Because of this anatomy, it also transmits compression forces from the hand to the forearm, which unfortunately increases its propensity for injury, making it the most common carpal bone fracture. The injuries usually result from a fall on an outstretched dorsiflexed hand or by an axial load directed along the thumb's metacarpal. There is pain along the radial side of the wrist and localized tenderness in the anatomic snuffbox. Examining the wrist in

ulnar deviation exposes more of the scaphoid to direct palpation in the anatomic snuffbox. Eliciting pain in this area when the patient resists supination or pronation of the hand, or pain with axial pressure directed along the thumb's metacarpal, is also suggestive of injury.

Standard and scaphoid views should be carefully examined for any cortical disruption (Figure 269-9). The scaphoid view profiles the bone lengthwise and may assist in detecting subtle fractures. Distortion of a soft tissue fat stripe that lies adjacent to the radial side of the scaphoid is also suggestive of injury. Two-thirds of the fractures occur at the waist or middle third of the bone, 16 to 28 percent in the proximal third, and 10 percent in the distal third. A scaphoid fracture may also have an associated injury in 12 percent of cases, involving either the radius, neighboring carpal, a carpal instability pattern, or dislocation.

A scaphoid fracture can develop avascular necrosis of the proximal fracture segment that can lead to disabling arthritis.¹² Since the vascular supply to the scaphoid enters the distal portion of the bone through small branches off the radial artery and the palmar and superficial arteries, a fracture can easily disrupt the blood supply to the proximal segment. In general, the more proximal, oblique, or displaced the fracture, the greater the risk of developing avascular necrosis. A scaphoid fracture is considered unstable if it is oblique; if there is as little as 1 mm of displacement; if there is rotation or comminution; or if a carpal instability pattern is present. Two-thirds of the scaphoid's surface is also articular. This only adds to the scaphoid's problems, because articular fractures are more difficult to heal. Thus the main complications of improperly healed scaphoid fractures are avascular necrosis, delayed union, nonunion, malunion, and subsequent early degenerative arthritis.

Because 10 percent of initial radiographs fail to detect a fracture, initial treatment should be directed by clinical suspicion until follow-up studies can exclude the diagnosis. Nondisplaced fractures and those that are only clinically suspected can be treated in a short-arm thumb spica splint. Splinting in dorsiflexion and radial deviation helps to compress the fracture fragments. Patients with unstable fractures should be placed in a long-arm thumb spica splint and should be seen promptly by an orthopedic surgeon for definitive treatment.

Arthroscopic surgery is a promising alternative in acute management of scaphoid fractures. The repair reunites the two fracture fragments with a cannulated screw. The procedure is minimally invasive and allows early use of the hand, markedly decreasing the adverse effects of immobilization, such as muscle atrophy, articular cartilage breakdown, and osteopenia.

Triquetrum Fractures

Triquetrum fractures are either dorsal avulsion fractures or fractures through the body. Avulsion fractures are produced when a twisting motion of the hand is suddenly resisted, or a hyperextension shear stress pushes the hamate or ulnar styloid against the triquetrum. Fractures of the body occur from direct trauma and are seen in association with perilunate and lunate dislocations (part of the arc fractures). There will be localized tenderness over the dorsum of the wrist in the area immediately distal to the ulnar styloid. The dorsal avulsion fracture is best seen on the lateral view or an oblique view in partial pronation. It appears as a tiny flake of bone on the dorsum of the triquetrum. Triquetrum body fractures are usually nondisplaced because numerous ligaments encase the bone. These are best seen on the PA view. Nonunion is possible, but avascular necrosis has not been reported. Patients with a dorsal avulsion fracture have an excellent prognosis for full recovery. Symptomatic patients are treated with a wrist splint for 1 to 2 weeks. Asymptomatic or minimally symptomatic patients may be treated with early range of motion. Stable body fractures are treated in a cast for 6 weeks. Unstable body fractures (>1 mm displacement) and those associated with perilunate/lunate dislocations may require internal fixation, either percutaneous or open. Patients with triquetrum body fractures should be referred to an orthopedist.

FIG. 269-8. Lunate dislocation. A. PA view demonstrates pathognomonic triangular shape of the lunate (*piece-of-pie sign* arrow) B Lateral view shows the lunate tilting into the palm (*spilled teacup sign*, arrow) and the capitate positioned posterior to the lunate (arrowhead) Note as-

Lunate Fracture

Lunate fractures generally occur in association with other carpal injuries. It is rare to have an isolated lunate injury. Like many other carpal injuries, it usually is the result of a fall on the outstretched hand. There will be localized tenderness in the middle of the wrist. The lu-

nate is present in the shallow indentation on the mid-dorsum of the wrist. If the wrist is flexed, the lunate is easily palpable as it rises out of the floor of this indentation. Axial pressure applied along the third metacarpal ray may also elicit pain in this same area and is suggestive of injury. Like the scaphoid, the lunate's blood supply enters through the distal end. A fracture risks producing avascular necrosis in the proximal portion. Because the lunate is nestled in the middle of the wrist, overlap with other carpal bones may make it difficult to identify an injury on a plain radiograph. Clinical suspicion should dictate the acute treatment. A thumb spica splint should be applied until further evaluation is made by the orthopedist. MRI and CT to identify occult fractures have replaced tomography and bone scans. The major complication is avascular necrosis (Kienbock disease), that can lead to lunate collapse, osteoarthritis, chronic pain, and decreased grip strength. Repetitive trauma to the lunate can also produce microfractures of the bone and subsequent osteonecrosis. Individuals with ulnar negative variance are at increased risk of developing Kienbock disease, because a shorter ulna provides less support to the lunate.

Trapezium Fracture

The trapezium is a saddle-shaped bone that is adjacent to the thumb metacarpal. Injuries are produced by a direct blow to the thumb or from a dorsiflexion and radial deviation force. Fractures occur either at the trapezial ridge or body and are often intraarticular. Vertical

FIG. 269-9. Scaphoid fracture in the middle third or waist (arrow).

fractures occur and are analogous to a Bennett's fracture (an intra-articular proximal thumb metacarpal fracture). Examination reveals painful thumb movement and a weak pinch. There is tenderness at the apex of the anatomic snuffbox and at the base of the thenar eminence. This injury is best profiled on a 20-degree pronated oblique view. The major complication is nonunion.

Emergency treatment of nondisplaced fractures is in a thumb spica splint. Displaced fractures >1 mm or diastasis >2 mm require surgery, either percutaneous or open reduction and internal fixation.

Pisiform Fracture

The pisiform is a sesamoid bone within the flexor carpi ulnaris tendon. It is positioned immediately volar to the triquetrum and is the palpable bony prominence at the base of the hypothenar eminence. Injuries usually result from a fall directed on the hypothenar eminence. There will be localized tenderness on the pisiform itself. If the wrist is flexed, the pisiform can be grasped and palpated between the examiner's fingers. This should elicit pain. Because the pisiform and hook of the hamate form the bony walls of Guyon's canal that contains the ulnar nerve and artery, it is important to exclude injury to them. Radiographs in partial supination, or the carpal tunnel view, are optimal because they remove the overlap with the triquetrum that is present on standard views (Figure 269-10).¹³ The pisiform is the last carpal bone to ossify; it is usually complete by age 12. Before this age, multiple ossification centers in the pisiform may be confused with a fracture; however, these will have smoother margins and lack the perfect jigsaw-puzzle fit seen with fracture fragments. After age 12, any radiographic lines suggest fractures.

Emergency treatment of pisiform fractures is either in a compression dressing or in a splint in 30 degrees of flexion and ulnar deviation that relaxes the tension from the flexor carpi ulnaris. These fractures have an excellent prognosis.

Hamate Fracture

Hamate fractures may involve the body of the hamate, the hook of the hamate, or any of its articular surfaces. Body fractures are rare and are generally associated with fracture-dislocations of the fourth or fifth metacarpals. Most hamate fractures involve the hamate hook, which is

FIG. 269-10. Pisiform fracture. PA view with a thin lucency in the center of the bone (arrow). (Reproduced with permission from Chin HW, Visotsky J: Wrist fractures. *Emerg Med Clin North Am* 11:3, 1993.)

a small bony prominence on its volar aspect. The classic mechanism is an interrupted swing with a golf club, bat, or racquet. The handle impacts against the hypothenar eminence and compresses the bone. The hook of the hamate is palpable in the soft tissue of the hypothenar eminence, distal and radial to the pisiform. There will be localized tenderness here. Standard and carpal tunnel views are necessary to visualize the fracture. Occult fractures may be identified by bone scan or computed tomography.

Hamate hook fractures are treated with a compression dressing or splint. Nonunion is common and excision of the bone may be necessary. Injury to Guyon canal and the ulnar nerve or artery are potential complications. Nondisplaced body fractures are treated by splint immobilization. Displaced body fractures are unstable and are surgically treated. Emergency treatment is splint immobilization and orthopedic referral.

Capitate Fracture

The capitate is the largest carpal bone. It is an elongated bone with a large proximal head that articulates with the lunate; the midportion is the neck; and the distal end, or body, articulates with the third metacarpal. Capitate fractures most often occur in the neck, and usually occur in conjunction with a scaphoid fracture. This association of scaphoid and capitate fractures is called the "scaphocapitate syndrome." Isolated capitate fractures are rare. These injuries result from forceful dorsiflexion of the hand with impact on the radial side. The scaphoid is fractured first, followed by the capitate through its neck. This can continue around the lunate, creating other so-called arc fractures (see Figure 269-6), and eventually a perilunate or lunate dislocation. Like the scaphoid and lunate, the capitate's blood supply enters through the distal end. Thus capitate fractures also share the same legacy of potential avascular necrosis of the proximal fracture segment.

Physical examination reveals diffuse swelling and tenderness over the capitate, just proximal to the third metacarpal. The capitate neck fractures are best seen on the lateral radiograph. The head of the capitate should be carefully noted because it can rotate as much as 180 degrees. Unfortunately, capitate fractures are most often overlooked because the accompanying scaphoid fracture or perilunate/lunate dislocation overshadows it. Complications include avascular necrosis, delayed union, nonunion, and malunion.

Emergency treatment of undisplaced, isolated capitate fractures is splint immobilization and early orthopedic referral. Most capitate fractures, however, are displaced or associated with the scaphocapitate syndrome, and require closed or open reduction and internal fixation.

Trapezoid Fracture

This is an extremely rare fracture, accounting for only 1 percent of all carpal fractures. The injury results from an axial load onto the index metacarpal. There will be tenderness on the radial side that is augmented by applying pressure along the index metacarpal ray. These injuries are difficult to see on standard radiographs, and CT or MRI may be necessary to visualize it. Emergency treatment is in a thumb spica splint.

DISTAL RADIUS AND ULNA FRACTURES

Fractures of the distal metaphysis of the radius and ulna are among the most common injuries affecting the wrist. Among the factors that influence the type and amount of displacement of the fracture are the point and direction of impact, the degree of force, and the patient's age (Table 269-1).

In general, the thinner cortices of the elderly make them more likely to sustain extraarticular fractures, whereas younger adults often sustain more complicated intraarticular fractures.

TABLE 269-1 Radiographic Appearance of Distal Radius Fractures

Colles fracture	
Dorsal angulation of the plane of the distal radius	
Distal radius fragment is displaced proximally and dorsally	
Radial displacement of the carpus	
Ulnar styloid may be fractured	
Smith fracture	
Volar angulation of the plane of the distal radius	
Distal radius fragment is displaced proximally and volarly	
Radial displacement of the carpus	
The fracture line extends obliquely from the dorsal surface to the volar surface 1-2 cm proximal to the articular surface	
Barton fracture	
Volar and proximal displacement of a large fragment of radial articular surface	
Volar displacement of the carpus	
Radial styloid may be fractured	

Colles Fracture

Colles fracture results most often from a fall on the outstretched hand. This mechanism produces a distal radial metaphysis fracture that is dorsally angulated and displaced proximally and dorsally. Compression forces on the dorsal side often produce dorsal comminution of bone. The fracture line may also comminute and extend into the radioulnar or radiocarpal joint ("die-punch" fracture). A fracture of the ulnar styloid is often present and may be suggestive of injury to the TFCC.

The wrist has the characteristic dorsiflexion, or "dinner-fork," deformity. Patients may complain of palmar paresthesias from tension or pressure on the median nerve. Posteroanterior radiographs reveal a distal metaphyseal fracture of the radius that often appears shortened from the angulation or comminution of the bone. The lateral view provides the best view of the dorsal angulation and comminution. In general, potentially unstable fractures have more than 20 degrees of angulation, intra-articular involvement, marked comminution, or more than a centimeter of shortening. These injuries are more likely to develop loss of reduction, distal radioulnar joint instability, radiocarpal instability patterns, and subsequent arthritis.

Stable fractures may be treated with a compression dressing and splint until they can be evaluated by an orthopedic surgeon. Otherwise, closed reduction is performed, with traction provided by finger traps while the fracture fragment is pushed distal and palmar and the patient's forearm is held firmly. The goal is to restore the volar tilt, radial inclination, and proper length to the radius. This is particularly important in younger patients. The volar tilt ideally should be restored to its normal position, but a minimum of neutral or zero degrees of angulation is acceptable.

Although most Colles fractures can be treated with closed reduction and cast immobilization, those that are unstable, severely comminuted, or intra-articular may require casting with pinning, external fixation with possible bone grafting, or open reduction and internal fixation. Good to excellent results are achieved in 56 to 81 percent of patients with these more aggressive treatment alternatives. All open and neurovascularly compromised fractures require prompt evaluation by the orthopedic surgeon.

**FIG. 269-11.** Colles fracture. PA (A) and lateral (B) views of the wrist, demonstrating typical radiographic findings.

Complications include malunion, median nerve injuries, TFCC injuries, secondary radioulnar and radiocarpal instability patterns, and arthritis. These complications can produce a weak, stiff, and painful wrist.

Smith Fracture

Smith fracture, or "reverse Colles fracture," is a volar angulated fracture of the distal radius. This results from a fall or direct blow on the dorsum of the hand and wrist, or from a fall on the outstretched hand in supination that then shifts into a pronated position. The hand is displaced palmar and produces a "garden-spade deformity" on physical examination. The posteroanterior radiograph looks much like the Colles fracture, with a distal metaphyseal radius fracture that may be shortened and comminuted. The lateral radiograph shows the volar angulated and displaced fracture (Figure 269-12).

The treatment objectives and complications are much like those seen with the Colles fracture. In this case, however, the angulation is volar rather than dorsal.

Barton Fracture

Barton fractures are dorsal or volar rim fractures of the distal radius. The dorsal rim fractures result from a dorsiflexion and pronation force, whereas the less common volar rim fracture is produced by a fall on the outstretched hand in supination. These injuries are often fracture dislocations or subluxations, because the carpus or hand is frequently displaced in the direction of the fracture. Accompanying ligamentous injuries create radiocarpal instability. This is often not

fully appreciated in the acute setting, but can lead to various secondary carpal instability patterns and premature degenerative arthritis. The posteroanterior radiograph often shows a comminuted fracture of the distal radial metaphysis. The lateral view reveals an intra-articular fracture of the volar or dorsal rim of the radius, which may be accompanied by carpal subluxation in the same direction (Figure 269-13).

Minimally displaced fractures can be treated acutely in a splint until evaluation by an orthopedist. Unstable fractures involving more than 50 percent of the radial articular surface or those with accompanying carpal subluxation, require open reduction and internal fixation.

Radial Styloid Fracture

A force directed along the radial side of the hand can produce a transverse or oblique fracture that runs from the scaphoid fossa to the metaphysis of the radius. It is best seen on the posteroanterior radiograph as a thin, lucent line beneath the radial styloid. Because the major carpal ligaments along the radial side of the wrist insert on the radial styloid, displacement of this fracture can produce carpal instability. Displaced fractures often require open reduction and internal fixation. Displacement of as little as 3 mm is often associated with accompanying scapholunate dissociation. Failure to recognize these intercarpal ligament tears adds to the potential for subsequent posttraumatic arthritis.

Ulnar Styloid Fracture

Forced radial deviation, dorsiflexion, and rotatory stress fracture the ulnar styloid. The ulnar styloid fracture may be isolated or may accompany other injuries, such as Colles fracture. Avulsion fractures are rarely clinically significant, the major consideration being the associated radial soft tissue and bony injuries. Displaced ulnar base fractures can be intra-articular and be associated with tears of the TFCC, which is the main stabilizer of the distal radioulnar joint. These patients complain of a painful clicking or locking sensation in the wrist. If the distal radioulnar joint (DRUJ) is stable, ulnar styloid fractures are treated acutely in an ulnar gutter splint in slight ulnar deviation and neutral positioning of the wrist. If there is any question about stability, these patients should be referred acutely for surgical evaluation. Arthrograms or MRI imaging may be necessary to delineate the full extent of these injuries.

Distal Radioulnar Joint Disruption

Distal radioulnar joint (DRUJ) disruption is generally seen with intra-articular or distal radial shaft fractures (Galeazzi fracture-dislocation; see Chap. 270),¹⁴ or with fractures of both bones of the forearm. These more apparent injuries often overshadow distal radioulnar joint disruption, and unfortunately cause these injuries to remain unrecognized until subsequent pain and diminished wrist movement are appreciated.

Isolated radioulnar joint dislocations are uncommon and are unrecognized acutely in as many as 50 percent of cases. Dorsal dislocation of the ulna results most often from falls on the wrist in hyperpronation. The rare volar dislocation results from forced hypersupination of the wrist. Patients with disruption of the distal radioulnar joint present with pain at the DRUJ, weak grip, and restricted range of motion, especially pronation and supination. The ulnar head is prominent, but this can be quite subtle and easily overlooked.

The posteroanterior radiograph reveals narrowing and overlap of the distal radioulnar joint. The lateral radiograph demonstrates either volar or dorsal displacement of the ulna, which is normally centered and overlapping the radius. Because slight oblique positioning of the wrist can produce a misleading appearance of ulnar displacement, it is crucial that a properly positioned lateral view be obtained. A true lateral view should have superimposition of the four ulnar metacarpals, superimposition of the proximal pole of the scaphoid with the lunate and triquetrum, and the radial styloid centered over its distal articular

FIG. 269-12. Smith fracture.

surface. CT scanning may be necessary to establish the diagnosis if plain films are inconclusive.

Immobilizing the wrist in supination reduces dorsal dislocations, whereas volar dislocations are placed in pronation. Patients with acute DRUJ disruption are referred acutely for orthopedic follow up. These injuries unfortunately have a high recurrence rate, particularly if there are delays in diagnosis, and may require reconstructive surgery.

ACKNOWLEDGMENT

The authors wish to acknowledge the contributions of Harold Chin, MD, to previous editions of this chapter.

ELBOW

Elbow Dislocation

The elbow with its ulnohumeral articulation is one of the most stable joints in the body. The inherent stability in the flexion-extension plane is augmented by the muscular attachments and collateral ligaments. Because of this stability, surgical repair for acute instability is usually not required, and chronic dislocations are unusual. Despite this, however, dislocations of the elbow are commonly seen, and rank third in large-joint dislocations, after glenohumeral and patellofemoral dislocations. Additionally, fractures of the coronoid process, radial head, medial epicondyle, or olecranon may be associated with an elbow dislocation, complicating its treatment.

There are five general types of elbow dislocations: (1) posterior, (2) anterior, (3) medial, (4) lateral, and (5) divergent. The vast major

ity of elbow dislocations are posterior; the others are rare. The mechanism of injury is usually due to a fall on the outstretched hand.

Clinically, the patient presents with the elbow in 45 degrees of flexion. The olecranon is prominent posteriorly, and the deformity resembles a displaced supracondylar fracture. If the patient is seen immediately after the injury, the bony landmarks can be identified. Later, however, the swelling may be quite severe, with no possibility of evaluating the injury topographically. The first priority of care is to assess neurovascular status, with specific attention to the brachial artery and the ulnar, radial, and median nerves, as these structures are the most vulnerable to entrapment. The examination must be performed before and after manipulation, since neurovascular complications occur in 8 to 21 percent of patients, the most frequent being injury to the ulnar nerve. Vascular complications occur in 5 to 13 percent of elbow dislocations, with brachial artery injury the most common.¹ Absence of a radial pulse before reduction, an open dislocation, and other systemic injuries (such as those of the head, chest, and abdomen) are significantly associated with arterial injury.^{2,3}

Radiographically, on the lateral view, both the ulna and radius are displaced posteriorly (Figure 270-1). In the anteroposterior view, there may be lateral or medial displacement, with the ulna and radius in their normal relationship to each other. A search for associated fractures should be performed. In a child, a fracture of the medial epicondyle is most commonly seen. In adults, fractures of the coronoid process, radial head, capitellum, or olecranon may occur. Initially, these fractures should only be noted, with primary attention focused on the dislocation.

After adequate sedation, closed reduction is accomplished by gentle longitudinal traction on the wrist and forearm (Figure 270-2). An assistant applies countertraction on the arm. Any medial or lateral displacement is corrected with the other hand. Downward pressure on the proximal forearm helps to disengage the coronoid process from the olecranon fossa. Distal traction is continued, and the elbow is flexed. With reduction, a palpable "clunk" is felt as the olecranon is seated in the humeral articular surface. The elbow is then moved through its full range of motion (ROM) to assess stability. If full smooth passive ROM is not possible, the postreduction radiograph should be examined for entrapment of the medial epicondyle, especially common in children (Figure 270-3). Instability in extension suggests associated fractures or disruption of the capsule. Entrapped soft tissue and/or loose intra-articular fragments indicate the need for open reduction.

After reduction, the elbow is placed in a plaster splint from the axilla to the base of the fingers with the elbow in at least 90 degrees of flexion. Because of the soft-tissue trauma and subsequent edema, cylinder casts should not be placed. A neurovascular follow-up examination should be obtained the following day. Treatment with an early ROM program after 1 to 2 weeks of splinting generally leads to favorable results.

Appropriate treatment of elbow dislocations requires adequate reduction and recognition of neurovascular complications, associated fractures, and postreduction instability. If there is any question of neurovascular compromise, the patient should be admitted for observation. Immediate orthopedic consultation should be sought with irreducible dislocations, neurovascular compromise, joint capsule disruption, associated fractures, and open dislocations. Potential late complications include posttraumatic stiffness, posterolateral joint instability, ectopic ossification, and occult distal radioulnar joint disruption.

Fractures about the Elbow

Fractures about the elbow include fractures of the intercondylar areas, supracondyles, epicondyles, condyles, trochlea, capitulum, and radial head.⁴

INTERCONDYLAR T OR Y FRACTURES Intercondylar fractures, in which the condylar fragments are separated, are much more common in adults than in children. Any distal humerus fracture in an adult

FIG. 270-1. Posterior dislocation of the elbow, on posteroanterior and lateral views.

FIG. 270-2. Reduction of posterior elbow dislocation. A. Operator applies gentle traction as assistant applies countertraction. Displacement is corrected with the other hand. Downward pressure on the proximal forearm disengages the coronoid process from the olecranon fossa. B. Distal traction is continued as the elbow is flexed.

should initially be assumed to be intercondylar rather than supracondylar (Figure 270-4). A careful search should be made for a fracture line separating the condyles from each other and from the humerus. This distinguishes intercondylar T or Y fractures from other fractures of the distal humerus.

The mechanism of injury is a force directed against the posterior elbow, driving the olecranon against the humeral articular surface, separating the condyles and producing the typical fracture. These fractures are associated with severe soft-tissue injuries. Treatment in the

young is directed at anatomic reduction. In older patients with severe injuries, treatment is often directed at reestablishing articular surface congruity. If this cannot be achieved by closed methods, then the integrity of the articular surface is restored by an open reduction. As in supracondylar fractures, patients with severe edema or displaced fractures should be admitted.

SUPRACONDYLAR FRACTURES Supracondylar fractures of the humerus are common and account for 60 percent of all fractures of the elbow in children. Ninety-five percent of these extra-articular fractures are displaced posteriorly as a result of an extension force. When the mechanism of injury is due to a flexion force, the much less common anterior displacement occurs. There can also be various degrees of abduction, adduction, and rotation of the distal fragment.⁵

Extension-Type Supracondylar Fractures In an extension-type fracture, the patient will have significant edema and tenderness at the elbow. The olecranon is prominent, and there is a depression proximally over the area of the triceps muscle. This appearance may be easily mistaken for a posterior elbow dislocation.

Extension-type supracondylar fractures are classified into three types. Type I fractures are undisplaced. Type II fractures are displaced and have cortical contact. Type III fractures are subdivided into posterolateral and posteromedial fractures based on displacement and have no cortical contact.

Radiographs may reveal a fat-pad sign in undisplaced fractures (Figure 270-5).⁶ Fat from the olecranon fossa is displaced posteriorly (posterior fat pad) by hemarthrosis, and the anterior fat pad may be quite prominent. Normally, a posterior fat pad is not visible, and an anterior fat pad may be visible as a thin lucent stripe. Abnormal fat pads may also be seen with nontraumatic joint effusions. In addition, they may be absent in severe trauma that disrupts the joint capsule and allows intra-articular fluid to extravasate. In some undisplaced fractures, the fracture line may not be seen, with **the fat-pad sign being the only evidence of injury. Treatment should be initiated as though a fracture were identified,** with splint immobilization and orthopedic consultation. In displaced fractures, the anteroposterior radiograph usually reveals a transverse fracture line. More severely displaced fractures may show medial or lateral displacement or rotation along the axis of the humerus (Figure 270-6). The lateral radiograph will reveal the fracture line extending obliquely from posterior proximal to anterior distal. The distal fragment will be displaced proximally and posteriorly.

Treatment of undisplaced or type I fractures consists of plaster immobilization. Type II and type III displaced fractures are treated by closed methods followed by pin fixation. The current major indications for open reduction are vascular insufficiency with a probable entrapped brachial artery in the fracture site or an irreducible fracture. Patients with displaced fractures or severe edema should be admitted for observation of neurovascular status.

Flexion-Type Supracondylar Fractures Flexion-type fractures occur in fewer than 5 percent of supracondylar fractures. The mechanism is direct anterior force against a flexed elbow. This results in anterior displacement of the distal fragment. Since the mechanism is direct force, these fractures are often open.

Radiographs reveal an oblique fracture from anterior proximal to posterior distal. The distal fragment is anterior to the humerus.

Management consists of closed reduction and plaster immobilization or surgery if reduction cannot be maintained by closed methods.

Complications of Supracondylar Fractures There are numerous complications of supracondylar fractures, including nerve and vascular injuries and those occurring late, such as nonunion, malunion, myositis ossificans, and loss of motion.

Neurologic complications have an incidence of 7 percent and are the result of traction, direct trauma, or nerve ischemia. Posteromedial

FIG. 270-3. Postreduction radiograph of a posterior elbow dislocation. The medial epicondyle is fragmented in the joint space and is seen in the anteroposterior (A) and lateral (B) radiographs (*arrow*).

displacement involves the radial nerve and posterolateral displacement usually affects the median nerve. Ulnar nerve injuries are uncommon; the highest incidence has been reported from pin placement. A high incidence of anterior interosseous nerve injuries has also been noted with supracondylar fractures. This nerve arises from the median nerve and innervates the flexor pollicis longus, the radial part of the flexor digitorum profundus, and the pronator quadratus. Since there is no sensory component to the anterior interosseous nerve, identification of the injury can be made only by specific muscle testing. Testing consists of flexion at the index finger distal interphalangeal and thumb interphalangeal joints. The mechanism of injury is usually traction and/or contusion. Complete transection is rare, and entrapment within the fracture occurs only occasionally. Joist and colleagues⁵ noted all patients regained full flexion and strength after 4 to 17 weeks.

Acute vascular injuries must always be suspected in patients with supracondylar fractures. Absence of a radial pulse is common in children. This is most frequently due to transient arterial spasm. Rarely, there is a partial or complete transection of the brachial artery, an intimal tear and thrombosis, or entrapment within the fracture fragment.

The most serious complication is **Volkmann's ischemic contracture**. This classically occurs following a supracondylar fracture. Post-ischemic swelling, producing increased pressure within the enclosed osteofascial forearm compartment, reduces capillary blood perfusion below the level necessary for tissue viability. If unrelieved, the end result is muscle and nerve necrosis, and eventual replacement by fibrotic tissue, producing a contracture. Refusal to open the hand in children, pain with passive extension of the fingers, and forearm tenderness are signs of impending Volkmann's ischemia. It is now well understood

that the mere lack of a radial pulse does not indicate ischemia unless accompanied by these signs.

Treatment of supracondylar fractures with absent radial pulse begins with closed reduction and percutaneous pinning. Extremities still without a pulse and with signs of ischemia are taken to the operating room for fasciotomy and/or brachial artery exploration. Extremities without a pulse and no signs of ischemia may be treated in one of three ways: (1) close observation, (2) observation for 24 to 36 h followed by arteriography and surgery if indicated, or (3) immediate surgical exploration.

DISTAL HUMERUS FRACTURES The distal humerus can be imagined as two columns of bone that end in the medial and lateral condyles (Figure 270-7). The flared proximal portions of the condyles are the epicondyles. The epicondyles are nonarticulating surfaces that serve as sites of origin for forearm, wrist, and digit flexors and pronators (medial), and extensors and supinators (lateral). The distal aspects of the condyles are the articular surfaces. Medially, the trochlea articulates with the olecranon to form a uniaxial hinge joint, and laterally, the capitellum abuts the radial head to form a pivot joint. Between the condyles is the coronoid fossa anteriorly and the olecranon fossa posteriorly. These allow for full flexion and extension of the ulna. Additionally, the radial fossa lies just proximal to the capitellum anteriorly and permits full flexion of the radius.

Several important neurovascular structures lie in close proximity to the distal humerus, and evaluation of their function is essential. These include the brachial artery, which is palpable just medial to the distal biceps tendon in the antecubital fossa, and the radial, median, and ulnar nerves. The latter is palpable as a cord just posterior to

FIG. 270-4. Comminuted displaced and rotated intercondylar fracture (type IV). A. Posteroanterior view. B. Lateral view.

the medial epicondyle and is vulnerable to injury with lacerations over this area. Sensory and motor function of each individual nerve should be assessed.

Standard radiographs of the elbow may have subtle findings, especially in the pediatric population. Knowledge of the age at which ossification centers appear is critical (see Chap. 136).

Routine emergency department care of distal humerus fractures includes immobilization, ice, elevation, analgesics, and orthopedic referral within 24 h if no neurovascular compromise, or in the emergency department if the latter is present.

Epicondyle Fractures *Lateral epicondyle fractures* almost never occur, since the anatomic position of the condyle reduces the exposure to direct

FIG. 270-5. Anterior and posterior fat pad signs.

blows, resulting instead in fractures of the lateral condyle. When they do occur, these fractures are usually avulsion fractures and may be treated by immobilization with the elbow flexed to 90 degrees and the forearm in supination. The patient is referred to an orthopedist within 1 week.

Isolated medial epicondyle fractures are considered extraarticular injuries and usually occur in children and adolescents. Mechanisms include a posterior elbow dislocation, repeated valgus stress, such as throwing a baseball (Little League elbow), or a direct blow. If there is an associated tear of the medial collateral ligament, the epicondyle itself may become entrapped in the joint space. Patients present with pain over the medial elbow that is exacerbated by supination of the forearm and flexion of the forearm, wrist, and digits. Edema and tenderness are noted in the same area. Standard radiographs should be obtained with special attention to any intraarticular fragment. Careful examination of ulnar nerve function is needed. Nondisplaced or minimally displaced medial epicondyle fractures are treated nonoperatively, with early motion. Fragment displacement greater than 1 cm or valgus instability are generally treated by internal fixation.

Emergency department management consists of immobilization of the forearm in flexion and pronation, and the wrists in flexion.

Condyle Fractures *Lateral condyle fractures* occur in children and are more common than their medial counterpart.⁷ They result from a direct blow to the lateral elbow or from varus stress with the forearm extended, as in a fall on an outstretched hand. Patients complain of pain in the lateral elbow, and swelling is noted in the same area.

Medial condyle fractures are uncommon and are mostly limited to children. Mechanism of injury is from either a transmitted force from the ulna, such as a fall on an outstretched hand, or excessive valgus stress. Pain and swelling medially are prominent findings. The injury is often confused with the more common medial epicondyle fracture for two reasons. First, the mechanism and examination findings are similar. Second, because the trochlea ossification center does not appear until age 9 to 10 years, it is often missed on radiographs.

Complications of lateral and medial epicondyle fractures are frequent and include nonunion, cubitus valgus or varus deformity, ulnar nerve palsy, and avascular necrosis.⁸ Careful neurovascular assessment is needed for these injuries. Because surgical correction is generally preferred, emergent orthopedic consultation is generally recommended for both lateral and medial epicondylar fractures.

FIG. 270-6. Type III displaced supracondylar fracture. The distal fragment is displaced posteriorly, proximally, and medially. The proximal fragment is displaced anteriorly and distally.

ARTICULAR SURFACE FRACTURES

Trochlea Fractures Isolated trochlea fractures are rare, and they are more often associated with other elbow injuries, such as posterior elbow dislocations. Physical findings usually include swelling, tenderness, and limited movement of the elbow joint. Radiographic findings can be subtle, and ultrasound or magnetic resonance imaging may be required for diagnosis. Complications are common and include limited

flexion and extension, elbow joint instability, avascular necrosis, nonunion, and arthritis. Surgical repair is usually indicated.

Capitellum Fractures Isolated capitellum fractures are rare. They are usually associated with radial head fractures. Pain and tenderness are present over the lateral elbow, and examination reveals swelling, lateral tenderness, and limitation of flexion and extension. If pain and tenderness are present medially, injury to the medial collateral ligament

FIG. 270-7. Elbow anatomy.

should be suspected. Radiographic findings may be subtle and are best seen on a lateral view. The capitellum has no tendinous or ligamentous attachments, so many fractures are nondisplaced. A radial head-capitellum view can be helpful in addition to standard views. Definitive care is surgical and complications are similar to those of trochlea fractures.

Radial Head Fractures The radial head is located just distal to the lateral epicondyle. It can be palpated by rotating the forearm while flexed. It articulates with the capitellum and the lesser sigmoid notch of the ulna to form a pivot joint. The radial head serves as a stabilizer of the elbow against valgus stress, along with the medial collateral ligament, and against longitudinal forces.

Radial head fractures are the most common fractures of the elbow. They result from a fall on an outstretched hand causing the radial head to be driven into the capitellum. Associated injuries are common and may include capitellum, olecranon, and coronoid fractures, medial collateral ligament injury, medial epicondyle avulsion fracture secondary to valgus stress, and elbow dislocation. A specific associated injury, the *Essex-Lopresti lesion*, occurs when there is disruption of the triangular fibrocartilage of the wrist and the interosseous membrane between the radius and ulna, causing pain in the wrist and forearm. The result is a distal radioulnar joint dissociation, which can cause migration of the radius proximally if radial head excision is performed.

Radial head fractures cause pain in the lateral elbow, especially with pronation and supination of the forearm. On examination, there may be swelling laterally and tenderness with palpation of the radial head. On standard elbow radiographs, radial head fractures may be subtle. Additional images, including obliques and a radial head-capitellum view, may be helpful. Furthermore, two radiographic clues can aid in the diagnosis. **The first is the radiocapitellar line. On lateral films, a line drawn from the center of the radial shaft should transect the radial head and capitellum (Figure 270-8).** This is especially helpful in children whose epiphysis has not fused. **The other clue is the appearance of an abnormal fat pad (see Figure 270-5).**

Nondisplaced fractures with no mobility restrictions can be treated conservatively with immobilization. For these, emergency department treatment consists of sling immobilization with the elbow in flexion, ice, elevation, analgesics, and referral to an orthopedic surgeon within 1 week. For displaced fractures or those with restricted range of motion, surgical repair is generally indicated, and orthopedic referral in 24 h is needed. Complications of radial head fracture include chronic pain and restricted range of motion at the elbow.

PROXIMAL ULNA FRACTURES The distal humerus articulates with the proximal ulna to form a uniaxial hinge joint, which allows flexion and extension of the forearm and provides some intrinsic stability. The

trochlea of the humerus rests in the greater sigmoid (semilunar) notch of the ulna. The anterior projection of the notch is the coronoid, and the posterior prominence, which is easily palpable, is the olecranon. The brachialis muscle inserts at the coronoid, and the triceps muscle inserts at the olecranon. A subtendinous bursa separates the triceps tendon from the olecranon, and a subcutaneous bursa lies just distal to the tendinous insertion. The latter frequently becomes inflamed. All proximal ulna fractures are considered intra-articular.

Coronoid Fractures Coronoid fractures are uncommon and usually associated with posterior elbow dislocations as the trochlea is driven into the coronoid, or as an isolated injury secondary to elbow hyperextension. There is pain, swelling, and tenderness over the antecubital fossa. Radiographic visualization is best with lateral and oblique films.

If elbow dislocation is present, careful neurovascular examination should be done prior to and after reduction, with special emphasis on the ulnar nerve (see elbow dislocation above). Emergency department treatment should include immobilization with the elbow in flexion and the forearm in supination, ice, elevation, analgesics, and referral to an orthopedic surgeon within 24 h. Severe fractures or those associated with joint instability require open reduction and internal fixation, and frequently have poor outcomes.

Olecranon Fractures The olecranon is usually fractured by direct trauma, or by a fall on an outstretched hand with the elbow in flexion. Associated injuries are common, including open wounds, dislocations, other fractures (especially of the radial head), and ulnar nerve injury. Pain is present over the posterior elbow and examination reveals swelling, tenderness, and occasionally crepitus. Because the triceps muscle inserts at the olecranon, triceps function is usually compromised when tested by forearm extension. **Ulnar nerve injury is common, and therefore a careful neurologic examination is needed.** Lateral films offer the best view of the olecranon. In adolescents, the epiphysis ossifies by age 11 and fuses by age 16, so comparison films and the appearance of an abnormal fat pad can aid in the diagnosis.

Emergency department treatment should include immobilization with the elbow in flexion forearm neutral, ice, elevation, analgesics, and referral to an orthopedist in 24 h. Nondisplaced fractures (less than 2 mm in both flexion and extension) can be treated conservatively with immobilization, but all others require surgical repair.

FOREARM FRACTURES

The radius and ulna are joined together along their entire length by a fibrous interosseous membrane, and touch only at their ends to form the complex proximal and distal radioulnar joints. The ulna is a comparatively straight bone, whereas the radius has an important outward bowing. During the motions of supination and pronation, the radius rotates around the relatively fixed ulna. Because these bones have such a close relationship to one another, injury to either will have a direct impact on the other. A displaced or angulated fracture of one bone typically disrupts the other or causes a dislocation at the proximal or distal radioulnar joint, such as in the Monteggia and Galeazzi fracture-dislocations.

The radius and ulna are also under the influence of numerous muscle groups, such as those that supinate and pronate. The biceps brachii and the supinator insert on the proximal radius and are the powerful supinators of the forearm. The pronator teres inserts on the radial shaft and exerts a pronating force. Radius fractures that are located between these muscle groups will result in marked displacement of the bone, with supination of the proximal segment and pronation of the distal portion. However, if the fracture is distal to the insertion of the pronator teres, these forces tend to neutralize one another and result in less rotational deformity. When considering treatment of these fractures, careful attention must be paid to the maintenance of length and align-

FIG. 270-8. The radiocapitellar line. On lateral views a line drawn through the center of the radius transects the radial head and middle third of the capitellum. This relationship is lost even in subtle fractures.

ment. Also, the lateral bow of the radius must be preserved to allow full pronation and supination after healing.

The neuroanatomy is most easily understood by appreciating the neural control of the most basic components of wrist and finger movement (Figure 270-9). The radial nerve travels over the lateral epicondyle and supplies the muscles of wrist extension before it gives off a branch, the posterior interosseous nerve. This branch travels around the proximal radius and controls the muscles of finger and thumb extension. The remainder of the radial nerve is purely sensory and innervates the posterior aspect of the hand from the thumb to radial half of the ring finger. Thus the proximal portion of the radial nerve controls the more proximal function of wrist extension, the distal branch (posterior interosseous nerve) controls the more distal function of finger extension, and another branch is purely sensory. Therefore, an isolated injury (e.g., to the posterior interosseous branch) would affect finger extension but spare wrist extension and sensation to the dorsum of the hand. **The single best test of radial nerve motor function is to have the patient extend both the wrist and fingers against resistance. Sensation is tested over the dorsum of the thumb index web space.**

The median nerve controls the basic movements of wrist and finger flexion and sensation on the volar surface of the hand from the

thumb to the radial half of the ring finger. The proximal portion of the median nerve innervates the muscles that control wrist flexion and the flexor digitorum superficialis before it gives off the anterior interosseous nerve. This branch controls portions of the remaining deep finger flexors: flexor digitorum profundus, flexor pollicis longus, and pronator quadratus. The remaining portion of the median nerve provides sensation to most of the volar surface of the hand plus a motor branch to the thenar muscles of the thumb (recurrent branch of the median nerve). The median nerve is evaluated by assessing each of these distal branches. **A simple test of anterior interosseous nerve function is the ability to make a circle, or "OK" sign, with the thumb and index finger. Abduction of the thumb (recurrent branch of the median nerve) and intact sensation on the radial side of the palm complete the evaluation of the median nerve.**

The ulnar nerve provides innervation to forearm muscles, but more important, it controls the intrinsic muscles of the hand and provides sensation to the little finger and the ulnar half of the ring finger. The ability to abduct the index finger against resistance (palpate the first interosseous muscle) and two-point discrimination over the tip of the little finger are easy tests of ulnar nerve function.

In adults, solitary fractures of the forearm are uncommon due to the close relationship of the radius and ulna. The fibrous interconnection

FIG. 270-9. A. The radial nerve controls wrist extension before branching into the posterior interosseous nerve. B. The median nerve controls wrist flexion and the flexor digitorum superficialis before branching into the anterior interosseous nerve (which controls the deep finger flexors in the forearm) and a branch that innervates the thenar muscles and provides sensation to most of the palm. C. The ulnar nerve controls the intrinsic muscles and provides sensation to the ulnar side of the hand. [Reproduced with permission from Chin HW, Propp DA, Orban DJ: Forearm and wrist, in Rosen P, Barkin RM, et al (eds): *Emergency Medicine Concepts and Clinical Practice*, 3d ed. Vol 1. St. Louis: Mosby-Year Book, 1992.]

SECTION 23 • INJURIES TO THE BONES, JOINTS, AND SOFT TISSUE

between the radius and ulna transmits traumatic energy above and below the injury. Thus fractures usually occur at two or more sites or involve a fracture of one bone with a ligamentous injury, with or without an associated joint dislocation. Because distant structures are commonly injured, the clinician must examine joints above and below the involved bones both clinically and radiologically. This occurrence is usually present with significantly angulated injuries.

Fractures of Both Radius and Ulna

A great amount of force is necessary to fracture both the radius and ulna. This injury occurs most often from vehicular trauma, falls from a height, or a direct blow to the forearm. The magnitude of the force determines the type of injury. A moderate force produces transverse or mildly oblique fractures. Comminuted and segmental fractures are produced by a high-impact force. As one might expect, these fractures are often displaced. Open fractures of the radius and ulna are second only to tibia fractures because of the subcutaneous location of the entire ulna and the distal portion of the radius.

Nondisplaced fractures of both bones are exceedingly rare because the force necessary to produce the injury is also sufficient to displace it. Examination reveals swelling, deformity, and tenderness of the forearm. Careful assessment of the neurovascular status is needed. Nerve injuries can be seen with severe open fractures, but fortunately are uncommon with most closed injuries. Because of the excellent collateral circulation of the forearm, vascular compromise is generally not a major problem if either the radial or ulnar circulation is intact.

The fractures are clearly visible on the radiographs. The amount and degree of angulation, displacement, and shortening should be noted. Changes in rotational alignment may be subtle. A rough estimate of rotational alignment can be made by noting the normal orientation of various bony prominences of these bones. On the anteroposterior radiograph, the radial styloid and radial (bicipital) tuberosity normally point in opposite directions, whereas the ulnar styloid and coronoid process do so on the lateral view. A change in this arrangement suggests rotation malalignment. Since these bones are also oblong rather than circular in their cross-sectional appearance, a sudden change in the bone's width at the fracture site is another clue to a rotational deformity. The wrist and elbow may also be x-rayed because of the likelihood of an associated dislocation or articular fracture.

Treatment depends upon the type of fracture. Torus or greenstick fractures in children can be treated with plaster immobilization. All other fractures in children or adults require operative reduction and internal or external fixation.

Complications include reduced ability to supinate and pronate, osteomyelitis, nonunion, malunion, neurovascular injury, and compartment syndrome. Recognizing the development of a compartment syndrome is particularly important to prevent debilitating ischemic or Volkmann's contractures of the forearm. The diagnostic findings are palpable induration of the area, pain with passive movement of the fingers, and pain that appears to be disproportionate to the physical findings. The presence of a palpable pulse does not exclude the diagnosis of compartment syndrome. Alterations in sensation and the pulse are late findings. Direct measurements of elevated compartment pressures confirm the diagnosis. Urgent fasciotomy is required, ideally within 8 h of the onset of symptoms.

Ulna Fractures

ISOLATED ULNA FRACTURE (NIGHTSTICK FRACTURE) Isolated fractures of the ulna most often result from direct blows to the forearm. A fracture resulting from the natural response to raise the forearm in defense of a blow from a club is referred to as a *nightstick fracture*. Undisplaced fractures are immobilized in a long-arm splint and closely followed for subsequent displacement of the fracture.

Displaced fractures are those with greater than 10 degrees of angulation or displacement of more than 50 percent of the width of the bone at the site of the fracture. Open reduction and internal fixation with a compression plate and screws are necessary to prevent angulation, loss of length, and rotational deformity. These injuries should be closely scrutinized for any possible radius fracture or dislocation.

MONTEGGIA FRACTURE-DISLOCATION Fracture of the ulnar shaft with a radial head dislocation is often referred to as *Monteggia fracture-dislocation* (Figure 270-10). It is very easy to miss the associated radial head dislocation.⁹ Fractures are classified into four types, depending on the location of the ulna fracture and the direction of the radial head dislocation (Table 270-1). Most typical is a diaphyseal fracture in the proximal third of the ulna with an anterior dislocation of the radial head (60 percent of cases). Clinically, there is considerable pain and swelling at the elbow. The radial head may be palpable in an anterolateral or posterolateral location. The forearm may appear shortened and angulated. The ulnar fracture is clearly visible and may overshadow the less obvious radial head dislocation. As a rule, the radial head normally points to the capitellum in all radiographic views of the elbow. In a Monteggia fracture, the apex of the ulna fracture points in the direction of the radial head dislocation.

Monteggia fracture-dislocations are generally treated with open reduction and internal fixation of the ulna and closed reduction of the radial head dislocation, although children may be treated by closed reduction of both bones and long-arm cast immobilization. Complications include nonunion, redislocation, infection, and paralysis of the posterior interosseous nerve, a deep branch of the radial nerve (remember that the nerve wraps around the proximal radius).

Radius Fractures

FRACTURES OF THE PROXIMAL TWO-THIRDS OF THE RADIUS

Radius fractures can be divided into those that are proximal and those that are distal to the junction of the middle and distal thirds of the bone. Excluding radial head fractures, isolated fractures of the proximal two-thirds of the radius are rare because the radius is relatively well protected from direct blows by the ulna and surrounding forearm musculature. Undisplaced fractures are rare; these are treated with cast immobilization. Fractures of the proximal two-thirds of the radius are often displaced by both the force of the injury and the action of the supinators and pronators on the radius. They require internal fixation to prevent rotational deformity. Compartment syndrome is rare with these fractures. Most complications involve malunion or nonunion because of inadequate or lost reduction.

FRACTURES OF THE DISTAL ONE-THIRD OF THE RADIUS (GALEAZZI FRACTURE)

Fractures of the distal third of the radial shaft are produced by falls on the outstretched hand in forced pronation or by a direct blow. Much like the Monteggia fracture-dislocation, the distal radial shaft fracture is often associated with a distal radioulnar joint dislocation, hence the name *reverse Monteggia fracture* or, more commonly, *Galeazzi fracture*. There is localized tenderness and swelling over the distal radius and wrist. The radius fracture is usually short oblique or transverse with dorsal lateral angulation. The distal radioulnar joint injury can be subtle. Radiographs may show only a slightly increased distal radioulnar joint space on the anteroposterior view. On the lateral view, the ulna is displaced dorsally. This injury is treated by open reduction and internal fixation of the radius fracture. Complications include infection, nonunion, and malunion. Injuries to the ulnar nerve and anterior interosseous branch of the median nerve have been reported, but usually heal spontaneously. If the radius heals with a rotational deformity, there may be pain at the distal radioulnar joint with extreme pronation and supination.

FIG. 270-10. Type II Monteggia fracture-dislocation. The angulation of the comminuted fracture of the proximal ulna (*arrow*) points in the direction of the radial head dislocation (*arrowhead*).

BICEPS AND TRICEPS RUPTURE

Biceps Rupture

The biceps muscle has two proximal heads. The long head originates at the supraglenoid tubercle of the scapula and superior labrum of the

TABLE 270-1 Bado Classification of Monteggia Fracture-Dislocation

<i>Type I:</i>	60% Fracture of the proximal or middle third of the ulna with anterior dislocation of the radial head (fracture apex anterior)
<i>Type II:</i>	Fracture of the proximal or middle third of the ulna with posterior dislocation of the radial head (fracture apex posterior)
<i>Type III:</i>	Fracture of the ulna distal to the coronoid process with lateral dislocation of the radial head
<i>Type IV:</i>	Fracture of the proximal or middle third of the ulna and fracture of the proximal third of the radius with the anterior dislocation of the radial head

glenohumeral joint, and then travels through the capsule of the shoulder and along the intertubercle (bicipital) groove of the humerus (Figure 270-11). The short head originates at the coracoid process of the scapula. The distal attachments are to the radial tuberosity and forearm via the bicipital aponeurosis. A bicipitoradial bursa lies adjacent to the radial tuberosity. The biceps muscle is innervated by the musculocutaneous nerve (C5, C6), and functions to flex the supinated forearm and supinate the flexed forearm.

The vast majority of all injuries to the biceps are proximal, and nearly all involve the proximal long head. Injuries are usually the result of repetitive microtrauma and overuse. Steroids, whether injected locally or used systemically, can accelerate the breakdown of tendons. Rupture of the biceps tendon usually occurs in middle-aged to older individuals with a history of chronic bicipital tenosynovitis when there is sudden or prolonged contraction against resistance. A snap or pop is usually described and pain is present in the anterior shoulder. Examination of the anterior shoulder will reveal swelling, tenderness, and often crepitus over the bicipital groove. Flexion of the forearm, best accomplished with the arm abducted and externally rotated, will elicit pain and may produce a mid arm "ball," which represents the distally retracted biceps muscle. Comparing arms for

FIG. 270-11. Biceps muscle anatomy.

symmetry helps. Loss of strength is minimal due to the function of the brachialis and supinators. Radiographs of the shoulder should be obtained as avulsion fractures occasionally occur.

General emergency department treatment includes sling, ice, analgesics, and referral to an orthopedic surgeon for definitive care. Surgical repair is usually recommended for young, active patients. A conservative approach with immobilization may be adequate for elderly patients whose activities of daily living are not significantly compromised by the injury.

Distal biceps injuries are quite rare.^{10,11} Complete ruptures of the tendon are most common in middle-aged men and usually involve the dominant extremity. Partial tears are seen in men and women. Mechanism of injury is similar to that of proximal injuries. With rupture of the distal biceps, pain is felt in the antecubital fossa, with swelling, ecchymosis, and tenderness to palpation noted on examination. Inability to palpate the distal biceps tendon in the antecubital fossa and a mid arm "ball" indicate a distal rupture. Strength loss, especially supination, is usually greater than with proximal ruptures. Radiographs should be obtained to search for an associated avulsion fracture. While most complete distal ruptures are diagnosed clinically, magnetic resonance imaging and ultrasound can aid in confirming the diagnosis of partial tears.¹²

Emergency department treatment includes sling, ice, analgesics, and referral to an orthopedic surgeon for definitive care. Without surgical repair of complete ruptures, supination strength is decreased by approximately 50 percent and flexion strength by almost 30 percent. Therefore, in young active individuals, most authorities recommend surgical repair.

Triceps Rupture

The triceps muscle has three proximal heads. The long head originates at the infraglenoid tubercle of the scapula, the lateral head on the posterior surface of the humerus superior to the radial (spiral) groove, and the medial head inferior to the radial groove (Figure 270-12). The triceps inserts at the olecranon. A subtendinous bursa separates

the triceps from the olecranon, and a subcutaneous bursa lies just distal to the tendinous insertion. The latter frequently becomes inflamed. The triceps muscle is innervated by the radial nerve (C6, C7, C8) and is the sole extensor of the forearm. Additionally, it also aids in extension and adduction of the arm, and the long head stabilizes the head of the humerus in abduction.

Injury to the triceps is rare and almost always occurs distally. Rupture is more common in young men and results from either a fall on an outstretched hand causing a forceful flexion of an extended forearm, or a direct blow to the olecranon. Spontaneous ruptures from systemic illnesses, particularly hyperparathyroidism, have also been reported. With rupture of the triceps, pain is present in the posterior elbow. Examination of the elbow reveals swelling and tenderness posteriorly just proximal to the olecranon. A sulcus with a more proximal mass, representing the retracted triceps muscle, may be palpated. With partial tears some degree of function remains, whereas with complete ruptures, the ability to extend the forearm is lost. A modified Thompson test can be used to evaluate triceps function. The upper extremity is positioned such that the arm is supported and the forearm is hanging in a relaxed position with 90 degrees of flexion. Squeezing the triceps muscle should produce extension of the forearm unless a complete rupture is present. Radiographs are needed, as avulsion fractures of the olecranon are common.¹³ Ultrasound and magnetic resonance imaging may aid in diagnosis, especially of partial tears.

Emergency department treatment includes sling, ice, analgesics, and referral to an orthopedic surgeon for definitive care. Complete ruptures require surgical repair, while most partial tears can be treated conservatively with immobilization.

ACKNOWLEDGMENT

The authors wish to recognize the contributions of Harold Chin, MD, in previous editions of this chapter.

INJURIES TO THE SHOULDER COMPLEX AND HUMERUS **Dennis T. Uehara John P. Rudzinski**

Function of the upper extremity is intimately dependent on the shoulder complex. Movement is accomplished through an intricate mechanism with integration of muscles, ligaments, osseous components, and a system of joints all working in harmony. Through its joint system, which consists of four joints, the sternoclavicular, glenohumeral, acromioclavicular, and scapulothoracic, the upper extremity is able to move through a complex and wide range of motion. The following discussion focuses on the major soft tissue and osseous components of the shoulder complex and humerus and those injuries that create loss of motion, instability, and pain.

STERNOCLAVICULAR DISLOCATIONS

The sternoclavicular joint is the most frequently moved nonaxial joint of the body because almost any movement of the upper extremity is transferred proximally to this joint. It also has the least amount of bony stability of any major joint because less than half of the medial end of the clavicle actually articulates with the upper sternum. Joint stability therefore depends on the integrity of the surrounding ligaments, which give the sternoclavicular joint surprising strength. As a result, the majority of injuries to this area are simple sprains, dislocations being uncommon.

A sprain of the sternoclavicular joint can result from the shoulder being forced forward suddenly or from a medially directed force applied to the shoulder. Pain and swelling are localized to the joint, and treatment is symptomatic with ice, sling, and analgesics. Differential diagnosis should include consideration of septic arthritis, especially in intravenous drug abusers.

Sternoclavicular dislocations are uncommon, accounting for only 3 percent of a series of 1603 shoulder girdle injuries. Dislocations usually result from motor vehicle accidents or sports injuries, but spontaneous dislocations have been reported. Posterior sternoclavicular joint dislocations are much less common than anterior dislocations. A posterior dislocation may result from a direct blow or from an indirect force to the shoulder if the shoulder is rolled forward at the time of impact. An anterior sternoclavicular joint dislocation may result from the same indirect force if the shoulder is rolled backward at the time of impact. Of note is that the medial clavicular epiphysis is the last epiphysis of the body to appear radiographically (age 18) and the last to close (age 22 to 25). As a result, physal injuries in this age group can easily be misdiagnosed as a dislocation.

Patients with a sternoclavicular joint dislocation have severe pain that is exacerbated by arm motion and when in the supine position. The shoulder appears shortened and rolled forward. On examination, anterior dislocations have a prominent medial clavicle end that is visible and palpable anterior to the sternum. In posterior dislocations, the medial clavicle end is less visible and not palpable, and the patient may have signs and symptoms of impingement of the superior mediastinal contents. Routine radiographs may not be diagnostic, although specialized views or tomograms may be helpful. Computed tomography (CT) is the imaging procedure of choice.

Closed reduction of anterior sternoclavicular joint dislocations is usually attempted with the patient supine and with a sandbag or pad between the shoulders. Direct pressure over the clavicle may reduce the dislocation. The patient is usually discharged in a figure-of-eight clavicle harness. Unfortunately, many anterior dislocations prove unstable and recur as soon as direct pressure is released. Patients may subsequently undergo open reduction, or the position of the deformity may be accepted and no further treatment rendered.

In posterior dislocations, life-threatening injuries to adjacent structures may result in a pneumothorax or in compression or laceration of the great vessels, trachea, or esophagus. Local swelling may obscure any deformity, and routine radiographs are often not conclusive, making diagnosis difficult. Additional injuries should be aggressively sought and addressed. Orthopedists may attempt closed reduction, with thoracic surgical back-up. A towel clip is often used to grasp and pull the medial clavicle forward and back into place. Open reduction may be necessary.

CLAVICLE

Clavicle fractures account for nearly half of significant injuries to the shoulder girdle and are the most common fracture of childhood, with almost half of these injuries occurring by the age of 7. The clavicle functions as a strut, connecting the shoulder girdle to the trunk, and provides support and mobility for upper extremity function. The clavicle also protects the adjacent lung, brachial plexus, and subclavian and brachial blood vessels.

The most common mechanism of injury is a blow to the shoulder. Transmission of the compressive force results in a buckling of the clavicle, which fractures once a critical force is achieved. Children will often have a greenstick or buckle-type fracture or a bowing deformity without a definite fracture. Open fractures, from extreme tenting and piercing of the overlying skin, may occasionally be seen.

Eighty percent of clavicle fractures involve the middle third, 15 percent the distal third, and 5 percent the medial third. Patients typically present with swelling, deformity, and tenderness localized to the clavicle. The arm is slumped inward and downward and is supported by the other extremity. Routine clavicle radiographs may miss fractures due to overlap of surrounding structures, particularly with fractures at either end of the bone. Diagnosis may require CT.

Numerous forms of treatment have been described for this common injury. Simple immobilization with a sling is often successful, with displaced fractures often treated with a figure-of-eight brace. A shoulder spica or open reduction may be required for severely displaced fractures, poor patient compliance, or for complications. Healing may occur as rapidly as 2 weeks for infants, with most adults healing in a 4- to 6-week period. The nonunion rate varies from 0.1 to 15 percent.¹ Factors associated with nonunion are marked initial displacement and shortening.² Delayed internal fixation is sometimes done for severely displaced clavicle fractures with functional disability.^{1,2}

Although the vast majority of these fractures have a benign course, serious associated injuries and complications may occasionally occur. Penetrating or blunt trauma may result in associated lung, neurovascular, or first-rib injuries. Injury to the adjacent vascular structures, usually the subclavian artery, subclavian vein, internal jugular vein, or axillary artery, may be life-threatening. **Distal clavicle fractures with displacement typically are associated with rupture of the coracoclavicular ligament and may require operative intervention to avoid nonunion. Medial clavicle fractures may be associated with intrathoracic injuries or develop late complications, such as arthritis.** Significant callus formation may result in subsequent compression of adjacent neurovascular structures and is cosmetically deforming.

SCAPULA

The scapula links the axial skeleton to the upper extremity and serves as a stabilizing platform for motion of the arm. Fracture of the scapula is infrequent, accounting for less than 1 percent of all fractures. Due to the high energy typically required to fracture this protected bone, there is a greater than 80 percent association of injuries to the ipsilateral lung, thoracic cage, and shoulder girdle.

Significant scapular injury occurs most frequently in men between 25 and 40 years of age, usually as a result of motor vehicle accidents,

falls, or other severe trauma. The mechanism of injury is from a direct blow, trauma to the shoulder sometimes with injury of the acromion or coracoid, or a fall on the outstretched arm. An indirect axial load transmitted by the outstretched arm may result in a scapular neck fracture, while the indirect force of a shoulder dislocation may result in fracture of the glenoid. Scapular fractures may be classified by their anatomic location: body, glenoid neck, intraarticular glenoid, spine, coracoid, and acromion (Figure 271-1). Fractures of the body and glenoid neck are the most common.

A patient with an isolated scapular fracture typically will present with localized tenderness over the scapula and the ipsilateral arm held in adduction. The shoulder may have a flattened appearance. Radiographs consisting of an anteroposterior shoulder, lateral scapula, and axillary views will identify most fractures. However, scapula fractures are often associated with other significant injuries, and hence diagnosis may be delayed or initially missed entirely. In Ada and Miller's series,³ 96 percent of scapular fractures had associated injuries, of which rib fractures were the most common, followed by pulmonary, humeral head, and shoulder girdle injuries. Other injuries may include neurovascular, abdominal, and spine trauma.

Rarely, significant trauma may result in scapulothoracic dissociation. This syndrome consists of lateral scapular displacement, clavicular disruption, and severe soft-tissue injury. This injury is sometimes associated with brachial plexus avulsion, subclavian artery disruption, or both. Its presence may be suspected by neurovascular findings or by lateral displacement of the scapula visualized on a nonrotated chest radiograph.

The vast majority of scapular fractures are treated nonsurgically, with a sling for immobilization, ice, analgesics, and early range-of-motion exercises. Surgical intervention may be necessary for significant or displaced articular fractures of the glenoid, angulated glenoid neck fractures, acromial fractures associated with a rotator cuff tear, and some coracoid fractures. Fractures of the glenoid, acromion, or coracoid are more likely to be associated with long-term disability.

Complications of scapular fractures themselves are uncommon. Although many of these fractures heal with some degree of malunion, typically this does not result in significant disability. Most long-term disability is a result of other, associated injuries.

ACROMIOCLAVICULAR JOINT INJURIES

Injuries to the acromioclavicular joint are commonly seen in emergency practice. Although they may occur in any age group, the majority occur in young, active males. Emergency management consists of identifying the severity of injury, recognizing associated injuries, and managing selected patients as outpatients.

Anatomy

The acromioclavicular joint is a diarthrodial joint that, together with the sternoclavicular joint, connects the upper extremity to the axial skeleton. The support of the acromioclavicular joint is through the acromioclavicular and coracoclavicular ligaments and the strong attachment of the trapezius and deltoid muscles (Figure 271-2). The acromioclavicular joint is surrounded by a thin capsule, which is reinforced by the acromioclavicular ligaments. The superior fibers of this ligament blend with the fascia of the trapezius and deltoid muscles, which attach to the clavicle and acromion. The acromioclavicular ligaments provide horizontal stability to the joint. The tough coracoclavicular ligaments consist of two parts, the more lateral trapezoid and the medial conoid. They attach the distal inferior clavicle to the coracoid process of the scapula. The coracoclavicular ligament is the major suspensory ligament of the upper extremity and provides vertical stability to the acromioclavicular joint.

Mechanism of Injury

The mechanism of injury is usually direct trauma to the acromioclavicular joint from a fall with the arm adducted, as typically may occur in a sporting activity. An indirect mechanism is a fall on the outstretched hand with transmission of force to the acromioclavicular joint. The result is that the scapula and shoulder girdle are driven inferiorly while the clavicle remains in its normal position. This is confirmed by observing the opposite clavicle, which is at the same level as the injured one.

Clinical Features

The diagnosis of acromioclavicular joint injuries is made clinically. The typical mechanism of injury, as well as tenderness and deformity at the acromioclavicular joint, is confirmatory. Radiographs are useful for identifying other fractures and determining the severity of injury. Acromioclavicular radiographs should specifically be ordered because

FIG. 271-2. Anatomy of the acromioclavicular joint.

they require only one-third to one-half the penetration of standard shoulder films. Shoulder technique will overpenetrate the acromioclavicular joint, and small fractures may be missed. Although standard acromioclavicular radiographs are generally sufficient, an axillary view is required to identify posterior clavicular dislocation (type IV, see below). Routine use of stress radiographs has been standard practice; Bossart and colleagues⁴ have called this practice into question. Their study suggests that stress radiographs are of low yield and that their routine use should be abandoned. Although some agree, others disagree, citing occult type III (see below) injuries that can be unmasked only with stress radiographs.

Classification of Injury

The classification of acromioclavicular joint injuries classically describes three types of injuries. Rockwood describes three others (Figure 271-3). Types I, II, and III are common; types IV, V, and VI are rare. The anatomic injury, radiographic findings, and physical findings are summarized in Table 271-1.

Treatment

Treatment of type I injuries consists of rest, ice, analgesics, and immobilization, followed by early range-of-motion exercises.⁵ Most agree that type II injuries should be similarly treated. Various straps and braces have been used to reduce the dislocation, but none have proven successful. A simple sling remains the most convenient and ef-

fective. Prognosis for type I and II injuries is excellent, with only a small percentage who develop late symptoms requiring excision of the distal clavicle. Treatment of type III injuries is controversial, with proponents for both conservative and operative philosophies.⁶ A trend, however, reveals a shift to conservative treatment with sling immobilization. Both strategies have yielded good results in selected patients, with the specific management operator-dependent. Treatment decisions are based on such factors as age, occupation, and activity level. Types IV, V, and VI are severe injuries, and most authors recommend surgical repair. Because other injuries are associated with these more severe forms of acromioclavicular joint injuries (especially type VI), a careful clinical and radiographic examination must be performed.

DISLOCATION OF THE GLENOHUMERAL JOINT

Anterior dislocations of the glenohumeral joint are the most common major joint dislocations. Posterior dislocations are described, but occur in less than 2 percent of cases. Other dislocations include inferior (luxatio erecta) and superior (very rare). Neurovascular examination should always be done before and after reduction.

Anterior Glenohumeral Dislocations

There are four types of anterior dislocations. In subcoracoid dislocation, the most common type, the humeral head is displaced anterior to the glenoid and inferior to the coracoid. In a subglenoid dislocation, the humeral head lies inferior and anterior to the glenoid fossa. In a

FIG. 271-3. Classification of acromioclavicular joint injuries. (Reproduced with permission from Rockwood CA, Green DP, Bucholz RW: *Rockwood & Green's Fractures in Adults*, 3d ed. Philadelphia, PA: Lippincott, 1991.)

TABLE 271-1 Classification and Physical Findings in Acromioclavicular Joint Injuries

Type	Injury	Radiograph	Examination
I	Sprained acromioclavicular ligaments	Normal	Tenderness over acromioclavicular joint
II	Acromioclavicular ligaments ruptured; coracoclavicular ligaments sprained	Slight widening of acromioclavicular joint; clavicle elevated 25–50% above acromion; may be slight widening of the coracoclavicular interspace	Tenderness and mild step-off deformity of acromioclavicular joint
III	Acromioclavicular ligaments ruptured; coracoclavicular ligaments ruptured; deltoid and trapezius muscles detached	Acromioclavicular joint dislocated 100%; coracoclavicular interspace widened 25–100%	Distal end of clavicle prominent; shoulder droops
IV	Rupture of all supporting structures; clavicle displaced posteriorly in or through the trapezius	May appear similar to type II and III; axillary radiograph required to visualize posterior dislocation	Possible posterior displacement of clavicle
V	Rupture of all supporting structures (more severe form of type III injury)	Acromioclavicular joint dislocated; generally 200–300% disparity of coracoclavicular interspace compared to normal shoulder	More pain; gross deformity of clavicle
VI	Acromioclavicular ligaments disrupted; coracoclavicular ligaments may be disrupted; deltoid, and trapezius muscles disrupted	Acromioclavicular joint dislocated; clavicle displaced inferiorly	Severe swelling; multiple associated injuries

subclavicular dislocation, the head of the humerus is displaced medial to the coracoid below the clavicle. In the very rare intrathoracic dislocation, the head of the humerus lies between the ribs and thoracic cavity.

The mechanism of injury may be direct force, but an indirect force is more common. The combination of abduction, extension, and external rotation with sufficient force will cause an anterior dislocation.

The patient is usually in severe pain. The arm is in slight abduction and external rotation. The shoulder is "squared off," lacking the normal rounded contour. The patient resists abduction and internal rotation. The humeral head can often be palpated anteriorly. Because neurovascular injuries occur, a careful examination must be performed. The axillary nerve is most commonly injured. This nerve may be tested by pinprick sensation over the skin of the deltoid muscle.

Anteroposterior and scapular lateral or "Y" radiographs should be obtained before reduction is attempted. Although the anteroposterior radiograph will reveal the dislocation, the scapular Y radiograph will indicate the direction of dislocation: anterior or posterior. Bony injuries reported in the literature include fractures of the anterior glenoid lip, greater tuberosity, coracoid, and acromion, and compression fractures of the humeral head (Hill-Sachs lesion).

Many reduction techniques have been described.⁷ The three main categories are traction, leverage, and scapular manipulation.⁸ Success rates are between 70 and 96 percent regardless of technique. The use of conscious sedation is recommended, but any reduction technique may be attempted without medication when performed slowly and atraumatically. It is important for the physician to be comfortable with two or three techniques in case of a failed first attempt. Considerations in selection of a technique include ease of performance, effectiveness, as little trauma and pain as possible, requirement for medication, number of assistants, and time for procedure.

HIPPOCRATIC (MODIFIED) A modification of the Hippocratic method uses traction-countertraction (Figure 271-4). The patient is supine with the arm abducted and elbow flexed at 90 degrees. A sheet is tied and placed across the thorax of the patient and then around the waist of the assistant. Another sheet is tied and placed around the forearm of the patient at the elbow and the waist of the physician. The physician gradually applies traction as the assistant provides countertraction. Gentle internal and external rotation or outward pressure on the proximal humerus may aid reduction.

STIMSON The patient is placed prone on a gurney with the dislocated extremity hanging over the side and a 10 lb. weight attached to

the wrist. Complete muscle relaxation is required. Reduction occurs in 20 to 30 min.

Although safe, effective, and easy to learn, the time involved and constant monitoring by a nurse are drawbacks to this technique.

MILCH The patient is supine. The physician slowly abducts and externally rotates the arm to the overhead position (Figure 271-5). With the elbow fully extended, traction is applied. With the other hand, pressure may be placed on the humeral head to manipulate it over the lip of the glenoid.

This technique is well tolerated by the patient, effective, and atraumatic. It is the technique of choice for many physicians.

SCAPULAR MANIPULATION The patient is positioned with weights in the same manner as the Stimson technique (Figure 271-6). After adequate sedation, the physician pushes the tip of the scapula medially using the thumbs, while stabilizing the superior aspect with the cephalad hand.

Physicians have found this technique relatively painless, fast, and in one study 96 percent successful.⁹

EXTERNAL ROTATION The patient is supine with the arm adducted to the patient's side. With the elbow at 90° of flexion, the arm is slowly externally rotated. No longitudinal traction is applied. It is important to perform the movement slowly to allow time for spasm and pain to

**FIG. 271-4.** Modified Hippocratic technique.

FIG. 271-5. Milch technique.

resolve. Reduction is usually complete prior to reaching the coronal plane and is often not noted either by the patient or physician. This method has been reported to be 78 percent successful, relatively atraumatic, safe, and easily learned.

COMPLICATIONS Complications are frequently encountered in patients with anterior glenohumeral dislocations.¹⁰ The most common complication is recurrent dislocation, which is age dependent. Those patients less than 20 years of age may have a greater than 90 percent recurrence; those older than 40 years have a 10 to 15 percent recurrence.^{10,11} The high recurrence rate in younger patients is thought to be related to the higher incidence in this group of avulsions of the anterior inferior glenohumeral ligament, the major anterior stabilizer of the glenohumeral joint (Bankart lesion). Early surgical repair, open or arthroscopic, may significantly decrease the recurrence rate. Younger patients with first-time shoulder dislocations should be referred for or-

FIG. 271-6. Scapular manipulation technique.

thopedic evaluation.¹²⁻¹⁴ Other complications include fractures and injuries to nerves and to the rotator cuff. Vascular injuries are rare, but when they occur tend to involve the axillary artery in elderly patients. Clinical findings of vascular injury include absent radial pulse, axillary hematoma, bruising of the lateral chest wall, and an axillary bruit.

Bony injuries are common and include fractures of the humeral head (Hill-Sachs lesion), anterior glenoid lip, and greater tuberosity. Neural injuries occur in 10 to 25 percent of acute dislocations. Of these injuries, which are the result of traction neuropraxia, most occur in the axillary nerve. This injury is temporary and resolves spontaneously. The common test of sensation over the skin of the deltoid muscle may not be reliable, with only an electromyogram providing an accurate evaluation. Other nerves injured are the radial, ulnar, median, musculocutaneous, and brachial plexus.¹⁰

A frequent but often missed injury is a tear of the rotator cuff. The rotator cuff weakens with advancing age, and as many as 86 percent of patients older than 40 years with an anterior dislocation have an associated rotator cuff tear. Pain or weakness 2 to 4 weeks after a glenohumeral dislocation is an indication for imaging such as MR or arthrogram. Early diagnosis is important since prompt surgery yields the best results.

Posterior Glenohumeral Dislocations

Posterior dislocation may occur with the humeral head in the subacromial (most commonly with the humeral head posterior to the glenoid and inferior to the acromion), subglenoid, or subspinous. The latter two are rare.

The usual mechanism is an indirect force that produces forceful internal rotation and adduction. This may occur during a fall or from violent muscle contraction due to a seizure or electric shock. Direct force to the anterior shoulder can also produce a posterior dislocation.

Posterior dislocations are reported to be commonly missed. Thus a careful examination and radiographic evaluation are essential. Clinical findings include the following:

1. The arm is adducted and internally rotated.
2. The anterior shoulder is flat and the posterior aspect full.
3. The coracoid process is prominent.
4. The patient will not allow external rotation or abduction because of severe pain.

Although the anteroposterior radiograph is helpful, the scapular Y radiograph is diagnostic. In this radiograph, the humeral head is seen in a posterior position.

Since severe pain and muscle spasms are the norm, muscle relaxation and analgesia are paramount. The reduction is performed with the patient supine. Traction is applied to the adducted arm in the long axis of the humerus. An assistant gently pushes the humeral head anteriorly into the glenoid fossa.

Most complications are fractures, including fractures of the posterior glenoid rim, humeral head (reversed Hill-Sachs deformity), humeral shaft, and lesser tuberosity. Neurovascular and rotator cuff tears are less common than in anterior dislocations.

Inferior Dislocations (Luxatio Erecta)

Although inferior dislocation is a rare injury, it is one that will be seen in a busy emergency practice. It is always a severe injury and is associated with significant soft-tissue trauma or fracture. The mechanism of injury is a hyperabduction force, which levers the neck of the humerus against the acromion. As the force continues the inferior capsule tears, and the humeral head is forced out inferiorly.

The patient is in severe pain. The humerus is fully abducted, the elbow is flexed, and the patient's hand is on or behind the head. The humeral head can be palpated on the lateral chest wall. This clinical presentation is difficult to mistake for another condition.

Reduction consists of traction in an upward and outward direction in line with the humerus (Figure 271-7). The assistant applies counter-traction. Reduction is signaled by a "clunk." The arm is then brought to the patient's side and immobilized in a shoulder immobilizer.

Complications include severe soft-tissue injuries and fractures of the proximal humerus. The rotator cuff, which is always detached, requires orthopedic follow-up. Neurovascular compression injuries are usually found, but almost always resolve following reduction. When the humeral head is buttonholed through the inferior capsule, the dislocation is irreducible, and operative reduction is required.

HUMERUS FRACTURES

Proximal Humerus

Fractures of the proximal humerus typically occur in elderly osteoporotic patients through an indirect mechanism, such as a fall on an outstretched hand with the elbow extended. Simple, one-part fractures without significant displacement can be initially managed by the emergency physician, but the remainder have significant displacement and are a challenge to correctly diagnose and treat. Fortunately, the shoulder joint has an intrinsic reserve of range of motion, which can often provide a surprisingly functional outcome despite seemingly crippling injuries.

The proximal humerus is composed of the articular segment, the greater and lesser tuberosities, and the proximal humeral shaft. Muscles of the rotator cuff insert on the humeral tuberosities, and the biceps tendon travels between them. The humeral circumflex arteries enter in the area of the bicipital groove and the tuberosities to supply blood flow to the articular segment.

FIG. 271-7. Reduction of luxatio erecta.

Patients with fractures typically present with pain, swelling, and tenderness about the shoulder. Crepitus and ecchymosis may be present, and the arm is generally held closely against the chest wall. A neurovascular examination should be performed, since the brachial plexus and axillary arteries are near the coracoid process and not uncommonly injured. The axillary nerve is the most commonly injured nerve, and sensation over the skin of the deltoid muscle should be tested routinely. Injury to the axillary artery is the most common vascular injury and may be suggested by paresthesias, pallor, pulselessness, or an expanding hematoma. Vascular injuries may occur with even trivial trauma in atherosclerotic elderly patients.

Radiographs consisting of anteroposterior, lateral shoulder, and axillary views will correctly diagnose most proximal humerus fractures. Fractures of the articular surface may be suggested by a fat fluid level or by a superior joint hematoma that appears to push the humerus downward in the joint as a "pseudosubluxation." A transthoracic lateral radiograph, tomograms, CT scan, and magnetic resonance imaging scan may also be of value.

The Neer classification system uses the relationship of the proximal humerus segments (greater and lesser tuberosities, anatomic neck, and surgical neck) to guide the management of these fractures. **Significant fragment displacement is defined as greater than 1 cm separation or greater than 45 degrees of angulation between fragments.** The number of fracture fragments significantly displaced determines the classification in the Neer system (Figure 271-8).

Displaced Fractures			
	2-part	3-part	4-part
Anatomic Neck			
Surgical Neck			
Greater Tuberosity			
Lesser Tuberosity			

FIG. 271-8. The Neer classification system for displaced proximal humerus fractures.

A one-part fracture under the Neer system may have any number of fracture lines, but no major segment is significantly displaced. The surrounding soft tissue and periosteum hold fracture fragments together. Treatment generally consists of immobilization with a sling and swathe or collar and cuff, ice, analgesics, and referral. Early exercise is important to avoid adhesive capsulitis. The overall prognosis is generally good.

Proximal humerus fractures with significant displacement and/or angulation between fracture fragments are classified as multipart fractures under the Neer system. Treatment considerations include integrity of the blood supply, integrity of the rotator cuff, likelihood of union, associated dislocations and neurovascular injuries, and the functionality of the patient. These fractures are more frequently associated with complications and are often difficult to manage. Closed reduction, intraoperative treatment, or a combination of the two may be necessary.¹⁵ Emergent orthopedic consultation for multipart fractures facilitates subsequent reduction and referral.

Any fracture involving the anatomic neck or the articular surface may result in compromise of the blood supply to the articular segment. Ischemic necrosis of the articular segment may ultimately require insertion of a humeral head prosthesis for these relatively uncommon fractures. Greater tuberosity fractures accompany up to 15 percent of anterior shoulder dislocations. Significant displacement of a greater tuberosity fragment implies a concomitant rotator cuff tear, with surgical repair often necessary for the active patient. Fracture of the lesser tuberosity should alert the examiner to a potential posterior shoulder dislocation. Significantly angulated surgical neck fractures are at risk for neurovascular damage (axillary neurovascular structures and brachial plexus) and should be immediately immobilized and radiographed in the position of presentation. Children may have significant displacement or separation of the proximal humeral epiphysis and may require exact reduction if near skeletal maturity. A shoulder spica is often used after reduction.

Humeral Shaft

Fractures of the humeral shaft occur in a bimodal age distribution, with peaks in the third and seventh decades of life, representing active

young men and osteoporotic elderly women, respectively. The most common site of fracture is the middle third. **Neurovascular Injuries are a common complication of these fractures and are due to the anatomy of the upper extremity.** Displacement of fracture fragments is common as a result of the insertions and actions of the various muscles (deltoid, biceps, triceps, supraspinatus, and pectoralis major) that act on the upper arm (Figure 271-9).

Humeral shaft fractures may be caused by a direct blow that produces a bending force, which results in a transverse fracture. They may also be caused by an indirect mechanism, such as a fall on the outstretched hand that produces a torsion force, resulting in a spiral fracture. A combination of bending and torsion forces results in an oblique fracture, sometimes with comminution, producing the "butterfly" fragment. The humerus is also a common site of pathologic fractures, especially from metastatic breast cancer.

Clinical examination reveals localized tenderness, swelling, pain, and abnormal mobility or crepitus on palpation. Displaced fractures are associated with shortening of the upper extremity. Attention must be given to the initial neurovascular status, and reevaluation must be performed, especially after manipulation. Radiographs should include two views of the humerus, and consideration should be given to radiographic examination of the shoulder and elbow as well. The vast majority of closed fractures of the shaft of the humerus are managed nonoperatively. The treatment of uncomplicated fractures includes immobilization, ice, analgesia, and referral. Closed treatment options include the coaptation splint (sugar tong), a hanging cast, functional bracing, and external fixation. A simple sling and swathe are adequate for most emergency management. Some surgeons favor internal fixation for patients with transverse fracture lines, very proximal or very distal humerus fractures, pathologic fractures, multiple trauma, and fractures associated with neurovascular injuries.

Complications include injury to the brachial artery or vein, or the radial, ulnar, or median nerves. A radial nerve injury, which is the most common, may be manifested by a wrist drop and altered sensation at the dorsal first web space. The incidence of radial nerve palsy ranges from 10 to 20 percent. **Fractures of the distal third are particularly prone to entrapment of the radial nerve, either as a result of the**

FIG. 271-9. The actions of the muscles inserting on the humeral shaft determine fracture angulation and displacement. Humeral fractures anterior view: A. Angulation of fragments with fracture line distal to deltoid insertion.

initial injury or after closed reduction. The majority of patients have eventual return of nerve function without operative intervention.

BRACHIAL PLEXUS INJURIES

The brachial plexus originates from the fourth through eighth cervical and first thoracic nerve roots, and a knowledge of its anatomy is crucial. At the lateral border of the interscalene triangle, formed by the anterior and middle scalene muscles, the fifth and sixth cervical (C5 and C6) nerve roots form the upper trunk of the plexus, the root of C7 the middle trunk, and the roots of C8 and T1 the lower trunk. Upon reaching the clavicle, each trunk then divides into anterior and posterior divisions. Lateral to the first rib, the anterior divisions of the upper and middle trunks combine to form the lateral cord, the anterior division of the lower trunk forms the medial cord, and all posterior divisions combine to form the posterior cord. Then, lateral to the pectoralis minor, these cords further divide into the peripheral nerves of the upper extremity: median, ulnar, musculocutaneous, axillary, and radial. Injuries to the brachial plexus can occur from penetrating, compression, or traction injuries. Traction injuries from high-speed motor vehicle crashes are the most common emergency presentation, with an overall incidence of brachial plexus injuries ranging from 0.67 to 1.3 percent. The nerves are stretched longitudinally, typically by a mechanism in which there is simultaneous traction of the arm and opposite distraction of the head.¹⁶ Motorcycle crashes have a much higher incidence of brachial plexus injuries, due to the forces applied to an unprotected body.

The initial presentation of brachial plexus injuries in such patients is often overshadowed by their associated injuries. The most common of these is closed head injury, with chest trauma, fractures of nearby structures (clavicle, scapula, and long bones), shoulder dislocation, and trauma to the subclavian or neck vessels also frequently encountered. Significant swelling and soft tissue injury to the neck and shoulder girdle suggest traumatic forces sufficient to injure the brachial plexus. The accumulation of cerebrospinal fluid from avulsed spinal roots may cause swelling in the posterior triangle. Homer's sign may be present due to adjacent ganglion damage. However, brachial plexus injury may not be clinically apparent until a responsive patient can indicate the extent of motor and sensory deficits, days to weeks after initial stabilization and treatment. Arm pain that is constant and burning in character is common. Upper limb and shoulder girdle motor and sensory deficits define the extent of damage to the brachial plexus. Adduction and internal rotation of the shoulder indicates weakness of the deltoid and infraspinatus muscles (C5), while elbow extension is due to weakness of the biceps (C6), and flexion of the digits and wrists is due to weakness of the extensors (C7).

Magnetic resonance imaging and CT myelography are common radiographic imaging procedures. Electromyographic and nerve conduction velocity studies may aid in diagnosis, and surgical exploration of the area may be necessary. The delineation of pre- and postganglionic injury may not be possible until wallerian degeneration is completed 2 weeks after injury.

Treatment and prognosis¹⁷ will depend on the location and extent of nerve damage. Complete supraclavicular traction injuries with rupture of the nerve roots from the spinal cord may be the most devastating of all lesions of the peripheral nerves. A multidisciplinary approach with nerve transfers and long-term physical therapy may provide surprisingly good functional outcomes. In general, early neurosurgical consultation and timely referral to a facility capable of handling the complex multiple trauma patient will result in the best outcome.

INJURIES TO THE SPINE

James L. Larson, Jr.

Injuries to the spine are due to blunt trauma in about 90 percent of cases. The most common injury mechanism is a motor vehicle accident, followed by assaults, mostly gunshot wounds, falls, and sporting accidents. The cervical spine is the most common site for injury (61 percent), followed by the thoracolumbar junction (19 percent), the thoracic spine (16 percent), and the lumbosacral spine (4 percent).¹ This chapter discusses the radiologic identification and evaluation of spinal injuries. A thorough discussion of resuscitation, assessment, neurologic evaluation, and treatment are covered in Chaps. 35 and 256.

EVALUATION

Resuscitation and Spinal Immobilization

Injuries to the spine and spinal cord are frequently associated with other injuries. Initial resuscitation of the patient with multiple injuries from trauma focuses on airway, breathing, and circulation (the ABCs). The patient with a potential spine injury should undergo immobilization to prevent deterioration during resuscitation. Patients who are at high risk for spinal injury include those who have had automobile and motorcycle accidents, falls, and diving accidents. Any patients complaining of neck pain, weakness, paresthesias, or paralysis should be considered to have a spinal cord injury. A patient with a history of trauma and an altered level of consciousness should always be treated as if a spinal cord injury were present.

Spinal immobilization is important to prevent secondary injury. The components of spinal immobilization include a long spine board, a semirigid cervical spine collar, and "sandbags" or other devices to limit head and neck motion. Athletes wearing helmets and shoulder pads should be immobilized in their equipment. Removal should occur in the emergency department after radiographic evaluation.²

Cervical collars vary in their ability to restrict movement. In general, cervical spine collars alone reduce flexion and extension movement somewhat and are ineffective in limiting lateral movement. The process for moving a patient onto a spine board or for examination of the back involves a "log-roll." One person is required to maintain the head and neck in neutral position while a minimum of two other people gently roll the patient. The person holding the head directs the team to avoid nonsynchronous motion. Manual in-line stabilization using a dedicated person to hold the head and neck in a neutral position is superior to the use of a cervical collar alone. During proper in-line stabilization, no traction is applied to the head and spine. Axial traction is discouraged, because it can cause distraction of cervical spine fractures.

RADIOGRAPHIC EVALUATION

Clinical Clearance

The use of clinical criteria to "clear" the cervical spine and avoid unnecessary radiographs in selected trauma patients has been examined by two large, multicenter studies. The NEXUS group prospectively validated five criteria (Table 272-1) in blunt trauma patients. The criteria have a sensitivity of 99.6 percent for detecting clinically significant cervical spine injury.³ A second large study is currently under way to validate the Canadian C-spine decision rule for cervical spine trauma.⁴

Plain Cervical Spine Radiographs

Cervical spine radiographs are often the initial screening test for cervical spine injury. A cervical spine series consists of a lateral view, an anteroposterior (AP) view, and an odontoid view. The lateral view radiograph detects 70 to 80 percent of traumatic cervical spine injuries.⁵ The lateral view should include the cervicothoracic junction, because 20 percent of cervical spine fractures will occur at C7.⁶ Gentle traction on the upper extremities may move the shoulders out of the way and improve C7-T1 visualization. Another radiographic technique for defining the bony anatomy of the cervicothoracic junction is the "swimmer's" view. The lateral view should be inspected methodically to detect abnormalities (Table 272-2). Alignment should be evaluated by following anatomic lines (Figure 272-1). There should be no step-offs or breaks in the lines. The anterior longitudinal ligament line follows the anterior surface of the vertebral bodies. This line should follow the normal lordotic curve of the spine. The line of the posterior longitudinal ligament runs along the posterior bodies of the vertebrae and is immediately anterior to the spinal cord. A change of 11 degrees or more in the angle of this line at an interspace should be considered evidence of ligamentous injury (Figure 272-2). The spinolaminar line is formed by the junction of the lamina with the spinous process at each vertebra. Fractures of the odontoid or C2 pedicles can be detected by examining the spinolaminar line. The spinolaminar line connecting

TABLE 272-1 NEXUS Criteria for Cervical Spine Radiography

According to NEXUS low-risk criteria, cervical spine radiography can be omitted for trauma patients only if they exhibit *all* of the following criteria:

- No posterior midline cervical spine tenderness
- No evidence of intoxication
- Normal level of alertness
- No focal neurologic deficit
- No painful distracting injuries

TABLE 272-2 Criteria for Clearing the Cervical Spine Cross-Table Lateral View

All seven vertebral bodies must be clearly seen, including the C7—T1 junction Evaluate proper alignment of the posterior cervical line and the four lordotic curves; anterior longitudinal ligament line, posterior longitudinal ligament line, spinolaminar line, and tips of spinous processes Evaluate the predental space (3 mm in adults, 4-5 mm in children) Evaluate each vertebra for fracture and increased or decreased density (e.g., suggestive of a compression fracture, metastatic lesion, osteoporosis) Evaluate the intervertebral and interspinous processes (abrupt angulation of more than 11 degrees at a single interspace is abnormal) Evaluate for fanning of the spinous processes, suggestive of posterior ligament disruption Evaluate the prevertebral soft tissue distance <7 mm at C2 or <5 mm at C3-C4 is considered normal In children <2 y, the prevertebral space may appear widened if the film is obtained during expiration Evaluate the atlantooccipital region for possible dislocation

Source: Van Hare RS: The ring of C2 and evaluation of the cross-table lateral view of the cervical spine. *Ann Emerg Med* 21:733, 1992.

C1 with C3 should pass within 1 mm of the spinolaminar junction of C2. Displacement of more than 1 mm suggests anterior or posterior displacement of the odontoid, or a hangman's fracture (Figure 272-3). The last line is the line connecting the tips of the spinous processes.

Examination of the soft tissues of the neck may be helpful in defining injury. Injury to the cervical spine can cause hematomas and edema that increase the size of the prevertebral space as seen on the lateral view radiograph. Prevertebral soft tissue distances greater than 7 mm at C2 or 21 mm at C6 result in a sensitivity of 53 percent and specificity of 95 percent for detecting spinal injury.⁷

FIG. 272-1. Alignment of the lateral cervical spine.

FIG. 272-2. Angulation relative to the posterior longitudinal ligament. (Reproduced with permission from Galli RL, Spalte DW, Simon RR: *Emergency Orthopedics: The Spine*. Norwalk, CT, Appleton & Lange, 1989, p. 9.)

The AP view is used to examine for angulation of the lateral cortex of the articular masses as compared with superior or inferior neighbors. In addition, the spinous processes can be seen on end, and abnormal widening or malalignment may indicate a hyperflexion sprain or interfacetal dislocation.

The odontoid or open-mouth view shows the odontoid and its relation to the lateral masses of C1. The dens should be centered between the lateral masses, and the lateral masses of C1 should be directly over the lateral portions of C2. Rotation of the head may cause some displacement of the lateral masses and asymmetry of the relation of the dens and C1. Rotation can be detected by using the space between the central incisors as a reference point, which should be in the midline in an unrotated view. Possible fracture lines through the dens should be sought (Figure 272-4).

Plain radiography is a screening tool and cannot detect all injuries. In the largest cervical spine study to date, an adequate three-view cervical spine series had a sensitivity of 89.4 percent for detecting at least one lesion in an injured patient.⁸ Additional radiographic studies may be needed to detect injury when clinical suspicion is present.

Computed Tomography

Computed tomography (CT) is indicated in any major fracture or dislocation of the spine. Computed tomography can improve the detection of fractures in areas poorly visualized by plain radiography—these areas comprise the C1, C2, C6, and C7 vertebrae. Figures 272-5 and 272-6 show the benefit of CT in evaluating the upper cervical spine. Computed tomography is indicated if clinical suspicion for occult fracture exists after normal plain radiographs of the spine. Screening helical CT combined with a single lateral view in lieu of plain radiography is cost effective and accurate in groups at high risk for cervical spinal injury.⁹ (Table 272-3) It is also helpful for evaluating the cervical spine in the elderly or those with prior spinal surgery or underlying spinal disease. Computed tomography is less useful for purely soft tissue injuries seen with ligamentous disruption.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is better than CT for defining the soft tissue injury seen with spinal fractures and is indicated in all patients who have neurologic deficits from a spinal cord injury. Magnetic resonance imaging can evaluate the epidural space for herniated intervertebral disks, hematoma, and bone fragments and can image the

FIG. 272-5. Subtle fracture of dens on lateral C-spine film.

FIG. 272-6. Sagittal computed tomography of dens fracture.

spinal cord for edema, hemorrhage, or laceration. Magnetic resonance imaging is more time consuming than CT and should be used only for patients who are hemodynamically stable.

Flexion-Extension Views

An injury to the ligamentous structures of the spine may occur without a bony fracture. If the initial radiographs show no evidence of fracture but are suggestive of subluxation, or if suspicion of a ligamentous injury exists, flexion and extension views may be performed. However, their indications and even some measurement parameters are controversial. Anterior subluxation injuries are exacerbated in flexion and reduced in extension. Flexion-extension films should be per-

formed only in awake, cooperative patients and should be halted at the point when they cause the patient pain. The pain associated with cervical spinal injuries may prevent adequate flexion and extension. Some authorities do not recommend flexion-extension views at the time of initial evaluation and opt for acute MRI or delayed flexion-extension testing.¹⁰ The patient should wear a well-fitting cervical collar until the delayed flexion-extension testing is performed.

CERVICAL SPINE INJURIES

Upper Cervical Spine (Occiput, C1, C2)

ANATOMY The upper cervical spine (occiput, C1, and C2) is anatomically and functionally distinct from the lower cervical spine (C3 to C7). The upper cervical spine is designed for rotary motion. C1 (atlas) is a ring structure with large lateral masses which articulate with the skull and vertebral column. C2 (axis) is composed of a body with an anterior projection (dens) that articulates with the anterior inner surface of C1. The dens is stabilized to C1 by the transverse ligament.

OCCIPITOATLANTAL DISSOCIATION In occipitoatlantal dissociation, the skull may be displaced anteriorly or posteriorly or distracted from the cervical spine. Occipitoatlantal dissociation frequently results in death. Severe occipitoatlantal dissociation is easily detected on the lateral radiograph. Occipitoatlantal subluxation is more difficult to detect on radiographs. Harris described a method for detecting occipitoatlantal injury.¹¹ The basion-axial interval can be measured in most lateral radiographs. This is the distance between the basion (the tip of the clivus) and a line extending from the posterior cortex of C2. The basion-axial interval should not exceed 12 mm (Figure 272-7K). The basion-dental interval is the distance between the basion and the superior cortex of the dens. This distance also should be less than 12 mm (see Figure 272-7B).¹¹ Atlantooccipital injuries are extremely unstable.

C1 (Atlas) Fractures

JEFFERSON FRACTURE The Jefferson fracture is usually produced when the cervical spine is subjected to an axial load due to a direct blow to the top of the head. The occipital condyles are displaced downward and produce a burst fracture by driving the lateral masses of C1

FIG. 272-7'A. Basion-axial interval (BAI).

TABLE 272-3 High-Risk Criteria for Selection of Use of Screening Cervical Computed Tomography

Mechanism
High-speed motor vehicle collision (>35 mph combined impact)
Fall from height (> 10 ft)
Pedestrian struck by car
Evaluation
Significant closed-head injury or intracranial hemorrhage
Unconscious at time of examination
Neurologic symptoms or signs referred to the cervical spine

FIG. 272-7B. Basion-dental interval (BDI).

apart (Figure 272-8). The lateral masses will be displaced laterally on the open-mouth odontoid radiograph. A fracture through one lateral mass will cause unilateral displacement on the open-mouth view. Instability is likely if the lateral masses are displaced significantly. If the displacement of the lateral masses on each side added together is greater than 7 mm, rupture of the transverse ligament is likely.

TRANSVERSE LIGAMENT DISRUPTION The transverse ligament is located anteriorly on the inside of the ring of C1 and runs along the posterior surface of the dens. The transverse ligament is crucial to maintaining the stability of the first and second vertebrae. Pure ligamentous rupture without an associated fracture can occur in older patients with a direct blow to the occiput, as would occur in a fall. Without a fracture present, radiographic diagnosis relies on identifying the atlantodens interval, also known as the *predental space*, which is viewed on the lateral x-ray. The space is between the posterior aspect of the anterior arch of C1 and the anterior border of the odontoid. The space should be 3 mm or less in adults. **More than 3 mm of space implies damage to the transverse ligament; more than 5 mm implies rupture of the transverse ligament.** Immediate specialist consultation is necessary for these injuries.

AVULSION FRACTURE OF THE ANTERIOR ARCH OF THE ATLAS A hyperextension injury may avulse the inferior pole of the anterior

tubercle of C1. This is most readily detected on the lateral (Figure 272-9). The presence of perivertebral soft tissue swelling and absence of cortication distinguish it from the ununited secondary ossification center of the inferior pole of the tubercle. A fracture involving the entire anterior arch is unstable.

C2 (Axis) Fractures

ODONTOID FRACTURES Fractures of the odontoid are usually caused by major forces and frequently involve other injuries to the cervical spine and multisystem trauma. Awake patients usually will complain of immediate and severe high cervical pain with muscle spasms exacerbated by movement. The pain may not be severe and can radiate to the occiput of the head. Neurologic injury presents in 18 to 25 percent of cases. This can range from minimal sensory or motor loss to quadriplegia. Classification of odontoid fractures relies on identifying the level of injury. Type I fractures are avulsions of the tip. The transverse ligament remains attached to the dens, the fracture is stable, and the injury carries a good prognosis. Type II fractures occur at the junction of the odontoid and the body of C2. This is the most common odontoid fracture. Type III odontoid fractures occur through the superior portion of C2 at the base of the dens (see Figure 272-4).

HANGMAN'S FRACTURE (TRAUMATIC SPONDYLOLISTHESIS OF THE AXIS) The hangman's fracture is located in the pedicles of C2, displacing C2 anteriorly on C3 (Figure 272-10). The fracture is caused by an extension mechanism and is seen in judicial hangings. Suicidal hangings do not usually cause the extreme hyperextension seen in judicial hangings and do not cause a hangman's fracture. The same fracture is seen in motor vehicle and diving accidents. When sudden hyperextension forces are applied in deceleration, the large diameter of the spinal canal at the level of C2, even if C2 is displaced on C3, may not cause neurologic injury, and the patient may be neurologically intact. This injury is unstable.

Lower Cervical Spine (C3 to C7)

ANATOMY An understanding of the anatomy of the cervical spine is essential to the classification of injuries. For the purpose of understanding how mechanisms of injury affect the spine, consider the spine as consisting of three columns.¹² The anterior column resists flexion (flexion) with the vertebral centrum and intervertebral discs and resists distraction (extension) with the anterior longitudinal ligament and the anterior annulus fibrosus. The middle column resists compression through the posterior vertebral body wall and resists distraction by the posterior longitudinal ligament and the posterior

FIG. 272-10. "Hangman's" fracture.

lus fibrosis. The posterior column resists compression through the facet joints and lateral masses and resists distraction through the facet joint capsules and intraspinal ligaments.¹³

UNSTABLE FRACTURES The three-column model of the spine is useful when assessing for the stability of fractures. Instability of the anterior column can occur when the anterior 20 percent of the vertebral body is damaged by compression causing a teardrop fracture.¹⁴ Loss of 25 percent or more of the vertebral body height also is a marker of failure.¹⁵ Loss of integrity of the posterior wall of a vertebral body is a marker for instability in the middle column. Radiographic findings include widening of pedicles, loss of more than 25 percent of posterior vertebral body height, and the presence of sagittal plane fracture lines through the posterior vertebral body cortex.¹⁶ Instability of the posterior column is the result of damage to the facet complex.¹³

The ligaments providing stability to the spine can be damaged without causing radiographic abnormalities. Determining stability can involve dynamic testing (flexion-extension), MRI, and other investigations. Determination of stability should be left to the spine consultant.

MECHANISM OF INJURY The forces that lead to cervical spine injury have been studied in laboratory settings. These experiments have associated specific patterns of injury with the initial dominant force present at the time of injury. A classification system for describing cervical spine injuries based on the biomechanical force responsible for the injury has been proposed by Harris¹¹ (Table 272-4). A description of selected cervical spinal fractures based on this classification follows.

Mechanism: Hyperflexion

ANTERIOR SUBLUXATION Anterior subluxation is also known as *hyperflexion sprain*. The posterior ligamentous structures fail, because of the hyperflexion of the cervical spine. A pure subluxation injury has no associated fractures. Radiographic findings can include a "fanning," or widening, of the spinous processes at the level of injury. The disc space may be widened posteriorly and narrowed anteriorly. Abrupt angulation change of more than 11 degrees at a single interspace may also signal an injury¹⁶ (see Figure 272-2).

TABLE 272-4 Cervical Spine Injuries: Mechanism of Injury

Flexion
Anterior subluxation (hyperflexion sprain)
Bilateral interfacetal dislocation
Simple wedge (compression) fracture
Clay-shoveler's (coal-shoveler's) fracture
Flexion teardrop fracture
Flexion-rotation
Unilateral interfacetal dislocation
Pillar fracture
Fracture or separation (pedicolaminar fracture)
Vertical compression
Jefferson burst fracture of atlas
Burst (bursting, dispersion, axial-loading) fracture
Hyperextension
Hyperextension dislocation
Avulsion fracture of anterior arch of atlas
Extension teardrop fracture
Fracture of posterior arch of atlas
Laminar fracture
Traumatic spondylolisthesis ("hangman's" fracture)
Lateral flexion
Uncinate process fracture
Injuries caused by diverse or poorly understood mechanisms
Occipitoatlantal dissociation
Occipital condylar fractures
Dens fractures

Source: Harris J: Spine, including soft tissue of the pharynx and neck, in Harris J, Harris W (eds): *The Radiology of Emergency Medicine*, 4th ed. Baltimore, Lippincott Williams & Wilkins, 2000, p. 137.

Cervical spine radiographs may be normal or only demonstrate soft tissue swelling if the hyperflexion sprain has not caused a fracture and the subluxation has been reduced. Pain on movement, or neurologic findings, should prompt CT scanning or MRI for diagnosis.

CLAY-SHOVELER'S FRACTURE An avulsion of the spinous process of the lower cervical vertebrae, classically C7, is known as a clay-shoveler's fracture (Figure 272-11). Intense flexion against contracted posterior erector spinal muscles causes avulsion of the spinous process. An isolated clay-shoveler's fracture is mechanically stable.¹¹

FIG. 272-11. Clay-shoveler's fracture.

SIMPLE WEDGE FRACTURE A wedge fracture of a vertebra is caused by compression between two other vertebrae. The superior end plate fractures while the inferior surface of the vertebra remains intact (Figure 272-12). The posterior ligaments may be disrupted, leading to an increase in the distance between spinous processes. The simple wedge fracture is differentiated from a burst fracture by the absence of a vertical fracture of the vertebral body.

FLEXION TEARDROP FRACTURE Extreme flexion can cause the flexion teardrop fracture (Figure 272-13). The associated anterior cord syndrome is due to impingement of the spinal cord by the fracture hyperkyphosis. There is complete disruption of all ligamentous structures at the level of the injury. The "teardrop" is the anteroinferior portion of the vertebral body, which is separated and displaced from the remaining portion of the vertebra. This injury is mechanically unstable.¹¹

BILATERAL INTERFACETAL DISLOCATION Bilateral interfacetal dislocation (BID) occurs when disruption to all ligamentous structures due to hyperflexion allows the articular masses of the involved vertebra to dislocate superiorly and anteriorly over into the intervertebral foramen inferior to the involved vertebra (Figures 272-14 and 272-15). Radiographically, the vertebra can be seen dislocated anteriorly to at least 50 percent its width. The injury is mechanically unstable and usually presents with neurologic findings.¹¹ A "perched" vertebra is seen in partial BID, when the articular masses of the involved vertebra are perched on the superior articular processes of the subjacent vertebra. This configuration is also mechanically unstable but may not present with neurologic compromise.¹⁰ Using the term *locked facets* to describe a BID is misleading, because the injury is unstable.

Mechanism: Flexion and Rotation

UNILATERAL INTERFACETAL DISLOCATION Simultaneous forces of flexion and rotation can produce a unilateral facet dislocation. The articular mass and inferior facet on one side of the vertebra are anteriorly dislocated (Figure 272-16). Radiographically, the AP view will reveal the rotation, because the spinous processes will not be projected directly over one another. The affected spinous process will point toward the side of the vertebra that is dislocated. The involved vertebra will be displaced anteriorly less than 50 percent of the width of a vertebra on the lateral view. The dislocation is mechanically stable unless there is a fracture at the base of the inferior articular mass of the dislocated vertebra or a fracture of the superior articular mass of the inferior vertebra.

FIG. 272-12. Wedge fracture.

FIG. 272-13. Flexion teardrop fracture.

Mechanism: Extension and Rotation

PILLAR FRACTURE Extension and rotation can cause impaction of a superior vertebra on the articular mass of its inferior neighbor. The resultant vertical or oblique fracture of the articular mass is called a *pillar fracture* (Figure 272-17). The adjacent lamina and pedicle remain intact. The lateral view may show a "double-outline" sign at the level

FIG. 272-14. Bilateral interfacetal dislocation between C6 and C7.

FIG. 272-15. Sagittal computed tomography of bilateral interfacetal dislocation between C6 and C7 showing jumped facet.

of the injury. This can be differentiated from the normal lateral radiograph, in which the articular masses are imposed on one another and one radiographic density is seen. The double outline occurs when the fractured articular mass is displaced posteriorly and causes two radiographic shadows. The AP projection will show an abnormality of the lateral column and a fracture at the level of the injury. The fracture is considered stable.

FRACTURE SEPARATION Harris described the fracture and separation as a pedicolaminar fracture, because it involves fractures of the pedicle and lamina.¹¹ There are different degrees of fracture, ranging from fractures without displacement to disruption of the anterior longitudinal ligament and disk rupture. The lateral radiograph may show rotation of the involved articular mass as compared with the uninvolved lateral mass at the level of the injury. Anterior listhesis may be seen in more severe mechanisms. The AP view may show disruption of the lateral column.

Mechanism: Vertical Compression Injuries

BURST FRACTURE A direct axial load causes a burst fracture of the lower cervical spine. The axial force causes the vertebra to burst with fragments displacing in all directions (Figure 272-18). The spinal cord may be injured if a fragment enters the spinal canal. The lateral radiograph may show a fracture of the superior and inferior vertebral end plates and retropulsion of the posterior segment of the vertebra into the spinal canal. The AP view will show a vertical fracture and widening of the interpedicular distance. This injury is unstable.

Mechanism: Hyperextension Injuries

HYPEREXTENSION DISLOCATION A hyperextension injury involves a complete tear of the anterior longitudinal ligament and intervertebral disk, with disruption of the posterior ligamentous complex.

FIG. 272-16. Unilateral facet dislocation.

Facial trauma with a central cord syndrome is the most common clinical presentation. In the lateral cervical spine film, the vertebrae may be normally aligned, because the dislocation will be reduced. Diffuse prevertebral soft tissue swelling is usually present. Other signs include a disk-space widening anteriorly or a fracture of the anteroinferior end plate of the vertebrae.¹¹ If the patient has no neurologic deficit and no evidence of fracture, CT or MRI is generally used to confirm ligamentous disruption.

EXTENSION TEARDROP FRACTURE A hyperextension mechanism may cause the anterior longitudinal ligament to avulse the inferior portion of the anterior vertebral body at its insertion (Figure 272-19). The height of the fragment usually exceeds its width. This fracture is more common in older patients with osteoporosis. The extension teardrop fracture is unstable in extension.

LAMINAR FRACTURE Isolated laminar fractures are caused by hyperextension and may be subtle on plain radiographs. Associated spinous process fractures may be present. Computed tomography is required to define the extent of spinal cord involvement.

FIG. 272-17. Pillar fracture.

Mechanism: Lateral Flexion

UNCINATE PROCESS FRACTURE Pure lateral flexion is rare in most mechanisms of injury. Lateral flexion can cause a transverse fracture at the base of the uncinat process as the lateral aspect of the superior vertebral body fractures the inferior uncinat process. During the initial injury, the degree of lateral neck flexion is limited, because the head strikes the shoulder. This fracture may be seen in the AP or lateral view.

Spinal Cord Injury without Radiographic Abnormality

Spinal cord injury without radiographic abnormality (SCIWORA) is used to describe the condition of neurologic abnormality after injury but without fractures or bony malalignment on plain radiographs. Initially described in children, it also occurs in adults but is rare in both age groups.¹⁸ In one large study, only about 3 percent of those with spinal cord injury had SCIWORA.¹⁸

Neurologic findings are variable and can include central cord syndrome. Diagnosis is by MRI, with the most common findings of central disc herniation, spinal stenosis, intramedullary hematoma or contusion, and cord edema.

FIG. 272-19. Extension teardrop fracture.

THORACOLUMBAR SPINE INJURIES

Anatomy

The thoracolumbar spine is relatively more protected and stable than the cervical spine. Vertebrae T1 through T10 are fixed, owing to their articulation with the thoracic cage. Large forces are required to fracture thoracic vertebrae, and neurologic abnormalities are common. The mobility of the thoracolumbar junction predisposes it to injury. The thoracolumbar junction is second only to the cervical spine in frequency of injury. The spinal cord ends at approximately L1 at the conus medullaris. The individual nerve roots extending from the conus medullaris constitute the cauda equina. These nerve roots are less susceptible to damage and neurologic injury, because trauma to the lower lumbar and sacral segments occurs less often and is less severe. McAfee and associates classified thoracolumbar spine injuries into major and minor fractures¹⁹ (Table 272-5). A discussion of the classification follows.

Major Fractures and Dislocations

WEDGE COMPRESSION FRACTURES These fractures are the result of flexion causing compression of the anterior body of the vertebra. Plain radiographs demonstrate loss of anterior height in the traumatized vertebra. The posterior height and cortex are intact. Computed tomography should be performed to define the stability of the posterior elements and determine whether there is involvement of the neural canal. These fractures are not usually associated with neurologic

TABLE 272-5 of Thoracolumbar Spine Injury

compromise but should be treated as unstable until evaluation is complete.

BURST FRACTURE A flexion mechanism causing anterior vertebral compression with involvement of the posterior cortex defines the burst fracture. Lateral plain radiography will show the loss of anterior and posterior height; AP views will show an increase in the interpedicular distance; and CT will define the extent of the injury (Figure 272-20). The burst fracture should be considered unstable.

CHANCE FRACTURE A Chance fracture is caused by a flexion around an axis anterior to the anterior spinal longitudinal ligament. A high-speed motor vehicle accident with the occupant in a lap belt will produce this mechanism. The Chance fracture involves the spinous process, lamina, transverse processes, pedicles, and vertebral body.²⁰ The lateral radiograph will show the fracture through the posterior elements and vertebral body. Computed tomography may help to define the injury but can miss it if the fracture is in the same plane as the scan. The Chance fracture should be considered unstable.

FLEXION AND DISTRACTION INJURIES A flexion-distraction mechanism places the anterior portions of the spine under compression while distracting the posterior elements. The lateral radiograph shows loss of height in the anterior portion of the vertebra, with increased interspinous spaces posteriorly ("fanning"). Computed tomography and specialist consultation are recommended. This injury is unstable.

TRANSLATION INJURIES Translational injuries are the result of large shear forces that cause complete disruption of spine stability.

FIG. 272-20. T12 burst fracture.

The lateral radiograph will show translation of one or more vertebral segments on subsequent segments. Associated neurologic injury is common.

MINOR FRACTURES Minor fractures include spinous process fractures, transverse process fractures, and pars interarticularis fractures. Minor fractures that have no additional spinal or visceral injuries and associated neurologic compromise are considered stable. Computed tomography is needed to evaluate the extent of injury and to exclude concomitant major fractures.

Consultation and Disposition

The differentiation of spinal injuries as "stable" or "unstable" is not a useful categorization for the emergency physician. Acute bony or ligamentous injuries and injuries with actual or suspected neurologic deficits are best referred to the spinal surgeon to institute proper acute treatment, ensure absence of additional associated spinal injuries, determine appropriate disposition, and ensure follow-up care, which can minimize the development of delayed instability and pain syndromes.

Patients should remain in spinal immobilization until definitive diagnosis and evaluation of CT and MRI are made by the spinal surgeon.

TRAUMA TO THE PELVIS, HIP, AND FEMUR

Mark T. Steele
Stefanie R. Ellison

TRAUMA TO THE PELVIS

Pelvic fractures and associated injuries are a frequent cause of morbidity from blunt trauma sustained in automobile accidents. Most pelvic fractures are secondary to automobile passenger or pedestrian accidents, but are also the result of minor falls in older persons and from major falls or industrial accidents. This chapter discusses the most common fractures of the pelvis, femur, and hip, the mechanisms of injury, radiologic evaluation, and treatment.

ANATOMY AND BIOMECHANICS

The major functions of the pelvis are protection, support, and hematopoiesis. The pelvis consists of the two innominate bones, which are made up of the ilium, ischium, and pubis; the sacrum; and the coccyx. The two innominate bones and sacrum form a ring structure, which is the basis of pelvic stability. This stability is dependent on the strong posterior sacroiliac, sacrotuberous, and sacrospinous ligaments (Figure 273-1). Any single break in the ring will yield a stable injury without significant risk of displacement. An injury with two breaks in the ring is unstable with the risk of displacement. The iliopectineal, or arcuate line, divides the pelvis into the upper, or false, pelvis, which is part of the abdomen, and the lower, true pelvis. In addition, this line constitutes the major portion of the femorosacral arch, which, along with the subsidiary tie arch (bodies of pubic bones and superior rami), supports the body in the erect position. In the sitting position, the weight-bearing forces are transmitted by the ischiosacral arch augmented by its tie arch, the pubic bones, inferior pubic rami, and ischial rami. The tie arches fracture first, especially at the symphysis pubis, pubic rami, and just lateral to the sacroiliac (SI) joints. Incorporated in the pelvic structure are five joints that allow some movement in the

bony ring. The lumbosacral, SI, and sacrococcygeal joints, and the symphysis pubis allow little movement. The acetabulum is a ball-and-socket joint that is divided into three portions: the iliac portion, or superior dome, is the chief weight-bearing surface; the inner wall consists of the pubis, and is thin and easily fractured; and the posterior acetabulum is derived from the thick ischium.

The pelvis is extremely vascular, a fact that is significant in pelvic fractures. The nerve supply through the pelvis is derived from the lumbar and sacral plexuses. Injury to the pelvis may produce deficits at any level from the nerve root to small peripheral branches.

The lower urinary tract is contained in the pelvis (Figure 273-2). In the adult, the bladder lies behind the symphysis and pubic bones, and the peritoneum covers the dome and base posteriorly. The location of the bladder and the degree of peritoneal reflection are determined by urine content. The lower gastrointestinal tract housed in the pelvis includes a small portion of the descending colon, the sigmoid colon, the rectum, and the anus. In women, the uterus and vagina are also housed in the bony pelvis.

Clinical Evaluation

HISTORY All victims of serious or multiple trauma should be considered to have fractures of the pelvis. A patient with a suspected pelvic fracture should be questioned about details of the accident to determine the mechanism of injury and the prehospital evaluation and treatment. The patient should be specifically questioned to determine areas of pain, last urination or defecation, present bladder sensation, and the last solid and fluid intake. In addition, the time of the last menses or the presence of pregnancy, current medications, and allergies should be ascertained.

PHYSICAL EXAMINATION Symptoms and signs of pelvic injuries vary from local pain and tenderness, especially with walking, to pelvic instability and severe shock. On inspection, look for perineal and pelvic edema, ecchymoses, lacerations, and deformities. Look for hematomas above the inguinal ligament or over the scrotum (Destot sign). Roll the patient over, if appropriate, and examine the areas overlying the sacrum and coccyx. On palpation feel for irregularities, crepitation, or movement at the iliac crests, pubic rami, and ischial rami. The clinical examination in awake and alert trauma patients is very sensitive in diagnosing a pelvic fracture. Palpation of a bony prominence or large hematoma or tenderness along the fracture line is possible by rectal examination (Earle sign). Compress the pelvis lateral to medial through the iliac crests, anterior to posterior through the symphysis pubis, and anterior to posterior through the iliac crests. Compress the greater trochanters and determine the range of motion

FIG. 273-1. The major posterior stabilizing structures of the pelvic ring, that is, the posterior tension band of the pelvis, include the iliolumbar ligament, the posterior sacroiliac ligaments, the sacrospinous ligaments, and the sacrotuberous ligaments. of the hips.¹ On rectal examination, superior or posterior displacement of the prostate, or rectal injuries are indicative of intraperitoneal and urologic injury. Proctoscopic examination may be required to fully assess for the presence of rectal tears. Decrease in anal sphincter tone may suggest neurologic injury, and blood at the urethral meatus may suggest urologic injury. Pelvic examination should be carefully performed in women to detect the presence of blood or lacerations that suggest the possibility of open fracture. Carefully evaluate neurovascular function. If a pelvic fracture is found, assume intraabdominal, retroperitoneal, gynecologic, and urologic injuries until proven otherwise.

RADIOLOGIC EVALUATION Stabilization of the patient takes priority over obtaining x-ray films. Unnecessary movement may produce further injury or cause more blood loss. After stabilization, roentgenographic evaluation of the pelvis is a must in all unconscious patients who have sustained multiple injuries. Lower extremity long bone fractures, as well as pelvic symptoms or signs, are also indications for

roentgenograms. A standard anteroposterior (AP) view of the pelvis is indicated in the presence of multisystem blunt trauma or if pelvic fracture is suspected. If additional studies are needed, lateral views, AP views of either hemipelvis, internal and external oblique views of the hemipelvis, or inlet and outlet views of the pelvis may be done. An inlet view shows anterior-posterior displacement of ring fractures (Figures 273-3 and 273-4). An outlet view shows superior-inferior displacement. Oblique views of the hemipelvis are true AP and lateral views of the acetabulum. Tomography, computed tomography (CT) scans, and special studies may be needed to fully evaluate and manage patients, particularly for acetabular and sacral fractures. CT is superior to plain radiography in assessing the posterior pelvic arch and acetabulum and has the added advantage of being able to identify the presence or absence of ongoing pelvic hemorrhage.² Angiography or venography may be necessary to determine a source of bleeding. The patient's condition must dictate what is done and when.

Classification and Treatment of Pelvic Fractures

BREAK IN THE PELVIC RING Pelvic fractures include those that involve a break in the pelvic ring, fractures of a single bone without a break in the pelvic ring, and acetabular fractures. Pelvic fractures involving a break in the pelvic ring can be complex and therefore difficult to classify. These injuries range from low-energy stable fractures to high-energy unstable patterns. The most clinically useful classification, by Young, is presented in Table 273-1.³ It differentiates fracture patterns based on mechanism of injury and direction of causative force. Incidence of complications (i.e., urogenital and vascular) is correlated with the fracture pattern, making identification of the type more clinically significant and useful.

Three main types of patterns have been identified. The first and most-common mechanism, lateral compression (LC) (Figures 273-5 through 273-9), accounts for close to half the injuries. Motor vehicle accidents in which a car is broadsided or a pedestrian struck from the side are examples. Anteroposterior compression (APC), or open book fractures (Figures 273-10, 273-11, and 273-12), is the second type, accounting for approximately 25 percent of injuries. Head-on motor vehicle accidents are the classic example. The least-common mechanism is vertical shear (VS) (Figure 273-13), which is typified by a fall or jump from a height, accounting for approximately 5 percent of fractures. A combination of other injury patterns make up the other 20 to 25 percent of injuries.

The different injury types may be suggested by history, but can also be differentiated radiographically. The alignment of pubic rami fractures is one such clue to the mechanism and direction of force. Horizontal fractures suggest lateral compression injury, whereas vertical ones point to an anteroposterior direction of force. If there is sacroiliac joint diastasis and an associated crush fracture of the sacrum, then the injury is a result of lateral compression. Central hip dislocations

FIG. 273-3. A. Anatomic appearance in the inlet projection. B. Radiologic appearance in the inlet projection. [Reproduced with permission from Tile M, Kellam J, Helfet DL (eds): *Assessment in Fractures of the Pelvis and Acetabulum*. Baltimore: Williams & Wilkins, 1984, p 63.]

FIG. 273-4. A. Anatomic appearance in the outlet projection. B. Radiologic appearance in the outlet projection. [Reproduced with permission from Tile M, Kellam J, Helfet DL (eds): *Assessment, in Fractures of the Pelvis and Acetabulum*. Baltimore: Williams & Wilkins, 1984, p64.]

suggest a lateral compression mechanism, whereas posterior dislocation suggests an anteroposterior force. With vertical shear patterns, fractures are vertical in alignment with vertical displacement of fragments. Based on the recognition of the fracture pattern, one can then predict the likelihood of severe hemorrhage or urogenital injury (Table 273-2).

Mortality usually is a result of associated injuries, although pelvic hemorrhage is also a contributor. Mortality rates approach 25 percent for severe APC and VS injuries, whereas it is approximately 13 percent with LC injuries. Mortality is reduced with early fracture fixation and patient mobilization.⁴ In addition to mortality, the fracture type and severity can also predict the organ injury pattern and resuscitation needs. The treatment of LC-I and APC-I injuries consists of a few days of bedrest followed by protected weight-bearing. LC-II and III, APC II and III, and VS injuries typically require open reduction and internal fixation within 5 to 14 days of injury.³ The long-term outcome/disability following open reduction and internal fixation of unstable pelvic fractures is generally fair, with 75 percent of patients having some mild disability and approximately 75 percent of those employed preinjury returning to their preinjury occupations.⁵

True open-book-type fractures with an intact posterior ring have the greatest potential benefit from anterior external fixator placement. Stabilization decreases the volume of the pelvis with resultant tam-

ponade of hemorrhage.⁶ The tamponade effect is less if the posterior arch of the pelvis has been disrupted. Anterior stabilization should be considered in hemodynamically unstable patients with unstable pelvic fractures.^{7,8}

AVULSION AND SINGLE BONE FRACTURES For fractures of the anterior superior iliac spine, anterior inferior iliac spine, ischial tuberosity, pubic ramus, body of the ischium, iliac wing, sacrum, or coccyx, refer to Figures 273-14 and 273-15 and Table 273-3.

ACETABULAR FRACTURES Acetabular fractures are usually secondary to automobile accidents. The fracture force is either transmitted laterally through the hip or through the femur as with a knee-versus-dashboard mechanism. Acetabular fractures are seen commonly with other injuries including femur, hip fractures and dislocations, and knee injuries. The roentgenographic anatomy of acetabular fractures is shown in Figure 273-16. There are five simple types of fractures as classified by Judet-Letournel, and nearly all are associated with hip dislocations; posterior wall, posterior column, anterior wall, anterior column, and transverse⁹ (see Figure 273-17 and Table 273-4). In addition, combinations of any of these fractures can occur and are classified as complex acetabular fractures. If an acetabular fracture is suspected, it can best be evaluated with an anteroposterior film, a 45-degree iliac oblique, and a 45-degree obturator oblique view; together known as *Judet views*.

Posterior Wall Fracture The mechanism of injury in a posterior fracture is direct trauma to a flexed knee and hip. Anteroposterior and lateral radiologic views easily demonstrate the posterior acetabular fracture with the posterior hip dislocation. The fracture only involves the posterior border of the acetabulum.

Posterior Column Fracture In this fracture, the posterior column of the acetabulum is completely detached. The fracture originates at the

TABLE 273-1 Injury Classification Keys According to the Young System

Category	Distinguishing Characteristics
LC	Transverse fracture of pubic rami, ipsilateral or contralateral to posterior injury I—Sacral compression on side of impact II—Crescent (iliac wing) fracture on side of impact III—LC-I or LC-II injury on side of impact; contralateral open-book (APC) injury
APC	Symphyseal diastasis and/or longitudinal rami fractures I—Slight widening of pubic symphysis and/or anterior SI joint; stretched but intact anterior SI, sacrotuberous, and sacrospinous ligaments; intact posterior SI ligaments II—Widened anterior SI joint; disrupted anterior SI, sacrotuberous, and sacrospinous ligaments; intact posterior SI ligaments III—Complete SI joint disruption with lateral displacement; disrupted anterior SI, sacrotuberous, and sacrospinous ligaments; disrupted posterior SI ligaments
VS	Symphyseal diastasis or vertical displacement anteriorly and posteriorly, usually through SI joint, occasionally through the iliac wing and/or sacrum
CM	Combination of other injury patterns, LC/VS being the most common

Abbreviations: APC = anteroposterior compression; CM = combination; LC = lateral compression; SI = sacroiliac; VS = vertical shear.

FIG. 273-5. Type I lateral compression fracture: The lateral force is applied posteriorly (arrow). This causes a crush effect on the sacroiliac joint, which may be visible radiographically as a sacral fracture (A). The characteristic fracture pattern of the pubic rami will be seen (B). No ligamentous injury is seen.

FIG. 273-6. Type II lateral compression fracture: The force is applied anteriorly (arrow), causing the typical anterior pubic rami fractures (B). In this case, however, rotation of the pelvis around the anterior sacral margin may occur, causing rupture of the posterior sacroiliac ligaments (R). A crush fracture of the sacrum may also be seen (A).

greater sciatic notch, traverses through the weight-bearing portion of the acetabulum, and exits through the obturator foramen. On x-ray the AP view shows medial displacement of the femoral head and sciatic buttress. The ilioischial line is also clearly disrupted. The oblique view is best to identify this fracture. Complications are sciatic nerve injury, which may occur in up to 40 percent of this fracture type, and femoral fractures. CT scan is an invaluable tool for evaluating this fracture and determining if operative or nonoperative treatment is required.

Anterior Wall Fracture This fracture originates at the anterior inferior iliac spine, passes inferiorly through the junction of the articular dome and the superior ramus. It results from a lateral force applied to the greater trochanter with the hip externally rotated. On x-ray the iliopectineal line is disrupted and involvement of the weight-bearing dome can be seen. The most common complication is sciatic nerve injury.

Anterior Column Fracture This fracture extends from the middle of the pubic ramus through to any point exiting the anterior segment of the iliac crest. The iliac oblique view reveals disruption of the iliopectineal line and the weight-bearing dome of the acetabulum. CT scan can be useful in evaluating this fracture.

Transverse Fracture This fracture extends transversely from the anterior to the posterior column. It may or may not include the weight-bearing portion of the dome. The ischial ring remains intact in this fracture. The mechanism is force lateral to medial over the greater trochanter, or force posterior to anterior on the posterior pelvis with

FIG. 273-7. Alternatively (compared to Figure 273-6), a fracture of the iliac wing may occur, which dissipates the rotational forces and thus leaves the posterior ligaments intact.

FIG. 273-8. Type III lateral compression fracture: The force is applied laterally (arrow), causing internal rotation of the anterior hemipelvis. Continuing through to the contralateral hemipelvis (arrow), the force causes it to rotate externally. The result is a pattern of lateral compression on the ipsilateral side, with apparent anteroposterior compression on the contralateral side. (A) This results in rupture of the posterior sacroiliac ligaments on the ipsilateral side (R) and sacrospinous/sacrotuberous complex (I) and anterior ligaments on the contralateral side. (B) Typical public rami fractures are to be expected.

the hip flexed. An AP x-ray film clearly demonstrates the fracture with a central hip dislocation.

Early orthopedic consultation and hospital admission is indicated for patients with acetabular fractures. Nondisplaced fractures may be treated with bedrest and analgesics. Early reduction and internal fixation is indicated for displaced fractures. Significant long-term disability is associated with acetabular fractures.

Complications of Pelvic Fractures

Acute complications of associated injuries include hemorrhage, uro-gynecologic injury, rectal injury, ruptured diaphragm, and nerve root injury.

HEMORRHAGE Hemorrhage is a common cause of death in patients with pelvic injuries. Retroperitoneal bleeding is an inevitable complication, and up to 4 L of blood can be accommodated in this space until vascular pressure is overcome and tamponade occurs. It is thought that most pelvic bleeding is from the fractures and low-pressure sacral venous plexus. Both small and large vessels, especially the superior gluteal and internal pudendal branches of the internal iliac artery, can also be disrupted, with hemorrhage dissecting from the back to the buttocks.

FIG. 273-9. Alternatively (compared to Figure 273-8), as in type II B fractures (Figure 273-7), there may be an iliac wing fracture sparing the posterior sacroiliac joint on the ipsilateral side.

FIG. 273-10. Type I anteroposterior compression fracture: The force is delivered in an anteroposterior direction (*large arrow*), tending to "open" the pelvis. This gives rise to mild splaying of the symphysis, due to rupture of the anterior sacroiliac ligaments.

FIG. 273-12. Type III anteroposterior compression fracture: There is total disruption of the sacroiliac joint because of wide "opening" of the pelvis. All supporting ligament groups, including the posterior sacroiliac ligaments, may be disrupted.

General resuscitative measures include massive crystalloid, colloid, and blood replacement. In one series of high-energy pelvic fractures, patients on average required approximately 6 units of blood transfused.¹⁰ The average transfusion requirement for APC injuries was approximately 15 units, VS injuries averaged 9 units, and LC injuries average approximately 3.5 units. Aggressive resuscitation along with treatment of extrapelvic injuries and early or delayed open reduction and internal fixation of the fractures may reduce mortality.¹¹

The use of the antishock garment is controversial. It may be helpful in controlling bleeding sites by immobilizing fractures and compressing the pelvis. Disadvantages include decreased visibility and access to the abdomen and lower extremities, and the risk of compartment syndrome with prolonged application. This garment is generally only recommended for pelvic stabilization in the prehospital and ED setting. Reduction and stabilization of the unstable pelvis is reported to be an effective means of controlling hemorrhage.³ Advanced trauma life support (ATLS) now includes a protocol for pelvic ring fractures that advises use of a bedsheet for pelvic support and stabilization. Reduction may be accomplished in the prehospital setting and the emergency department with external circumferential pressure to stabilize lateral compression, and anterior-posterior compression

for open-book type pelvic fractures. One proposed mechanism suggests that reduction of pelvic volume by the circumferential pressure method decreases the pelvic space for potential bleeding. Another hypothesis is that apposition of the fracture surfaces may decrease bleeding from the fracture itself.¹² Early orthopedic consultation should be considered for placement of external fixator device to help control hemorrhage in patients with persistent hemodynamic instability.

If the patient is exsanguinating, angiography can be done and small arterial bleeding sites controlled by transarterial embolization. Most authorities agree that aggressive fluid and blood replacement is the best initial therapy along with correction of hypothermia and coagulopathy. Placement of an external fixator and laparotomy should also be considered prior to angiography. Overall only about 2 percent of patients with pelvic fracture require embolization and efficacy approaches 100 percent when used.¹³ Younger age, shorter time from injury to embolization, and hemodynamic stability are associated with improved survival.

FIG. 273-13. Vertical shear vector: The injury force vector is delivered in a vertical plane (*large arrow*), causing disruption along this line. Fractures of the pubic rami are usually seen anteriorly, while fractures

FIG. 273-11. Type II anteroposterior compression fracture: The anteroposterior force vector (*large arrow*) has caused further "opening" of the anterior pelvis, with additional rupture of the anterior sacroiliac, sacrotuberous, and sacrospinous ligaments.

of the sacrum, sacroiliac joint, or iliac wing are usually seen posteriorly. The fractures are vertical and are associated with vertical displacement of fragments. Ligamentous injury to the posterior (*R*) and anterior (*A*) sacroiliac ligaments may be seen, as well to sacrospinous/sacrotuberous (*T*), and (possibly) symphysis ligaments.

TABLE 273-2 Local Associated Injuries

UROGYNECOLOGIC INJURY Urinary tract injuries are discussed in Chap. 262. Gynecologic injuries are uncommonly associated with pelvic trauma. Vaginal laceration is the most common injury seen with anterior pelvic fractures. A bimanual pelvic examination should be performed on all women with pelvic fractures. If blood is found in a woman of childbearing age, a speculum examination is needed to distinguish menses from laceration. Treatment is irrigation, debridement, and wound repair in the operating room and antibiotic therapy.

A high fetal death rate is associated with pelvic trauma in pregnancy if the mother is in shock; if there is placental, uterine, or direct fetal injury; or if the mother dies. Immediate caesarean section must be considered (see Chap. 254).

RECTAL INJURIES Rectal injuries are uncommon and are usually associated with urinary injuries and ischial fractures. Diagnosis is by rectal examination or by proctoscopy, during which gross blood is found in the rectum. Treatment includes a diverting colostomy with washout of the distal colon and presacral space drainage. Antibiotics should be given as soon as the injury is discovered.

RUPTURED DIAPHRAGM Ruptured diaphragm associated with fracture of the pelvis may be more common than previously thought. It may be associated with rib injuries. Suspect the diagnosis with physical findings such as displacement of the heart toward the right, absent breath sounds, or presence of bowel sounds in the chest. Confirmation is by x-ray and CT scan. Diagnosis is difficult if the defect is small.

NERVE ROOT INJURY Nerve root or peripheral nerve injuries can occur because of traction, pressure from hemorrhage, callus or fibrous tissue, and impingement-laceration by bone fragments. The onset of symptoms and signs may be delayed, but deficits usually follow a nerve root pattern. Lumbar nerve root injuries are associated with SI joint dislocation or fracture. Sacral root injuries are associated with sacral fractures, especially fractures of SI and S2.

TRAUMA TO THE HIP AND FEMUR

Anatomy

The hip is a ball-and-socket joint made up of the acetabulum and the femur. The hip includes the acetabulum and the proximal femur 2 to 3 inches below the lesser trochanter. The functions of the hip are

Type I: Fracture of individual bones without break in pelvic ring. Examples shown above.

Type II: Single break in the pelvic ring. See examples above.

Type III: Double break in pelvic ring.

FIG. 273-14. Pelvic fractures (type I, II, and III) according to classification by Key JA, Conwell HE: *The Management of Fractures, Dislocations, and Sprains*, 4th ed. St. Louis, Mosby, 1946, p 857, as adapted by Kane WJ: Fractures of the pelvis, in Rockwood CA Jr, Green DP (eds): *Fractures in Adults*, 4th ed. Vol. 2. Philadelphia, Lippincott, 1996, p 1119.

weight-bearing and movement. The fibrous capsule that surrounds the joint on all sides is exceedingly strong. It attaches around the acetabulum proximally and runs to the intertrochanteric line distally on the anterior surface. Posteriorly, it falls short of the intertrochanteric crest and inserts on the neck of the femur. It is weakest posteriorly.

The blood supply of the femoral head is derived from nutrient branches of the obturator, medial femoral circumflex, lateral femoral circumflex, and superior and inferior gluteal arteries. These course

FIG. 273-15. Avulsion fractures of the pelvis. 1. Iliac wing fracture (Duverney fracture). 2. Superior pubic ramus fracture. 3. Inferior pubic ramus fracture. 4. Transverse sacral fracture. 5. beneath the reflection of the capsule on the neck of the femur and also along the ligamentum teres. The capsular vessels are much more important than those of the ligamentum teres.

Clinical Evaluation

PHYSICAL EXAMINATION The examination of the hip begins with a detailed history and complete examination of the patient. The pelvis

and hip are then carefully evaluated. The unclothed, erect patient is inspected for a list, injuries, scars, or asymmetry of the muscles. Gait should be tested, if possible.

If the patient is a trauma victim, after primary survey and initial stabilization observe the position of the extremities, looking for deformities, shortening, rotation, lacerations, or bruises, and test for stability and range of motion. On palpation, feel for irregularities in movement at the iliac crest, pubic rami, and ischial rami. Compress the pelvis lateral to medial through the iliac crest; anterior to posterior through the symphysis pubis; and anterior to posterior through the iliac crest, seeking pain and tenderness. Also, compress the greater trochanters of the hips.

If no significant abnormalities are found, range of motion of the hips should then be studied. If rotation of the hip with the leg in extension is painful all other maneuvers should be done cautiously. If a hip or pelvic fracture or dislocation is identified in a trauma victim, assume that intra-abdominal, retroperitoneal, and urologic injuries have occurred as well, until proven otherwise. Always perform a detailed neurovascular examination and a rectal examination, looking for displacement of the prostate in male patients. Associated femoral shaft fractures should be ruled out.

RADIOLOGIC EVALUATION Roentgenographic evaluation of the pelvis and hips is a must in all unconscious patients who have sustained multiple injuries. The threshold for obtaining radiographs in demented elderly patients who have sustained minor falls should also be relatively low because those patients may be particularly difficult to evaluate. Lower-extremity long bone fractures, as well as pelvic symptoms or signs, are also indications for these x-ray examinations. The x-ray evaluation should include a standard AP and a lateral view of the pelvis. If further studies are needed, AP views of either hemipelvis, in-

TABLE 273-3 Avulsion and Single Bone Fractures

Fracture	Description/ Mechanism of Injury	Clinical Findings/ Associated Injuries	Treatment	Disposition
Iliac wing (Duverney) fracture	Direct trauma, usually lateral to medial	Swelling, tenderness over iliac wing; abdominal pain; ileus; acetabular fractures; serious injury infrequent	Analgesics, strapping	Discharge with PCP or orthopedic follow-up in 1–2 weeks; admit for open fracture or concerning abdominal examination
Single ramus of pubis or ischium	Fall or direct trauma in elderly; exercise-induced stress fracture in young or in pregnant women	Local pain and tenderness; inability to ambulate; rectal injury	Analgesics, crutches	Discharge with PCP or orthopedic follow-up in 1–2 weeks
Ischium body	Violent, external trauma or from fall in sitting position; least-common fracture	Local pain and tenderness; pain with hamstring movement; rectal injury	Bedrest, analgesics, donut-ring cushion, crutches	Discharge with PCP or orthopedic follow-up in 1–2 weeks
Sacral fracture	Transverse fractures from direct AP trauma; upper transverse fractures from fall in flexed position	Pain on rectal examination; sacral root injury with upper transverse fractures	Bedrest, analgesics	Discharge with orthopedic follow-up 1–2 weeks; early consultation and surgery for neurologic disability
Coccyx fracture	Fall in sitting position; more common in women	Pain, tenderness over sacral region; pain on compression during rectal examination	Bedrest, sitz baths, donut-ring cushion	PCP or orthopedic follow-up in 2–3 weeks; surgical excision of fracture fragment if chronic pain
Anterior superior iliac spine	Forceful sartorius muscle contraction (e.g., adolescent sprinters)	Pain with hip flexion and abduction	NSAIDs, rest abducted and flexed 3–4 weeks, crutches	Discharge with PCP follow-up in 1–2 weeks
Anterior inferior iliac spine	Forceful rectus femoris muscle contraction (e.g., adolescent soccer players)	Pain in groin; pain with hip flexion	NSAIDs, rest in flexion 3–4 weeks	Discharge with PCP follow-up in 1–2 weeks
Ischial tuberosity	Forceful contraction of hamstrings	Pain with sitting or flexing the thigh	NSAIDs, rest, crutches	Discharge with PCP follow-up in 1–2 weeks

Abbreviations: AP = anteroposterior; NSAID = nonsteroidal anti-inflammatory drug; PCP = primary care physician.

FIG. 273-16. Roentgenographic anatomy of type IV acetabular fractures. (Reproduced with permission from Judet R, Judet J, Letournel E: Fractures of the acetabulum: Classification and surgical approaches for open reduction. *J Bone Joint Surg* 46A:1616, 1964.)

ternal and external oblique views of the hemipelvis as described by Judet and colleagues, or "inlet" and "tilt" views may be done. In certain instances, such views allow better identification and detail of the acetabulum and femoral head and neck. Always inspect not only the hip joint but also the femur and knee when evaluating hip disorders on x-ray films. Disorders to the knee and the femoral shaft often occur with hip injuries. Significant hip pain with weight-bearing following trauma and normal radiographs suggest the possibility of occult fracture, especially at the femoral neck or acetabulum.¹⁴ The patient should be prescribed protected weight-bearing and the emergency

physician should communicate with the patient's primary care provider or orthopedist regarding close follow-up for possible CT or MR hip imaging to rule out occult fracture.^{15,16} MR is reliable in detecting occult fractures within 24 h of injury.

Femoral nerve blocks can provide analgesia for hip dislocations, femoral neck fractures, and femoral shaft fractures. See Figure 37-14A and B for the technique.

Classification/Epidemiology of Hip Fractures

The estimated incidence of hip fractures in the United States is approximately 80 per 100,000 population.¹⁷ The incidence increases with age and doubles for each decade past the age of 50 years. The incidence is approximately two to three times higher in women than in men, and fractures are more common in white than in nonwhite women.

The possibility of elder abuse should be considered in all elderly patients with falls and fractures.¹⁸ See Chap. 300 for detailed discussion of elder abuse.

Hip fractures are classified as femoral head and neck (intracapsular) and trochanteric, intertrochanteric, and subtrochanteric (extracapsular) (Figures 273-18, 273-19 and Table 273-5). The prognosis for successful union and restoration of normal function varies considerably with the fracture.

In intracapsular fractures with displacement, the femoral neck vessels are compromised because of a tear or compression secondary to an intracapsular hemarthrosis. The blood supply to the femoral head originates from the medial and lateral femoral circumflex arteries. These arteries form an extracapsular ring that courses inside the capsule at its insertion to the proximal femur. Intracapsular fractures may disrupt blood flow but not the vascular structures. Vessels may kink because of fracture fragments or as a result of tension from the fracture. Urgent anatomic reduction of the fracture may restore blood flow. The blood supply through the ligamentum teres may not be sufficient to nourish the entire femoral head; consequently, avascular necrosis inevitably results (15 to 35 percent overall) unless some of the capsular vessels remain intact.¹⁹ Basilar neck and intertrochanteric fractures below the capsule rarely sever important arteries. Morbidity and mortality associated with hip fractures is primarily a result of patient immobilization and the development of deep venous thrombosis and pulmonary embolus. Even with modern treatment modalities, mortality following hip fracture ranges from 15 to 35 percent within 1 year of

FIG. 273-17. The Judet-Letournel classification of simple acetabular fractures. 1. Posterior wall fracture. 2. Posterior column fracture. 3. Anterior wall fracture. 4. Anterior column fracture. 5. Transverse fracture.

TABLE 273-4 Acetabular Fractures

Hip Fracture	Mechanism	Description	Associated Injuries	Treatment/Disposition
Posterior wall fracture	Direct trauma to flexed hip and knee	Acetabulum fracture	Sciatic nerve injury; femoral fractures	Bedrest, analgesics; early orthopedic consultation, hospital admission
Posterior column fracture	Posteriorly directed force to abducted, flexed leg	Fracture acetabulum through obturator foramen; ischial ring disrupted	Sciatic nerve injury (40%), weight-bearing disrupted	Same as above
Anterior wall fracture	Lateral force to the greater trochanter with hip externally rotated	Fracture extends anterior inferior iliac spine to superior ramus; ischial ring and iliopectineal line disrupted	Weight-bearing disrupted	Same as above
Anterior column fracture	Posterior force to knee with hip abducted and flexed	Fracture from pubic ramus through iliac crest; ischial ring and iliopectineal line disrupted	Weight-bearing disrupted	Same as above
Transverse fracture acetabulum	Force lateral to medial over greater trochanter	Fracture extends anterior to posterior through acetabulum; ischial ring intact	Sciatic nerve injury	Same as above

surgery and 25 to 50 percent of the survivors will not regain their ability to ambulate.²⁰ Factors predictive of increased mortality include male sex, increased age, dementia, institutionalization, poorly controlled systemic disease, and the development of postoperative complications. There is some evidence that early (<72 h) hip fracture fixation of low impact hip fractures in the elderly reduces morbidity and mortality.^{21,22,23}

FEMORAL HEAD FRACTURES Isolated femoral head fractures occur infrequently. They are usually associated with dislocations of the hip (see Table 273-5). Femoral head fractures occur in 10 to 16 percent of posterior hip dislocations and in 22 to 77 percent of anterior hip dislocations. Fracture types include depressions, flattening, and subchondral fractures of the femoral head. They are usually best seen on radiographs obtained after reduction of a hip dislocation. Shear fractures

FIG. 273-18. Fractures of the proximal femur are traditionally classified as intracapsular and extracapsular. (Used with permission from Greenspan A: *Orthopedic Radiology*. Philadelphia: JB Lippincott, 1988, p 5.17.)

FIG. 273-19. Classification of proximal femur fractures.

of the superior aspect of the femoral head are associated with anterior dislocations, and shear fractures of the inferior femoral head are associated with posterior dislocations.

In most instances, the symptoms and signs are those of the associated dislocation rather than of the fracture itself. The standard AP and lateral x-ray views usually demonstrate the fragment adequately.

Orthopedic consultation should be obtained in the ED for these fractures. Treatment is to reduce the associated dislocation and then at-

tain anatomic reduction of the fracture fragment. Treatment should be limited to a single attempt at closed reduction. If this fails, then open reduction and internal fixation is the next treatment of choice.

Complications are associated with the high-energy trauma that produces the fracture-dislocation, that is, the more comminuted the fracture, the more severe the dislocation and the greater the severity of trauma to the patient. Life-threatening injuries must then be ruled out.

The prognosis is related to the severity of the initial trauma resulting in the dislocation. Poor prognostic indicators include delay between hip dislocation and reduction, repetitive unsuccessful relocation attempts, and associated injuries. Posttraumatic arthritis occurs in up to 50 percent of patients, avascular necrosis in two to 40 percent, and myositis ossificans can also occur.²⁴

FEMORAL NECK FRACTURES Femoral neck fractures are commonly seen among older adults, most often because of osteoporosis, and occur more frequently in women than in men. These fractures are rare among the younger population. The cause of such fractures is usually minor trauma secondary to falls (90 percent) or torsion in the patient with osteoporosis or osteomalacia. In younger patients, the high kinetic energy sustained in the major trauma causes a fracture through normal bone with marked soft tissue disruption and comminution. These patients may have associated head, chest, abdominal or other serious concomitant injury. Femoral neck fractures are classified as subcapital, transcervical, and basicervical fractures (see Figure 273-19). Anatomically these fractures are intracapsular and the blood supply may be disrupted as discussed above.

The classification of femoral neck fractures is by fracture displacement. The higher the grade of fracture displacement implies a worse prognosis for healing and repair. The symptoms seen with femoral neck fractures range from complaints of mild pain in the groin or inner thigh in patients with an incomplete fracture, to moderate to severe pain in patients with displaced fractures. Patients who have sustained a fracture without displacement may walk with some limping rather than being completely unable to bear weight. Their only physi-

TABLE 273-5 Proximal Femur Fractures

Fracture	Description/ Mechanism of Injury	Clinical Findings/ Associated Injuries	ED Treatment	Disposition
Femoral head fractures	Superior aspect in anterior dislocations; inferior aspect in posterior dislocations	AVN from dislocation; multisystem injury from high-energy trauma	Analgesics; urgent reduction with anatomic reduction of fracture	ED orthopedic consultation; admission; possible ORIF for difficult reductions
Femoral neck fractures	Primarily from falls; older women with osteoporosis	AVN; nonunion; emboli; infection	Analgesics	ED orthopedic consultation, possibly for ORIF; displaced fractures require surgery; hospitalize all
Trochanteric fractures	Direct trauma; greater trochanter avulsion from forceful contraction of gluteus medius muscle	Pain with abduction; limp	Protective weight-bearing	Orthopedic follow-up 1–2 weeks; possible ORIF if displacement >1 cm
	Lesser trochanter avulsion caused by forceful contraction of iliopsoas muscles (in young gymnasts and dancers)	Pain with flexion, rotation	Bed rest; gradual weight-bearing; NSAIDs	Follow-up 1–2 weeks with PCP or orthopedics; possible ORIF if displacement >2 cm
Intertrochanteric fractures	Falls; primarily in elderly women	Pain, swelling of hip; externally rotated, shortened; AVN; nonunion; infection; thromboembolic disease	Buck traction; analgesics	ED orthopedic consultation for hospital admission; eventual ORIF
Subtrochanteric fractures	Falls, primarily in elderly; high-energy impact to femur in young patients	Severe hemorrhage into thigh; hypovolemic shock; compartment syndrome; fracture or dislocation of joint above or below	Hare or Sager splint; analgesics	ED orthopedic consultation for hospital admission; eventual ORIF

Abbreviations: AVN = avascular necrosis; NSAID = nonsteroidal anti-inflammatory drug; ORIF = open reduction and internal fixation; PCP = primary care physician.

cal findings are minor pain with movement and minimal muscle spasm limiting range of motion. In contrast, displaced fractures cause severe pain, inability to ambulate, limited range of motion, and no palpable movement of the extracapsular head. The patient lies with the extremity in slight external rotation, abduction, and shortening.

Radiographic evaluation is essential in any patient suspected of having a femoral neck fracture. Stress fractures, however, may not become evident on x-ray for days or weeks, so repeat films or bone scans in symptomatic patients are necessary. The standard AP view should have the patient maximally internally rotated to best demonstrate the femoral neck. The AP view should be inspected for a fracture line starting on the superior surface of the neck. These fracture lines routinely become complete within 10 to 14 days. Also, disruption of Shenton line (a smooth curvilinear line along the superior border of the obturator foramen and the medial aspect of the femoral metaphysis) may be appreciated on the AP view in some instances. If there is any concern that the patient has sustained a fracture that is not visible on the initial x-ray examination, the patient should be conservatively treated and x-ray films should be made again in 10 to 14 days; or the physician may order a CT or MRI, which demonstrates the fracture in most instances. In contrast, displaced fractures are obvious on the AP film, but a lateral view should also be done to ascertain the exact position. There is a 10 percent incidence of an ipsilateral femoral shaft fracture, of which 30 percent are missed on initial presentation.²⁵

Orthopedic consultation should be obtained in the ED for these fractures. The orthopedic surgeon's goal of treatment for femoral neck fractures is anatomic reduction and stability. Treatment for nondisplaced or impacted fractures is somewhat controversial but usually involves a form of internal fixation. Conservative treatment is generally only considered if the patient is medically unfit for surgery or the fracture is several weeks old and the patient is walking without pain. Displaced fractures definitely require emergency surgery for fixation, especially in the young and active patient. Older patients who are active with good bone stock and reasonable physiologic age may also benefit from open reduction and internal fixation. The older individual with marked osteopenia and a high degree of fracture displacement or existing arthritis should be considered for a total hip arthroplasty.²⁶

Skeletal traction is contraindicated with femoral neck fractures because it may further compromise femoral head blood flow.

The complications of femoral neck fractures are significant. They include infections, emboli, nonunion, and avascular necrosis, which is the most feared early complication. Avascular necrosis has an incidence of up to 15 percent in nondisplaced fractures, and rises to near 90 percent with untreated, completely displaced fractures.

TROCHANTERIC FRACTURES Greater trochanteric fractures are usually caused by avulsions at the insertion of the gluteus medius. In the younger population (7 to 17 years of age), this is a true epiphyseal separation, in contrast to the adult population, in which this is caused by direct trauma. The patient presents with pain, especially with abduction and extension, and a limp. Also, there is tenderness to palpation over the greater trochanter.

Standard AP and lateral x-ray views reveal displacement in the superior-posterior area, or comminution. The treatment is generally conservative with protected weight-bearing recommended until the patient is asymptomatic. Outpatient orthopedic referral is indicated. Orthopedic consultation for possible surgical fixation may be considered for fracture displacement of greater than 1 cm.²⁷

Lesser trochanteric fractures caused by an avulsion secondary to a forceful contraction of the iliopsoas are commonly seen in children and young athletic adults, particularly gymnasts and dancers. These patients present with pain during flexion and internal rotation maneuvers. In most instances, the treatment is bedrest and then gradual weight-bearing to regain full activity. Outpatient follow-up by primary care or orthopedics is advised. Full recovery generally occurs within 3 weeks.

If greater than 2-cm displacement is seen on the standard AP and lateral views, then screw fixation by the consulting orthopedic surgeon may be indicated.

INTERTROCHANTERIC FRACTURES These fractures are defined as extracapsular fractures occurring in a line between the greater and lesser trochanters. Intertrochanteric fractures generally occur in the elderly and are more common in women, again due to the high incidence of osteoporosis. The mechanism of injury is usually a fall or occasionally an automobile accident. It is postulated that a rotational component along with the direct trauma is involved in some instances as well.

Symptoms and signs include pain, swelling of the hip, local ecchymosis, and pain with any hip movement or weight-bearing. Moreover, the extremity is markedly externally rotated and shortened, in contrast to the minimal deformities associated with femoral neck fractures. These fractures are classified as stable or unstable. Stable fractures are defined as ones in which the medial cortices of the neck and femoral fragments abut. X-ray evaluation should include AP and lateral views, with the AP view having as much internal rotation as possible to adequately visualize the neck.

Severe life-threatening injuries must be excluded. The consulting orthopedic physician can then admit the patient to the hospital and perform surgical fixation to attain a stable reduction as soon as possible, although this is not an emergency. Buck traction may temporarily help reduce pain.

The complications and prognosis are related to other associated injuries and prior disease. The overall mortality is approximately 10 to 30 percent. Infection can be a major problem, with an incidence of up to 17 percent.²⁸ Thromboembolic disease is especially a problem if postoperative mobilization does not occur quickly. Avascular necrosis is rare in these patients, and nonunion is also uncommon. Morbidity is a result of the patient's inability to return to prefracture activity.

SUBTROCHANTERIC FRACTURES Subtrochanteric fractures may be seen in two different populations. They usually occur secondary to falling in the 40- to 60-year-old patient with osteoporotic or weakened bone. The second population is young persons who have suffered major trauma with significant kinetic energies directed into the femur. These fractures may be an extension of an intertrochanteric or other isolated fracture and are usually classified as stable or unstable, with stable defined as bony contact of the medial and posterior femoral cortices.

The symptoms and signs are similar to those of trochanteric or femoral fractures, with local pain, deformity, swelling, crepitance, and so forth. These patients can lose a large amount of blood into the thigh area and may present in hypovolemic shock. Because this injury is a result of significant trauma, other, more life-threatening injuries must be excluded prior to treatment of this specific fracture.

Standard AP and lateral x-ray views of the hip are necessary to properly assess the fracture. Moreover, x-ray studies of the pelvis, femur, and knee are indicated to rule out associated fractures.

Treatment consists of immobilization with a traction apparatus. Hare (Dyna-Med, Carlsbad, CA) or Sager (Minto Research & Development, Redding, CA) splints (Figures 273-20 and 273-21) may be

FIG. 273-20. Hare traction splint.

FIG. 273-21. Sager traction splint.

employed in the prehospital setting. Proper evaluation of the entire patient to rule out associated severe injuries should be conducted. After the patient has stabilized and secondary evaluation has occurred, orthopedics should be consulted. Open reduction and internal fixation is generally indicated for fracture management.²⁹

The complications are similar to those of intertrochanteric fractures, except that there is a higher incidence of nonunion. Malunion and delayed union occur as well in this population. Prognosis is better for proximal fractures that are not comminuted.

Hip Dislocations

Hip dislocations can be classified as anterior, posterior, and central. Acetabular fracture with central hip dislocation is discussed under acetabular fractures.

ANTERIOR DISLOCATIONS Approximately 10 percent of hip dislocations are anterior (Figure 273-22A and B), and the majority are secondary to automobile accidents, but they may also result from a fall, or a blow to the back while squatting. In anterior dislocations, the femoral

FIG. 273-22. A. Anterior superior dislocation of the hip. B. Inferior dislocations (obturator, thyroid, or perineal). C. Clinical appearance of a superior-type anterior dislocation of the hip. D. Clinical appearance of an inferior-type dislocation of the hip. [Reproduced with permission from Rockwood CA Jr, Green DP, Buchholz RW (eds): *Fractures in Adults*, 4th ed. Vol. 2. Philadelphia: JB Lippincott, 1996, pp 1757, 1759, 1767, 1768.]

head rests anterior to the coronal plane of the acetabulum. Anterior dislocations can be superior or inferior (obturator, thyroid, perinea!) depending on the degree of hip flexion present at the time of injury. If the hip is abducted, externally rotated, and flexed at the time of injury, inferior dislocation occurs. If the hip is abducted, externally rotated, and extended, superior dislocation occurs. The mechanism of injury is forced abduction that causes the femoral head to be levered out through an anterior capsular tear. The affected extremity is in abduction and external rotation. However, the clinical appearance of superior versus inferior dislocations is dramatically different (Figures 273-22C and D). Neurovascular compromise is an unusual, but possible complication.

An AP film of the pelvis easily demonstrates the femoral head to be anterior to the acetabulum. A lateral view illustrates the anterior dislocation more clearly, although it may be difficult to obtain because of the patient's pain.

Hip dislocations are true orthopedic emergencies. Treatment for the dislocation is early closed reduction, usually under conscious sedation in the emergency department. Strong, in-line traction is done with simultaneous flexion and internal rotation (see Figure 273-23). Finally, the hip is abducted once the head clears the rim of the acetabulum. The dislocation should be reduced quickly, within a few hours, because the longer the delay in reduction, the higher the incidence of avascular necrosis. Attempts at reduction in the emergency department should be limited. Difficulties with reduction may be due to occult fracture, or incarcerated tendon or capsule. Early decision for closed reduction under general anesthesia or open reduction should be made with in conjunction with your orthopedic consultant. Postreduction radiographs should be specifically examined for acetabular or femoral head fractures and the possibility of small fragments in the joint not appreciated on the initial films.

POSTERIOR DISLOCATIONS Posterior dislocations (Figure 273-24A) constitute 80 to 90 percent of hip dislocations.²⁴ They are caused by force applied to a flexed knee, directed posteriorly. Acetabular fractures may result as well. On examination, the extremity is found to be shortened, internally rotated, and adducted (Figure 273-24B). Concomitant life-threatening injuries must be ruled out.

Anteroposterior and lateral x-ray films of the pelvis and hip will reveal the dislocation, but further assessment of the acetabulum and femur must be done to rule out fractures. The oblique views of Judet and colleagues will reveal an acetabular fracture. Also, inferior femoral head fracture will be seen on the AP or oblique view. Hip dislocations are difficult to recognize if there is an associated femoral shaft fracture, so roentgenograms of the pelvis and hips should be routinely obtained in such cases.

The treatment of posterior dislocation without fracture is closed reduction under conscious sedation or general anesthesia, as quickly as possible and always within 6 h. In-line traction, gentle flexion to 90 degrees, and then gentle internal-to-external rotation is done (Allis maneuver, see Figure 273-23). The Stimson maneuver (Figure 273-25) may prove useful in certain situations.

Complications include sciatic nerve injury in approximately 10 percent of the patients and avascular necrosis that increases in direct proportion to the delay in adequate reduction.

Femoral Shaft Fractures

Fractures of the shaft of the femur most often occur in men during their most active period in life. Falls, industrial and automobile accidents, and gunshot wounds account for the majority of these fractures. Severe, direct trauma may result in transverse fractures (most common) with displacement, oblique or spiral oblique fractures, or badly comminuted segments. Pathologic fractures are uncommon but can occur secondary to metastases (breast, lung, or prostate most common) or rarely secondary to primary bone tumors such as osteogenic sarcoma.

Femoral shaft fractures are generally evident in the field to prehospital personnel because of the shortening, deformity and associated swelling. Initially, basic stabilization of the patient should take place in the field, along with spinal assessment and immobilization. External hemorrhage should be controlled by direct pressure, open wounds covered with a sterile dressing and then neurovascular examination of the extremities performed. It is best to splint the affected extremity with a traction splint at the time of injury. Hare (Dyna-Med, Carlsbad, CA) or Sager (Minto Research & Development, Redding, CA) traction splints can be placed over the trousers, applying traction to a sling around the ankle and forefoot (see Figures 273-20 and 273-21). Traction splints are relatively contraindicated in cases of open fracture with grossly contaminated exposed bone ends or when sciatic nerve injury is probable because traction can exacerbate nerve injury. For the latter, splint placement without application of traction is indicated.

Emergency department management includes basic stabilization of the patient followed by careful neurovascular examination of the affected extremity. Open fractures require broad spectrum antibiotics, debridement, and copious irrigation, generally in the operating room. Radiographs of the femur are generally lower priority in the acute resuscitation phase and parenteral analgesics are generally required if there is no contraindication to their use. Orthopedic consultation should be obtained early and most patients require hospitalization and surgical intervention.

Definitive management options include traction, external fixation, pins and plaster, and internal fixation. The intramedullary interlocking nailing is the method of choice for the treatment of uncomplicated fractures of the midshaft and junction of the upper and middle third of the femur in adults, except where comminution is so extensive that sta-

bility with the rod cannot be maintained.³⁰ In cases where comminution is severe, either dual-plating or the use of a compression plate device can result in excellent fixation. Open femur fractures require early orthopedic consultation for copious irrigation and debridement in the operating room. These injuries can generally be nailed immediately. In severely contaminated open fractures, external fixation may be the preferred method of treatment.

The overall prognosis of midshaft femur fractures is very good, with most patients being able to return to work within 6 months. Union rates approach 100 percent, with nonunion being very uncommon. Mild degrees of limb shortening or malalignment can result in limp and posttraumatic arthritis.

KNEE INJURIES

Mark T. Steele

Jeffrey N. Glaspy

Injuries to the knee are common in our exercise and sports-oriented society. Because the knee is essential for ambulation, one must be familiar with the examination of the normal and abnormal knee to be able to recognize, treat, and appropriately refer specific injuries. This chapter deals with examination of the knee and with recognition of fractures and dislocations of the patella; fractures of femoral condyles; fractures of the tibial spines, tuberosity, and plateaus; ligamentous and meniscal injuries of the knee joint; knee dislocation; quadriceps and patellar tendon ruptures; patellar tendinitis and chondromalacia patellae; penetrating injuries and foreign bodies; total knee replacement and postarthroscopy problems; and osteochondritis dissecans.

An accurate diagnosis of the injured knee is required before proper treatment can be instituted. The first examination is usually the easiest to perform and may be the most valid because the patient does not anticipate pain and therefore does not guard, and involuntary muscular spasm, and because inflammation and effusion causing further limitation of the examination may not yet have occurred.

EXAMINATION

The examination of the knee is divided into five phases: history, observation, inspection, palpation, and stress testing.

The current mechanism of injury as well as any prior serious injuries or surgical procedures frequently clarifies subtleties in the examination, allowing a more accurate diagnosis and appropriate treatment.

The patient should be examined while walking, if possible, and in both the sitting and lying positions. Take note of the gait, muscular development, functional range of motion, and the ability of the patient to extend the flexed knee against minimal resistance.

The knee should be inspected for swelling, ecchymoses, effusion, masses, patella location and size, muscle mass, erythema, and evidence of local trauma. With the patient supine, note whether leg lengths are equal or unequal. Lastly, ask the patient to perform the best possible active range of motion.

Initially the neurovascular status of the leg should be noted. As with all orthopedic examinations, the noninjured or normal knee should be compared with the injured knee during all aspects of the examination, but especially during palpation and stress testing. When palpating the knee, begin in the nontender areas and work toward the tender area so that the patient does not guard or become apprehensive. The patella and patellar facets, as well as the femoral and tibial condyles, should be palpated for pain and crepitation. Effusion, tenderness, increased temperature, strength, sensation, and location of pulses should be noted.

Examine the patella for size, shape, and location with the knee in flexion; check mobility with the knee in extension. The patella should be compressed to check for pain as well as moved laterally and medially to ascertain possible subluxation. The popliteal space should be palpated for masses, swelling, and pulses. Both the medial and lateral joint lines should be palpated because tenderness at those locations suggests the possibility of meniscal injury. Palpation of the medial and lateral collateral ligaments should also be performed with tenderness, again suggesting the possibility of injury.

The final phase of the examination of the knee is stress testing (also see "Ligamentous and Meniscal Injuries" below). This is the most difficult aspect of the examination, although potentially the most informative. The patient must be reassured and relaxed and made as comfortable as possible. This may require allowing the leg to hang over the side of the bed with the bed supporting the posterior thigh rather than the physician holding the leg, as is usually done during stress testing. The uninjured, hopefully normal, opposite knee should be examined first to determine the patient's normal laxity. A brief summary of the instabilities and tests to demonstrate them are presented in the section on ligamentous and meniscal injuries.

RADIOGRAPHIC EVALUATION

The Ottawa Knee Rules (Table 274-1) for determining the need for x-rays have proven sensitive for fracture¹ and have resulted in reduced emergency department waiting times and costs. The Pittsburgh Knee Rules (Table 274-2) are similar and recently were prospectively shown to be as sensitive, but more specific than the Ottawa Rules.² They also have the added advantage of being applicable to both children and adults. A recent evaluation³ suggested that point tenderness is not a good predictor of knee fracture in children. This study suggested that applying a rule of an inability to bear weight and inability to flex the knee to 90 degrees would decrease x-rays ordered by 75 percent without any missed fractures.

Anteroposterior, lateral, and oblique radiographs are typically obtained if x-rays are determined to be necessary.⁴ Fat fluid levels (lipohemarthrosis) may be identified on a lateral view of the knee which is suggestive of intra-articular fracture.⁵ Oblique views are particularly helpful at detecting subtle tibial plateau fractures (internal oblique view is best to visualize lateral plateau, external oblique film best to visualize medial plateau). A tunnel or intercondylar view provides a clear view of the intercondylar region and is particularly useful in identifying tibial spine fractures. The sunrise (skyline, axial, or tangential) view is most useful in detecting nondisplaced vertical or marginal fractures of the patella which may be missed with the conventional three views. The sunrise view is indicated if patellar subluxation or fracture is suspected. Computerized tomography (CT) scanning may be necessary to fully delineate the extent of tibial plateau fractures.⁶ Magnetic resonance imaging (MRI) is also helpful in this regard, having the added benefit of being able to assess soft tissue injury (i.e., ligamentous and meniscal).

FRACTURES

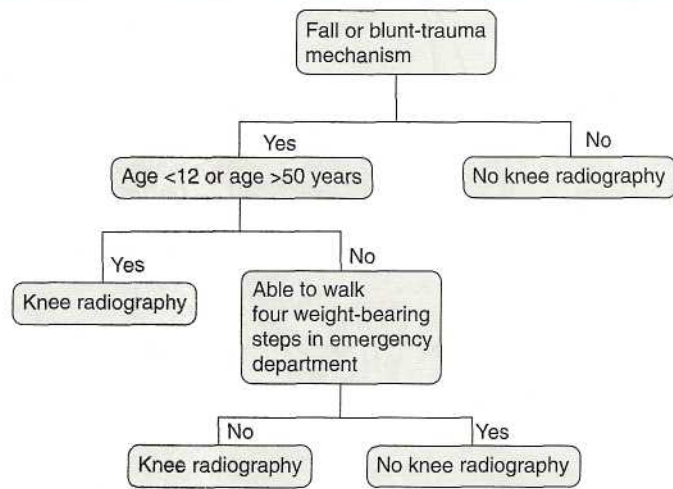

Fractures of the Patella

Fractures of the patella occur from a direct blow such as with the knee striking a car dashboard in a motor vehicle accident, a fall on the

TABLE 274-1 Ottawa Knee Rules: X-ray if One Criterion Is Present¹

Patient older than 55 years	Tenderness at the head of the fibula	Isolated tenderness of the patella	Inability to flex knee to 90 degrees	Inability to transfer weight for four steps both immediately after the injury and in the ED
-----------------------------	--------------------------------------	------------------------------------	--------------------------------------	---

TABLE 274-2 Pittsburgh Knee Rules²

flexed knee, or forceful contraction of the quadriceps muscles, which can occur with falling or stumbling. Fractures may be transverse, comminuted, or of the avulsion type, when the quadriceps or patellar tendon pulls off a small portion of the patella (Figure 274-1).

Transverse fractures of the patella are most common, followed by stellate and comminuted fractures.⁷ Patients with nondisplaced fractures may be ambulatory. Physical examination reveals focal patellar tenderness, swelling, and effusion. The integrity of the extensor mechanism of the knee should be checked by having the patient perform a straight-leg raise against gravity. Transverse fractures are more likely to be displaced and have a disrupted extensor mechanism. Differential diagnosis of patellar fractures radiographically includes bipartite patella. This condition involves the superior lateral corner of the patella, is typically bilateral, and is differentiated from fracture by its smooth cortical margins.

A nondisplaced fracture of the patella with an intact extensor mechanism is initially treated in the emergency department with a knee immobilizer, ice, elevation, and nonsteroidal anti-inflammatory drugs and/or opioid analgesics. Such fractures are generally treated in a long leg cast for a total of 6 weeks of immobilization.⁷ During this period the patient should be encouraged to walk on crutches initially, with partial weight bearing progressing to full weight bearing as tolerated. Fractures that are displaced greater than 3 mm, or that are asso-

FIG. 274-1. Classification of patellar fractures. [Reproduced with permission from Hohl M, Johnson EE, Wiss DA: *Fractures of the knee*, in Rockwood CA Jr, Green DP, Bucholz RW (eds): *Fractures in Adults*, 3d ed. Vol. 2. Philadelphia, JB Lippincott, 1991, p 1765.]

ciated with the disruption of the extensor mechanism, require early referral to orthopedics for open reduction and internal fixation.⁷ This generally consists of tension-band wiring of the patella and suturing of the retinaculum. Severely comminuted fractures may be treated surgically by removal of smaller fragments (or all fragments if they are small) and suturing of the quadriceps and patellar tendons. All open fractures must be debrided and irrigated by orthopedics in the operating room, and antistaphylococcal antibiotics should be administered. The overall prognosis for patellar fractures is good.⁷

Fractures of Femoral Condyles

Fractures of the femoral condyles account for 4 percent of femur fractures and include supracondylar, intercondylar, condylar, and distal femoral epiphyseal fractures (Figure 274-2). Most often, these injuries are secondary to direct trauma from a fall with axial loading or a blow to the distal femur. Examination reveals pain, swelling, deformity, rotation, shortening, and an inability to ambulate. Although neurovascular injuries are uncommon, the potential for popliteal artery injury exists so the status of distal sensation and pulses must be checked. The space between the first and second toe, innervated by the deep peroneal nerve, should be tested for sensation. In addition, a search for ipsilateral hip dislocation or fractures, and damage to the quadriceps apparatus must be made. Incomplete or nondisplaced fractures in any age group and stable impacted fractures in the elderly can be treated with cast immobilization.⁷ Open reduction and internal fixation is generally required for displaced fractures or if there is any degree of joint incongruity present.⁸ Therefore, leg splinting and orthopedic consultation is essential. The overall progress of these injuries is fair. Complications include deep venous thrombosis, fat embolus syndrome, delayed or malunion, and the subsequent development of osteoarthritis.

Fractures of the Tibial Spines and Tuberosity

Although isolated injuries of the tibial spine are uncommon, they usually result in cruciate ligament insufficiency. The injury is most often

FIG. 274-2. The supracondylar and condylar areas of the femur, and the medial and subcondylar areas of the tibia. [Modified with permission from Hohl M, Larson RL: *Fractures and dislocations of the knee*, in Rockwood CA Jr, Green DP (eds): *Fractures*. Vol. 2. Philadelphia, JB Lippincott, 1975, pp 1132, 1147.]

caused by a force directed against the flexed proximal tibia in an anterior or posterior direction, resulting in incomplete avulsion of the tibial spine, with or without displacement, or complete fracture of the spine. Vehicular and sporting accidents are the most common causes of these injuries.⁷ Fracture of the anterior tibial spine is about tenfold more common than fracture of the posterior spine. Examination shows a painful, swollen knee, secondary to hemarthrosis, inability to extend fully, and a positive Lachman sign (see "Ligamentous and Meniscal Injuries" below). If the fracture is incomplete or nondisplaced, it should be immobilized in full extension in a knee immobilizer. Protected weight bearing and outpatient orthopedic follow-up within a few days to a week is advised. Complete, displaced fractures require early orthopedic consultation and often need open reduction, and internal fixation.

The quadriceps mechanism inserts on the tibial tubercle. A sudden force to the flexed knee with the quadriceps muscle contracted may result in a complete or incomplete avulsion of the tibial tubercle. The fracture line may extend into the joint. Examination reveals pain and tenderness over the proximal anterior tibia with pain on passive or active extension. If the avulsion is small or nondisplaced, the fragment may be maintained in position by immobilization; otherwise, open reduction and internal fixation are necessary.⁷

Fractures of the Tibial Plateaus

Fractures of the tibial plateaus are seen more commonly in the older population and can be very difficult to detect. They are produced by valgus or varus forces combined with axial loading, which drives the femoral condyles into the articulating surface of the tibia. A fall from a height or the leg being struck by the bumper of a car are common causes of these fractures.⁹ Both medial and lateral plateaus may be fractured simultaneously, although the lateral plateau is more often fractured.⁷ Direct trauma to the lateral aspect of the knee may account for the preponderance of lateral tibial plateau fractures. The patient presents with painful swelling of the knee and limitation of motion. Radiographs may demonstrate a fracture but often only show a lipohemarthrosis on the lateral view. Careful review of the x-rays is essential. Ligamentous instability may be present in up to one-third of those injuries. Anterior cruciate and medial collateral ligament injuries are associated with lateral plateau fractures whereas posterior cruciate and lateral collateral ligament injuries occur with medial plateau fractures.⁷ If one plateau is fractured but not displaced, treatment in a knee immobilizer, without weight bearing, is indicated with outpatient orthopedic follow-up scheduled within a few days to a week. Long-term treatment of these nondisplaced fractures consists of a long leg cast and prolonged non-weight bearing. Depression of the articular surface necessitates early orthopedic consultation and open reduction and elevation of the bony fragment. The treatment goal is precise reconstruction of the articular surfaces to allow for early range of motion so as to minimize the development of osteoarthritis.⁷ Potential complications of those fractures include popliteal artery injury with high-energy displaced fractures, the development of deep venous thrombosis, and osteoarthritis. The prognosis for these injuries is fair.

LIGAMENTOUS AND MENISCAL INJURIES

The knee joint depends on ligaments and muscles for support (Figure 274-3). It is frequently subjected to injuries from traumatic forces while extended or in various stages of flexion. These traumatic forces include abduction, flexion, and internal rotation of the femur on the tibia; adduction, flexion, and external rotation of the femur on the tibia; hyperextension; and anteroposterior displacement. By far the most common are abduction, flexion, and internal rotation of the femur on the tibia, which produce injuries to the medial side of the knee. Injuries to the lateral side of the knee are produced by adduction, flexion, and external rotation. Such forces may result in a strain or rup-

FIG. 274-3. Ligaments of the right knee joint. The articular capsule and the patella have been removed. (Reproduced with permission from Spencer AP, Mason EB: *Human Anatomy and Physiology*. Menlo Park, CA: Benjamin/Cummings, 1979, p 174.)

ture of the medial or lateral collateral ligaments, the anterior or posterior cruciate ligaments, the capsular structures, or a tear in the medial or lateral meniscus, singularly or in combination. Functional instability of the knee is determined by stress testing, which may demonstrate abnormal laxity when properly done. Solomon et al. reviewed the literature and analyzed the reported sensitivity, specificity, and positive and negative likelihood ratios for diagnosis of ligamentous and meniscal injury.¹⁰ Table 274-3 summarizes the reported results from this study.

Initial stress testing is an abduction or valgus deformity (Figure 274-4) applied to the knee, which is in approximately 30 degrees of flexion, to determine the integrity of the medial capsular and ligamentous structures. The medial collateral ligament supplies the majority of restraint to valgus deformities of the knee in all stages of flexion. A varus or adduction force is then applied to the lateral aspect of the knee, again with approximately 30 degrees of flexion, to ascertain the integrity of the lateral structures. The lateral collateral ligament, similar to the medial collateral ligament, is the major restraint to varus laxity on the knee at all positions of flexion. If there is a demonstrated laxity of greater than 1 cm without a firm end point as compared to the other knee, there is a complete rupture of the medial or lateral collateral ligament.¹¹ If there is laxity with a firm end point or a laxity of less than 1 cm, an incomplete or partial tear is present. If there is no demonstrated instability but there is pain, the patient has suffered a strain in the ligamentous structures tested. The patient who is unstable with the varus or valgus test performed with 30 degrees of flexion should be brought into full extension, if possible, and similar maneuvers carried out. Medial instability in full extension indicates a severe lesion involving the cruciate ligaments and posterior capsule along with the medial ligaments. Lateral instability in extension likewise indicates a severe injury that may involve the posterolateral corner of the knee as well as the cruciate ligaments. Peroneal nerve injuries may also occur in lateral injuries. Although these tests may aid in the diagnosis of medial collateral ligament and lateral collateral ligament injuries, there are no adequate published reports to comment on their sensitivity and specificity.¹⁰

Injury to the *anterior cruciate ligament* may be the most common ligamentous injury today.¹¹ The mechanism of injury is usually non-contact; a deceleration, hyperextension, or marked internal rotation of the tibia on the femur results in an injury to the cruciate. This injury is often associated with a "pop" and swelling that develops within hours.

TABLE 274-3 Reliability of Physical Exam for Diagnosis of Knee Ligament and Meniscus Injuries

Structure	Maneuver	Mean Sensitivity (Range)	Mean Specificity (Range)	Positive Likelihood Ratio (95% CI)	Negative Likelihood Ratio (95% CI)	Comments
ACL	Composite exam*	82% (62-100)	94% (56-100)	25 (2.1-306)	0.04(0.01-0.48)	When limited to acute injury (one study), 62% sensitivity and 56% specificity.
	Anterior drawer	62% (9-93)	67% (23-100)	3.8 (0.7-22.0)	0.3 (0.05-1.5)	Variability of studies may be due to small sample sizes.
	Lachman's test	84% (60-100)	100% (100)	42 (2.7-651)	0.1 (0.0-0.4)	Only one study commented on specificity. Therefore specificity and likelihood ratios may be inaccurate.
	Lateral pivot shift	38% (27-95)	N/A	N/A	N/A	No study commented on specificity.
PCL	Composite exam*	95.5% (91-100)	89.5% (80-99)	21 (2.1-205)	0.05 (0.01-0.50)	Results limited to two studies.
	Posterior drawer	55% (51-86)	N/A	N/A	N/A	No study commented on specificity.
MCL/LCL	N/A	N/A	N/A	N/A	N/A	No study was identified that adequately examined diagnostic accuracy for these injuries.
Meniscal injury	Composite exam*	77% (64-82)	81% (78-84)	N/A	N/A	Only three of five studies commented on specificity.
	Joint-line tenderness	79% (76-85)	15% (11-43)	0.9 (0.8-1.0)	1.1 (1.0-1.3)	Only two of four studies included acute injury and all four included chronic injuries; consequently, applicability to ED is limited.
	McMurray test	53% (29-63)	59% (29-100)	1.3 (0.9-1.7)	0.8(0.6-1.1)	

*These studies reported the "composite exam" without giving data on the specific examination maneuvers.

Abbreviations: ACL = anterior cruciate ligament; CI = confidence interval; LCL = lateral collateral ligament; MCL = medial collateral ligament; N/A = not applicable; PCL = posterior cruciate ligament.

Source: Adapted from Solomon DH, Simel DL, Bates DW, et al: Does this patient have a torn meniscus or ligament of the knee? Value of physical exam. *JAMA* 286:1610,2001.

This pop is considered pathognomonic for anterior cruciate injury.¹² There may be an associated medial meniscal tear as well. Such a mechanism of injury combined with the presence of a traumatic effusion is very suggestive of a disruption of the anterior cruciate ligament.

The diagnosis of the anterior cruciate ligament injury is ascertained by using the Lachman test (Figure 274-5), the anterior drawer sign (Figure 274-6), and the pivot shift (Figure 274-7).¹³ Although the anterior drawer sign has been used for a long time, the sensitivity is only approximately 62 percent (see Table 274-3). The maneuver is done with 45-degree flexion at the hip and 90 degrees of flexion at the knee. The physician then attempts to forwardly displace the tibia from the femur. A displacement of greater than 6 mm as compared to the normal, opposite knee indicates that there has been an injury to the anterior cruciate ligament. There are false-negatives associated with this maneuver. The Lachman test is a much more sensitive test, with a re-

ported sensitivity of 84 percent.^{10,11} The examiner places the knee in 20 degrees of flexion by resting it on a pillow and stabilizes the femur above the knee with his or her nondominant hand. The dominant hand is placed behind the leg at the level of the tibial tubercle, and the examiner introduces an anterior force, attempting to displace the tibia forward. If a displacement of greater than 5 mm as compared to the opposite knee occurs, or if there is a soft, mushy end point, then a tear in the anterior cruciate ligament has occurred. Although this examination is more sensitive than the anterior drawer and able to identify partial tears in the anterior cruciate ligament when the examiner is skilled, it is difficult to perform on patients with large legs. The pivot shift is the third maneuver by which the examiner can determine the integrity of the anterior cruciate ligament. The pivot shift is easily performed once the examiner is familiar with it, but it may be somewhat painful to the patient. While the patient is supine and relaxed, the examiner

FIG. 274-4. Valgus stress in full extension (A) and in 30 degrees of flexion (B). (Reproduced with permission from Scott WN: *Ligament and Extensor Mechanism Injuries of the Knee: Diagnosis and Treatment*. St. Louis: Mosby-Year Book, 1991, p 91.)

lifts the heel of the foot to approximately 45 degrees of hip flexion with the knee fully extended. The opposite hand grasps the knee with the thumb behind the fibular head. The examiner then internally rotates the ankle and knee, applies a valgus force to the knee, and flexes the knee. If an anterior subluxation of the tibia is present, a sudden visible, audible, and palpable reduction of the subluxation occurs at about 20 to 40 degrees of flexion. This indicates a deficit in the anterior cruciate ligament, which is required to stabilize the knee in this position. There are other tests described in the literature to determine the integrity of the anterior cruciate ligament, including the jerk test and dynamic extension testing.

The *posterior cruciate ligament* can also suffer an isolated injury or be injured in combination with other ligamentous structures of the knee. In contrast to anterior cruciate injuries, isolated posterior cruciate injuries are seen much less frequently. The posterior cruciate ligament provides initial resistance to posterior translation at all angles of flexion of the knee. The mechanism of injury then is usually an anterior to posterior force applied to the tibia or lower leg. Posterior cruciate injuries are seen in association with other ligamentous injuries when a serious injury has occurred to the knee. A deficit in this ligament is determined by the posterior drawer test (Figure 274-8). The knee is examined with flexion at the hip and at the knee as described for the anterior drawer sign. The physician applies a posterior force to

the tibial tubercle. If there is displacement posteriorly, then the examiner can diagnose an injury to this ligament. The physician might also notice a posterior sag or drop back of the tibial tubercle because of loss of integrity of the posterior cruciate when observing the knee with 45-degree flexion at the hip and 90-degree flexion at the knee. This test can be misleading, however, if there is a straight anterior instability resulting in a subluxation of the knee forward. This abnormal position would give the physician the false impression of too much posterior play when performing the posterior drawer test because the knee would be reduced to its normal anatomic alignment from the forwardly subluxed position. Although the posterior drawer test has only a 55 percent sensitivity, the composite history and physical exam is much more accurate in the diagnosis of posterior cruciate ligament injuries (see Table 274-3).¹⁰

Combined instabilities of the knee are often seen, especially in athletes. Anteromedial and anterolateral instability are the two that occur most frequently. They result from external rotation and abduction or adduction forces placed on the knee. Virtually any combination of medial and lateral instabilities of the knee can occur, however.

One knee injury that is especially difficult to detect is injury to the posterolateral structures. Posterolateral instability usually involves a *tear of the popliteus-arcuate complex*, which may occur in combination with lateral ligament injury and possible anterior or posterior cruciate ligament injury. Isolated injuries to the popliteus-arcuate complex can occur themselves but are rare. Isolated posterolateral instability is demonstrated by testing at 0 to 30 degrees of flexion for maximal posterior translation, and at 90 degrees of flexion for maximal external rotation as compared to the normal opposite knee. Further testing to determine the integrity of the lateral collateral ligament and anterior or posterior cruciate ligaments must be done as well.

Most ligamentous injuries of the knee present with hemarthroses. **In fact, approximately 75 percent of all hemarthroses are caused by disruption of the anterior cruciate ligament.**¹¹ Serious ligament injuries, however, may present with minimal pain and no hemarthrosis because of complete disruption of the ligamentous and capsular fibers, allowing leakage of the blood into the soft tissue spaces. Hemarthrosis can also be caused by osteochondral fractures or fractures that extend into the joint line or peripheral meniscal tears. Traumatic hemarthroses usually occur within minutes to hours of injury, in contrast to chronic effusions of the knee because of synovial inflammation, which occur 1 to 2 days after strenuous use of the joint.

Plain radiographs in ligamentous injuries are typically normal or only reveal an effusion. An avulsion fracture at the site of attachment of the lateral capsular ligament on the lateral tibial condyle (Segond fracture) is a marker for anterior cruciate ligament rupture.¹⁴ Cortical avulsion of the medial tibial plateau (very uncommon) is associated with tears of the posterior cruciate ligament and medial meniscus. Continued refinements in MRI have resulted in high-quality images of

FIG. 274-7. In the pivot shift of Galway and Macintosh, the test is done with the knee in full extension with application of a valgus and internal rotation stress. The "clunk" of reduction is felt in the first 20 degrees to 30 degrees of flexion. (Reproduced with permission from Scott WN: *Ligament and Extensor Mechanism Injuries of the Knee: Diagnosis and Treatment*. St. Louis: Mosby-Year Book, 1991, p 95.)

the ligamentous and meniscal structures of the knee, resulting in an accuracy rate of close to 90 percent for meniscal and cruciate ligament disruption.⁷ The ordering of this examination, however, is typically done by the patient's primary care provider or orthopedist in follow-up.

Stable injuries involving a single ligament with minor strain can be managed with a knee immobilizer, ice packs, elevation, nonsteroidal anti-inflammatory agents, and ambulation as soon as is comfortable for the patient.¹⁶ **When knee immobilizers are placed, the patient must be instructed to perform daily range of motion exercises to avoid contracture and maintain mobility.** These complications are more common in the elderly and can occur after only a few days of immobilization. While there is no universally accepted regimen for range of motion exercise, one regimen is to first apply ice to relieve pain, and then to perform 10 to 20 knee flexion-extensions (no weights should be added) three or four times a day. These injuries should be referred to an orthopedic surgeon or to the patient's primary care provider within the next few days to a week for follow-up examination. Complete rupture of an isolated ligament can generally be treated conservatively in the same fashion with quadriceps strengthening, range of motion exercises, and functional bracing being part of the follow-up care.¹² Professional athletes with single ligament ruptures or patients with more than one ligament torn and an unstable knee necessitate immediate orthopedic consultation so that definitive surgical management can be planned.

Arthrocentesis may be of therapeutic benefit in patients with large, tense effusions of the knee; however, good evidence has not been reported. Wallman and Carley performed a literature review to ascertain whether aspiration improves symptoms in patient's with acute traumatic hemarthrosis and found no relevant articles.¹⁷ Furthermore, recurrence of the effusion following aspiration is common. Arthrocentesis may be of assistance diagnostically if the etiology of the effusion is not clearly due to trauma. **The presence of blood and glistening fat globules is pathognomonic of lipohemarthrosis, which indicates intraarticular knee fracture.** The major complication of arthrocentesis is septic arthritis.

Meniscal Injuries

Meniscal injuries of the knee occur by themselves or in combination with ligamentous injuries. For example, anterior cruciate injuries are commonly associated with meniscal injuries. Cutting, squatting, or twisting maneuvers may cause injury to the meniscus. The medial meniscus is approximately twice as likely as the lateral meniscus to be injured. Four-fifths of the tears involve the peripheral posterior aspect of the meniscus.¹⁸ Many maneuvers have been described in the literature to determine whether a meniscus has been injured. Most of these tests, however, have an unacceptable specificity and sensitivity (see Table 274-3). Although the diagnosis of a meniscal tear is difficult to make in certain patients, a combination of a suggestive history and physical findings on examination should lead the emergency physician to consider the diagnosis. On questioning the patient, the physician should ask if the patient experiences locking of the knee joint on either flexion or extension that is painful and limits further activity. This sign clearly points to the diagnosis of a torn meniscus. Effusions that occur after activity; a sensation of popping, clicking, or snapping; a feeling of an unstable joint, especially with activity; or tenderness in the anterior joint space after excessive activity suggests the diagnosis of a meniscal tear.

When performing a physical examination, a physician should attempt to identify atrophy of the quadriceps muscle because of disuse and joint-line tenderness, which is very suggestive. Various maneuvers, such as McMurray test or the grind test, are useful but, as mentioned earlier, are positive only about 50 percent of the time.¹⁹ If a tentative diagnosis of a meniscal tear is considered, referral to an orthopedic surgeon or the patient's primary care provider is warranted. Nonsteroidal anti-inflammatory agents and partial weight bearing are

advised pending follow-up. Definitive diagnosis can be made by MRI or arthroscopy with the latter having the advantage of allowing for definitive surgical treatment (usually partial meniscectomy or meniscal repair).

The patient who presents to the emergency department with a locked knee can experience a great deal of pain along with loss of mobility. Following conscious sedation, one can attempt to unlock the knee by positioning the patient with the leg hanging over the edge of the table with the knee in 90 degrees or greater of flexion. After a period of relaxation, the physician can apply longitudinal traction to the knee with internal and external rotation in an attempt to unlock the joint. If this maneuver is unsuccessful, consultation with the orthopedic surgeon is recommended.

Knee Dislocation

Knee dislocation (Figure 274-9) is a result of tremendous ligamentous disruption due to hyperextension, direct posterior force applied to the anterior tibia, force to the fibula or medial femur, force to the tibia or lateral femur, or rotatory force resulting in anterior, posterior lateral, medial, or rotatory dislocation. This injury typically occurs following sporting accidents and falls and posterior dislocation is most common. With posterior dislocation, there is complete disruption of the anterior and posterior cruciate ligaments and the posterior joint capsule. The extensor mechanism of the knee may also be disrupted and should be checked postreduction. Because of knee instability, reduction very often occurs spontaneously. A severely unstable knee in multiple directions is suspicious for a spontaneously reduced knee dislocation. Suspicion of the injury is important because of the high incidence of associated complications, including popliteal artery injury and peroneal nerve injury (mostly with posterolateral dislocations), in addition to ligamentous and meniscal injury.

Early reduction of the dislocation employing longitudinal traction is essential. Neurovascular status of the extremity should be documented pre- and postreduction. Hospitalization is required and orthopedic consultation should be obtained immediately.

Controversy exists regarding when to obtain arteriography in patients with knee dislocation. Because of the high incidence of popliteal artery injury (up to one-third of patients) and poor outcomes related to delays in vascular reconstruction, some authors recommend arteriography for all confirmed knee dislocations.²⁰ Others suggest that clinical examination alone is reliable in identifying patients requiring

FIG. 274-9. Types of dislocations: Anterior; Posterior; and Lateral. (Reproduced with permission from DePalma AF: *Management of Fractures and Dislocations: An Atlas*. Philadelphia: WB Saunders, 1970, p 1621.)

arteriography and/or surgical intervention.²¹ Patients with an absent pulse or other signs of vascular injury (i.e., bruit, distal ischemia) require immediate vascular surgical consultation for surgical exploration. Patients with an absent pulse prereduction with return of a pulse postreduction probably necessitate arteriography.²² Patients with normal pulses pre- and postreduction along with normal Doppler pressure indices (ankle-brachial index) can probably be safely observed in the hospital with serial vascular examinations. Presence of normal distal pulses, however, does not preclude occult popliteal artery injury.²³ As a result, if any doubt exists, arteriography should be performed.

Patella Dislocation

Dislocation of the patella usually occurs from a twisting injury on the extended knee and is more common in women. The patella is displaced laterally over the lateral condyle, resulting in pain and deformity of the knee (Figure 274-10). Tearing of the medial knee joint capsule often occurs. Reduction is accomplished following conscious sedation by flexing the hip, hyperextending the knee, and sliding the patella back into place. This results in immediate relief of pain, but further soreness from capsular injury persists for a period of time. The patella and knee should be x-rayed to rule out a fracture, and the knee should be immobilized after reduction. Follow-up with a primary care provider or orthopedist within 1 to 2 weeks is suggested. Partial weight bearing progressing to full weight bearing, nonsteroidal anti-inflammatory agents, and isometric quadriceps strengthening exercises are also indicated. Recurrent lateral dislocation of the patella occurs in approximately 15 percent of patients, and superior, horizontal, and intercondylar dislocations require referral to an orthopedic surgeon for possible surgical intervention.

Quadriceps/Patellar Tendon Rupture

Rupture of the quadriceps or patellar tendons can occur from forceful contraction of the quadriceps muscle or falling on a flexed knee. Patel-

lar tendon rupture occurs most commonly in individuals younger than age 40 years with a history of tendinitis or past steroid injections. Quadriceps tendon rupture is most frequent in the older than 40 years age group.⁷ There is significant pain, diffuse swelling, and the patient is unable to extend a flexed knee against mild resistance in both instances. Depending on the tendon ruptured, a defect may be palpable above or below the patella (Figure 274-12). A "high-riding patella" may be seen on the lateral x-ray of the knee with patellar tendon rupture (Figure 274-11). The treatment is surgical repair of the involved tendon²⁴ within the first 7 to 10 days following rupture to achieve the best results. Orthopedic consultation in the emergency department is indicated.

Osteochondritis Dissecans

Osteochondritis dissecans is a disorder in which a segment of articular cartilage and subchondral bone become partially or totally separated from the underlying bone. It is a rare condition of unknown etiology that has been thought to result from acute or chronic trauma. It typically is found in adolescents, is generally unilateral, and most often involves the non-weight-bearing lateral aspect of the medial femoral condyle. Patients generally complain of pain and swelling but typically do not recall any specific incident of trauma. The condition can be diagnosed on routine radiographs with tunnel views being particularly helpful. Treatment is conservative with protective weight bearing if the epiphyses are still open. If the epiphyses are closed and the fragments are detached, the prognosis for healing is poor. Arthroscopy for the retrieval of loose bodies or arthrotomy for pinning or bone grafting of the detached lesions is suggested in this instance.²⁵

1. Patella alta.

FIG. 274-12. Right patella tendon rupture. Note the depression distal to the patella.

Osteonecrosis

Osteonecrosis is a bony infarction caused by disruption of blood supply to the bone. Osteonecrosis is divided into two main categories, primary (spontaneous, idiopathic) and secondary. The etiology of primary osteonecrosis remains unknown. Secondary causes include steroid therapy, systemic lupus erythematosus, alcoholism, sickle cell disease, and renal transplantation. Patients with osteonecrosis are typically elderly women who present with acute knee pain. The weight-bearing surface of the medial femoral condyle of the knee is the most common site of involvement. Physical examination generally reveals tenderness over the involved femoral condyle or tibial compartment. Secondary osteonecrosis occurs in a younger age group. Plain radiographs are typically normal early in the course of the disease but magnetic resonance scanning is diagnostic. Initial treatment is nonoperative and consists of protected weight bearing and the use of nonsteroidal anti-inflammatory drugs. The outcome of the disease depends on the percentage of the weight-bearing surface of the joint involved. Treatment options for advanced stages of the disease include arthroscopic debridement, curettage or drilling of the lesion, bone grafting, high tibial osteotomy, use of osteochondral allografts, and total knee arthroplasty.²⁶

Patellar Tendinitis

Also known as "jumpers knee," patellar tendinitis is primarily seen in runners, basketball and volleyball players, and high jumpers. Pain is referred to the area of the patellar tendon and is worsened when going from sitting to standing or when running up hills. Point tenderness can be found at the distal aspect of the patella or proximal part of the patellar tendon. Treatment consists of heat, nonsteroidal anti-inflammatory agents, and quadriceps strengthening exercises. Steroid injections predispose to tendon rupture so should be avoided.

Chondromalacia Patellae

Chondromalacia patellae is an overuse syndrome of the articular cartilage of the patella. The condition is caused by patellofemoral malalignment, which leads to a tracking abnormality of the patella, placing excessive lateral pressure on the articular cartilage. It is most common in young, active women and the pain is generally localized to

the region of the anterior knee. Stair climbing and rising from a chair exacerbate the pain.

Two tests may aid in the diagnosis. The patellar compression test is performed by pushing the patella distal in the trochlear groove with the knee extended and quadriceps muscles tightened. This maneuver elicits pain. The apprehension test is performed on a relaxed leg. When the patella is pushed laterally, the quadriceps muscles contract in anticipation of pain. Treatment of this condition consists of rest, nonsteroidal anti-inflammatory medication, and quadriceps strengthening exercises.²⁷

Postarthroscopy Presentations

Patients may rarely present to the emergency department following arthroscopy secondary to pain and swelling. Effusions are common following arthroscopy, but joint infection is very uncommon. Diagnostic arthrocentesis should be performed if joint infection is suspected. Arthrocentesis may be helpful therapeutically for large tense effusions. Intraarticular injection of bupivacaine and morphine after traumatic knee injuries and arthroscopy reduces the need for systemic analgesia, but morphine is more effective and can provide relief longer.²⁸

Penetrating Knee Injury/Joint Foreign Bodies

If the knee joint has clearly been violated as a consequence of penetrating injury, orthopedic consultation should be obtained for joint irrigation in the operating room. If penetration is suspected, but is in doubt, injection of the joint with sterile methylene blue can help to confirm the diagnosis. Extravasation of dye indicates penetration and the need for irrigation. **Remember that the history obtained must recreate the position of the knee when the penetrating injury occurred.** Many occupational injuries occur with the knee flexed, but the joint is examined with the knee resting in extension. Failure to anticipate the trajectory of injury with the knee flexed could lead to misdiagnosis and failure to anticipate joint penetration.

Radiopaque foreign bodies (i.e., metal, glass) will visualize on conventional radiographs. In general, foreign bodies in the knee joint need to be removed. A bullet in the joint can destroy the cartilage and lead poisoning can occur.²⁹ A bullet lodged in the bone only, however,

does not necessitate removal. Antibiotics to cover streptococci and staphylococci are generally indicated for both penetrating knee wounds and foreign bodies. Tetanus prophylaxis should be administered if indicated.

LEG INJURIES

Paul R. Haller

Lower leg injuries are common. The tibia is the most common long bone fractured. Significant soft tissue injuries to the leg can also occur. Documentation of the history and the physical examination are crucial to the proper evaluation of lower leg injuries.¹ A knowledge of the anatomy aids in the interpretation of findings.

ANATOMY

Bone

Support for weight bearing is provided primarily by the tibia, a bone triangular in cross section that lies subcutaneously in the anterior aspect of the leg. Although it is in harm's way, it has a thick cortex and significant force is required to fracture it. Proximally, the tibia is splayed out to form the medial and lateral plateaus that articulate with the femoral condyles. The lateral plateau is higher and smaller than the medial and is more susceptible to fracture. The distal tibia articulates with the fibula laterally and the talus inferiorly. This articulation is supported by the ankle syndesmosis, a series of ligaments that lie inferior to the interosseous membrane. The fibula lies lateral and posterior to the tibia. Its smaller diameter allows it to be broken with less force than the tibia. Patients can remain ambulatory after a fibula fracture, because it bears little weight. The tibia and fibula are connected by a dense interosseous membrane.

Compartments

The cylinder of the lower leg is divided into four chambers or compartments by bone and dense layers of fascia. It is useful to describe the neurovascular and muscular anatomy in terms of the position of the nerves and muscles in these four compartments, the anterior, lateral, superficial posterior, and deep posterior compartments. The *anterior compartment* is bordered by the tibia medially, the interosseous ligament posteriorly, and the anterior crural septum on its lateral aspect. It contains the muscles that dorsiflex the ankles and toes. The anterior tibial artery runs through this compartment before becoming the dorsal pedal artery of the foot. The deep peroneal nerve that also traverses this compartment supplies motor function to the dorsal flexors of the foot and toes. It provides sensory innervation to the web space of the first and second toes. The *lateral compartment* is circumscribed by the anterior peroneal septum, the fibula, and the posterior peroneal septum. It houses the superficial peroneal nerve, which is sensory to the lateral dorsum of the foot, and motor control for the muscles within the compartment that evert the foot. The peroneal nerve runs just lateral to the fibular head, where it is exposed to direct trauma. The *superficial posterior compartment* contains muscles that plantar flex the ankle (gastrocnemius, soleus, and plantaris). The sural nerve runs through it before providing sensory innervation to the lateral heel. No major arteries traverse this compartment. The *deep posterior compartment* contains muscle groups that plantar flex the toes. The tibial nerve provides motor control to these muscles and sensation for the sole of the foot. This compartment also contains the posterior tibial artery, whose pulse can be felt posterior to the medial malleolus of the ankle. The physical findings produced by increased pressure within each compartment are tabulated in Chap. 278.

EVALUATION

Leg injuries are initially evaluated with a directed history, including the amount and type of violence that occurred. The history may also give clues about nontraumatic soft tissue injuries. On examination, nerves should be evaluated by checking sensation in the web space, lateral heel, and sole of the foot. Motor tests should include the ability to plantar and dorsal flex the foot, as well as to evert the foot. The extent of soft tissue injury is evaluated visually and by palpating the muscle groups. The tibia and fibula should be palpated along their entire lengths. The popliteal, dorsal pedal, and posterior tibial pulses should be palpated. An absent or decreased pulse may indicate the need for urgent fracture reduction and vascular evaluation. Patients with tibial shaft fractures are unable to bear weight or lift their foot off of the cart. Patients with fibular fractures alone are often able to bear weight.

Simple anteroposterior and lateral x-rays of the leg that include the knee and ankle are sufficient to evaluate leg injuries. If ankle or knee injuries are suspected, then further x-ray evaluation is needed. If a tibial shaft fracture is suspected, the leg should be splinted with a radiolucent device to control pain and prevent further soft tissue damage prior to obtaining films. Check pulses, movement, and sensation before and after moving the leg.

Detailed attention to soft tissue injuries is critical to treating lower leg injuries properly. Often it is the extent of such injury, rather than the fracture itself, that determines the outcome. Wounds should be cleansed and debrided of loose tissue and foreign material. Tetanus immunization should be given, if indicated. Splinting of fractures will prevent further damage to soft tissue caused by movement of the sharp bone fragments. Carefully palpate the compartments to detect any possible compartment syndrome. If suspected, inform the consulting surgeon so that appropriate priorities can be set in the management of the injury. Parenteral antibiotics should be administered in open-fracture cases.

COMPLICATIONS

Wounds that are not adequately cleansed and debrided are very prone to infection, an event not preventable by the use of antibiotics alone. Patients with compartment syndromes may develop permanent disability if the syndromes are not suspected or diagnosed. Fractures that are not adequately aligned or immobilized heal poorly or not at all. If a vascular injury is not urgently repaired, amputation can result.

SPECIFIC INJURIES

Fibula Fractures

Most fibular shaft fractures occur in the setting of a tibia fracture, in which case, treatment and expected outcome are determined by the injury to the tibia. Isolated fibula fractures usually result from a direct blow. They are relatively uncommon. Because this bone only bears 15 percent of the body weight, patients are often able to walk despite the fracture. Proximal fibula fractures are often the result of external rotation, whereas distal fibula fractures usually result from internal rotation. A low velocity injury leading to a fibula fracture can be treated with immobilization using elastic wrap (distal fibula) or a knee immobilizer (proximal fibula). More impressive pain and disability can be treated with crutches and casting, or splinting. Nonunion is uncommon.

Repetitive trauma, particularly in runners beginning their training, may result in a stress fracture of the distal fibula. Radiographs in stress fractures are often normal initially, with a fracture being detected ei-

ther by bone scan acutely, or by repeat x-ray 1 to 2 weeks after the event. Pain medication, cessation of the causative activity, and ice and elevation are recommended.

Tibia Fractures

A significant amount of force must be applied to the tibia in one of three ways for a fracture to occur. A torsional injury occurs when the body rotates on a planted foot. This low-energy force often results in a spiral fracture. A bending force on the tibia often produces a transverse or short oblique fracture line. Direct force, such as a crush injury, may result from a blow from a baseball bat. The scant amount of tissue between the tibia and the skin results in little protection of the shaft from direct blow.

The goal of treatment of tibial fractures is to avoid infection, obtain bony union, and restore function. Most closed fractures that are minimally displaced can be treated with reduction and immobilization by an orthopedist. If pain control is adequate, and the patient reliable, discharge from the emergency department to home is possible. Injuries with more than minimal displacement require orthopedic evaluation for reduction and immobilization of the fragments. Patients often require admission for pain control, further fracture care, and observation for the possibility of compartment syndrome.

An open fracture of the tibial shaft requires prompt consultation by an orthopedist while the other associated injuries are addressed. The management and expected outcome of an open tibia fracture is determined by a number of factors. Wounds with small lacerations (< 1 cm), minimal muscle contusion, and simple transversal fracture lines have <5 percent incidence of infection, and generally heal within 20 weeks. Injuries that involve more extensive soft tissue damage to the muscle, skin, and vascular system from crush injuries or high-velocity violence have up to 25 percent infection rate, and take up to twice as long to heal. Severe injury may result in amputation. Thus, factors that assist in the evaluation of the patient with an open tibial shaft fracture include (1) general health of the patient and presence of other injuries; (2) pattern of fracture line; (3) number of fracture fragments; (4) whether the fibula is intact or fractured; (5) extent of soft tissue damage; (6) amount of contamination of the wound; and (7) presence of vascular compromise.

ED evaluation of open injuries includes prompt immobilization of the fractured extremity, along with sterile coverage of the wound. Often this must be done in conjunction with the care of the other injuries the patient has sustained. Intravenous antibiotics should be administered in the emergency department. This may be first-generation cephalosporin for low-energy injuries without significant soft tissue damage. More severely injured extremities may benefit from broader coverage, such as that offered by ticarcillin-clavulanate. Treatment includes prompt irrigation and debridement of the wound in the operating room.

Achilles Tendon Rupture

When the soleus and gastrocnemius muscles contract, the Achilles tendon pulls up the calcaneus, plantar flexing the foot. Rupture often occurs in sports settings, especially in poorly conditioned players. Forceful plantar flexion results in rupture of the tendon. A popping sound is heard by the patient, who then has difficulty ambulating. This injury is also likely to occur in individuals who have rheumatoid arthritis, lupus erythematosus, have received quinolone antibiotics, or prior steroid injection of the tendon.²³ It frequently ruptures 2 to 6 cm above its attachment to the calcaneus, where it has its poorest vascular supply. A gap may be palpated at this point, and a dent may be visible. Achilles tendon function should be checked when patients complain of injuries to the ankle or heel. The Thompson-Doherty test is performed by squeezing the midportion of the calf of the patient lying in the prone position. An intact Achilles tendon is demonstrated by a plantar flexion

of the foot. Another test is to have the patient walk on his or her toes. The diagnosis does not usually require imaging, but ultrasonography, computed tomography, or magnetic resonance imaging can be helpful in ambiguous cases. In the emergency department, the patient should be splinted in neutral position with a Robert Jones splint, with prompt referral to an orthopedist. Crutches will be needed for ambulation.

Gastrocnemius Rupture

The medial head of the gastrocnemius is frequently injured during athletic events. A forceful plantar flexion of the foot, often with an extended knee, results in partial tear or rupture of the medial head of the gastrocnemius near its origin on the distal femur. This may be the result of a fall on a plantar-flexed foot or the sudden plantar flexion that occurs in the back leg of an athlete serving a tennis ball. Predisposing factors include inadequate stretching, prior muscle injury, and advanced age.

The athlete feels a sudden sharp pain on the medial aspect of the proximal gastrocnemius. It is painful to ambulate and plantar flexion is uncomfortable. On examination, the proximal medial calf is tender, and may be swollen and bruised. Walking on tiptoes is possible, but uncomfortable. The history is similar to that of Achilles tendon rupture, but the pain and tenderness are more proximal, and the Thompson test is negative in patients with gastrocnemius muscle rupture. Rupture of a Baker cyst should also be considered in the diagnosis, along with deep vein thrombosis.

Treatment typically consists of immobilization with a posterior splint, crutches for ambulation, ice, and pain medications. A mild rupture may be treated simply with rest and non-weight bearing.

Shin Splints

The term *shin splints* describes pain over the medial or anterior tibia that occurs with exertion and is relieved by rest. The cause is microtears of the muscular fibers at their point of bony attachment. Pain is often described as burning during running, or aching after exercise is completed. The only physical finding may be tenderness to the anterior or medial tibial surfaces. Radiographs may be useful to detect a stress fracture of the tibia, but a bone scan is more sensitive to diagnose stress fracture. Treatment of shin splints consists of cessation of the offending activity, orthotics to decrease excessive pronation, and strengthening and flexibility programs.

Osgood-Schlatter Disease

This lesion is typically seen in athletic teenagers of both genders. Football, soccer, basketball, gymnastics, and ballet can cause this injury. The anatomic lesion is the partial separation of the tibial tuberosity at the insertion of the patellar tendon. In about one-fourth of cases, it is a bilateral process. Palpation of the tibial tuberosity reveals tenderness and induration. A lateral x-ray of the proximal tibia with the knee flexed 30 degrees reveals an elevation of the distal portion of the tubercle off of the tibia. Alternatively, ultrasonography can be used for diagnosis. Cold compresses, anti-inflammatory drugs, and stopping the offending activity is standard treatment. Follow-up with an orthopedist is advisable for this sometimes chronic condition.

ANKLE INJURIES

John A. Michael Ian
G. Stiell

EPIDEMIOLOGY

Injuries to the ankle are a common presenting complaint in EDs. Most patients are younger than 40 years and are equally distributed between males and females. Fractures, most commonly of the lateral malleolus, are seen in 15 percent of these patients.^{1,2} For patients younger than 50 years, fractures are more common in men; for those older than 50 years, fractures are more common in women. Fracture-dislocations are more common in women.

ANATOMY

The ankle joint bears the weight of the body. An understanding of ankle injuries depends not only on a thorough knowledge of the anatomy of the joint but also on the mechanism of force that caused the injury.

The proximal part of the joint, or mortise, is comprised of the distal fibula and the tibia. This part fits on top of the talus, or plafond, the distal part of the joint. These three bones are bound together by three groups of ligaments. Bony stability is provided by the medial and lateral malleoli extending over the plafond. Ligamentous stability is provided by the lateral ligament complex, the medial deltoid ligament, and the syndesmosis. The lateral malleolus is attached to the anterior and posterior aspects of the talus and to the calcaneus, respectively, by the anterior talofibular, posterior talofibular, and the calcaneofibular ligaments. The medial collateral or deltoid ligament is a thick triangular band of tissue that originates on the medial malleolus. The superficial fibers insert on the navicular, the sustentaculum of the calcaneus, and the talus, and a deep set of fibers inserts on the medial aspect of the talus. The syndesmosis is a group of four distinct ligaments that attach the distal fibula to the tibia just above the plafond (Figure 276-1).

The ankle joint is sometimes described as having a range of motion in only the plantar and dorsiflexion plane; however, a small degree of medial and lateral movement does occur. The four groups of muscles that serve the ankle joint are supplied by branches of the sciatic nerve. Dorsiflexion is accomplished by tibialis anterior, extensor digitorum longus, and extensor hallucis longus muscles that run over the anterior aspect of the joint. On the medial side of the joint, the tibialis posterior, flexor digitorum longus, and flexor hallucis longus run behind the medial malleolus and contribute to inversion of the joint. Laterally, running behind the distal fibula, the peroneus and brevis muscles contribute to eversion and plantar flexion. These two peroneal tendons share a common synovial sheath that is held in place by a groove on the posterior aspect of the lateral malleolus and the superior retinaculum. Plantar flexion is provided by the soleus and gastrocnemius muscles. The blood supply of the foot is served by branches of the popliteal artery.

Almost all injuries of the ankle joint are due to an abnormal motion of the talus within the mortise. Motion of the talus causes a stress on the malleoli and the ligaments, thus causing injury. If the injury allows shifting of the position of the talar dome within the mortise, then the injury has the potential to be unstable. Fractures above the plafond may be unstable, and injuries that cause disruption on both sides of the joint are unstable. Instability can result from a fracture of a malleolus and rupture of a ligament, fracture of both malleoli, or rupture of both ligaments. The definition of instability is usually made radiographically, because it is difficult to make a satisfactory functional examination in an acutely injured ankle. Essentially, if there is an asymmetry in the gap between the talar dome and the two malleoli on the talus view of the ankle, then the injury is presumed to be unstable (Figure 276-2).

FIG. 276-1. Anatomy of the ankle joint.

EVALUATION

History

Although knowledge of the mechanism of the injury is important, many patients cannot recollect the exact movement that caused the injury. The classification systems used to describe ankle injuries use the direction of the deforming force to describe the potential injury. This information is useful, but, to emergency physicians, the circumstances surrounding the injury are of greater importance in consideration of other injuries. The potential for associated injuries is greater in an individual who has jumped from a 12-ft fence than in a basketball player who came down on one foot from a hoop jump. Likewise, an elderly woman is more likely to have a second injury when she trips on a curbstone and falls to the pavement on an outstretched hand. The treatment of patients who have chronic medical conditions, such as diabetes or peripheral vascular disease, which can cause sensory deficits, or who

FIG. 276-2. X-ray of widened mortise.

are on chronic immunosuppressive therapy has to be approached with caution. A normal-appearing ankle or minimal tenderness on examination does not exclude the necessity of further evaluation. The ability to bear weight immediately after an injury, with subsequent increase in pain and swelling as the patient continues to ambulate, suggests a sprain rather than a fracture. The time of the injury and previous bony or soft tissue injuries to the ankle need to be documented.

Physical Examination

Once significant swelling has taken place, the examination of the ankle becomes more difficult. This difficulty may be temporized in the busy ED by the application of ice at triage and getting the patient to elevate the foot. Although tempting, the patient should not be examined in a wheelchair, but on a stretcher.

It is critical to examine the joint above and below the injury. Note the position, swelling, and skin integrity of the injured ankle. Ask the patient to plantar and dorsiflex the ankle actively and then put the ankle through a passive range of motion. Soft tissue injuries are more likely when there is a significant difference between the passive and active ranges of motion.

Palpate the area of obvious injury last: Hurt the patient initially and any cooperation will rapidly diminish. Tenderness of the knee, the fibular head, or the proximal fibular shaft suggests a fibulotibialis ligament tear or a Maisonneuve fracture. Compress the fibula toward the tibia just above the midpoint of the calf to exclude clinically an isolated syndesmotic sprain. Starting at least 6 cm proximally, palpate the posterior aspects of lateral and medial malleoli to the distal tips of the shaft.

Examine the Achilles tendon. If there is tenderness or a defect, perform the Thompson test. With the patient prone on a stretcher, squeeze the calf; loss of plantar flexion indicates a complete rupture of the tendon.

Palpate the midfoot and hindfoot over the calcaneus, the tarsals, and the base of the fifth metacarpal. Patients can complain of an ankle injury when they have actually injured the foot or the Achilles tendon. Injuries to these structures are not excluded with the three-view ankle series.

Perform a neurovascular examination, which includes palpation of the dorsalis pedis and posterior tibial pulse and capillary refill. Check the foot for motor and sensory impairment. If the patient cannot plantar flex the great toe, suspect a peroneal nerve injury; if the patient cannot dorsiflex the toes, then suspect a tibial nerve injury. These nerves are rarely injured in ankle injuries. Ask the patient to walk four steps; if the patient can transfer weight from one foot to the other and the findings on physical examination as outlined above are normal, the likelihood of a significant fracture is nil.

IMAGING

The Ottawa Ankle Rules have provided a significant advance in the evaluation of ankle injuries in the ED. Previous studies suggested that not all patients who present to the ED need radiographs.³ The Ottawa Ankle Rules were derived from an initial series of studies^{4,6} and then were prospectively validated.^{17,18} These studies involved more than 9000 patient encounters and 200 emergency physicians. Two other studies by the same group found the implementation of the rules to be cost-effective and that, once taught, emergency physicians continue to use them.^{9,10} Although these studies were carried out in eight academic and community EDs in Canada, other studies at independent sites in the United States,^{11,12} the United Kingdom,¹³ and France² have validated their use. In addition, it has been demonstrated that nurses at triage can apply the rules successfully.^{11,13} Only two studies failed to replicate these results,^{14,15} but these studies were found to have a flawed methodology or did not accurately assess the rules as developed.

The rules are simple to apply and are illustrated in Figure 276-3. The rules can be used on patients with an injury to the ankle, which is clinically broadly defined as the area of the distal leg and the midfoot

subject to twisting injuries. Mechanisms of injury include twisting, direct blunt trauma, and falls. **The Ottawa Ankle Rules were not developed for patients younger than 18 years.** Clinical judgment should prevail if the examination is unreliable due to lack of cooperation, intoxication, distracting injuries, or a diminished sensation in the leg. To assess the ability to bear weight, ask the patient to take four steps. If the patient can complete two transfers to the injured ankle, then the patient passes the test.

Various objections that have been raised in the United States to applying these rules include, but are not limited to, the malpractice potential of missing any fracture, however insignificant; the patient's expectation of a radiograph and perception of a full assessment; and the physician's perception that the proportion of patients with fractures who present with ankle injuries is higher in the United States. Communication with the patient, such as an explanation of the thoroughness of the clinical examination, and the fact that a chip fracture, if missed, is treated like a sprain, is often effective. The saving of time and money for the patients should help them to accept the completeness of the evaluation. In addition, studies done in the United States showed a similar 15 percent fracture rate as demonstrated in Canada, the United Kingdom, France, and Scandinavia.

An excellent review of radiologic subtleties in the diagnosis of extremity injuries is found in Weissman.¹⁶ The use of computed tomography and magnetic resonance imaging in the assessment of ankle injuries, although useful, is not a common practice in the ED.

INJURIES, TREATMENT, AND PROGNOSIS

Soft Tissue

LIGAMENTOUS SPRAINS

Lateral Ligament Complex Sprains of the lateral ankle are the most common ankle injury, and most are minor. The classification systems for ligamentous injuries to the lateral ankle are quite confusing. Older texts described a purely anatomic classification scheme, whereas more recent articles described a more functional system. These two classification systems are probably of little value to emergency physicians. A much more useful approach divides the injuries into two groups: stable and potentially unstable or unstable.¹⁷ If stress testing can be accomplished in the ED and the findings are normal, then the patient has a stable lateral ankle sprain and can be so treated. If results on stress testing are clearly abnormal or indeterminate because of excessive swelling or pain, then the sprain should be treated as unstable.

Treatment of lateral ankle sprains has been controversial. However, a review of more recent literature included some fairly well-performed prospective studies.^{18,21} Most of these studies treated patients with grade 2 or 3 ankle sprains with compression, rest, and cryotherapy for 24 to 72 h. They then usually compared two treatment groups: (1) weight bearing with an ankle brace that allows plantar-dorsiflexion while resisting inversion and (2) eversion and plaster immobilization for up to 6 weeks. Patients in the early-mobilization groups returned to work or sport earlier than did the immobilization groups, but at late follow-up there were no differences in outcomes. In addition, direct comparisons of operative repair with cast, cast alone, and early controlled mobilization of acute grade 3 ankle sprains suggested no difference in long-term outcome.²²

The data indicate that individuals with stable and unstable ankle sprains, who are unable to bear weight easily, should be treated with rest, ice, compression, and elevation (RICE) for 24 to 72 h, depending on the amount of swelling and degree of pain. Individuals who can easily bear weight and have a stable joint probably need no more than simple analgesics and an elastic bandage, near-normal activity with no sports involvement or prolonged walking, and follow-up in 1 week if

FIG. 276-3. Ottawa Ankle Rules for ankle and midfoot injuries.

they still have discomfort. Patients who are unable to bear weight in the ED but appear to have a stable joint can be given an ankle brace and be told to apply it in 24 to 72 h and to follow up with their primary care physician or orthopedist within 1 week for a repeat evaluation. Patients who clearly have an unstable joint should be referred to an orthopedic surgeon, with consideration of a posterior mold. Timing of consultation depends on local preferences, but it would be prudent to establish communication early, because the ultimate decision on the method of treatment lies with the orthopedic surgeon.

Medial Ligament Complex An isolated sprain of the deltoid ligament is rare and usually associated with a fibular fracture or significant tear of the tibial-fibular syndesmosis resulting from an eversion stress. When there is significant medial malleolus tenderness and swelling, Maisonneuve fracture is suspected, and careful attention should be paid to the proximal fibula and fibular shaft. If the radiographs of the ankle and the fibula are negative, then a significant syndesmosis tear should be suspected. Patients with this type of injury should be treated with RICE and early referral to an orthopedist.

Tibiofibular Syndesmotic Complex These injuries are usually associated with a hyperdorsiflexion injury. The talus moves in a superior direction and separates the fibula and tibia, resulting in a partial or complete rupture of the syndesmosis. Patients usually complain of pain just above the plafond. These are significant injuries with prolonged recovery time and should be treated with RICE and early consultation. An excellent review of deltoid ligament, syndesmosis, and other "atypical ankle sprains" can be found in the work by Clanton and Porter.¹⁷

PROGNOSIS OF LIGAMENTOUS INJURIES The long-term complications of ankle sprains include functional instability (a subjective sensation of giving way without mechanical instability), mechanical instability (a demonstrable laxity), chronic pain, stiffness, and recurrent swelling. The documented incidence of complications is highly variable, from 6 to 40 percent.¹⁹ The long-term sequelae can be reduced with early rehabilitation. Physical therapy should be directed initially at active and passive range-of-motion exercises followed by early mobilization, strengthening exercises, proprioceptive training, and restoration of normal activity.

STRAINS AND CONTUSIONS Strains are injuries to muscles or tendons and usually are not associated with a specific injury but rather are due to repetitive stress. The stress can be due to overuse secondary to athletic activity or to poorly fitting footwear. Treatment includes simple analgesics (anti-inflammatory medications may be beneficial), rest, identification and correction of provocative factors, and specific rehabilitative exercises. Contusions are usually caused by direct trauma, typically from a baseball or a hockey puck. Fractures are rare and usually are of the bone cortex only. Treatment is symptomatic with simple analgesics and ice.

PERONEAL TENDON SUBLUXATIONS AND DISLOCATIONS These injuries can be easily misdiagnosed as lateral ankle sprains. The mechanism is described by a sudden hyperdorsiflexion of the foot while the peroneal tendons are taut in eversion. This injury most often is associated with skiing. The superior retinaculum holding the peroneal tendons in place is stripped off the posterolateral malleolus. In more severe injuries, a small avulsion fracture is noted on a radiograph, and the peroneal tendons dislocate or, more often, sublux anteriorly over the distal tip of the fibula. Consider this injury when tenderness and ecchymosis over the posterior edge of the lateral malleolus are noted in the absence of tenderness over the anterior talofibular ligament. It is important to consider this diagnosis in the acute setting; the treatment is frequently operative repair of the retinaculum.¹⁷

ACHILLES TENDON RUPTURES These injuries are most common in sedentary males engaging in a weekend of sporting activity and are a result of sudden plantar flexion of the foot. Treatment is individual, although the tendency is toward operative repair of the tendon in individuals who want full return to all activities.

Fractures and Dislocations

CLASSIFICATION SCHEMES There are multiple classifications of ankle fractures. The more complex use the position of the foot at the time of injury and the deforming force. These classifications are useful in predicting associated injuries. In the Lauge-Hansen classification system, the first word refers to the position and the second word refers to the force. The Danis-Weber classification is based on the level of the fracture of the fibula. Proximal fractures of the fibula are associated with damage to the syndesmosis and the increased likelihood of an unstable fracture. There are three types of injury in this classification scheme: type A (fracture of the fibula below the syndesmosis) is a supination injury and corresponds to the Lauge-Hansen type of supination and adduction injury; type B (fibular fracture at the level of the syndesmosis) is associated with an external rotation force and corresponds with the supination and eversion injury of Lauge-Hansen; and type C (fibular fracture above the syndesmosis) is associated with an external rotation and abduction force and corresponds with the pronation and eversion or abduction Lauge-Hansen injuries. The AO classification system amplifies the Danis-Weber system by subdividing each classification type into three subtypes to better describe associated medial injuries. The simplest classification system is based on radiographic appearance. This scheme is commonly employed and uses the terms *unimalleolar*, *bimalleolar*, and *trimalleolar* to describe fractures of the ankle.

Although it is important to have a basic understanding of these classification systems, the most essential aspects of ankle injuries to appreciate is the stability of the injury and the exclusion of associated injuries (Table 276-1).

TREATMENT All fractures of the ankle, with the exception of fibular avulsion fractures, require immobilization by cast alone or surgical reduction with subsequent casting. **Avulsion fractures are treated as stable ankle sprains if they are minimally displaced, smaller than 3 mm in diameter, and there is no indication of a medial ligamentous injury.** The treatment goal with all other ankle fractures is to restore the anatomic relationship of the ankle, maintain reduction during the healing process, and institute early mobilization of the ankle. To obtain these goals, the talus has to be anatomically positioned in the mortise, the joint line has to be parallel to the ground, and the articular surface has to be smooth. The means to attain this goal depends not only on the type of fracture but also on the age and athletic expectations of the patient. Local preferences also may play a role in this decision. Most fractures, with the exception of unimalleolar injuries, require open reduction and fixation. The Maisonneuve fracture (AO types C2 and C3), although considered an unstable injury, can generally be treated with cast immobilization for 6 to 8 weeks, depending on the stability of the syndesmosis.¹⁵ The Bosworth fracture, a rare variation of the Maisonneuve fracture in which the proximal fibula gets trapped behind the tibia, usually requires operative reduction. The debate over the necessity of operative treatment for unimalleolar fractures with associated syndesmosis and deltoid ligamentous injuries is complex and beyond the scope of this chapter. Stable fibular fractures are treated with a short leg-walking cast for 6 weeks.

The timing of consultation is discussed below. In the interim, fractures should be splinted with a posterior mold and kept non-weight bearing in all cases and elevated with application of ice in many cases. The analgesic need of the patient should be addressed. There is absolutely no basis for the practice of withholding analgesics until operative consent is obtained.

TABLE 276-1 Associated and Occult Injuries of the Ankle

Injury	Clinical Suspicion	Confirmatory Test
Important to identify in the ED		
Fracture of base of fifth metatarsal	Examine lateral foot, tenderness to palpation	Anteroposterior foot radiograph
Maisonneuve fracture	Examine proximal fibula and shaft, tenderness to palpation	Fibula radiograph
Peroneal tendon dislocation	Palpable anterior tendon dislocation or subluxation	Clinical examination
Usually identified in follow-up of ankle sprains		
Osteochondral injuries	Diffuse ankle swelling, passive plantar flexion	Ankle mortise view/CT
Syndesmosis tear	Significant ankle pain, positive squeeze test	Widened mortise with weight bearing
Anterior calcaneal process fracture	Tenderness more inferioanterior than a typical ankle sprain	Lateral ankle radiograph/CT
Lateral talar process fracture	Tenderness just distal to the tip of fibula	Ankle mortise view/CT
Os trigonum	Tenderness anterior to Achilles tendon	Lateral ankle radiograph

Abbreviation: CT = computed tomography.

OSTEOCHONDRAL FRACTURES Osteochondral fractures are due to acute trauma or repetitive stress. These injuries vary from a deformation of the cartilage overlying the talar dome to a free-floating avulsion fracture. The staging and treatment of these lesions are complex, and orthopedic consultation is required. Treatment can involve excision or cast immobilization for up to 6 weeks.¹⁷

PROGNOSIS OF ANKLE FRACTURES Early complications and sequelae of ankle fractures are several and include skin necrosis and osteomyelitis in the short term and chronic pain, osteoarthritis, malunion, nonunion, and reflex sympathetic dystrophy in the long term. Although most of these problems are rare, postreduction arthritis can complicate up to 30 percent of fractures.

FRACTURE-DISLOCATIONS AND OPEN FRACTURES Dislocations of the ankle joint can occur in one of four planes and are frequently associated with a fracture. The posterior dislocation is most common and happens usually when the foot is plantar flexed and a backward force is applied. The injury is usually associated with rupture of the tibiofibular ligaments or fracture of the lateral malleolus. The anterior dislocation occurs with a dorsiflexed foot and fracture of the anterior aspect of the tibia. Lateral displacement is accompanied by ligamentous disruption and fracture of either or both malleoli. The talus can be displaced upward with a significant impaction. There will be an associated fracture of the talar dome or tibial plafond and disruption of the syndesmosis.

Patients with fracture-dislocations of the ankle are at considerable risk of neurovascular compromise and conversion of a closed fracture to an open one. Under most circumstances, the reduction of fracture-dislocations is left to an orthopedic surgeon. However, if there is vascular compromise, indicated by absent pulses and a cool dusky foot or tenting of the skin caused by fractured bone, the emergency physician should perform the reduction. Do not delay reduction to obtain radiographs. If possible, place the patient on the stretcher, with the affected foot hanging over the side with a flexed knee. This position forces the leg into external rotation and the foot into internal rotation. It also gives the physician the advantage of gravity. Administer adequate intravenous analgesia with the appropriate cardiorespiratory monitoring. The heel and foot should be grasped with both hands (with an assistant stabilizing the proximal leg), and downward traction and rotation should be applied in the opposite direction of the mechanism of the injury. Little force is required. A splint is applied once distal perfusion is restored and the foot is again elevated. Irreducible fractures are quite rare and, of course, require open reduction.

Protect open fractures from further contamination by applying a wet, sterile dressing over the wound with a gauze roll. No studies have substantiated the application of Betadine-soaked gauze to the laceration

site. Splint the injury until radiographs and definitive treatment are available. Tetanus-diphtheria toxoid is given as necessary, and tetanus immunoglobulin is considered if the wound is grossly contaminated. The antibiotic of choice is cephalexin, and an aminoglycoside is added if the wound is grossly contaminated. Consider clindamycin for patients with penicillin allergy.

TIMING OF CONSULTATION

No set of rigid rules for the timing of orthopedic consultation exists to guide emergency physicians for specific ankle injuries. Although it may be reasonable to request an in-person orthopedic consultation in an academic center at 3 o'clock in the morning for a stable ankle fracture, this will not endear a community-based emergency physician to his or her orthopedic colleagues. Although it may be perfectly acceptable for an emergency physician in some countries to apply a circular short leg cast to an AO type A1 fracture and arrange follow-up, this approach would not be common practice in other locales (Table 276-2).

EMERGENCY DEPARTMENT TREATMENT ISSUES

Pharmacotherapy

The need for analgesia should always be addressed. Because individual perception of pain varies, a simple ankle sprain may require only an elastic bandage or acetaminophen in most patients, whereas some will require oral narcotics. **Studies have suggested that there is no benefit of using nonsteroidal anti-inflammatory drugs in the treatment of ankle fractures.**²³ Patients who are in significant distress or who should be kept nonoral because of anticipated surgery require parenteral analgesia.

Immobilization

Noncircular cast immobilization can be accomplished with a Jones bandage or a posterior mold.

A Jones bandage has more padding and probably is more comfortable for patients with severe bruising and swelling, but may not accomplish the same degree of immobilization as a posterior mold. The patient should be supine on a stretcher. Apply two to three layers of abdominal pads, extending from the distal foot to just below the knee, and hold the pads in place with 4-in. elastic bandages. A 4-in. cotton cast padding can be applied, in place of the abdominal pads, in a circular fashion overlapping by at least 50 percent with a minimum of three complete layers. The Jones bandage should not be used for more than a couple of days.

A posterior mold is most easily applied if the patient is prone on a stretcher with the knee flexed to 90 degrees. Most EDs have prepack-

TABLE 276-2 Timing of Consultation

Immediate Consultation in ED	Deferred Consultation*	Within 1 Week
All open fractures	Stable unimalleolar fractures	Potentially unstable sprains
All fracture dislocations	Unstable ligamentous injuries	
All dislocations	Acute peroneal dislocations	
All trimalleolar fractures!	Pediatric Salter I, II	
All bimalleolar fracturesf		
Unstable unimalleolar fracturesf		
Pediatric Salter III, W, Vf		
Maisonneuve fractures"!!		

*Implies that communication is established at time of diagnosis and specific time of consultation has been set.
tConsultation can be delayed in the ED in fractures without neurovascular compromise and appropriate splinting.

aged padded splint material available. For extra padding, apply a single layer of 4-in. cotton cast padding from the toes to the knee, followed by the fiberglass splint (Figure 276-4). If more support is required, especially in the setting of an unstable joint, another slab can be added to provide additional medial and lateral support.

Size the patient, if necessary, for crutches and instruct in their appropriate use. For a weight-bearing patient, a cast shoe can be applied.

Ankle Braces and Cast Boots

Several different ankle braces (which allow dorsoplantar flexion but do not allow inversion or eversion of the ankle) are available. These devices vary from complex applications of athletic tape to lace-up splints and inflatable plastic stirrup-type braces (see Chap. 267). Although few studies have compared these braces, it is clear that any device that speeds mobilization and weight bearing will promote early return to full function.^{2,19} A recent useful addition is the cast boot. This appliance, which resembles a ski boot, is easily applied and molds to the joint by inflatable air bladders. It can be used with significant ankle sprains, nondisplaced metatarsal fractures, and stable ankle fractures.

FIG. 276-4. Short-leg posterior splint without (A) and with (B) a stirrup splint.

Cryotherapy and Other Modalities

Ice packs have been shown to limit swelling and decrease pain. The pack is applied directly to the ankle or the splint and is left on for 20 min at a time. It can be repeated every few hours. Ultrasound has not been shown to promote healing.²⁴

FOOT INJURIES

John A. Michael Ian
G. Stiell

The foot is a complex, highly evolved structure that bears the weight of the body and acts as a lever to propel the body forward while walking or running. It is designed to carry the body over varied terrain with little apparent difficulty. Although most injuries are minor and heal with time, undertreated and unrecognized injuries can result in significant long-term pain and disability. Radiographs are sometimes difficult to interpret, and seemingly minor abnormalities can be associated with a significant injury.

ANATOMY

Chopart and Lisfranc joints divide the foot into three regions. The talus and the calcaneum comprise the hindfoot. The midfoot contains the cuneiforms, the cuboid, and the navicular. The metatarsals and the phalanges make up the forefoot (Figure 277-1). The foot consists of 28 bones and 57 articular surfaces. Numerous intrinsic muscles and ligaments contribute to the integrity of the foot's structure. The biomechanical specifics of the foot involved in ambulation are extremely complex. In general, eversion and inversion occur about the subtalar and calcaneus tarsal joints, whereas adduction and abduction and flexion and extension occur about the metatarsophalangeal and interphalangeal joints, respectively.

The body weight when standing is distributed about the heel to the rear and the five metatarsal heads to the front. The curved shape of the foot is held in position by three arches. The shape of the bones, the arrangement of the ligaments, and the tone of the muscles maintain the position of the arches. The plantar aponeurosis covers the sole of the foot and is a strong band of fascia that originates on the medial side of the calcaneum and fuses with the fibrous sheaths of the phalanges.

The blood supply of the foot comes from branches of the popliteal artery. The anterior tibial artery serves the dorsum of the foot, and its branch, the dorsalis pedis, can be palpated over the dorsum of the midfoot. Branches of the posterior tibial and the peroneal arteries serve the sole. The motor and sensory nerves of the foot include branches of the femoral and sciatic nerves and include branches of the saphenous, sural (sensory), and deep and superficial peroneal nerves (sensory and motor) (see Figure 267-1B).

The essential parts of the anatomy of concern include, but are not limited to, the following. The first metatarsal bears twice the weight as any other metatarsal, and injuries to this bone require a more conservative approach. The blood supply to the foot is tenuous, and major fractures of the talus and subtalar dislocations are complicated by avascular necrosis. The base of the second metatarsal is the "keystone"

FIG. 277-1. Bony anatomy of the foot.

of the Lisfranc complex, and any injury to this area has to be carefully evaluated.

EVALUATION

History

As with all injuries, it is important to obtain an adequate history. Many injuries to the foot are associated with significant forces or falls from a height, and other injuries have to be sought. In general, most foot injuries are caused by direct or twisting forces. Twisting forces are associated with avulsion-type injuries and are generally more minor than the injuries caused by direct trauma. Previous injuries, general medical condition, and repetitive mechanisms are important to elicit from the patient. Increasing inability to ambulate after an injury and increasing pain may be suggestive of a minor sprain or of an impending vascular catastrophe. Special care should be paid to puncture wounds. Consider the type of shoes worn, the possibility of a foreign body, and the potential of tetanus.

Physical Examination

Elevation of the foot and the application of ice at triage will facilitate the physical examination. The patient should be examined on a stretcher. Examination of the foot includes an ankle examination (see Chap. 276, "Ankle Injuries"). The foot should be inspected for any loss of skin integrity, deformity, and swelling and ecchymosis. Passive range of motion should be assessed and compared with the uninjured foot. Palpate the Achilles tendon, the calcaneum, the dorsum of the midfoot, and then the metatarsals and phalanges. Pay special attention to the base of the fifth metatarsal and the area over the base of the second metatarsal. Actively move the various joints of the foot through their ranges of motion. Next, grasp two adjacent metatarsal heads and move them in opposite

dorsoplantar directions. If the foregoing examination does not suggest a specific injury, observe the patient ambulating. Normal findings on examination and the ability to complete several weight transfers to the injured foot essentially exclude a significant injury.

IMAGING

Patients with normal findings on examination of the hindfoot and forefoot and on examination of the ankle and midfoot (see Figure 276-3 for the Ottawa Ankle Rules) probably do not need radiographs. Clinical judgment should always prevail in the decision-making process. Abnormal findings on examination mandate a complete, three-view, standard foot series. If there is pain about the heel, an axial view of the calcaneum should be added. The lateral view of the foot and the axial view of the calcaneum are important in excluding hindfoot injuries, whereas the anteroposterior and oblique projections are more useful in delineating midfoot and forefoot injuries.

Other plain radiographic views, bone scans, and computed tomographic (CT) scans are seldom used by emergency physicians in the evaluation of foot injuries. Emergency physicians, however, occasionally should order CT scans of the foot to exclude a subtle diastasis (> 1 mm) at the Lisfranc joint.

INJURIES AND TREATMENT

Acute Soft Tissue Injuries

Puncture wounds are discussed in Chap. 46. Complicated foot infections, gunshot wounds to the foot, and many lawn mower injuries require consultation and/or operative debridement.^{1,2} The latter two open injuries require a careful search for associated vascular and tendon injuries, radiographs to document foreign-body presence and bony involvement, consideration of tetanus vaccine and immunoglobulin administration, aggressive wound irrigation, analgesics, and antibiotics in most cases. Do not rely on the presence of fever, abnormal radiographs, or elevated white cell counts and erythrocyte sedimentation rates to exclude the diagnosis of osteomyelitis.^{3,4}

TURF TOE Forced hyperextension of the first proximal phalanx causes a sprain or tear of the metatarsophalangeal joint capsule with dorsal subluxation. The injury is usually associated with repetitive push-off mechanism from a hard surface. The initial treatment is conservative, with analgesics and a supportive shoe to prevent further dorsiflexion. Orthopedic referral is needed for continued pain.

PLANTAR FASCIA RUPTURE This is a tear in the plantar fascia at the point of insertion on the calcaneum. Patients describe a sudden pop and pain that is usually associated with sudden plantar flexion of the foot. Treatment is nonoperative.

TENDON RUPTURES Acute ruptures of the tendons of the foot are rare and usually associated with penetrating or lacerating injuries. Extensor and flexor hallucis tendon injuries are repaired primarily. The treatment of other tendon transections is controversial.

CRUSH INJURIES AND COMPARTMENT SYNDROME Injuries caused by crush-type mechanisms without associated skin or bone injuries may appear innocuous. These injuries, however, place the foot at risk for the development of compartment syndrome. Compartment syndrome should be suspected when there is pain out of proportion to the injury. Typically, the foot is tensely swollen, and the pain is not relieved by elevation and is increased by passive dorsiflexion of the big toe. Paresthesias may be present, but pedal pulses and capillary refill are often preserved. If compartment syndrome is suspected, intracom-

partmental pressures must be measured. There are multiple compartments in the foot. The measure of pressure in these small compartments is technically difficult, and orthopedic consultation may be necessary to exclude this diagnosis. Immediate fasciotomy is required once the diagnosis is confirmed.

Fractures and Dislocations

HINDFOOT Talar fractures are uncommon. Minor avulsion fractures of the neck, body, and lateral process are usually treated with a posterior slab, crutches, and orthopedic follow-up. Os trigonum and transchondral talar dome fractures are difficult to identify in the emergency department and sometimes are diagnosed in the follow-up of "ankle sprains." Major fractures of the talar neck and body are associated with severe dorsiflexion and axial forces. These injuries often require open reduction and merit immediate orthopedic consultation. These fractures are frequently complicated by avascular necrosis.

Peritalar or subtalar dislocations are rare. In this injury, the calcaneus talar and talonavicular joints are disrupted, and the tibiotalar joint remains intact. Although the dislocation can occur in any direction, medial dislocation is by far the most common and is the result of a severe rotational-inversion force. These injuries require immediate orthopedic consultation and emergent reduction. Closed reduction sometimes can be accomplished by using conscious sedation in the emergency department, although frequently a general or regional anesthetic in the operating room is required.

An axial load to the heel, caused by a fall from a height, is the mechanism associated with most fractures of the calcaneum. These injuries are frequently associated with other injuries, most commonly vertebral column, forearm, and other lower extremity fractures. Fractures should be categorized as intra-articular or extra-articular.

Although the more common subtalar, intra-articular fractures are usually obvious on the lateral foot radiograph, some compression fractures may be subtle. When this injury is suspected by mechanism or examination, carefully examine the radiograph by using the measurement of Boehler angle. **If the angle is smaller than 20 degrees, suspect a fracture** (Figure 277-2). The criterion for open reduction of these fractures is controversial, with CT scanning playing an important diagnostic and preoperative planning role. Seek immediate orthopedic consultation. In the interim, apply a well-padded posterior splint, elevate the foot, and address analgesic needs. Comminuted fractures of the calcaneum can be extremely painful. **The incidence of compartment syndrome with these fractures is high.**

FIG. 277-2. Boehler angle is formed by two lines, one between the posterior tuberosity (A) and the apex of the posterior facet (B), and the other between the apex of the posterior facet (B) and the apex of the anterior process (C). An angle smaller than 20 degrees suggests a calcaneal compression fracture.

Extra-articular fractures are less common and usually associated with a rotational mechanism and an axial load. Included are fractures of the tuberosity, the sustentaculum tali, anterior process avulsion, and extra-articular oblique body fractures. Most nondisplaced fractures can be treated conservatively with a posterior slab, crutches, and early orthopedic consultation.

MID FOOT Isolated fractures of the navicular, cuboid, and cuneiforms are uncommon and difficult to identify on radiograph. Fractures of the navicular are most common and can involve the tuberosity, the dorsal surface, and the body. Isolated fractures of the cuboid and cuneiforms are extremely rare, and an associated injury to the Lisfranc joint should be sought. Most isolated injuries of the tarsal bones are treated conservatively.

The six-bone tarsometatarsal complex is known as the *Lisfranc joint*. Injuries to this joint are not uncommon, and unfortunately up to 20 percent of these injuries are missed in the emergency department.⁵ The plantar ecchymosis sign, a bruise on the plantar surface of the midfoot, is suggested as an occult sign of an injury.⁶ The force required and the mechanism of injury are varied and can range from a seemingly minor rotational force to a severe axial load, as seen in an automobile accident. The great majority of injuries to the Lisfranc joint are associated with fractures, usually of the metatarsals, the cuboid, or the cuneiforms. **A fracture of the base of the second metatarsal is pathognomonic of a disruption of the Lisfranc ligamentous complex** (Figure 277-3). The Lisfranc injury is classified by the direction of the dislocation. A divergent dislocation describes metatarsals splayed in medial and lateral directions, usually between the first and second metatarsals. In isolated dislocations, one or more metatarsals are displaced from the rest. In homolateral dislocations, all five metatarsals are displaced in the same direction, either laterally or medially. Suspect this injury if there is point tenderness over the midfoot or when there is laxity between the first and second metatarsals in a dorsal-to-plantar direction. Diagnosis is made radiographically on the anteroposterior view when there is a gap larger than 1 mm between the bases of the first and second metatarsals. Other radiographic signs

FIG. 277-3. Fracture of the base of the second metatarsal.

are loss of alignment of the medial edge of the base of the second metatarsal with the medial edge of the middle cuneiform on the anteroposterior or oblique view; loss of alignment of the lateral border of the third metatarsal shaft with the lateral border of the lateral cuneiform on the oblique view; or loss of alignment of the medial border of the fourth metatarsal with the medial border of the cuboid on the oblique view (Figure 277-4).⁵ Weight-bearing radiographs have been suggested to make the diagnosis, but recent studies have suggested that CT scanning is the imaging modality of choice.⁷ Injuries to the Lisfranc joint frequently require open reduction and fixation or percutaneous placement of Kirschner wires and non-weightbearing for several weeks. These injuries are complicated by dorsalis pedis artery damage in the short term and degenerative arthritis and chronic pain in the long term.

FOREFOOT Metatarsal fractures are associated most often with a crush or more occasionally with a twisting injury. Metatarsal fractures are divided into shaft and neck fractures. Nondisplaced shaft injuries are usually treated conservatively with a walking cast or an orthopedic shoe. An exception is a fracture of the first metatarsal shaft. Keep this injury non-weight bearing. Likewise, displaced shaft fractures of the middle metatarsals can be treated with closed reduction, followed by immobilization in a cast and non-weight bearing for 6 weeks. A displaced first metatarsal fracture often will require an open reduction and fixation. Metatarsal neck fractures generally follow the treatment of shaft fractures, but postreduction instability of displaced neck fractures is not uncommon, and open fixation is sometimes required.

Fifth metatarsal fractures are the most common of the metatarsal fractures. Shaft fractures usually can be treated conservatively, as above. **The Jones fracture is described as a transverse fracture through the base of the fifth metatarsal 10 to 20 mm distal to the proximal part of the metatarsal** (Figure 277-5). This fracture is fre-

FIG. 277-4. Radiograph of Lisfranc fracture with large gap between the bases of the first and second metatarsals and malalignment of the second, third, and fourth metatarsals with the middle cuneiform, lateral cuneiform, and cuboid, respectively.

FIG. 277-5. Radiograph of a Jones fracture.

quently complicated by nonunion or malunion and should be treated with a non-weight-bearing cast for 6 weeks. The "pseudo-Jones" is an avulsion fracture of the tuberosity of the base proximal to the articulation between the bases of the fourth and fifth metatarsals. It can be treated with a cast shoe (Figure 277-6).

Most nondisplaced phalangeal fractures can be treated conservatively with "buddy taping" and, occasionally, a cast shoe. Address the patient's analgesic need and arrange orthopedic consultation on a pro re nata basis. Advise against prolonged ambulation or standing in the first week. Displaced fractures can be manipulated into position by using a digital block and manual traction. Some investigators advocate open reduction of some displaced fractures, especially of the big toe.

Most dislocations of the forefoot involve the distal interphalangeal and posterior interphalangeal joints of the second through fifth toes.

FIG. 277-6. Fractures of the fifth metatarsal.

These injuries can be easily reduced by manual traction and treated with buddy taping, as needed. Dislocations of the big toe are rare, occasionally difficult to reduce, and require walking-cast immobilization for 3 weeks.

OPEN FRACTURES

Open fractures of the foot require immediate orthopedic consultation. In the interim, protect open fractures from further contamination by applying a wet, sterile dressing over the wound with a gauze roll. Splint the injury until definitive treatment is available. Consider tetanus immunoglobulin if the wound is grossly contaminated. The antibiotic of choice is cephalexin and add an aminoglycoside if the wound is grossly contaminated. Consider clindamycin for patients with a penicillin allergy. If there is going to be a significant delay to operative management, the wound should be irrigated.

TIMING OF CONSULTATION

Like ankle injuries, no set of rigid rules for the timing of orthopedic consultation exists to guide emergency physicians for each specific foot injury. In Table 277-1 a general guideline is set forth. Timing of consultation will vary with local preferences.

EMERGENCY DEPARTMENT TREATMENT ISSUES

Analgesia

The need for analgesia should always be addressed by the emergency physician. Because individual perception of pain varies, a fifth metatarsal tuberosity fracture may require acetaminophen and a cast shoe in most patients, whereas others will require hydrocodone or oxycodone with acetaminophen. Patients who are in significant distress, or who should be kept nonoral because of anticipated surgery, require parenteral analgesia.

TABLE 277-1 Timing of Consultation for Foot Injuries

Immediate Consultation in Emergency Department	Deferred Consultation*	Within 1 Week	PRN
All open fractures	Extra-articular calcaneus fractures	Avulsion fractures, calcaneus	Pseudo-Jones fracture
All fracture dislocations	First metatarsal fractures	Avulsion fractures, tarsal	Phalangeal fractures
Major talar neck and body fractures ^f	Displaced metatarsal shaft	Metatarsal fractures	Phalangeal dislocations
Intra-articular calcaneus fractures ^f	True Jones fractures	Pediatric metatarsal fractures	Soft tissue injuries
All Lisfranc injuries ^f	Tendon ruptures and lacerations	Ruptured plantar fascia	
Most gunshot wounds	Retained foreign bodies		
Suspected compartment syndrome			

*Implies that communication is established at time of diagnosis and that the specific time of consultation has been set.

^f Consultation can be delayed in the emergency department in fractures without neurovascular compromise and with appropriate splinting.

Immobilization

Most fractures of the foot can be splinted by a posterior slab or a Jones bandage (the appropriate method of application is discussed in Chap. 276, "Ankle Injuries"). Cast shoes, variably called orthopedic, Reece, or post-op shoes, are useful in splinting minor foot fractures when the patient is allowed to bear weight on the injured extremity. Cast shoes also can be applied over a posterior splint to allow weight bearing. Apply an appropriately sized piece of felt or cotton padding between the two phalanges when they are being buddy taped.

Cryotherapy

Ice packs have been shown to limit swelling and decrease pain.⁸

ures can be taken to reduce the pressures, thereby preventing nerve dysfunction or muscle death.

PATHOPHYSIOLOGY

Normal tissue perfusion is dependent on an adequate difference between arterial and venous pressures at the capillary level. When pressure within a compartment increases, tissue perfusion is compromised either by loss of vasomotor tone of the arterioles, or collapse of the thin-walled veins. When muscles become ischemic, histamine-like substances act locally to dilate the capillary bed and increase endothelial permeability. The resulting transudation of plasma causes erythrocyte sludging and a further decreasing of microvascular flow.

Elevated compartment pressure results from either extrinsic forces constricting the compartment (i.e., a circular cast that is too tight), or from an increase in the volume of the contents of the compartment. Compartment volume may increase secondary to a hematoma that has formed within a compartment, or may be due to edema accumulating after reperfusion of ischemic muscle after its vascular supply has been restored (Table 278-1).

Normal tissue pressure is about zero and usually less than 10 mm Hg. Capillary blood flow within the compartment is compromised at pressures greater than about 20 mm Hg, and muscle and nerves are at risk for ischemic necrosis at pressures greater than about 30 to 40 mm Hg. Of the tissues within the compartments, nerve is most sensitive, followed by muscle tissue.

Blood flow through arteries, arterioles, and collaterals is not compromised significantly at these pressures. Nevertheless, tissues within the compartment that are dependent on the nutrient capillaries become ischemic and then necrotic if the compartment pressure is not reduced promptly. By the time that distal pulses are reduced, muscle necrosis has occurred. Ischemic muscles hurt, and this pain is exacerbated by active muscle contraction and by passive stretching of the muscle.

COMPARTMENTS

A compartment is a structure made up of an outer perimeter dense enough to limit swelling within it. This perimeter is made up of a com-

COMPARTMENT SYNDROMES Paul R. Haller

Compartment syndrome occurs when tissue pressures in a confined space rise to the point of compromising perfusion. The resulting tissue hypoxia causes damage to the structures coursing through that compartment. Particularly susceptible to this ischemia are the nerves and muscles. Prolonged muscle hypoxia leads to necrosis and permanent posttraumatic muscle contracture: Volkmann's ischemia. The goal of the clinician is to diagnose elevated tissue pressures promptly so meas-

bination of bone and dense connective tissue such as interosseous membranes. Compartments in the body that have elastic enough borders to permit some stretching (such as the upper arm or upper leg) are less likely to undergo elevation of tissue pressures.

Upper Extremity

The upper arm has an anterior and a posterior compartment. The anterior compartment contains the biceps and brachialis muscles, and the ulnar, median, and radial nerves (Figure 278-1). The posterior compartment contains the triceps muscle. Fortunately, the compartments of the upper arm are relatively roomy, and compartment syndromes are uncommon in this location.

The forearm is the portion of the upper extremity most prone to compartment syndrome. An interosseous membrane, along with the radius and ulna, separate the volar compartment from the dorsal (Figure 278-2). The dorsal compartment contains the radial nerve and the wrist and finger extensors. The volar compartment of the forearm envelops the wrist and finger flexors, the radial and ulnar arteries, along with the median and ulnar nerves (Table 278-2).

There are four compartments in the hand: thenar, hypothenar, central, and interossei (Figure 278-3). The thenar and hypothenar compartments contain the intrinsic muscles of the thumb and little finger, respectively. The interosseous muscles of the hand are contained in their own compartments.

Lower Extremity

There are three gluteal compartments of the buttocks. One contains the tensor muscle of the fascia lata, another the gluteus medius and minimus, and the third the gluteus maximus. The sciatic nerve lies adjacent to the gluteus maximus and can be compressed by it.

The thigh has three compartments: the anterior, medial, and posterior. The anterior compartment contains the vastus lateralis, the vastus intermedius, and the vastus medialis muscles, as well as the sartorius and rectus femoris muscles. The femoral artery and nerve also traverse the anterior thigh compartment. The medial compartment contains the adductor longus, the adductor brevis, and the adductor magnus muscles, plus the gracilis muscle. The posterior compartment contains the semimembranosus, the semitendinosus, and the biceps femoris muscles. The sciatic nerve also traverses the posterior compartment.

FIG. 278-1. The biceps-brachialis (*anterior*) and triceps (*posterior*) compartments of the right arm.

FIG. 278-2. Forearm compartments: transverse sections through the right forearm at various levels.

The leg has four compartments (Figure 278-4 and Table 278-3). The interosseous membrane, forming a plane that spans from the tibia to the fibula, forms one wall of the anterior compartment; the tibia and fibula form the lateral and medial walls of this compartment. The anterior compartment contains the extensor muscles of the toes, the anterior tibial artery, and the deep peroneal nerve. This compartment is most susceptible to compartment syndrome. The lateral compartment of the leg is described by the fibula, along with the intermuscular septum that projects anteriorly and posteriorly from the fibula's edges. The lateral compartment contains the peroneal muscles which evert the foot and the superficial peroneal nerve, which innervates these muscles and is sensory to the lateral dorsum of the foot.

The posterior aspect of the lower leg is divided into a superficial compartment (containing gastrocnemius and soleus muscles), and a deep compartment. The transverse intermuscular septum is the sheet that separates them. The deep posterior compartment contains the flexor muscles of the foot, the tibial artery, and the tibial and peroneal nerves.

The four compartments of the foot are the medial, lateral, central, and interosseous, similar to the compartments of the hand.

CLINICAL FEATURES

Two classic sets of findings are based upon the letter *P*: Pain (out of proportion to findings), Paresthesia (decreased sensation to pinprick, light touch, or two-point discrimination), *Pain* with Passive Stretch (PPS), and Paresis¹; or Pain, Pallor, and Pulseless Paralysis.

TABLE 278-2 Anatomy of the Forearm

Compartment	Muscles	Vessels	Nerves
Volar forearm	Wrist & finger flexors	Radial artery Ulnar artery	Median & ulnar
Dorsal forearm	Wrist & finger extensors		Radial

FIG. 278-3. Hand compartments: transverse section through the right hand.

The history in a patient with compartment syndrome usually involves trauma. This may be due to a direct blow to the muscle in the compartment. Hematoma formation in the compartment or induced edema may elevate the pressure. Force sufficient to cause a fracture is often present, but compartment syndrome may occur without fracture. If the vascular supply to a muscle group has been disrupted, as is seen with a knee dislocation, the muscles may become edematous and increase in volume after vascular supply has been restored.¹

Pain is an early and almost universal finding in an alert patient with compartment syndrome. The pain of tissue ischemia is described as deep, unremitting, and poorly localized. This pain is difficult to control with the normal dosages of narcotics used to treat fractures. The pain of compartment syndrome is exacerbated when the muscle group within the compartment is stretched, either passively or actively.

Another early sign is paresthesia in the cutaneous distribution of the nerves coursing through the affected compartment. Sensory disturbance generally precedes motor dysfunction. Pulselessness is either a late finding or is not present at all, since large arteries that course

through a compartment remain patent even with prolonged and dramatic tissue pressure elevation. For paralysis to occur, the affected limb must be ischemic for some time, and permanent damage may well have already occurred.

Palpation of a compartment will increase pain in an alert patient. The compartment may feel tense. Stretching of the muscles in the compartment also exacerbates pain.

A recent meta-analysis was able to identify only four useful articles reporting clinical findings of compartment syndrome.² The sensitivity, specificity, positive predictive value, and negative predictive value of each individual finding were as follows: pain: 0.19, 0.97, 0.14, 0.998; paresthesia: 0.13, 0.98, 0.15, 0.98; pain with passive stretch: 0.19, 0.97, 0.14, 0.98; and paresis: 0.13, 0.97, 0.11, 0.98. Therefore the absence of any of the findings is helpful to exclude the diagnosis. In the presence of any one clinical finding, the likelihood of the diagnosis of compartment syndrome is about 25 percent (19 to 26 percent); with any two findings 68 percent; with any three findings 93 percent; and with all four, 98 percent. The sensitivity of clinical findings is under 20 percent, positive predictive value about 15 percent, specificity 97 percent, and negative predictive value 98 percent.¹ The clinical features of compartment syndrome are more useful by their absence, which can exclude the diagnosis.

If compartment syndrome is suspected, constricting casts or circular dressings must be removed immediately. The pressure within the compartment should be measured.

Pressure Measurement

When compartment syndrome is suspected, the tissue pressures should be measured.³ Commercial kits are available, such as the Stic Catheter (Stryker Instruments, Kalamazoo, MI). The apparatus consists of a fluid-filled syringe attached to a needle. The side-ported needle is inserted into the compartment and a small amount of saline is injected to ascertain that the needle does not rest against fibrous tissue. A pressure monitor that is attached between the needle and the syringe detects the pressure in the compartment. Normal compartment pressure is 0 mm Hg. When the system is initially flushed after insertion, the pressure reading will overshoot as resistance to flow and inertia are overcome.

An accurate measurement of the compartment pressure will then be displayed. Care must be taken to be sure that the apparatus is level. The accuracy of the needle and transducer can be verified by holding it level and open to the atmosphere; it should read zero.

The needle should be placed in the suspect compartment near the site of the fracture or where the compartment seems most tense. The highest pressures within a compartment are within 5 cm of the fracture site.

Compartments in the hand and foot are small, and elevated pressures there are difficult to detect. Often, the decision to perform a fasciotomy is made solely on clinical grounds.⁴

TREATMENT

The definitive treatment of compartment syndrome is fasciotomy.

A surgical incision is made along the length of the compartment to relieve the pressure. The wound is left open. Several days later, after resolution of the edema, the patient returns to the operating room for closure of the wound.

Compartment pressures of <15 mm Hg are safe. Pressures between 20 and 30 mm Hg may cause damage if they persist for several hours. Levels in this range may be closely followed clinically with repeat pressure measurements. Pressures of 30 to 40 mm Hg are generally considered grounds for emergent fasciotomy. Injuries resulting in an inability to closely follow borderline elevations in compartment pressures may be an indication for fasciotomy.

FIG. 278-4. The four compartments of the leg.

TABLE 278-3 Anatomy of the Leg

Compartment	Muscles	Vessels	Nerves	Sensory Distribution
Anterior	Extensor muscles of toes	Anterior tibial artery	Deep peroneal nerve	Web space of first & second toes
Deep posterior	Deep flexor muscles	Posterior tibial artery	Tibial nerve Peroneal nerve	Heel
Superficial posterior	Superficial flexor muscles (gastrocnemius and soleus)			
Lateral	Peroneal muscles		Superficial peroneal nerve	Lateral dorsum of foot

279 RHABDOMYOLYSIS

Francis L. Counselman

PATHOPHYSIOLOGY

Rhabdomyolysis is a syndrome characterized by injury to skeletal muscle with subsequent release of intracellular contents. These contents include myoglobin, creatine phosphokinase (CK), aldolase, lactate dehydrogenase, serum glutamic oxaloacetic transaminase, and potassium. Although numerous causes of rhabdomyolysis have been described, the common terminal event appears to involve the disruption of the $\text{Na}^+\text{K}^+\text{ATPase}$ pump and calcium transport, resulting in increased intracellular calcium and subsequent muscle cell necrosis. In addition, calcium activates phospholipase A_2 and various vasoactive molecules and proteases and the production of free oxygen radicals.¹

Several classification systems have been developed to characterize the numerous causes of rhabdomyolysis. None of these systems is universally recognized, and each has its limitations. In addition, many patients have multiple causes of rhabdomyolysis (e.g., alcohol abuse and hypokalemia). Table 279-1 lists commonly recognized causes. **In general, the most common causes of rhabdomyolysis in adults appear to be alcohol and drug abuse, toxin ingestion, trauma, infection, strenuous physical activity, and heat-related illness.** In the pediatric population, rhabdomyolysis is an uncommon disorder.² In one study of pediatric patients, the most common causes of nonrecurrent rhabdomyolysis were trauma, nonketotic hyperosmolar coma, viral myositis, dystonia, and malignant hyperthermia.³ For adult and pediatric patients, inherited metabolic disorders should be suspected in recurrent episodes of rhabdomyolysis, especially if associated with exercise intolerance.

Patients in coma are at risk for development of rhabdomyolysis due to immobility from unrelieved pressure on gravity-dependent body parts. In one study, the most common positions leading to rhabdomyolysis were the lateral decubitus, lithotomy, sitting, knee-to-chest, and prone positions.⁴ Alcohol consumption can result in rhabdomyolysis secondary to coma-induced muscle compression and a direct toxic effect. Nutritional compromise, hypokalemia, hypomagnesemia, and hypophosphatemia, all common in alcoholics, increase the risk of rhabdomyolysis. Alcohol and drugs are thought to play a role in up to 80 percent of cases of rhabdomyolysis in adults.⁵⁻⁷ Drugs of abuse that

have commonly been implicated in acute rhabdomyolysis include cocaine, amphetamines (including "Ecstasy"), lysergic acid diethylamide, heroin, and phencyclidine. Common medications associated with the development of rhabdomyolysis include diuretics, lipid-lowering agents (e.g., statins and clofibrate), narcotics, theophylline, corticosteroids, benzodiazepines, phenothiazines, and tricyclic antidepressants. Viral and bacterial infections have been known to cause rhabdomyolysis. Influenza virus is the most frequently cited infectious cause, and *Legionella* is the most frequently reported bacterial cause of rhabdomyolysis.⁸ Strenuous physical activity, as seen in athletes, military recruits, and outdoor laborers, is a common cause of rhabdomyolysis. Factors that increase the risk in this group of patients include poor physical conditioning, inadequate fluid intake, high ambient temperatures, and high humidity levels.⁹

CLINICAL FEATURES

The presenting symptoms of rhabdomyolysis are usually acute in onset and include myalgias, stiffness, weakness, malaise, low-grade fever, and dark (usually brown) urine. Symptoms relating to the musculoskeletal system, however, may be present in only 50 percent of cases.⁵ Nausea, vomiting, abdominal pain, and tachycardia can occur in severe rhabdomyolysis. On occasion, mental status changes are present secondary to urea-induced encephalopathy. Swelling and tenderness of the involved muscle groups and hemorrhagic discoloration of overlying skin may be observed, but only in a minority of cases. Muscle swelling may not become apparent until after rehydration with intravenous fluids. The muscle groups involved may be localized or diffuse, depending on the etiology. Commonly, the postural muscles of the thighs, calves, and the lower back are involved. An important point to remember is that acute rhabdomyolysis may be present without any of these signs or symptoms, and the patient may have essentially normal findings on physical examination. For this reason, the diagnosis often is made only after soliciting a historical clue (e.g., recent cocaine use) or finding an elevated serum CK or the presence of myoglobinuria on routine laboratory testing.

DIAGNOSIS

An elevated serum CK level is the most sensitive and reliable indicator of muscle injury. The degree of CK elevation correlates with the amount of muscle injury and the severity of illness, but not the development of renal failure or other morbidity. Most investigators consider a fivefold or greater increase in serum CK, without cardiac or brain injury, as the requirement for making the diagnosis of rhabdomyolysis. In general, serum CK begins to rise approximately 2 to 12 h after the onset of muscle injury, peaks within 24 to 72 h, and then declines at the relatively constant rate of 39 percent of the previous day's value.⁵ Ongoing muscle necrosis should be suspected in patients with elevated CK values that fail to decrease in this manner. The isoenzyme CK-MM (found in skeletal and cardiac muscle) is responsible in large part for the elevation in serum CK. The CK-MB fraction (found primarily in cardiac but also in skeletal muscle) also may be elevated but should not exceed 5 percent of the total CK level.

TABLE 279-1 Common Causes of Rhabdomyolysis

Direct muscle injury	<i>Shigella</i>
Crush	<i>Staphylococcus aureus</i>
Electrical or lightning injury	<i>Streptococcus pneumoniae</i>
Drugs of abuse	Viral
Amphetamines (including Ecstasy)	Coxsackie virus
Caffeine	Cytomegalovirus
Cocaine	Epstein-Barr virus
Ethanol	Enterovirus
Heroin	Hepatitis
Lysergic acid diethylamide	Herpes simplex virus
Methamphetamines	Human immunodeficiency virus
Opiates	Influenza (A and B)
Phencyclidine	Rotavirus
Excessive muscular activity	Ischemic injury
Contact sports	Compartment syndrome
Delirium tremens	Compression
Dystonia	Medications
Psychosis	Barbiturates
Seizures	Benzodiazepines
Sports and basic training	Clofibrate
Genetic disorders	Colchicine
Glycolysis and glycogenolysis disorders	Corticosteroids
Fatty acid oxidation disorders	Isoniazid
Mitochondrial and respiratory chain metabolism disorders	Lithium
Immunologic diseases	Monoamine oxidase inhibitors
Dermatomyositis	Narcotics
Polymyositis	Neuroleptic agents
Infection	Phenothiazines
Bacterial	Salicylates
<i>Clostridium</i>	Serotonergic agents
Group A B-hemolytic <i>Streptococcus</i>	Statins
Legionnaires' disease	Theophylline
<i>Salmonella</i>	Tricyclic antidepressants

Myoglobin is an oxygen-binding protein found in skeletal and cardiac muscles and is involved in oxidative metabolism. Myoglobin elevation occurs before CK elevation after muscle injury and then is rapidly cleared from the plasma through renal excretion and metabolism to bilirubin. Myoglobin enters the urine when the plasma concentration exceeds 1.5 mg/dL and causes the typical reddish brown discoloration when urine myoglobin exceeds 100 mg/dL.⁵ Because myoglobin contains heme, qualitative tests such as the dipstick (which uses the orthotoluidine reaction) does not differentiate between hemoglobin, myoglobin, and red blood cells. Therefore, suspect myoglobinuria when the urine dipstick is positive for blood, but no red blood cells are present on microscopic examination. Radioimmunoassay is slightly more sensitive than the dipstick technique in identifying myoglobinuria, but usually is not necessary. Because myoglobin levels may return to normal within 1 to 6 h after the onset of muscle necrosis, the absence of an elevated serum myoglobin or of myoglobinuria does not exclude the diagnosis. In one study, 26 percent of patients with rhabdomyolysis did not have myoglobinuria.⁵

Other laboratory studies may be useful to identify the common complications of rhabdomyolysis and the underlying etiology. Electrolytes, calcium, phosphorus, and uric acid levels should be determined to identify hyperkalemia, abnormal calcium and phosphorus levels, and hyperuricemia. A urinalysis should be performed on all patients. Serum creatinine and blood urea nitrogen are useful as a baseline and to identify acute renal failure. Because disseminated intravascular coagulation (DIC) is a complication, all patients suspected of rhabdomyolysis should have a baseline complete blood cell count and DIC screen (e.g., prothrombin time, partial thromboplastin time, fibrin split products, and fibrinogen). Other common laboratory findings in rhabdomyolysis include elevated levels of aldolase, lactate dehydrogenase, urea, creatine, and aminotransferases. Magnetic reso-

nance imaging, especially when using gadolinium enhancement, has recently been shown to be very effective in localizing rhabdomyolysis and is more sensitive than computed tomography or ultrasound in detecting abnormal muscle (e.g., edema and inflammation).¹⁰ Further laboratory testing to identify the underlying cause(s) of rhabdomyolysis should be based on the medical history and clinical presentation.

COMPLICATIONS

The complications of rhabdomyolysis include acute renal failure (ARF), metabolic derangements, DIC, and mechanical complications (e.g., compartment syndrome or peripheral neuropathy; Table 279-2). Acute renal failure is the most serious complication of rhabdomyolysis. Although rhabdomyolysis is thought to account for up to 10 percent of all cases of ARF,¹¹ the incidence of this complication in rhabdomyolysis is less clear. It is estimated that between 0¹² and 50¹³ percent of patients with rhabdomyolysis develop ARF, with 33 percent being the most often quoted figure.⁵ This wide range probably reflects the multifactorial etiology necessary for the development of ARF. Factors known to contribute to rhabdomyolysis-induced ARF include hypovolemia, acidosis or aciduria, tubular obstruction, and the nephrotoxic effects of myoglobin. Renal tubular obstruction occurs secondary to precipitation of uric acid and myoglobin. Ferriheme, the breakdown product of myoglobin, is responsible for the direct toxic effect on the kidneys. This effect, however, appears to occur only in the presence of hypovolemia and aciduria (pH < 5.6). The ARF may be oliguric (most common) or nonoliguric. The need for dialysis, serum potassium and calcium levels, and mortality rates appear to be similar for rhabdomyolysis-induced and non-rhabdomyolysis-induced ARF. Patients with rhabdomyolysis-induced ARF, however, have higher serum uric acid and anion gap levels.⁵ Neither the presence of myo-

globinuria nor the degree of CK elevation is predictive of which patients are at risk for developing ARE

The serum potassium level is elevated in 10 to 40 percent of cases, due to release of potassium from injured skeletal muscle.^{5,14} Renal function, however, appears to be the most important determinant of the degree of elevation. Hyperkalemia can be a significant complication of rhabdomyolysis if acute renal failure occurs.

Elevated uric acid levels can occur, especially in crush injuries, due to release of muscle adenosine nucleotides and subsequent conversion to uric acid by the liver. Uric acid levels usually correlate with serum CK levels.

In rhabdomyolysis, serum phosphorus levels initially may be elevated, due to its leakage from injured muscle. Later in the disease course, mild hypophosphatemia may be seen but rarely requires treatment. Hypocalcemia, the most common metabolic complication, occurs early in rhabdomyolysis and is usually asymptomatic. It has been attributed to the deposition of calcium salts in necrotic muscle, due to the hyperphosphatemia and decreased levels of 1,25-dihydroxycholecalciferol. These soft tissue calcifications sometimes can be observed on x-ray of the involved limb muscles. The hypocalcemia can occur, however, without elevated levels of phosphorus. Later, as calcium is mobilized from damaged muscle, serum calcium levels rise and symptomatic hypercalcemia may be observed.

Disseminated intravascular coagulation occurs in severe rhabdomyolysis and can result in hemorrhagic complications. The DIC usually resolves spontaneously within several days.

The mechanical complications of rhabdomyolysis consist of compartment syndrome and peripheral nerve injury. Compartment syndrome occurs secondary to marked swelling and edema of the involved muscle groups. Characteristic signs and symptoms include pain, paresthesias, paralysis, pallor, and pulselessness. Of these, a sensory deficit is the most reliable physical finding.¹⁵ Presence of a pulse is not helpful in excluding the diagnosis. If the intracompartmental pressures exceed 30 to 35 mm Hg, fasciotomy should be considered. The associated muscle swelling also may cause pressure on peripheral nerves, resulting in neuronal ischemia and causing paraesthesias or paralysis. Nerve injury is often proximal, and multiple nerves may be involved in the same extremity.¹⁶ These peripheral neuropathies usually resolve within a few days or weeks, although, in a minority of patients, they can be permanent.

TREATMENT

Prehospital Care

For victims of crush injury or patients strongly suspected of having rhabdomyolysis and prolonged extrication and transport times, intravenous rehydration with NS should be initiated as soon as possi-

ble. Recently, a volume replenishment protocol for victims of crush injuries has been proposed.¹⁷ Once a limb is extricated, intravenous NS should be initiated at 1 L/h. After extrication, continue intravenous NS at 500 mL, alternating with D5NS, at 1 L/h. Potassium- or lactate-containing solutions should be avoided. The addition of sodium bicarbonate to each liter of crystalloid may be considered, but there are no controlled studies in the prehospital setting to confirm its benefit.

Emergency Department

Once in the emergency department, aggressive intravenous rehydration remains the mainstay of therapy. This treatment should be continued for the first 24 to 72 h. Curry and colleagues recommended rapid correction of the fluid deficit with intravenous crystalloids followed by infusion of 2.5 mL/kg per h, with the goal of maintaining a minimum urine output of 2 mL/kg per h.¹⁸ Others recommend a goal of 200 to 300 mL of urine output each hour. Sodium bicarbonate, one ampule (44 mEq) added to 1 L of NS or two to three ampules (88 to 132 mEq) in D5W to run at a rate of 100 mL/h, has been recommended to maintain a urine pH of 6.5 or above to prevent the development of ARE.⁶ Alkalinization is not without risks, however, because it can exacerbate the hypocalcemia observed in rhabdomyolysis.

To assist in diuresis, 20 percent mannitol is commonly recommended, although there are no prospective studies on its benefit. This solution may be given as 1 g/kg IV over 30 min,¹⁸ or as 25 g IV initially, followed by 5 g/h IV, for a total of 120 g/day. Proposed benefits of mannitol include increased renal blood flow and glomerular filtration rate; hyperosmotic pull of fluid from the interstitial compartment, counterbalancing hypovolemia, and reducing muscle swelling and nerve compression; increased urinary flow and flushing of myoglobin; and the scavenging of free radicals.^{1,17} Mannitol should be given only after volume replacement and avoided in patients with oliguria. The use of loop diuretics (e.g., furosemide) in rhabdomyolysis is controversial, with some researchers recommending their use^{6,14} and others opposing it because loop diuretics acidify the urine.⁸ Despite appropriate treatment, dialysis may be necessary to treat rhabdomyolysis-induced ARE

All patients should have a Foley catheter placed to monitor urine output. Patients should be placed on a cardiac monitor, because of the risk of dysrhythmias secondary to metabolic complications. For patients with heart disease, comorbid conditions, or preexisting renal disease or for elderly patients, hemodynamic monitoring may be necessary to avoid fluid overload. Serial measurements of urine pH, arterial pH, electrolytes, CK, calcium, phosphorus, blood urea nitrogen, and creatinine should be performed.

Hypocalcemia observed early in rhabdomyolysis usually requires no treatment. Calcium should be given only to treat hyperkalemia-induced cardiotoxicity or profound signs and symptoms of hypocalcemia. In contrast, hypercalcemia is frequently symptomatic and normally responds to saline diuresis and intravenous furosemide. Hyperphosphatemia should be treated with oral phosphate binders when serum levels exceed 7 mg/dL. Similarly, the hypophosphatemia, which may occur late in rhabdomyolysis, requires treatment only when the serum level is below 1 mg/dL. Hyperkalemia, which is usually most severe in the first 12 to 36 h after muscle injury, can be significant when associated with ARE. Treatment should be initiated to prevent cardiac complications. Traditional insulin and glucose therapy, although recommended, may not be as effective in rhabdomyolysis-induced hyperkalemia. The use of ion-exchange resins (e.g., sodium polystyrene sulfonate) is effective, as is dialysis.

Avoid the use of prostaglandin inhibitors such as nonsteroidal anti-inflammatory agents, because of their vasoconstrictive effects on the kidney. Most importantly, treat the underlying etiology of the rhabdomyolysis.

DISPOSITION

All patients with suspected rhabdomyolysis require admission for intravenous hydration, diuresis, management of complications, and treatment of the underlying etiology. For at least the initial 24 to 48 h, these patients probably should be admitted to a monitored bed to identify dysrhythmias secondary to the metabolic complications. The nephrology service should be consulted to evaluate the need for dialysis for all patients presenting with ARF or symptomatic hyperkalemia unresponsive to therapy.

This chapter reviews potential problems with orthopedic implants. Postoperative complications related to orthopedic devices that are commonly seen in an emergency department, including implant failure, loss of fixation, nonunion, and infection, are also discussed.

COMMON ORTHOPEDIC IMPLANTS STABILIZING BONE TO BONE

Internal Fixation

PLATES AND SCREWS Plates with screws are used to provide stability while fractures and osteotomies heal or arthrodeses fuse. The variety of shapes and sizes fit different areas of the skeleton. They share the common function of stabilizing bone in an anatomically acceptable position while it heals. To perform this function, the plate must be securely attached to bone with multiple screws. When managing fractures with plates, the bones are often placed in direct contact, and healing usually occurs without the large amount of callus formation seen with casting or intramedullary nailing (Figure 280-1 A, B). Therefore, it is often difficult to determine when fracture union is complete, and it is not uncommon for the fracture line to be visible more than 1 year after surgery (Figure 280-2).

Complications Wound infection is the most common early complication. Superficial infections usually are amenable to antibiotics. In contrast, deep wound sepsis often requires surgical debridement. Nonunion of the fracture is a late complication, which may be related to a deep chronic infection.

Plate-and-screw constructs are simply temporizing measures. If the bone does not heal, the plate eventually will break or the screws will pull out of the bone (Figure 280-3). Plates and screws sometimes are removed after the fracture has healed, and the bone is then at risk for refracture for approximately 3 months (often through a screw hole).

RIGID INTRAMEDULLARY RODS A rigid, single intramedullary rod is the most common implant used to treat femoral and tibial shaft fractures (Figure 280-4) and, occasionally, selective humeral fractures. They are also used to stabilize osteotomies and arthrodeses. The rigidity of the fracture immobilization is less than that with plates and screws; therefore, the healing process involves visible callus formation at the fracture site (Figure 280-5).

Although the designs of modern intramedullary rods have been standardized, there are several different techniques for their application. An entry site for the rod is first established at the end (usually proximal) of the bone, through a small skin incision. Closed fractures typically are reduced with manipulation under fluoroscopic guidance; the fracture hematoma and periosteum are left undisturbed, resulting in high union rates. Open fractures may be reduced directly through the wound but heal less reliably than closed injuries, because of the soft tissue disruption and compromised vascularity of the bone. Before passing the rod across the reduced fracture, the intramedullary canal is usually mechanically reamed to a size slightly larger than the nail, thus facilitating passage of a larger rod and potentially stimulating healing by generating bone debris. Occasionally, for the sake of preserving the endosteal blood supply of the bone and to avoid creating fat emboli, an unreamed nail is used. After the insertion of the rod, interlocking screws usually are added to provide rotational stability at the fracture or osteotomy and to maintain the appropriate length of the bone (see Figure 280-4). Rarely, the rod is placed without interlocking screws. Partially locking the rod (screws at one end only) is a technique sometimes used to allow compression at the fracture while controlling migration of the nail.

FLEXIBLE INTRAMEDULLARY RODS Multiple flexible intramedullary rods are gaining popularity for the treatment of pediatric

ORTHOPEDIC DEVICES AND RECONSTRUCTIONS

Scott S. Kelley Carroll
P. Jones

Orthopedic surgery requires a wide variety of implants to reconstruct the musculoskeletal system (Table 280-1). Processes ranging from traumatic soft tissue disruption to degenerative arthritis may affect multiple anatomic areas. Each area has unique mechanical requirements, and the universal goal of surgical intervention is to provide painless musculoskeletal function. Implants are used for joint and ligament reconstructions, soft tissue repairs, and fusion and fracture fixation. The purpose of an orthopedic device dictates whether its role is temporary or permanent.

TABLE 280-1 Common Orthopedic Implants, Expected Time to Heal, and Radiographic Guidelines to Assess for Potential Complications

Implants	Time to Heal	Ideal Radiograph	Radiographic Evidence of Failure
Bone to bone			
Internal fixation	6–8 wk		
Plates/screws (Figure 280-1)		Bone-to-bone opposition	Broken hardware (Figures 280-3 and 280-7)
Intramedullary rods			Screw/wire pullout
Rigid (Figure 280-4)		Bridging bone or callus (Figure 280-5)*	Gross change in alignment
Flexible (Figure 280-6)		Intact hardware	Interval displacement of fracture (Figure 280-7)
Tension band/cerclage wires (Figures 280-9 and 280-10)		Adequate alignment	
Percutaneous pins (Figure 280-11)	3–8 wk		
External fixation (Figure 280-12)	8–12 wk		
Spine implants	6–9 mo		
Tension band wires (Figure 280-13)		Maintained alignment	Migrated hardware
Plates/screws (Figures 280-14 and 280-16)		Intact hardware	Dislodged hooks (Figure 280-20)
Cages (Figure 280-15)		Fusion mass	Broken hardware (Figure 280-21)
Rods (Figures 280-17 and 280-18)			
Pedicle screws (Figure 280-19)			
Soft tissue to bone			
Interference screws (Figure 280-22)	6–8 wk	Well fixed in bone	Usually no radiographic abnormality†
Suture anchors (Figure 280-23)			Screw/anchor pullout (rare)
Arthroplasty			
Hemiarthroplasty (Figure 280-24)	6 wk (uncemented)	Reduced joint (biplanar views)	Periprosthetic fracture (Figure 280-10); Dislocation (Figure 280-26)
Total joint arthroplasty (Figure 280-25)		Appropriate alignment	Change in implant position (Figure 280-27)
			Complete radiolucent line around implant

*Rigidly fixed fractures with plate/screws often heal with minimal callus.

†Failure of soft tissue fixation is best detected clinically.

long bone fractures. These devices can be inserted through a small hole created in the side of the metaphysis to avoid injury to open growth plates (Figure 280-6). Because flexible rod fixation is less stable than rigid intramedullary nailing, it is seldom used for the slower healing adult population. Another advantage of this technique for pediatric patients is the avoidance of cumbersome external immobilization (i.e., spica casts), which allows early joint range of motion.

Complications Infection is a relatively uncommon early complication and occurs in 1 to 2 percent of closed fractures treated with intramedullary rods and perioperative antibiotics. Open fractures treated with intramedullary nails, however, have an infection rate up to 25 percent.

Largely related to their central location, rods have a greater mechanical strength than do plates and screws. Rare implant failures usually occur at interlocking screws or holes. However, they also may fail (usually after 1 year) by breaking at an unhealed fracture site (Figure 280-7). Because open fractures treated with intramedullary rods have higher nonunion rates than closed fractures, hardware failure is also more common.

A noninterlocked nail may work its way back out of the bone and irritate surrounding soft tissue. The multiple, small, flexible rods are notorious for this problem and often become palpable under the skin (Figure 280-8).

TENSION BAND AND CERCLAGE WIRES Tension band wires often are used to reapproximate and stabilize structures that have fractured under tension. Examples are greater tuberosity avulsions of the proximal humerus and olecranon fractures (Figure 280-9A, B). They often are applied in a "figure-of-eight" fashion through a drill hole placed in the bone distal to the fracture, and then around and deep to the tendinous attachment on the avulsed fragment.

Internal cerclage wires are used to approximate bone fragments to each other, with or without a plate. This technique is advantageous in situations when screw fixation is not feasible. For example, cerclage wires are commonly used to stabilize fractures around a prosthetic stem, in combination with a plate (Figure 280- 10A, B).

Complications Patients may present with a painful bursitis over prominent wires, especially when the hardware is in a superficial location (i.e., olecranon tension band). Occasionally, wire perforation occurs through thin overlying skin. As with all types of internal fixation, hardware failure (wire breakage) may occur before bony union.

PERCUTANEOUS PINS Small smooth or threaded percutaneous pins (Figure 280-11 A, B) often are used in the small bones of the hand or foot to add stability while fracture union occurs. The hand and foot possess an excellent blood supply, which usually results in early union. The pins are usually cut off outside the skin, so that they may be removed between 3 and 8 weeks postoperatively.

Complications As with external fixation pins, one of the most common complications of using percutaneous fixation is pin tract infection. These infections usually resolve after removing the pin, but removal should be done only after consultation with an orthopedist. A course of oral antibiotics also may be necessary.

Pin migration and breakage, easily detected radiographically, are also common.

External Fixation

The external fixator is divided into two components: the fixation pins (or wires) and the external frame. The threaded pins (or wires) are in-

FIG. 280-1. A. This clavicle fracture was rigidly fixed with a plate and screws. B. The fracture is healing without significant callus formation.

serted into each fragment proximal and distal to the fracture (Figure 280-12) or osteotomy. When connected to the frame, they are able to hold the bone so that union occurs.

External fixators are preferentially used to stabilize open fractures (over cast immobilization), allowing the physician easier access to the soft tissue injury. External fixators are also used to temporarily stabilize an extremity or pelvis while life- or limb-threatening surgery is performed. Certain types of closed injuries, such as distal radius fractures, may be treated with external fixation, often in combination with percutaneous pins.

In addition to fracture fixation, uses of external fixators include stabilization of arthrodeses and osteotomies. Complex wire and ring (Ilizarov) fixators are commonly used to lengthen bones and correct angular deformities.

COMPLICATIONS Because external fixation is often chosen for severe open fractures (which have a higher rate of complications), emergency department visits are more frequent. Patients may present with increased redness, swelling, or drainage at the previous open wound site or at the pin sites. If a deep wound infection is suspected, the skin should be prepared and cultures obtained by aspiration or swab (before antibiotics are administered). The treating orthopaedist should be contacted.

Releasing the skin around the pin with a scalpel, after adequate local anesthesia, may easily treat superficial pin tract infections. Oral antibiotics should be given empirically. Even in the absence of infection,

FIG. 280-2. This femur fracture has rigidly healed at 1 year, but the fracture line (arrow) is still present.

loosening of the fixator pins in the bone commonly occurs weeks after their application.

The clamps connecting the pins to the frame also may loosen. This loosening may result in instability or loss of reduction at the fracture site, which is usually detectable clinically (unstable fractures are painful when stressed) or radiographically.

Spine Implants

Cervical Spine The cervical spine is unique from the rest of the vertebral column due to its vulnerable location relative to the skull. This relation allows for a unique stabilization method, halo fixation. A halo is a ring external fixator that is rigidly attached to the outer skull table with pins. Usually, four rods are used to connect this ring to a well-molded plastic or plaster body jacket. The halo limits the motion of the cervical spine, allowing fractures to heal or arthrodeses to unite.

Similar to internal fixation used in the extremities, common cervical implants include posterior tension band wires (Figure 280-13) and, more recently, plates and screws (Figure 280-14). In addition, bone grafts may be used as structural biologic implants to facilitate single- or multilevel cervical fusions.

A relatively new device used to achieve single-level fusions in the spine is the cage. Cages are hollow cylindrical devices, typically titanium, that are inserted between two vertebral bodies in the disc space, usually from an anterior approach (Figure 280-15). In addition to providing stability and restoration of the disc height, the structure of cages serves as a delivery system for bone graft, which can be packed into its hollow center.

COMPLICATIONS Similar to other types of external fixation, the most common complication of halo fixation is pin tract infection. In-

FIG. 280-3. A. This severely comminuted, open distal femur fracture was fixed with a plate and screws. B. Despite bone grafting, the screws broke before the fracture healed.

FIG. 280-4. This tibia fracture was stabilized with a rigid intramedullary rod. Proximal and distal interlock screws were placed to control length and rotation.

FIG. 280-5. A large callus formation at the fracture site.

FIG. 280-6. Flexible intramedullary rods were inserted through the metaphyses to treat this pediatric forearm fracture.

FIG. 280-7. This distal femoral intramedullary nail broke before fracture union occurred. There is also gross change in the alignment of the fracture.

FIG. 280-8. These flexible rods "backed out" of the bone and were prominent just under the skin.

B

FIG. 280-9. A and B. A tension band wire and two smooth pins were used to stabilize this olecranon fracture.

FIG. 280-10. A and B. This periprosthetic femur fracture was stabilized with a plate, cerclage wires, and screws.

FIG. 280-11. A and B. Smooth percutaneous pins were used to stabilize this foot with multiple metatarsal fracture-dislocations.

ected pins are usually removed and a new pin is placed in an alternative site. Loose pins should rarely (if ever) be tightened, because of the risk of inner skull table penetration and resultant meningitis.

The internal implants will fail if the vertebrae fail to unite. A potentially devastating complication of spinal implants is migration of the hardware into the spinal canal, which can be detected radiographically.

Thoracolumbar Spine Although there are many different spinal instrumentation systems, the basic concepts are simple. Rigid internal fixation is used to limit motion between vertebral segments and allow healing or fusion to occur. Similar to the cervical spine, this may be achieved with plates and screws (Figure 280-16), tension band wires, and cages (see Figure 280-15). Implants unique to the thoracolumbar spine include rods combined with hooks, wires, or screws (pedicle screws from T12 to the sacrum).

Rods are used in the spine to provide stability for fusions. Applications include the treatment of traumatic instability, arthrodesis for degenerative arthritis, and fusions for scoliosis.

Most advances in spinal instrumentation arose from the treatment of childhood scoliosis. One of the earliest constructs was the Harrington rod-and-hook system, which was introduced in 1960. Two major lessons were learned in the development of this system: (1) extremely durable materials are needed to avoid hardware failure, and (2) even

the most rigid instrumentation will fail if fusion does not occur. Modifications to this system may include a combination of hooks, screws, and wire (Figure 280-17) and have resulted in improved fixation and correction of deformity, higher fusion rates, and, subsequently, less failure of the hardware. A different system consisting of smooth metal rods placed along the posterior aspect of the spine and wired to each segment, rather than using hooks (Figure 280-18), is commonly used to correct neuromuscular scoliotic deformities. These extremely rigid constructs do not require postoperative bracing.

One drawback of rod-and-hook and rod-and-wire systems is the need for the implant to immobilize a large number of vertebral levels to achieve adequate fixation for fusion. This problem has been addressed by pedicle screws placed directly into the vertebral body, which are then connected to a rigid rod or plate (Figure 280-19). Because the screw passes through the posterior and anterior spinal elements, excellent fixation is obtained and fewer segments need to be immobilized.

COMPLICATIONS Early emergency department visits usually involve wound problems. Diagnosis of an infection is supported by the presence of wound drainage, severe pain, an increased erythrocyte sedimentation rate, and, less frequently, an elevated temperature and white blood cell count. Although early implant failure is uncommon,

FIG. 280-12. An external fixator was used to stabilize this open tibia fracture and allow access to the soft tissue wound. Note the percutaneous pins in the foot.

failure of fixation may occur in the acute postoperative period. Harrington-type hook implants may disengage from the spine, and the patient may experience an acute "pop" and increase in pain. A lateral radiograph will demonstrate a hook disengaged from, and no longer under, the vertebral lamina (Figure 280-20A, B).

Rod breakage is usually a late occurrence (more than 3 to 6 months postoperatively) due to failure of the fusion to prevent motion. A broken rod should be clearly visible on standard anteroposterior and lateral radiograph views (Figure 280-21). Complaints of back pain from spine surgery patients are commonly encountered in the emergency department. If there is no clear evidence of a postoperative complication, narcotics should be given sparingly. Communication with the orthopedic surgeon is often helpful in the management of patients with chronic pain.

COMMON ORTHOPEDIC IMPLANTS STABILIZING SOFT TISSUE TO BONE

The fitness craze of the past 20 years has led to a larger number of sports-related injuries and has resulted in more surgery performed for repairing avulsed ligaments and tendons to bone. Reconstructions using autogenous and allogenic graft implants are also more common

FIG. 280-13. This patient underwent posterior fusion of the entire cervical spine with multiple tension band wires.

FIG. 280-14. An anterior cervical plate and screws and posterior rod instrumentation were used to stabilize this cervical burst fracture.

FIG. 280-15. This titanium cage was placed in the disc space between L4 and L5 to achieve single-level lumbar spine fusion.

FIG. 280-16. An anterior spinal plate and screws were used to stabilize this lumbar burst fracture. The numerous buckles are part of a molded plastic orthosis, which adds additional support.

and must be stabilized while they heal to the host bone. Thousands of anterior cruciate ligament reconstructions are performed each year in the United States. The ruptured ligament may be replaced with harvested hamstring tendons or part of the patella tendon still connected at each end to a bone block from the patella and the tibia. Cadaveric graft tissues are also used. These reconstructions improve knee stability and protect the menisci from future injuries.

The graft may be stabilized to bone with heavy sutures or with a metallic implant. Grafts that do not have attached bone (i.e., hamstring tendon) are stabilized with heavy nonabsorbable suture tied to a screw, staple, or "button." The free bone-patella-bone grafts are typically stabilized with interference screws that are placed parallel to the graft bone in the tunnel. The threads engage and secure the graft bone to the host bone (Figure 280-22A, B).

Tendon avulsions are often repaired back to their insertion on the bone. This may be accomplished by drilling small holes in the bone, through which the suture can be threaded and tied. More recently, special

FIG. 280-18. A rod with segmental sublaminar wires was used to provide stability for a posterior spinal fusion for neuromuscular scoliosis. The ends of the rods insert into the pelvis for additional stability.

FIG. 280-19. The fracture has been reduced and stabilized with pedicle screws attached to posterior bars.

A more common complication of soft tissue-stabilizing implants is loss of fixation. This may occur through failure of the suture or the bone-to-implant interface. Suture anchors and interference screws usually do not pull out of the bone or migrate. Because radiographs are often normal, the diagnosis of a failed soft tissue-to-bone procedure is made clinically (history and physical examination).

Often an athlete will present to an emergency department with an injury to a previously reconstructed knee. The reconstructed anterior cruciate ligament may be reinjured in the same manner as the original ligament, or the patient may sustain an injury to a different structure, such as the meniscus. Great psychological stress may accompany reinjury, and this diagnosis should therefore be communicated by an orthopedist. If surgery was performed less than 6 weeks previously, the knee examination also should be deferred to the treating orthopedist, because the graft itself may not have fully healed to bone. Placement of a knee immobilizer is usually a simple temporizing measure if orthopedic evaluation can be arranged to occur within days. The orthopedist often is unable to perform an optimal clinical examination until 7 to 10 days after the injury, but earlier referral may be necessary to quell the patient's anxiety. If orthopaedic evaluation is delayed 7 to 10 days, then cold therapy, gentle active range-of-motion exercises, and nonsteroidal anti-inflammatory drugs may be beneficial.

TOTAL JOINT ARTHROPLASTY

Prosthetic replacement of damaged joints is common in the United States. They have been designed for almost every joint of the upper and lower extremities. The weight-bearing joints of the lower extremity must tolerate much higher forces than the joints of the upper extremity. Fortunately, the bones of the lower extremity are much larger, which allows for better fixation of the prosthetic devices.

Prosthetic Types

Joint arthroplasties are divided into total (complete) joint arthroplasty and hemiarthroplasty (partial), based on whether both sides or one side

suture anchors and screws have been developed that are drilled into the bone. The attached suture is then used to reapproximate the tendon to its insertion on the bone. These devices are commonly used around the shoulder and have greatly simplified surgical techniques (Figure 280-23).

Complications

Although rare, postoperative infection (presenting as increased pain and low-grade fever) is a catastrophic early complication of ligament reconstructions. Immediate surgical debridement is usually indicated.

FIG. 280-20. A. This hook-and-rod system was used to stabilize a lumbar burst fracture. B. The patient noted a "pop" with forward bending, and the lateral radiograph confirms that the top hook was disengaged.

FIG. 280-21. This double rod construct broke before fusion.

of the joint is replaced, respectively. Hemiarthroplasties are used most often to replace the humeral or femoral head because of a displaced fracture (Figure 280-24). The prosthetic head is attached to a stem that is inserted into the intramedullary canal.

Sir John Charnley popularized total joint arthroplasty for the treatment of hip arthritis. The most common hip replacement has a metal femoral prosthesis that articulates with a plastic acetabular cup, which usually has a metal backing that is secured to the pelvis (Figure 280-25). Metal-on-plastic prostheses are now used to replace almost every other extremity joint, including the knee, shoulder, elbow, wrist, ankle, and, infrequently, the small bones of the hand and feet.

Total joints may be constrained but are more frequently stabilized by the patient's native joint ligaments and tendons. The rate of loosening from the bone is higher with constrained implants, which are designed with the two components locked together. These designs are used primarily for revision surgery when soft tissue loss and attenuation increase the risk of dislocation. The exception is the elbow, where primary (first time) constrained prostheses are often used, because the surgical exposure violates significant stabilizing structures.

Two methods of fixing the prosthesis to the bone may be used. The implant may be press-fit by wedging the implant into the gross bone structure. Additional stability can be achieved with a special surface

FIG. 280-22. A and B. These interference screws rigidly fix a bone-patellar-bone autograft used for an ACL reconstruction.

FIG. 280-23. These metal-anchored sutures were used to repair a ruptured pectoralis major insertion to the proximal humerus.

coating, which allows the bone to grow directly onto the prosthesis. The second method of fixation is polymethylmethacrylate cement, which stabilizes the bone and the implant in a similar manner that mortar secures a post in a hole.

The results of modern joint arthroplasty are excellent. Currently, total hip and total knee arthroplasty have a greater than 90 percent success rate at 15- to 20-year follow-up.

Complications

When a patient presents with new onset of periprosthetic pain, dislocation, periprosthetic fracture, implant loosening, or infection should be suspected.

It is possible for nonconstrained and constrained implants to dislocate. The diagnosis is usually obvious but should be confirmed with biplane radiographs. One view may not clearly show the dislocation and appear deceptively normal (Figure 280-26A, B). Because many of today's implants are modular (i.e., snap together in the operating room), relocation should not be attempted without discussion with an orthopedic surgeon. Disassembly of modular prosthesis during attempted closed reduction has been reported. Dislocated constrained implants are rarely amenable to reduction in the emergency department, and these designs often require open reduction in the operating room.

Modern alloys have greatly reduced the incidence of prosthetic breakage. More commonly, the bone around the prosthesis fractures (see Figure 280-10). Once the emergency medicine physician makes the diagnosis of a periprosthetic or prosthetic fracture, an orthopedist should be consulted.

Implant loosening is the most common long-term complication of joint arthroplasty, but it is usually characterized by insidious onset of pain and rarely presents to the emergency department. Although pros-

FIG. 280-24. A cemented hemiarthroplasty was used to treat this displaced femoral neck fracture.

FIG. 280-25. This "hybrid" total hip arthroplasty has a cemented femoral component and an uncemented acetabular component that is also fixed with screws.

FIG. 280-26. A and B. This patient's total hip arthroplasty is dislocated. The slight asymmetry on the first view was not detected, and additional radiographs were needed to diagnose the dislocation.

thetic loosening most often is not related to infection, deep wound sepsis may be the cause and should be considered. Radiographic criteria for loosening reported in the orthopedic literature include migration of the implant (Figure 280-27), lytic destruction of bone around the prosthesis, or a complete radiolucent line around the bone-to-prosthetic construct interface.

Infection of a total joint arthroplasty is a catastrophic event. Deep infection typically presents with wound drainage, intractable pain, and increases in the erythrocyte sedimentation rate or C-reactive protein. It is rarely associated with systemic symptoms, and blood cultures are usually negative. Aspiration of the joint should be performed before administration of antibiotics and never without a surgeon's approval. It is possible for an aseptic implant to be infected by a needle aspiration. Infections after primary arthroplasties now have an incidence of less than 1 percent when using modern sterile techniques.

The emergency department physician is more likely to see a patient with a history of a joint infection previously treated with a one- or two-stage debridement. Because one-stage revisions (or simple debridements) for infected arthroplasties are associated with higher recurrence rates, this information has prognostic value and should be sought from the patient.

Other serious complications of total joint arthroplasties involve the soft tissue structures around the joint. Ligaments holding the joint together can disrupt, causing instability of the joint. Tendons that pass around the joint can rupture, leading to loss of function of the joint. If diagnosed early, they can often be repaired with an excellent result.

Complications of Upper Extremity Arthroplasties

The prosthetic elbow joint has more frequent complications than other commonly replaced joints. Even in the best centers, infection rates of 10 percent or greater are not uncommon. This infection rate may be due to the thin soft tissue over the posterior elbow. High loosening

rates of elbow prostheses may be related to the frequent use of constrained designs and the limited bone available for fixation.

The shoulder's humeral component is extremely durable. The glenoid component is prone to failure because of its small bone surface area for fixation. Dislocation of the shoulder can be diagnosed only with a true anteroposterior and an axillary or transscapular lateral radiograph. Acute loss of motor power may be the result of a rotator cuff tear.

Complications of Lower Extremity Arthroplasty

Ankle arthroplasty has had limited success in the past because the small bones of the hindfoot do not allow adequate fixation to withstand the high forces placed across the ankle joint. More recently, improved designs have demonstrated better short-term results.

The knee has excellent inherent ligamentous stability, and minimally constrained implants are usually used. Although not as common as in the shoulder or hip, it is possible for these implants to dislocate. Instability can develop in knee arthroplasties if a ligament (such as the medial collateral) is disrupted. Diagnosis is by the same examination methods used on unreplaced knees. Disruption of the quadriceps mechanism is a devastating complication and must be considered if the patient is unable to perform a straight leg raise. When the patella tendon ruptures, repair rates are extremely poor, especially if not diagnosed and treated early.

The hip, like the shoulder, may be replaced with a hemi- or total arthroplasty. The acetabulum usually is not replaced in fracture management but is almost always resurfaced for arthritis. The hip is the most common joint arthroplasty to dislocate. Dislocation is confirmed by biplane radiographs. Because these prostheses are often modular, great care should be used during relocation. Reattachment of the trochanter after the occasional transtrochanteric surgical approach is usually performed with wire. These wires commonly break during the healing process but are not usually a problem.

FIG. 280-27. The acetabular component loosened and has migrated into the pelvis.

NONTRAUMATIC MUSCULO SKELETAL DISORDERS

NECK PAIN William

J. Frohna

The causes of neck pain include trauma and biomechanical injuries, degeneration, inflammation (arthritis), infection (e.g., discitis, meningitis, epidural abscess), and infiltration (e.g., metastatic carcinoma, spinal cord tumors, osteoid osteoma).^{1,2} In most cases of neck pain, no specific etiology can be identified.¹ A knowledge of cervical spine anatomy and a complete history and physical examination, focusing on the presence or absence of neurologic signs, are needed to identify pathologic causes and prevent complications.

ANATOMY

The cervical spine consists of seven vertebrae. The upper cervical spine (occipitoatlantoaxial complex) is unique and is made up of the base of the skull, atlas (C1), axis (C2), and several strong ligaments. The atlas (C1) supports the occipital condyles in its lateral masses. This articulation allows for flexion and extension but no rotation. The articular surfaces of the atlas (C1) and axis (C2) are convex to each other and allow flexion, extension, and especially rotation to occur. The transverse, accessory, and alar ligaments are the primary stabilizing ligaments of the occipitoatlantoaxial complex. The mid and lower cervical spine (C3 to C7) consists of vertebrae which are similar in size and shape. These vertebral bodies articulate with each other via their superior and inferior articular processes, enabling limited rotation and lateral flexion. The transverse processes of each of the cervical vertebrae are perforated by a foramen through which the vertebral vessels pass. Topographically, the first cervical vertebra is located immediately behind the angle of the mandible, the transverse process of the atlas is positioned between the angle of the mandible and the mastoid process, the hyoid bone is anterior to the level of C3, the thyroid cartilage is anterior to C4, and the cricoid cartilage is at the level of the sixth cervical vertebra.

The muscles of the neck are compartmentalized into seven fascial planes. These planes normally enable pain-free movement of one muscle group on the other. Following acute neck trauma, petechial hemorrhages and edema within these same fascial planes may produce limited motion associated with complaints of stiffness, pain, and swelling.

The stable but flexible cervical spine is linked by both ligaments and disks. Because of major structural differences, the cervical disks are less likely than lumbar disks to prolapse. The cervical spine is more mobile, the superincumbent weight is less, the nucleus pulposus is located more anteriorly, and unlike the lumbar spine, the annulus is reinforced posteriorly in its entire width by the posterior longitudinal ligament.

The eight paired cervical spinal roots exit the intervertebral foramina between the superior and inferior pedicles, except for the first cervical roots. The nerve roots exit the spinal canal above the level of the same numbered vertebra, with the exception of the C8 nerve root, which exits at the C7-T1 interspace.³ Unique to the cervical spinal roots, the ventral and dorsal roots are separate at the neural foramina in over half of cases. Therefore isolated irritation of the dorsal (sensory) root posteriorly by an osteophyte may produce only sensory complaints. Similarly, ventral root (motor) compromise by a degenerative or herniated disk may produce only painless, progressive weakness.

The sinuvertebral nerves from the dorsal root reenter the intervertebral foramina, supplying sensory innervation to the ligaments of the

spinal canal. Anteriorly, they supply the posterior longitudinal ligament and posteriorly the ligamentum flavum, meninges, and associated vessels. Ascending and descending branches supply the zygoapophyseal joints and provide position sense.

CLINICAL FEATURES

In general, it is helpful to classify patients with neck pain into two groups: (1) those with pain arising mainly from the joints and associated ligaments and muscles of the neck, and (2) those with neck pain and *radiculopathy* (signs and symptoms attributable to a single nerve root) and/or *myelopathy* (signs or symptoms due to a spinal cord lesion, stenosis, or compression).^{1,4} Most patients do not exhibit either radiculopathy or myelopathy, but the course and treatment for those who do may be quite different from those patients with isolated neck pain.⁴

History

Ask about onset, duration, and location of the neck pain; recent or remote trauma, associated symptoms; stiffness; deformity; neurologic complaints (e.g., weakness, changes in sensation, gait, or vision); constitutional symptoms such as fever, anorexia, and weight loss; and comorbid conditions such as arthritis, cancer, and infections.¹ Several rheumatologic conditions predispose to neck pain and instability of the atlantoaxial (C1-C2) joint. Rheumatoid arthritis, ankylosing spondylitis, and psoriatic spondyloarthropathy may involve the C1-C2 joint and damage the transverse ligament and erode the odontoid process. Subluxation may occur spontaneously or following a trivial injury. Morning stiffness may signify arthritic joints, unremitting night pain may indicate a malignant process, and fever and night sweats suggest an infection.³ Identify precipitating and palliative factors, maneuvers, or activities. Inquire about prior episodes of neck pain, past diagnostic studies, and treatment. Determine the character of pain and its distribution. Patients with radiculopathy often complain of sharp, burning, intense pain that radiates to the trapezius, periscapular area, or down the arm.¹ Weakness or paresthesias may develop weeks after pain onset.⁴ Patients with myelopathy may have neck pain that progresses insidiously and may complain of clumsy hands, gait disturbances, and sexual or bladder dysfunction.⁴ Table 281-1 summarizes important differences in symptoms between mechanical neck pain and neck pain associated with radiculopathy or myelopathy.¹

Physical Examination

The physical examination should begin with a general assessment of the patient, noting evidence of weight loss, pallor, adenopathy, and abnormalities of posture, movement, and facial expression.¹ Pain may cause splinting of the head on the shoulders during position change. Active and passive movement should be assessed, including rotation (chin to shoulder), lateral flexion (ear to shoulder), and flexion-extension. Most mechanical causes of neck pain result in asymmetric lesions and asymmetrically limited or painful movements.¹ Inflammatory or neoplastic disorders are typically more widespread, with pain and movement restriction being more symmetric.¹ When localized ipsilateral neck pain is felt toward the side of head movement, zygoapophyseal joint irritability is suspected. *Spurling sign* (gentle pressure applied to the patient's head during extension and lateral rotation) may reproduce radicular pain with radiation into the ipsilateral upper extremity. The *abduction relief sign*, performed by having the

TABLE 281-1 Symptoms and History Associated with Neck Pain

Group 1: Cervical Problems Arising Mainly from Neck Joints and Associated Ligaments and Muscles	Group 2: Cervical Problems Involving the Cervical Nerve Roots or the Spinal Cord
<p>Patients complain of pain and stiffness</p> <p>Pain is a deep, dull aching sensation and often episodic</p> <p>Patients have a history of excessive or unaccustomed activity or of sustaining an awkward posture There is no history of specific injury Ligament and muscle pain are localized and asymmetric Pain from upper cervical segments is referred toward the head; pain from lower segments, to the upper limb girdle Symptoms are aggravated by neck movement and relieved by rest</p>	<p>Patients complain of significant root pain</p> <p>Pain is sharp and intense and is often described as a burning sensation</p> <p>Pain may radiate to the trapezial and periscapular areas or down the arm Patients complain of numbness and motor weakness in a myotomal distribution</p> <p>Headache may occur if the upper cervical roots are involved</p> <p>Symptoms often become more severe with neck hyperextension</p>

Source: Reproduced with permission from Tsang.¹

patient place the hand of the affected upper extremity on the top of his or her head to obtain relief, may indicate soft disc protrusion causing radicular pain.³ When neck pain occurs on the side away from head movement, a ligamentous or muscular source for the pain is suspected as these structures are stretched.

Further assessment should include palpation of the structures of the head and neck and a thorough musculoskeletal and neurologic examination. Palpate the posterior cervical triangle, the supraclavicular fossa, carotid sheaths, and the anterior neck. C5-C6 root lesions often elicit tenderness over the brachial plexus at Erb's point in the supraclavicular fossa, whereas a C8-T1 root lesion may cause tenderness over the ulnar nerve at the elbow.

Pathology in the lymph nodes, salivary glands, or thyroid gland may result in neck pain. Auscultation of the carotid and the subclavian arteries may demonstrate bruits, in the former associated with potential cerebral insufficiency and in the latter with thoracic outlet or vascular steal syndrome. The temporal artery should be examined for signs of inflammation, as temporal arteritis may be the cause of neck and shoulder pain.

Sensory symptoms of pain or dysesthesias are difficult to evaluate, particularly when motor signs are absent. This is often the case in cervical spinal radiculopathies. The discrete separation of the motor and sensory roots at the cervical neural foramina is the explanation for motor sparing despite severe sensory symptoms. For example, C7 root irritability without motor weakness can present as aching at the medial to middle scapular border, aching in the myotome distribution to the chest, axilla, or triceps, or as numbness or tingling in the middle finger.

Early cervical spinal myelopathies can only be recognized if the examiner looks for them by performing a complete neurologic examina-

tion. Findings in patients with myelopathy include hyperreflexia, a positive Babinski sign, clonus, gait disturbance, sexual or bladder dysfunction, lower extremity weakness, impaired fine hand movement, and upper and lower extremity spasticity. In the patient with cord compression, the clinician may elicit *Lhermitte sign*, an electric-like shock radiating down the spine and often into the extremities, with neck flexion. *Hoffman sign* indicates an upper motor neuron lesion and is performed by flicking the tip of the middle finger as the hand is relaxed in a neutral position. A positive response is flexion of the thumb and index finger in a pinching motion.³

Table 281-2 summarizes the sensory, motor, and reflex findings in cervical radiculopathy. This information should be used to determine the level of motor and sensory involvement, and to compare findings in the affected and unaffected sides. Bilateral or multilevel involvement usually implies serious pathology.¹

Imaging Studies

The need for radiographs depends on the clinical condition suspected and the duration of neck pain. Acute (days to weeks), uncomplicated, nonradicular, nonmyelopathic, atraumatic neck pain typically requires no imaging studies, as the cause is likely benign and the treatment is conservative.^{1,4} Obtain three-view cervical spine films in patients with chronic (weeks to months) neck pain with or without a history of trauma, those with neck pain and a prior history of malignancy or remote neck surgery,⁵ and in those with neck pain and preexisting spinal disorders such as rheumatoid arthritis, ankylosing spondylitis, and psoriatic spondyloarthropathy. Films are obtained to identify bone destruction or cervical spine instability.

TABLE 281-2 Signs and Symptoms of Cervical Radiculopathy

Disk Space	Cervical Root	Pain Complaint	Sensory Abnormality	Motor Weakness	Altered Reflex
C1-C2	C2	Neck, scalp	Scalp		
C4-C5	C5	Neck, shoulder, upper arm	Shoulder	Infraspinatus, deltoid, biceps	Reduced biceps reflex
C5-C6	C6	Neck, shoulder, upper medial, scapular area, proximal forearm, thumb, index finger	Thumb and index finger, lateral forearm	Deltoid, biceps, pronator teres, wrist extensors	Reduced biceps and brachioradialis reflex
C6-C7	C7	Neck, posterior arm, dorsum proximal forearm, chest, medial third of scapula, middle finger	Middle finger, forearm	Triceps, pronator teres	Reduced triceps reflex
C7-T1	C8	Neck, posterior arm, ulnar side of forearm, medial inferior scapular border, medial hand, ring, and little fingers	Ring and little fingers	Triceps, flexor carpi ulnaris, hand intrinsic	Reduced triceps reflex

If degenerative disease is suspected, oblique views of the cervical spine can identify foraminal narrowing. Flexion-extension films may be useful if instability is suspected. Patients with normal radiographs, patients with radiographic evidence of cervical spondylosis and no neck instability (degenerative changes manifested by osteophyte formation, disc space narrowing, and facet disease), or patients with radiographic evidence of previous trauma *and* no neurologic signs or symptoms need no further imaging.⁵ **Magnetic resonance imaging (MRI) is indicated for those patients with neurologic signs or symptoms regardless of the plain film findings.**⁵ MRI is also indicated when plain radiographs reveal bone or disc margin destruction, if there is cervical instability, and (with intravenous contrast) if epidural abscess is suspected.⁵ CT myelography is recommended when contraindications to MRI exist.

ETIOLOGY

Cervical Soft Tissue Injury

Soft tissue neck injury is also known as hyperextension strain, acceleration-deceleration injury, hyperextension-hyperflexion injury, neck strain, neck sprain, and whiplash. The most common precipitating events are motor vehicle collisions, falls, sports injuries, and work-related injuries. Acute and chronic pain may develop secondary to trauma to the richly innervated structures of the neck and cervical muscle groups. The forces applied during motor vehicle crashes are multiple and depend on the position of the head and neck as well as the type of accident. Typically, whiplash injury results from sudden acceleration-deceleration trauma that occurs when an unaware victim in a stationary vehicle is struck from behind. Patients often complain of pain and stiffness and examination may reveal tender paracervical muscles with decreased range of motion. Typically, pain is delayed for a number of hours following an accident.

Other uncommon and highly variable postinjury complaints include headache, vertigo or dizziness, spatial instability, dysphagia, or hoarseness. Headache can occur from stretching and tearing of occipital muscles and the occipital nerve. The cause of vertigo is unknown, but it could be due to brainstem contusion, vertebral artery dissection, trauma to sympathetic fibers that accompany vertebral arteries, vertebral artery insufficiency secondary to atherosclerosis, or osteophytic compression of the vertebral arteries. Patients may describe true vertigo, or a feeling of "sliding" or "veering" with changes of direction. Any neurologic findings after whiplash injury should be evaluated for brain or spinal cord injury or vertebral artery dissection.^{6,7} Dysphagia or hoarseness are symptoms of severe blunt neck or laryngeal injury and require thorough evaluation.

The most devastating complication of hyperflexion-hyperextension injury is the central cord syndrome, which may occur in the presence of cervical spondylosis, spinal stenosis, ankylosing spondylitis, or disk herniation. There may be no radiographic evidence of spinal trauma. Physical examination findings of central cord syndrome include weakness that is disproportionately greater in the upper extremities than the lower extremities, and it can be accompanied by variable sensory loss (see Chap. 272, for further discussion).

The NEXUS criteria can be followed to determine indications for cervical spine imaging after such injuries (see Chaps. 256 and 272 for detailed discussion of spine injuries.)

Cervical Disk Herniations

Cervical disk herniations occur as the nucleus pulposus protrudes through the posterior annulus fibrosis, producing either an acute radiculopathy or occasionally a myelopathy. Protrusions are usually confined by the posterior longitudinal ligament, but can occasionally extrude through this ligament as free fragments. Direct posterior rup-

tures, although infrequent, can produce progressive myelopathy, whereas the more common posterolateral herniations can cause acute cervical radiculopathy. Disk prolapse is more common in males, occurring most often in the fourth decade. The levels of most frequent involvement are C5-C6 (C6 root) usually right sided, and C6-C7 (C7 root), usually left sided. C6 root compression accounts for 20 percent of cases, while C7 root compression accounts for 70 percent of cervical disk herniation cases.⁴

The symptoms of an acute cervical disk prolapse include neck pain, headache, pain referred to the shoulder and along the medial scapular border, and dermatome pain and dysesthesia in the spinal root distribution to the shoulder and arm. Motor signs include fasciculations, atrophy and weakness in the dermatome distribution of the spinal root, loss of deep tendon reflexes, and with cervical myelopathy, lower extremity hyperreflexia, Babinski sign, and rarely loss of sphincter control. Cervical hyperextension and lateral flexion to the symptomatic side (Spurling sign) may replicate the symptoms, as can a Valsalva maneuver, whereas manual cervical distraction in flexion alleviates them. A thorough physical examination, including strength, sensory, and reflex testing, easily delineates the level of root involvement (see Table 281-2).

Cervical spine radiographs are often more useful in these syndromes for what they fail to reveal rather than what they demonstrate. Magnetic resonance imaging is necessary for diagnosis.

Cervical Spondylosis and Stenosis

Cervical spondylosis is a progressive, degenerative condition that often presents either as a loss of cervical flexibility, neck pain, occipital neuralgia, radicular pain, or occasionally as progressive myelopathy. There is progressive degeneration of the discs, ligaments, facet joints (zygoapophyseal joints), and uncovertebral joints (joints of Luschka).³ Other common clinical terms used for this condition are osteoarthritis of the neck and degenerative disk disease. From a radiographic standpoint, cervical spondylosis may be diagnosed if any of three findings are present: osteophytes, disc space narrowing, and facet disease.⁵ However, there is a high prevalence of cervical spondylosis in asymptomatic individuals, and care must be taken in ascribing painful syndromes to distinct anatomic abnormalities.³ Degenerative disk disease predisposes to progressive osteoarthritis of the cervical spine, joint instability, and incongruous joint motion during neck movement. Spondylosis most commonly occurs at the C5-C6 and C6-C7 levels.

Osteophytic spurs can encroach posteriorly on the spinal canal, producing cervical myelopathy; laterally on the intervertebral foramen, producing cervical radiculopathy; and anteriorly on the esophagus, producing dysphagia. Spurious osteophytes may also produce Horner's syndrome, vertebrobasilar symptoms, severe radicular symptoms without associated neck pain, painless upper extremity myotome weakness, and chest pain mimicking angina. Neurologic findings (radiculopathy or myelopathy) may be gradual in onset unless there is a history of recent trauma.

The combination of a congenitally narrowed spinal canal further compromised by a vertebral osteophytic bar anteriorly and a buckling ligamentum flavum posteriorly, increases the risk of myelopathy secondary to cervical spinal stenosis as the diameter of the spinal canal is reduced to less than 13 mm. Cervical spinal stenosis can also occur in about 20 percent of patients with lumbar spinal stenosis.

Cancer

Metastatic cancer should be in the differential diagnosis of the patient who presents with chronic neck pain, even though a past history of cancer is lacking. The complaint of unremitting night pain may be indicative of a malignant process.³ Lung, breast, and prostate cancers as well as lymphoma and multiple myeloma may involve the cervical spine causing neck pain.⁴ Although most cases of epidural cord compression

occur in the thoracic spine (70 percent), approximately 10 percent involve the cervical spine.⁸ Myelopathy, typically caused by disk or degenerative disease, is rarely caused by metastatic tumors.⁴ Plain films of the cervical spine may reveal destruction of the vertebral bodies and pedicles, lytic lesions of the pedicles, and pathologic compression fractures.⁴ Cancer patients with radiographic evidence of bone or disc margin destruction should undergo magnetic resonance imaging.⁵ Imaging of the cervical spine with CT scan or tomograms should be considered in the patient with questionable findings on plain film.

Myofascial Pain Syndrome

Myofascial pain syndrome (MPS) is a cause of chronic neck pain and is often confused with radiculopathy. Although it has been defined as pain persisting more than several months, MPS may present acutely, especially after trauma, with typical clinical characteristics.⁹ Psychological distress and specific personality traits contribute to the conversion of emotional distress into bodily complaints and focus on the body so that nonpainful sensations are perceived as painful.⁹ The location of pain may help in discriminating MPS from true radicular pain. MPS patients often complain of pain in the neck, scapula, and shoulder and in a nondermatomal radiation into the upper extremity. On physical examination, the MPS patient will not have neurologic abnormalities, while the patient with radiculopathy may exhibit weakness or an altered deep tendon reflex. Patients with MPS have tender spots, "trigger points," that may be found on palpation of the head, neck, shoulder, and scapular region. Because cervical spine abnormalities develop with age in the asymptomatic population, radiographic findings cannot be relied upon to verify the source of neck pain or upper extremity complaints. Imaging of the MPS patient reveals either nonspecific degenerative or disc changes that do not correlate with the clinically suspected site.⁹

Other Conditions

Epidural abscess, osteomyelitis, and temporal arteritis are infectious and inflammatory causes of neck pain. Cervical spinal epidural hematoma often presents with neck pain followed by symptoms and signs of cord compression. Pain from ischemic heart disease may radiate into the neck and shoulder. Peripheral nerve involvement, such as carpal tunnel syndrome, may present as a C6-C7 sensory radiculopathy, while multiple sclerosis, amyotrophic lateral sclerosis (ALS), subacute combined degeneration, and syringomyelia are in the differential of myelopathy.⁴

TREATMENT

Treatment issues can be divided into three categories: neck pain, neck and arm pain (radiculopathy), and myelopathy.³ There is little evidence-based material to support many of the recommended physical medicine modalities [traction, thermotherapy, electrical stimulation, massage, electromyographic biofeedback, transcutaneous electrical nerve stimulation (TENS), and therapeutic ultrasound].^{10,11} However, individual patients may indeed benefit from one or more of these therapies.

Neck Pain

Most cases of neck pain without clear underlying pathology will improve with minimal intervention. The patient should be advised to avoid activities that produce pain. Initial medications may include nonsteroidal anti-inflammatory drugs, muscle relaxants, and for significant pain, a short course of oral opiates. Follow-up with the primary physician should be encouraged to assess the need for physical or manual therapies. In patients with chronic neck pain (>12 weeks

duration), The Philadelphia Panel¹⁰ recommends the use of proprioceptive and therapeutic exercises.

Patients with acute neck pain following an acceleration-deceleration (whiplash) injury may benefit from a similar pharmacologic regimen as that described above. There is insufficient data to recommend corticosteroid treatment for whiplash injuries.^{12,13} Rest and immobilization using collars are not recommended ("rest makes rusty") and usual activities should be maintained.¹⁴

Treatment of neck pain in patients with a predisposing rheumatologic or neoplastic condition will depend on whether or not there is cervical spine instability (C1/C2) and/or evidence of cord compression. Pain medications and consideration of a course of oral glucocorticoids may be considered as first-line treatment if neither instability nor cord compression is present. Admission and neurosurgical consultation should be undertaken if either complication is present.

Therapy for neck pain from myofascial pain syndrome should address both muscular tension and psychobehavioral issues.⁹ Initial treatment includes nonsteroidal anti-inflammatory drugs, muscle relaxants, and short-course opioid analgesics for severe symptoms. Follow-up with the primary care physician is needed to arrange optimal therapies.

Radiculopathy

Most authors recommend a trial of conservative treatment as long as there is no evidence of myelopathy.³ Initial treatment consists of activity modification, oral medications, and immobilization with a soft cervical collar. The patient should be encouraged to follow-up closely with their primary physician for consideration of specialist consultation, electrodiagnostic evaluation, and additional rehabilitation interventions. Oral medications may include anti-inflammatory agents, opioid analgesics, and muscle relaxants. A course of steroids, oral (e.g., methylprednisolone self-weaning dose pack) or epidural, may be useful in the acute phase of radicular pain.³ If the symptoms and signs of acute cervical root compression fail to respond to conservative treatment or recur, surgery may be recommended if imaging demonstrates concordant findings. Indications for hospital admission include:

1. Intractable radicular pain unresponsive to treatment
2. Progressive upper extremity weakness, especially in the C7 distribution
3. Acute or progressive symptoms or signs of myelopathy

Myelopathy

Treatment decisions for patients with symptoms and signs of cord compression should be made in conjunction with specialists. Cervical spondylotic myelopathy is the condition causing the greatest amount of impairment and disability in the continuum of spondylosis.³ Myelopathy is the most common cause of spastic paraparesis in patients older than 55 years of age, thus paralleling the time course of spondylosis.³ The patient with myelopathy should be referred to a neurosurgeon for consideration of decompressive surgery. Additional therapeutic considerations will depend on the time course of symptoms and signs and etiology, but should be made in conjunction with a neurosurgeon.

THORACIC AND LUMBAR PAIN SYNDROMES David Della-Giustina Marco Coppola

INTRODUCTION

Back pain is second only to upper respiratory tract infection as a symptom-related reason for visits to primary care physicians.^{1,2} It is the most common cause of work-related disability in persons younger than 45 years of age and the second most common cause of temporary disability for all ages.^{1,2} The majority of patients that present to the ED with back pain have a nonspecific etiology that has no life-threatening or neurologically impairing concerns. However, due to the high volume of ED patients with back pain, one can develop an indifference to this complaint and potentially overlook serious causes for the symptoms. The best approach to this complaint is to perform a systematic evaluation based on *risk factors* in the history and physical examination and let this guide one's approach in terms of diagnostic testing and management (Table 282-1).

CLINICAL EVALUATION

History

The history should focus on the risk factors for serious disease, which includes duration of symptoms, age, pain location, trauma history, systemic symptoms, specific pain features, neurologic deficits, and past medical history.

DURATION OF SYMPTOMS Back pain is categorized into three groups based on the duration of symptoms: acute is less than 6 weeks, subacute is pain continuing between 6 and 12 weeks, and chronic is pain more than 12 weeks.³ Pain lasting greater than 6 weeks is a risk factor for specific problems as most episodes of nonspecific back pain (80 to 90 percent) resolve within 6 weeks.^{2,4}

PATIENT AGE Patients under age 18 and over age 50 have a higher likelihood of a serious cause for back pain. In both of these age groups, back pain is more likely to be caused by tumor or infection than in the 18 to 50 age group. Patients younger than 18 have a higher incidence of congenital and bony abnormalities such as spondylolysis, spondylolisthesis, and Scheuermann kyphosis. In those aged 50 and older, nonmechanical causes such as a rupturing abdominal aortic aneurysm and other intra-abdominal processes are more common.

LOCATION OF THE PAIN Pain that originates from muscular, ligamentous, vertebral, or disk disease without nerve involvement is located primarily in the back, possibly with radiation into the buttocks or thighs. Sciatica is radicular pain in the distribution of a lumbar or sacral nerve root and is often accompanied by sensory or motor deficits.³ It occurs in only 1 percent of patients with back pain.^{3,5} Sciatica is associated with disk herniation or nerve root impingement below the L3 nerve root. This is based on the dermatomal distribution of the nerve roots and the fact that the pain associated with nerve root impingement radiates along the entire pathway of the nerve. Ninety-five percent of herniated disks occur at the L4-L5 or the L5-S1 lumbar disk spaces, impinging on the L5 or S1 nerve roots, respectively.³

HISTORY OF TRAUMA History of major trauma is a risk factor for fracture and should prompt one to order plain radiographs of the involved spine. One special situation involves elderly patients who may sustain a vertebral fracture with even minor trauma such as falling from standing or from sitting in a chair. This is due to the bony changes with aging, predominantly osteoporosis. Thus a history of minor trauma in an elderly patient with back pain suggests fracture and warrants ordering plain radiographs.

SYSTEMIC COMPLAINTS Systemic symptoms such as fever, chills, night sweats, malaise, and an undesired weight loss suggest infection or malignancy. These symptoms are more worrisome for infection if the patient has any of the following risk factors: recent bacterial infection, especially urinary tract infection or pneumonia; recent genitourinary or gastrointestinal procedure; immunocompromised status; or injection drug use. Injection drug use is a substantial risk factor for spinal infection, and one should follow the axiom that back pain

TABLE 282-1 Summary of Risk Factors in Back Pain

	Concern
Historical Risk Factors	
Pain >6 weeks	Tumor, infection
Age <18, >50	Congenital anomaly, tumor
Major trauma	Fracture
Minor trauma in elderly	Fracture
History of cancer	Tumor
Fever and rigors	Infection
Weight loss	Tumor, infection
Injection drug use	Infection
Immunocompromise	Infection
Night pain	Tumor, infection
Unrelenting pain, even when supine	Tumor, infection
Incontinence	Epidural compression
Saddle anesthesia	Epidural compression
Severe/progressive neurologic deficit	Epidural compression
Physical Risk Factors	
Fever	Infection
Patient writhing in pain	Infection
Unexpected anal sphincter laxity	Epidural compression
Perianal/perineal sensory loss	Epidural compression
Major motor weakness	Nerve root or epidural compression
Positive straight leg raise test	Herniated disk

SECTION 24 • NONTRAUMATIC MUSCULOSKELETAL DISORDERS

in a patient who is an injection drug user is vertebral osteomyelitis or epidural abscess until proven otherwise.

However, it is important to review the abdomen, chest, and urinary system to avoid overlooking extraspinal disease processes referring or radiating to the back. The most serious of these is a rupturing abdominal aortic aneurysm. Other potential causes of pain referred to the back include pancreatitis, a posterior lower lobe pneumonia, nephrolithiasis, and renal infarct.

ATYPICAL PAIN FEATURES Most patients with a benign etiology for their back symptoms complain of a dull, aching pain that generally worsens with movement but improves with rest and lying still. Risk factors for tumor and infection include pain that occurs at night, often awakening the patient from sleep, or is unrelenting despite appropriate use of analgesics and rest. Pain suspicious for disk herniation is that which is worsened by coughing, Valsalva maneuver, or sitting, and is relieved by lying in the supine position.^{13,15} Spinal stenosis is associated with bilateral sciatic pain that is worsened by activities such as walking, prolonged standing, and back extension, and is relieved by rest and forward flexion. In the authors' experience, night pain and unrelenting pain are worrisome symptoms that are commonly overlooked in the evaluation of patients with back pain.

ASSOCIATED NEUROLOGIC DEFICITS Most patients with non-specific back pain have no associated neurologic deficits or complaints. Any neurologic deficit is a risk factor for structural back disorders. Neurologic complaints such as paresthesias, numbness, weakness, and gait disturbances must be further addressed in the history and delineated in the physical examination to determine whether the symptoms involve single or multiple nerve roots. Bowel or bladder incontinence is a symptom worrisome for an epidural compression syndrome such as spinal cord compression, cauda equina syndrome, or conus medullaris syndrome. If a patient presents with back pain and a history of urinary incontinence (acute or chronic), but an otherwise completely normal history and evaluation, measure the postvoid residual volume. A large postvoid residual volume (e.g., >100 mL) indicates overflow incontinence, which in the setting of low back pain suggests neurologic compromise and an epidural compression syndrome.⁶

PAST MEDICAL HISTORY History of cancer is a risk factor as back pain is the initial symptom in the majority of those with spinal metastases. Malignant neoplasm is the most common systemic disease affecting the spine. Approximately 80 percent of the patients with this diagnosis are over age 50.⁶ Patients with a history of cancer of the breast, lung, thyroid, kidney, or prostate, and those with a history of myeloma, lymphoma, or sarcoma are at highest risk for metastatic disease to the spine.⁷ However, only one-third of patients diagnosed with spinal malignancy have a known history of cancer.⁶ Thus one must rely on other symptoms such as unremitting pain, night pain, and weight loss to direct one to further diagnostic testing to make this diagnosis.

Physical Examination

The physical examination does not need to be comprehensive, but is must be focused on ruling out risk factors and identifying neurologic deficits.

VITAL SIGNS Fever is a risk factor for infection. Unfortunately, the sensitivity of fever is low, varying from 27 percent for tuberculous osteomyelitis to 50 percent for pyogenic osteomyelitis and 83 percent for spinal epidural abscess.⁶ Approximately 2 percent of patients with non-specific back pain will present with fever that is not due to a spinal infection. In these cases it is usually attributed to a concomitant viral illness.⁶ However, the first concern is for a spinal infection until it is ruled out by further history, physical examination, and possibly diagnostic testing.

GENERAL APPEARANCE Patients with a benign source of back pain are generally most comfortable when lying still. In patients with severe or excessive pain, consider acute spinal infection, abdominal aortic aneurysm, or nephrolithiasis.

ABDOMEN Examine the abdomen of all patients with back pain. The examination should include auscultation for bruits and palpation for masses, tenderness, and an enlarged aorta.

BACK Examine the back for signs of underlying disease. Erythema, warmth, and purulent drainage are consistent with infection. Contusion and swelling are concerning for trauma. Palpate the back and percuss the vertebral bodies. Point tenderness to percussion is found with fractures and bacterial infection, with a sensitivity of 86 percent and specificity of 60 percent for infection.⁶

The final portion of the back examination consists of straight leg raise testing. With the patient lying supine, passively lift each leg separately to approximately 70 degrees in an attempt to reproduce the pain (Figure 282-1). A positive straight leg raise test results in a re-

FIG. 282-1. Instructions for the straight leg raising (SLR) test. 1. Ask the patient to lie as straight as possible on a table in the supine position. 2. With one hand placed above the knee of the leg being examined, exert enough firm pressure to keep the knee fully extended. Ask the patient to relax. 3. With the other hand cupped under the heel, slowly raise the straight limb. Tell the patient "If this bothers you, let me know, and I will stop." 4. Monitor for any movement of the pelvis before complaints are elicited. True sciatic tension should elicit complaints before the hamstrings are stretched enough to move the pelvis. 5. Estimate the degree of leg elevation that elicits complaint from the patient. Then determine the most distal area of discomfort: back, hip, thigh, knee, or below the knee. 6. While holding the leg at the limit of straight leg raising, dorsiflex the ankle. Note whether this aggravates the pain. Internal rotation of the limb can also increase the tension on the sciatic nerve roots.

production of the patient's sciatic pain or a radicular pain into the affected leg below the knee. The radicular pain is worsened by ankle dorsiflexion and improved with ankle plantar flexion or decreasing the elevation. Reproduction of the patient's back pain or pain in the gluteal or hamstring area does not constitute a positive result. An important point regarding the straight leg raise test is that it can be easily and surreptitiously confirmed from the seated position with similar leg extension and foot dorsiflexion (Figure 282-2). Straight leg raise testing is a screening examination for herniated nucleus pulposus (disk). A positive straight leg raise test is approximately 80 percent sensitive for a L4-L5 or L5-S1 herniated disk. Radicular pain down the affected leg when lifting the asymptomatic leg is called a positive crossed straight leg raise test. A positive result is highly specific, but insensitive for nerve root compression by a herniated disk.^{2,3,5}

NEUROLOGIC EXAMINATION The neurologic examination is the most important aspect of the physical examination. It is directed to detecting deficits in each of the specific spinal nerve roots. Sensation may be tested by using light touch initially, followed more formally by pinprick, temperature, proprioception, and vibration testing if there are any questions regarding diminished sensation. Next one assesses strength, with a focus on those muscle groups innervated by individual nerve roots (Figure 282-3). Specifically, individually test the ankle dorsiflexors (L4), extensor hallucis longus (great toe dorsiflexion) (L5), and ankle plantar flexors (S1/S2). Finally, evaluate the patellar (L3-L4), Achilles (S1), and Babinski reflexes. There is no easily obtainable reflex for the L5 nerve root. Babinski sign is an abnormal reflex that appears when upper motor neuron innervation through the corticospinal tract is lost. A positive Babinski sign is extension of the great toe and abduction of the other toes with plantar stimulation, rather than the normal flexion response.

Digital rectal examination should be performed in those patients with any risk factors, especially those with neurologic complaints, and in those with severe pain. The test is performed to evaluate for rectal sphincter tone and sensation, the presence of prostatic and rectal masses, and to rule out perirectal abscess. Poor rectal tone in association with back pain and saddle anesthesia indicates an epidural compression syndrome.

FIG. 282-2. Instructions for sitting knee extension test. With the patient sitting on a table, both hip and knees flexed at 90 degrees, slowly extend the knee as if evaluating the patella or bottom of the foot. This maneuver stretches nerve roots as much as a moderate degree of supine SLR.

FIG. 282-3. Testing for lumbar nerve root compromise.

DIAGNOSTIC TESTING

Laboratory Testing

Laboratory testing is indicated if one has concern for infection, tumor, or rheumatologic causes of the back pain. Order a CBC, erythrocyte sedimentation rate (ESR), and urinalysis (UA). With infection, the white blood cell count may be normal or elevated. However, the ESR is invariably elevated, even in those with immunocompromise.^{8,9,10} The C-reactive protein is also elevated. The ESR will also be elevated in patients with a rheumatologic etiology of their symptoms, as well as in the majority of patients with neoplastic disease of the spine.¹¹ Urinalysis is obtained to rule out urinary tract infection as an infectious source for seeding of the spine and to rule out renal disease being referred to the back.

Radiographic Imaging

PLAIN SPINAL RADIOGRAPHS Plain spinal radiographs can be considered when one suspects fracture, tumor, or infection. In ordering these images, only anteroposterior and lateral views are necessary. The cone-down L5-S1 and oblique views rarely add clinically useful information while more than doubling gonadal radiation exposure and cost.³

MR! MRI is the definitive imaging modality in most emergent situations involving back pain. It offers the best resolution for lesions in the vertebral bodies, spinal canal, spinal cord, and disk disease. It is the gold-standard study in cases of suspected spinal infection, neoplasm, and epidural compression syndromes. Furthermore, its routine or urgent use is indicated in evaluating for neoplastic processes of the entire spine and disk disease, or when the patient's symptoms fail to resolve after 6 to 8 weeks.^{2,12}

CT SCAN CT scanning is most useful in evaluating vertebral fractures, the facet joints, and the posterior elements of the spine. It shows good detail of the vertebral bodies, but has poor resolution of the spinal canal and spinal cord in comparison to MRI. Because of its widespread availability, it is useful in those settings in which MRI is either unavailable or unsuitable. In the setting of suspected spinal canal or cord involvement, such as epidural abscess or compression, CT myelography is the best substitute when MRI is unavailable.¹³

DIFFERENTIAL DIAGNOSIS AND MANAGEMENT

Nonspecific Back Pain

The majority of patients seen in the ED with acute back pain will receive this diagnosis. This is a symptom complex that has countless names, including back strain/sprain, mechanical back pain, and lumbago. However, because strain and/or sprain have never been histopathologically documented in these patients, a more accurate diagnosis is idiopathic or nonspecific back pain. Nonspecific back pain is the authors' choice, especially since up to 85 percent of these patients will never be given a more precise diagnosis.²

SYMPTOMS AND DIAGNOSIS The patient with nonspecific back pain typically complains of mild to moderate pain that is aggravated with movement and relieved with rest. While the typical mechanism is usually minor exertion or lifting, the patient may not recall any remarkable etiology. The history and physical examination generally reveal an absence of risk factors, or if any risk factors are present, the diagnostic evaluation is normal.

MANAGEMENT The management strategy for nonspecific back pain is multifaceted, including activity, analgesia, manipulation, and other physical modalities. First, patients should be monitored for 4 to 6 weeks for improvement of their symptoms before embarking on a diagnostic evaluation, because 80 to 90 percent will resolve on their own within this time period.¹⁴ Thus, watchful waiting avoids wasting time, money, and unnecessary radiation exposure to the patient. This point should be discussed with the patient, as they commonly expect to have plain spinal radiographs, at a minimum, obtained for their symptoms in the ED.

The therapeutic value of activity has gained significant recognition as a cornerstone of management. While bed rest had been previously advocated, it has been demonstrated that patients who resume their normal activities to the extent tolerable recover more rapidly than those on 2 or 7 days of bed rest or those who performed back-mobilizing exercises.^{3,15} Thus, patients should continue with their daily activities as much as possible, using pain as the limiting factor. Withhold exercise programs until the acute painful episode has resolved or improved significantly.

The foundation of pharmacologic therapy is acetaminophen and NSAIDs. Acetaminophen is an excellent first-line agent and there is no evidence that NSAIDs are more effective for symptomatic relief. However, most physicians use NSAIDs. Most NSAIDs are equally efficacious for back pain, yet there are significant differences in the side effect profiles and toxicity.^{16,17} In one review, ibuprofen was the least toxic of the twelve studied, particularly with regard to upper GI bleed-

ing.¹⁷ Since there is a linear relationship between dose and toxicity, the lowest dose possible should be used in patients at risk. In those patients at risk for GI bleeding, the addition of misoprostol or omeprazole can reduce the risk.¹⁷ The NSAID ketorolac is no more effective than oral ibuprofen in patients with musculoskeletal pain, but it has a higher rate of side effects.

We recommend using acetaminophen in combination with NSAIDs or as the sole initial agent when treating patients at higher risk for adverse effects of NSAIDs, such as the elderly and patients with renal disease or peptic ulcers. One regimen is acetaminophen 650 to 975 mg q 4 to 6 h, either alone or in conjunction with either ibuprofen 800 mg tid, or naproxen 250 to 500 mg bid.

Opioid analgesics should be offered to patients with moderate to severe pain, but for a limited (1 to 2 weeks) duration. When prescribing opioid analgesic combinations that include acetaminophen, warn patients not to combine them with other acetaminophen products.

Muscle relaxants are useful for treating back pain, especially when accompanied by muscular spasms. Muscle relaxants such as diazepam 5 to 10 mg q 6 to 8 h, and methocarbamol 1000 to 1500 mg qid, are effective. Although their efficacy appears equal to NSAIDs, there does not appear to be any additional pain relief or synergistic benefit when used in combination with them.¹⁶ Corticosteroids taken systemically, injected locally or into the epidural space, have no role in the treatment of nonspecific back pain.¹⁶

Manipulative therapy, while not generally an ED treatment, is one of the more controversial treatment options for back pain. Recent research showed that acute manipulation is no better than physical therapy and only slightly better in terms of patient satisfaction than giving the patient a one-dollar educational booklet.¹⁸ Furthermore, manipulation fared no better than standard medical therapy in terms of clinical outcome.¹⁹ Consequently, we question the utility and cost-effectiveness of manipulative therapy and do not recommend it in patients with acute back pain.

Other physical modalities include traction, diathermy, cutaneous laser treatment, exercise, ultrasound treatment, and transcutaneous electrical nerve stimulation. None of these have any proven efficacy in the treatment of acute low back symptoms. The application of heat or ice may provide temporary symptomatic relief in some patients.

Chronic Nonspecific Back Pain

There is a higher concern for serious disease in patients with ongoing or intermittent symptoms for months to years. The best approach is to review the past evaluation to ensure that it has been complete and that abnormalities have not been overlooked. Specifically, review laboratory testing and plain spinal radiographs. If the evaluation has been incomplete, then complete it in the ED at that visit. If the evaluation has been thorough and negative, then treat as described for nonspecific back pain. If opioid analgesics are needed, prescribe them for only a week or so, until a primary care physician can assume care.

Sciatica

While sciatica only affects 1 percent of all patients with back pain, it is present in 95 percent of patients with a symptomatic herniated disk.³ Although disk herniation is the most common cause of sciatica, other etiologies to consider include intraspinal tumor or infection, foraminal stenosis, extraspinal plexus compression, piriformis syndrome, and lumbar canal stenosis (spinal stenosis).

Disk Herniation

SYMPTOMS AND DIAGNOSIS Patients who present with sciatica due to a herniated disk generally complain more about the radicular symptoms than the back pain. Because more than 95 percent of

disk herniations occur at the L4-L5 (L5 nerve root) or L5-S1 (S1 nerve root) level, the radicular pain extends below the knee in the dermatomal distribution of the nerve root.^{2,3} The remaining 5 percent of patients are usually older patients who have a relatively increased risk of disk herniation at the L2-L3 (L3 nerve root) and L3-L4 (L4 nerve root) levels. The physical examination generally demonstrates localization of pain and a neurologic deficit in a unilateral single nerve root, usually L5 or S1, and frequently a positive result on straight leg raise testing.

If the patient has no risk factors in the history and physical examination for serious disease other than sciatica, treat conservatively and do not perform any diagnostic tests in the ED.^{1,3,5-13,14} If the patient has a demonstrable neurologic deficit, then one may consider obtaining plain radiographs to rule out other possible causes for symptoms such as tumor, fracture, spondylolisthesis, and infection. It is the authors' practice not to obtain any plain radiographs in this setting. If the patient returns to the ED for a worsening condition or the sciatica fails to improve, then an MRI is indicated. However, if the symptoms have not progressed rapidly or the symptoms are not severe, the MRI can be ordered routinely or urgently but not emergently.

MANAGEMENT The treatment of patients with herniated disk is similar to that of patients with lumbosacral strain. Routine daily activity is as good as 2 weeks of bed rest in terms of intensity of pain, bothersomeness of symptoms, and functional status.²⁰ The use of analgesics (acetaminophen, NSAIDs, and narcotics) and muscle relaxants is the same as that described for lumbosacral strain. Interestingly, NSAIDs are less effective in treating the symptoms than they are in treating lumbosacral strain.¹⁶

Corticosteroid therapy for herniated disk has a limited benefit. Specifically, epidural corticosteroid injection has been shown to have a minor reduction in leg pain and sensory deficits in comparison to placebo. However, the improvement in symptoms is not associated with any significant functional benefit nor does it reduce the need for surgery.^{16,21} Although epidural steroid injection is not an ED procedure, it offers an alternative for the moderately to severely symptomatic patient in follow-up. Local and systemic administration of corticosteroids has not been proven beneficial in herniated disk.

Manipulation is not recommended for the routine management of symptoms from herniated disk.^{3,14} Other physical modalities have not been shown to be useful in managing sciatica, although as in the case of lumbosacral strain, application of heat or ice may provide temporary relief.

Most patients with a herniated disk may be treated and monitored by their primary care physician without specialist referral. Approximately 80 percent of patients will ultimately improve with nonsurgical therapy, with more than 50 percent recovering in 6 weeks.^{1,3} Most spine surgeons agree that surgery is appropriate only when all three of the following criteria are met:

1. Definitive evidence of herniation as demonstrated by an imaging study
2. This evidence exists in conjunction with a corresponding clinical picture and neurologic deficit
3. Conservative treatment for 4 to 6 weeks fails to produce improvement

The major benefit of surgery is to cure the sciatica and the neurologic deficits. Approximately 70 percent of patients who undergo surgery obtain relief of their back pain.⁵ Emergency decompressive surgery is required only in patients with acute epidural compression syndromes. Conservative nonsurgical treatment has been compared with surgery for herniated disks in two studies. The results showed that patients who underwent surgery had improved function and fewer symptoms at 1 and 2 years postoperatively, compared with those treated conservatively; however, by 4 and 10 years postoperatively, both groups had comparable results.^{2,3}

Spinal Stenosis

Spinal stenosis is a narrowing of any part of the lumbar spine, including the spinal canal, nerve root canal, and intervertebral foramina, that may occur at single or multiple spinal levels. Degenerative disease causes narrowing and compression of vascular and neural structures. It is a cause of chronic back pain, generally over a period of years, which may have associated sciatica. The symptoms, which usually begin in the sixth decade, include low back pain that is aggravated by prolonged standing and spinal extension, and is relieved by rest and forward flexion. Typically, symptomatic patients present with low back and lower extremity pain with walking that is symptomatically similar to vascular claudication. This symptom is termed pseudoclaudication. Pseudoclaudication, which occurs in 60 percent of patients with spinal stenosis, is pain of the lateral legs that occurs with walking and is relieved with rest. It is called pseudoclaudication because it is caused by neurologic compression, not arterial occlusion. Physical examination findings are often absent. The diagnosis is made by history with confirmation by CT scan or MRI. Referral to a spine surgeon is indicated to determine if surgery can be beneficial. Symptomatic treatment is as for chronic back pain.

Ankylosing Spondylitis

Ankylosing spondylitis is an autoimmune arthritis that primarily affects the spine and pelvis. It has been also associated with HLA B-27, trauma, and infection. It most commonly occurs in patients under age 40 with a 3:1 male predilection. Patients complain of awakening with low back pain and stiffness that improves throughout the day with mild activity, as well as other constitutional symptoms such as malaise and fatigue. The diagnosis is made by history in individuals with symptoms longer than 3 months' duration. Radiographic studies demonstrate sacroiliitis and squaring of the vertebral bodies, the so-called "bamboo spine." Patients are treated symptomatically with NSAIDs and should be referred to a rheumatologist for further management.

Epidural Compression Syndromes

Epidural compression syndrome is a collective term encompassing spinal cord compression, cauda equina syndrome, and conus medullaris syndrome. This term is used to group these syndromes together for two reasons. First, the presentation for these syndromes is similar, except for the level of the neurologic deficit. Secondly, the initial evaluation and management for these syndromes is similar, until the actual diagnosis is known.

While the diagnosis of a complete epidural compression is obvious, the challenge to emergency physicians is in detecting those patients with early signs and symptoms. The initial differential diagnosis is broad and includes most conditions that cause weakness, sensory changes, or autonomic dysfunction. The history and physical examination will enable one to narrow the differential to a compressive lesion of the spinal cord or cauda equina.

Possible causes of epidural compression include spinal canal hemorrhage, tumors of the spine or epidural space, spinal canal infections, and massive midline disk herniation. Transverse myelitis is a noncompressive condition that may present exactly like a compressive lesion of the spinal cord.⁷

The history for patients with epidural compression usually includes back pain with associated neurologic deficits, incontinence, and sciatica in one or both legs. The duration of symptoms does not help differentiate these syndromes from benign causes of back pain. Important features are a history of malignancy and a rapid progression of neurologic symptoms, especially bilateral symptoms.

The physical examination findings vary depending on the level of compression and the amount and area of the spinal cord or cauda equina that is compressed. The most common finding in cauda equina

syndrome is urinary retention with overflow incontinence, with a sensitivity of 90 percent and a specificity of about 95 percent.⁶ Other common findings for epidural compression include weakness or stiffness in the lower extremities, paresthesias or sensory deficits, gait difficulty, and abnormal results on straight leg raising.² The most common sensory deficit occurs over the buttocks, posterosuperior thighs, and perineal regions, and is commonly called "saddle anesthesia." Anal sphincter tone is decreased in 60 to 80 percent of cases.⁶

When one clinically suspects epidural compression, especially due to tumor, treat the patient with dexamethasone 10 mg IV before obtaining any confirmatory tests.²¹ This is done in an attempt to minimize progression of the compression, edema, and the resultant neurologic damage. The reason to treat before determining a definitive diagnosis is because the diagnostic evaluation may take several hours or longer, and there may be a progression of the neurologic deficit while the patient is waiting.

After the patient has received dexamethasone, obtain an emergent MRI of the spine. If investigating the possibility of epidural compression due to neoplasm, obtain an MRI of the entire spine, as 10 percent of patients with vertebral metastases have additional silent epidural metastases, which would be missed by a localized imaging study.²² The presence of tumors remote from the symptomatic site may change patient management. Additionally, the neurologic examination may falsely localize the spinal lesion(s), and limited regional MRI may not detect the lesion. If one suspects a pure cauda equina syndrome, then it is reasonable to obtain a localized MRI.

The functional clinical outcome for epidural compression from tumor depends on patient symptoms at presentation. Patients who cannot walk before treatment rarely walk again. Those who are too weak to walk without assistance but who are not paraplegic have a 50 percent chance of walking again. Those who are able to walk when treatment begins are likely to remain ambulatory.²² Of those patients who require a catheter for urinary retention before treatment, 82 percent will continue to require the urinary catheter after treatment.²³

Spinal Infections

Spinal infections are very serious but uncommon causes of back pain. Infections are often associated with immunocompromised states such as cancer, diabetes, organ transplant, and injection drug use. Patients with spinal infections usually have had prolonged symptoms, and in greater than 50 percent, the symptoms have been present for greater than 3 months.¹² The principal symptom is pain, which is present in almost all patients.

Physical examination demonstrates fever in approximately 50 percent of patients and vertebral body tenderness to percussion. Laboratory evaluation usually shows an elevated WBC count, although this may be normal, and the erythrocyte sedimentation rate is universally elevated. Blood cultures are positive in approximately 40 percent of cases of osteomyelitis, and even higher in patients with epidural abscess. In osteomyelitis, plain radiographs will be normal until the process has had sufficient time to demineralize the bone, which can range from 2 to 8 weeks. The most common radiographic abnormalities with vertebral osteomyelitis are bony destruction, irregularity of vertebral end plates, and disk space narrowing. In epidural abscess, the plain films will be normal unless there is a concomitant vertebral osteomyelitis. MRI is the gold standard imaging study to make the diagnosis of these spinal infections.

The treatment of epidural abscess is primarily surgical and requires emergent evaluation and treatment by a spine surgeon. The treatment for vertebral osteomyelitis is primarily medical, consisting of 6 weeks of intravenous antibiotics, followed by a 4- to 8-week course of oral antibiotics. However, in treating vertebral osteomyelitis, consultation with a spine surgeon is important and should be performed prior to the administration of antibiotics, as they may wish to obtain core bone biopsies, and prior antibiotic therapy may result in negative culture re-

sults. However, one should not withhold antibiotic therapy unless specifically directed by the spine surgeon. The remainder of treatment is symptomatic, with bed rest and immobilization commonly employed, along with appropriate analgesia.

SPECIAL SITUATIONS

Back Pain in the Patient with a History of Cancer

The patient with a history of cancer who presents with back pain is a unique situation due to the possibility of spinal metastases. The best way to approach these patients is by dividing them into three groups based on their symptoms.

GROUP I: PATIENTS WITH NEW OR PROGRESSIVE SYMPTOMS

Group I includes patients with new or progressing signs or symptoms of epidural compression that have been present for several hours to several days. These symptoms may include new urinary urgency or incontinence, paresthesias, numbness, weakness, gait disturbances, absent reflexes, or the involvement of two or more nerve roots. Treat this group with immediate corticosteroid therapy, and obtain an emergent MRI as you would for other patients with epidural compression.²²

GROUP II: PATIENTS WITH STABLE SYMPTOMS Group II includes those patients with stable symptoms or signs that have been present for several days to several weeks. These signs include an isolated Babinski sign or radiculopathy without other neurologic deficits or evidence of cord compression. Radiculopathy is characterized by radicular pain, weakness, sensory changes, or reflex changes involving only one nerve root. Involvement of more than one nerve root places the patients into group I. Evaluation and treatment are similar to those for group I. The major difference is that patients with stable symptoms do not require immediate MRI, although evaluation within 24 h is advisable. If one does not obtain an MRI from the ED, then one should obtain plain films of the involved area to look for evidence of metastatic disease. If there is evidence of metastatic disease on the plain films, obtain an MRI in the ED. We recommend initiating dexamethasone 10 mg orally while awaiting definitive diagnostic evaluation.²² We feel the side effects of 1 to 2 days of dexamethasone are negligible in comparison to the potential benefit.

GROUP III: PATIENTS WITHOUT NEUROLOGIC SIGNS OR SYMPTOMS

Group III includes those patients with back pain only, without any neurologic signs or symptoms. In the ED, obtain plain radiographs of the involved spine that include anteroposterior (AP) and lateral views. If any focal bony lesions are discovered, obtain an MRI of the entire spine. Note that normal findings on plain radiographs do not rule out epidural metastases. In fact, more than 60 percent of patients with lymphoma and epidural metastases have normal plain radiographs.²² If patients have negative plain films, they should be followed-up by their primary physician within 5 to 7 days to ensure improvement and no worsening in their symptoms.

FUNCTIONAL ANATOMY

The shoulder is designed for mobility rather than stability.² Its functions are to help position the hand and upper extremity for accurate and efficient use, and to provide strength and power to upper extremity movements. To meet the many demands placed on it, the shoulder uses three bones, four joints, and a specialized set of soft tissues consisting of muscles, tendons, ligaments, and bursae.

Bones and Joints

The humerus, clavicle, and scapula make up the bony structures of the shoulder complex. The scapula has two bony extensions, the coracoid and the acromion, which help protect the rotator cuff and play important roles in shoulder function.

The four joints of the shoulder are the glenohumeral, acromioclavicular, sternoclavicular, and scapulothoracic. The glenohumeral joint is a ball-and-socket joint and is the central axis of shoulder motion. While the glenohumeral joint is the most mobile joint in the body, it is the least stable. To help improve its stability, this joint relies on three components. The first is the glenoid labrum, which is a fibrous ring of tissue encircling the glenoid cavity. The glenoid labrum increases the surface contact area of the humeral head within the relatively shallow glenoid fossa. The second component consists of three glenohumeral ligaments, which aid stability by reinforcing the joint capsule. Finally, four specialized muscles, known as the rotator cuff, encompass the glenohumeral joint and provide significant stability during motion.

The sternoclavicular and acromioclavicular joints work together to contribute to glenohumeral motion. Rotation at the acromioclavicular joint and elevation at the sternoclavicular joint allow complete arm elevation. The scapulothoracic joint represents the articulation of the scapula on the posterior wall of the thorax. Scapular motion is essential for overall shoulder motion: every degree of scapulothoracic motion allows two degrees of glenohumeral motion.

Muscles

The deltoid, which drapes the shoulder complex and forms its contour, acts as a powerful and independent elevator of the arm. Along with the pectoralis, the deltoid is the major mover of the upper extremity.

The rotator cuff consists of four muscles: supraspinatus, infraspinatus, teres minor, and subscapularis. All originate on the scapula, traverse the glenohumeral joint, and insert on the proximal humerus. The rotator cuff functions primarily as a dynamic stabilizer of the glenohumeral joint. The rotator cuff muscles also contribute significantly to the power of the upper extremity, providing 30 to 50 percent of the power in abduction and 90 percent in external rotation (Figures 283-1 and 283-2).

The supraspinatus originates on the posterior and superior aspect of the scapula, passes beneath the acromion, and inserts on the great tuberosity of the humerus. It initiates arm elevation and abducts the shoulder. It also balances the power of the deltoid, keeping the humerus centered in the glenoid during deltoid contraction. The infraspinatus originates on the posterior scapula just inferior to the scapular spine. It inserts on the posterior aspect of the greater tuberosity and acts primarily as an external rotator of the arm (see Figure 283-1). The teres minor originates on the lateral border of the scapula just inferior to the infraspinatus and inserts on the posterior aspect of the humerus. It works with the infraspinatus to provide external rotation (see Figure 283-1). The subscapularis is the only rotator cuff muscle that arises from the anterior aspect of the scapula. It attaches to the lesser tuberosity of the humerus and provides internal rotation of the arm (see Figure 283-2).

The long head of the biceps tendon, although not formally considered part of the rotator cuff, assists in rotator cuff function. This tendon courses superiorly in the bicipital groove of the humerus between

SHOULDER PAIN

David Della-Giustina
Benjamin Harrison D.
Monte Hunter

Injuries involving the rotator cuff are the most common cause of shoulder pain.¹ While these injuries can be acute, they more commonly occur from chronic overuse. Overuse can produce pathologic changes in the rotator cuff structures that progress along the continuum starting with subacromial bursitis from mechanical irritation, progressing to rotator cuff tendinitis, and eventually leading to partial- and full-thickness rotator cuff tears. Laborers who work with their arms above the horizontal and athletes of all ages, especially throwers, swimmers, and racquet sports enthusiasts, are the most susceptible to chronic overuse injuries. Acute injuries to the rotator cuff usually require significant trauma such as extreme forced hyperabduction or hyperextension of the upper extremity.

Conditions affecting other intrinsic structures of the shoulder complex can also cause pain. Additionally, extrinsic disorders can refer pain to the shoulder and must be considered in the differential diagnosis. A focused history and physical examination carried out with an understanding of the complex anatomy and function of the shoulder is essential in determining the source of shoulder pain. Establishing the proper diagnosis, initiating the appropriate treatment, and making timely referrals for follow-up are critical in preserving the function and mobility of the shoulder.

FIG. 283-1. Posterior view of shoulder illustrating rotator cuff muscles.

the greater and lesser tuberosities, passes between the subscapularis and supraspinatus tendons, and penetrates the glenohumeral joint to insert on the labrum (see Figure 283-2). During arm elevation, the tendon of the long head of the biceps depresses the humeral head, helping it remain centered in the glenoid.

Bursae

The bursae facilitate motion between the components of the shoulder. There are eight identifiable bursae in the shoulder complex. However, only the large subacromial bursa is clinically significant. The subacromial bursa is extra-articular; its roof adheres to the undersurface of the deltoid, and its floor to the underlying rotator cuff. This bursa, lubricated by synovial fluid and surrounded by a layer of peribursal fat, aids in a smooth, frictionless motion between the rotator cuff and adjacent structures.

FIG. 283-2. Anterior view of shoulder illustrating supraspinatus and longhead of biceps.

Coracoacromial Arch

The coracoacromial arch is an important anatomic concept in understanding shoulder pathology. The arch is formed by the coracoid posteriorly, by the acromion anteriorly, and by the coracoacromial ligament, which forms the anterior roof of the arch (Figure 283-3). The humeral head provides the floor of the arch. This arch defines the space within which the tendons of the rotator cuff, the tendon of the long head of the biceps, and the subacromial bursa must function.

IMPINGEMENT SYNDROME

(Subacromial Bursitis, Rotator Cuff Tendinitis, Supraspinatus Tendinitis, Painful Arc Syndrome)

Repetitive overhead use of the arm or movement of the shoulder above the horizontal causes encroachment of the subacromial space by the humeral head (Figure 283-4). This results in a loss of the normal gliding mechanism between the rotator cuff and related soft tissues within the coracoacromial arch.

Impingement syndrome refers to the pathologic changes that occur to the rotator cuff, subacromial bursa, and other soft tissues within the coracoacromial arch due to this repetitive compression.³ In the past, these symptoms were referred to separately as subacromial bursitis, rotator cuff tendinitis, supraspinatus tendinitis, and painful arc syndrome. However, impingement syndrome is the current terminology that encompasses all of these previous terms and pathologic processes. Impingement syndrome is the leading cause of shoulder pain and dysfunction.

Pathophysiology

Repetitive impingement of the bursa, rotator cuff, and biceps tendon produces pathologic changes in these structures that evolve in a progressive pattern classified in three stages. In stage 1, reversible edema

FIG. 283-3. Lateral view of shoulder illustrating coracoacromial arch with rotator cuff and subacromial bursa.

FIG. 283-4. Impingement of subacromial bursa and rotator cuff.

and hemorrhage about the rotator cuff occurs. While this stage can occur at any age, it is classically seen in young athletes under age 25 who engage in sports that require excessive overhead use of the shoulder. During this stage, patients complain of a dull ache over the antero-lateral shoulder that is aggravated by activity and improved by rest. The clinical course at this point is typically reversible with rest, activity modification with avoidance of the aggravating activity, anti-inflammatory agents, and ice.

If patients continue the aggravating activities and do not follow the prescribed treatment, then the repeated mechanical trauma from the impingement can progress to stage 2. In stage 2, the edema and hemorrhage progress to tendinitis of the rotator cuff with subsequent fibrosis and thickening of the tendons of the rotator cuff and bursa. This stage is typically seen in patients between the ages of 25 and 40. However, it is the prolonged duration (weeks to months) or recurrence of symptoms that is most useful in making this diagnosis. During this stage, patients will complain of a recurrent or chronic aching pain with daily activities, vigorous activity, and night pain. The nocturnal pain is a deep aching pain that interferes with sleep and especially occurs when the patient lies on that shoulder or sleeps with his or her arms overhead. Treatment is conservative as for stage 1. Continued overuse can lead to stage 3. Stage 3 consists of rotator cuff tears, rupture of the long head of the biceps, and subacromial spurs. Patients at this stage have a history of progressive symptoms and disability and often require surgical decompression of the subacromial space.

Some of the earliest and more significant pathologic changes in the rotator cuff due to impingement occur near the humeral insertion of the supraspinatus tendon. This area, called the critical zone, is affected early because it is a relatively avascular site. Repetitive compression in this area causes a relative ischemia, which leads to tissue degeneration over time and ultimately tissue failure.³

Physical Examination

On examination, disuse atrophy of the shoulder musculature may be present if symptoms have been chronic (stages 2 and 3). Palpation of the rotator cuff insertion at the lateral aspect of the proximal humerus will usually produce pain and tenderness. During range-of-motion maneuvers, fibrosis and scarring within the tendon can cause crepitus. A sensation of catching also may be present if scar tissue is trapped beneath the acromion. Rotator cuff strength testing will reveal mild to moderate weakness. Pain will usually be present when resistance is applied. The individual muscles of the rotator cuff can be isolated and

tested individually. *To test the supraspinatus*, abduct the arm to 90° and place it forward 30° with the thumb pointed down in the so-called "empty beer can" position (Figure 283-5). Pain or weakness against resistance in this position suggests injury to the supraspinatus. *To test the infraspinatus and the teres minor*, externally rotate the shoulder with the patient's arm against the body, and the elbow bent to 90° and the forearm in neutral position. Stabilize the elbow against the patient's waist and instruct the patient to rotate the arm outward. *To test the subscapularis*, maintain the elbow flexed to 90° and fixed against the patient's body, and have the patient rotate the arm inward around the front of the body against resistance.

Specific maneuvers on physical examination test for signs of impingement by compressing the rotator cuff and bursa between the humeral head and coracoacromial arch. In the classic impingement maneuver of Neer, the examiner prevents scapular rotation with one hand, while raising the patient's straightened arm smoothly in full forward flexion to overhead. This maneuver impinges the critical zone of the rotator cuff and bursa between the undersurface of the acromion and the greater tuberosity of the humerus. A second test, Hawkins impingement test (Figure 283-6), requires the examiner to position the patient's arm in 90° of abduction and 90° of elbow flexion. Rotation of the arm inwardly across the front of the patient with internal rotation of the shoulder compresses the cuff and bursa between the humeral head and coracoacromial ligament. These tests are considered positive if they reproduce pain, but cannot be used to stage the impingement as they elicit symptoms in all three stages.

Radiography

Radiography plays a minor role in the diagnosis of impingement syndrome, as it is primarily a clinical diagnosis. However, early radiographic signs include nonspecific sclerosis and cyst formation of the greater tuberosity of the humerus or osteoarthritis of the acromioclavicular joint. These findings are seen with impingement syndrome, but are nonspecific.³ A specific but late finding is that of an anterior acromial enthesophyte (spur).³ This spur may be seen on the anteroposterior shoulder radiograph.

Emergency Department Treatment

The goals of treatment of impingement syndrome are twofold: to reduce pain and inflammation and, more importantly, to prevent progression of

FIG. 283-5. The "empty beer can" position, which isolates the supraspinatus tendon on physical examination.

FIG. 283-6. Hawkins impingement test. The examiner positions the patient's shoulder at 90° of abduction and 90° of elbow flexion. The examiner then rotates the shoulder internally and brings the arm across the front of the patient.

the process. Regardless of the stage of impingement identified, a conservative treatment program should include the following:

1. *Relative rest and activity modification.* The patient should avoid the aggravating activity and minimize all overhead activities. While brief periods of support with a sling may be prescribed, complete immobilization should be avoided whenever possible. At a minimum, the patient should perform range-of-motion exercises (see below) three to four times daily to minimize the chance of developing adhesive capsulitis.
2. *Medication to reduce pain and inflammation.* Analgesics are often required to control pain during stage 2 and 3 impingement. Non-steroidal anti-inflammatory drugs (NSAIDs) should be prescribed for a 7 to 21 day course. Short-term opioid analgesics will be needed for moderate to severe pain.
3. *Cryotherapy.* The application of ice to the affected shoulder for 10 to 15 min two to three times daily can have analgesic effects and is thought to reduce local inflammation and edema.
4. *Gentle range of motion.* Two simple exercises can help the patient maintain glenohumeral motion. Pendulum swings are done with the patient slightly bent at the waist with the arm hanging freely in front of the body. Gentle arcs of motion in both a clockwise and counter clockwise direction to the level of pain tolerance can be carried out for 5 to 10 min three to four times daily. The size of the arcs should increase daily as symptoms allow. Have the patient stand sideways an arm's length from a wall, and walk the fingers up the wall to the level of pain tolerance, and repeat three to four times daily.
5. *Stretching and strengthening.* Stretching and strengthening exercises are best prescribed by the primary care physician or orthopedist, carried out under the supervision of a physical therapist.
6. *Corticosteroid injections.* While local corticosteroid injections into the subacromial space can be effective for pain relief, adverse effects include muscular atrophy, weakness, and further tissue degeneration. Injection directly into the substance of the tendon can lead to necrosis and rupture. Injection is best left to the primary care physician or orthopedist.
7. *Follow-up.* Clinical follow-up is usually recommended after 7 to 14 days.

ROTATOR CUFF TEARS

Rotator cuff tears present with acute shoulder pain and are either due to acute traumatic injury, chronic injury, or an acute extension of a chronic injury to the rotator cuff tendons. Chronic rotator cuff tears account for 90 percent of all rotator cuff tears, and are almost always due to progressive degeneration of stage 3 impingement. Healthy rotator cuff tendons are resistant to acute injury unless weakened by some other factor such as age, repetitive stress such as that seen in swimmers or baseball pitchers, steroid injections, or impingement. Acute rotator cuff tears account for only 10 percent of all rotator cuff tears and usually occur as a result of significant trauma. Traumatic causes typically involve forced or extreme hyperabduction or hyperextension, such as from a fall on an outstretched arm, lifting a heavy object, or catching a heavy object as it falls. Glenohumeral dislocations are also a common cause of acute rotator cuff tears, and the incidence of such tears rises significantly in patients over age 40 with shoulder dislocations.

Rotator cuff tears are further classified as full thickness or partial thickness. Partial-thickness tears are twice as common as full-thickness tears and most commonly occur on the inferior aspect of the tendon. Partial-thickness rotator cuff tears are more likely to occur from an acute injury, especially in younger patients. The type and extent of the tear have significant implications for the ultimate treatment and prognosis. Full-thickness tears usually require surgical treatment, whereas partial thickness tears often respond to a trial of conservative management.

As previously described, the critical zone of the rotator cuff is near the humeral insertion of the tendon. Repetitive compression and impingement cause ischemia in this area, and over time this area degenerates and ultimately tears. The supraspinatus, due to its location within the coracoacromial arch, is the most commonly affected tendon of the rotator cuff. The critical zone is the most common site of all rotator cuff tears (Figure 283-7).

Acute traumatic rotator cuff tears in a healthy tendon require a significant force. The tensile strength of a normal tendon is greater than that of bone; therefore, a bony avulsion injury of the humerus is much more common than an isolated rotator cuff tear following acute trauma.

FIG. 283-7. Rotator cuff tear. MRI coronal image of shoulder reveals tear in supraspinatus tendon at the critical zone (arrow) with edema (arrowhead).

Clinical Features

Middle-aged patients are most commonly affected, and this process is rarely seen in patients over 70. Females are slightly more likely to be affected than males, and calcification is often present bilaterally.

The onset of pain typically coincides with the resorption of the calcium deposit rather than the formation of it. Symptomatic patients experience sudden onset of shoulder pain, usually at rest, and any shoulder motion reproduces significant pain. The pain is often worse at night and interferes with sleep.

During an acute attack with intense pain, patients hold their arm across their body and often are reluctant to move it. Laboratory testing is unnecessary as it is usually normal in most patients. A point of maximum tenderness may be palpated over the proximal humerus near the tendinous insertion of the rotator cuff. Active and passive range of motion of the glenohumeral joint is usually limited to varying degrees. Flexion, extension, abduction, and internal/external rotation of this joint should be documented. Muscle atrophy and crepitus may also be present.

Radiographic Findings

Routine shoulder radiographs may reveal calcific deposits, and anteroposterior views with the humerus in the neutral position as well as in internal and external rotation may increase sensitivity. During the initial formative phase, calcium deposits are usually dense and well-defined if visualized. The presence of visible calcifications, however, is not necessarily specific for this disorder. Calcification in the rotator cuff tendons is found on radiographs in approximately 7 percent of patients older than age 30 with shoulder pain. In asymptomatic patients between 31 and 40, 10 to 20 percent demonstrate rotator cuff calcification on routine radiographs. Of these patients, only 35 to 45 percent will eventually become symptomatic. Conversely, most patients presenting to the ED will most likely be experiencing acute pain during the resorptive phase, when calcium deposits are ill-defined and less visible.

Emergency Department Treatment

Treatment is similar to that for impingement syndrome. During an acute attack, NSAIDs, opioid analgesics, and ice help calm the intense pain. Resting the shoulder with a sling for brief periods of immobilization may be utilized, but prolonged immobilization should be avoided to prevent loss of motion. The patient should be instructed to rest the shoulder in abduction on the back of a chair as often as is tolerable. Sleeping with a pillow beneath the axilla can also help prevent restricted motion. Local heat application may be used once acute symptoms have diminished. Gentle and progressive range-of-motion exercises should be emphasized and encouraged. Physical therapy is indicated in patients with more chronic cases who have significantly limited range of motion of the shoulder.

There is controversy regarding the effectiveness of subacromial corticosteroid injection,⁷ so this is best left to the primary care physician or orthopedist. Therapeutic ultrasonography, transcutaneous electrical nerve stimulation (TENS), and oral steroid administration are other modalities that can be prescribed by the primary care physician.⁸

The patient should follow-up with an orthopedist within a week. Calcific tendinitis is a self-limited process in the vast majority of cases. Surgical removal of the calcium deposit is usually considered only after all conservative measures have been exhausted.

ADHESIVE CAPSULITIS

Adhesive capsulitis, commonly referred to as the *frozen shoulder syndrome*, begins as painful inflammation of the glenohumeral joint, followed by eventual fibrosis of the joint capsule and restriction of shoulder motion. Primary or idiopathic adhesive capsulitis is associated with a wide variety of unrelated conditions, including postmenopause, diabetes, thyroid disease, pulmonary neoplasms, and autoimmune dis-

orders. Secondary adhesive capsulitis has similar clinical and pathologic findings, but results from a known cause, such as prolonged immobilization after trauma, surgery, or stroke, or a primary inflammatory condition of the shoulder such as impingement syndrome or bicipital tendinitis. The condition resolves with conservative therapy in most patients, although some are left with residual pain or stiffness.

Pathophysiology

Four stages of this disorder have been described based on arthroscopic and clinical findings correlated with pathologic changes of the capsule. However, controversy exists with regard to the classification of adhesive capsulitis, and patients do not necessarily follow these stages in a uniform fashion.⁹

Stage 1, which occurs during the first 2 to 3 months, is marked by acute synovial inflammation with limitation of shoulder movement due to pain. Stage 2 (*freezing stage*), which occurs from months 3 to 9, is characterized by decreased shoulder motion from capsular thickening and scarring, and chronic pain. In stage 3 (*frozen stage*), which occurs from months 9 to 15, the pain has diminished to a low level, but there is a more fibrotic and thick capsule and continued significantly decreased flexion, abduction, and internal/external rotation. Stage 4 (*thawing stage*), which generally occurs after 15 months, is associated with minimal pain and progressive improvement in the range of motion of the shoulder.⁹

Clinical Features

Pain is described typically as diffuse and aching, is poorly localized, and often extends down the upper arm. The pain is often described as worse at night and is also present at rest, especially in earlier stages. A painful stiffened shoulder is the hallmark finding on examination. Active and passive range of motion are limited, especially in abduction and in internal/external rotation. Disuse atrophy may be present. Pain is not usually reproducible by palpation, but is present at the limits of motion. Impingement testing is difficult due to restricted motion. Posterior glenohumeral dislocation must always be considered in the patient with restricted motion of the shoulder in an appropriate clinical scenario.

Radiographic Findings

There are no specific radiographic findings other than disuse osteopenia in long-standing cases. Radiographs should be ordered to exclude other disorders, such as posterior glenohumeral dislocation after trauma or seizure.

Emergency Department Treatment

The overall goals of treatment, regardless of stage, are to reduce pain and initiate restoration of motion and function. NSAIDs, analgesics, ice, and progressive range-of-motion exercises should be prescribed in the ED. Shoulder immobilization with a sling should be avoided unless absolutely necessary. If administered in those early stage 1 patients with severe pain, its use should be discontinued as soon as possible to prevent increased loss of motion due to further capsular restriction.

Follow-up should be provided with the primary care physician or orthopedist in 1 week for initiation of physical therapy and consideration of steroid injection.

DISORDERS OF THE BICEPS TENDON

Disorders of the biceps tendon can be a source of shoulder pain for patients and may result from progressive impingement or from isolated tendon inflammation or injury. The tendon of the long head of the biceps

Clinical Features

Middle-aged patients are most commonly affected, and this process is rarely seen in patients over 70. Females are slightly more likely to be affected than males, and calcification is often present bilaterally.

The onset of pain typically coincides with the resorption of the calcium deposit rather than the formation of it. Symptomatic patients experience sudden onset of shoulder pain, usually at rest, and any shoulder motion reproduces significant pain. The pain is often worse at night and interferes with sleep.

During an acute attack with intense pain, patients hold their arm across their body and often are reluctant to move it. Laboratory testing is unnecessary as it is usually normal in most patients. A point of maximum tenderness may be palpated over the proximal humerus near the tendinous insertion of the rotator cuff. Active and passive range of motion of the glenohumeral joint is usually limited to varying degrees. Flexion, extension, abduction, and internal/external rotation of this joint should be documented. Muscle atrophy and crepitus may also be present.

Radiographic Findings

Routine shoulder radiographs may reveal calcific deposits, and anteroposterior views with the humerus in the neutral position as well as in internal and external rotation may increase sensitivity. During the initial formative phase, calcium deposits are usually dense and well-defined if visualized. The presence of visible calcifications, however, is not necessarily specific for this disorder. Calcification in the rotator cuff tendons is found on radiographs in approximately 7 percent of patients older than age 30 with shoulder pain. In asymptomatic patients between 31 and 40, 10 to 20 percent demonstrate rotator cuff calcification on routine radiographs. Of these patients, only 35 to 45 percent will eventually become symptomatic. Conversely, most patients presenting to the ED will most likely be experiencing acute pain during the resorptive phase, when calcium deposits are ill-defined and less visible.

Emergency Department Treatment

Treatment is similar to that for impingement syndrome. During an acute attack, NSAIDs, opioid analgesics, and ice help calm the intense pain. Resting the shoulder with a sling for brief periods of immobilization may be utilized, but prolonged immobilization should be avoided to prevent loss of motion. The patient should be instructed to rest the shoulder in abduction on the back of a chair as often as is tolerable. Sleeping with a pillow beneath the axilla can also help prevent restricted motion. Local heat application may be used once acute symptoms have diminished. Gentle and progressive range-of-motion exercises should be emphasized and encouraged. Physical therapy is indicated in patients with more chronic cases who have significantly limited range of motion of the shoulder.

There is controversy regarding the effectiveness of subacromial corticosteroid injection,⁷ so this is best left to the primary care physician or orthopedist. Therapeutic ultrasonography, transcutaneous electrical nerve stimulation (TENS), and oral steroid administration are other modalities that can be prescribed by the primary care physician.⁸

The patient should follow-up with an orthopedist within a week. Calcific tendinitis is a self-limited process in the vast majority of cases. Surgical removal of the calcium deposit is usually considered only after all conservative measures have been exhausted.

ADHESIVE CAPSULITIS

Adhesive capsulitis, commonly referred to as the *frozen shoulder syndrome*, begins as painful inflammation of the glenohumeral joint, followed by eventual fibrosis of the joint capsule and restriction of shoulder motion. Primary or idiopathic adhesive capsulitis is associated with a wide variety of unrelated conditions, including postmenopause, diabetes, thyroid disease, pulmonary neoplasms, and autoimmune dis-

orders. Secondary adhesive capsulitis has similar clinical and pathologic findings, but results from a known cause, such as prolonged immobilization after trauma, surgery, or stroke, or a primary inflammatory condition of the shoulder such as impingement syndrome or bicipital tendinitis. The condition resolves with conservative therapy in most patients, although some are left with residual pain or stiffness.

Pathophysiology

Four stages of this disorder have been described based on arthroscopic and clinical findings correlated with pathologic changes of the capsule. However, controversy exists with regard to the classification of adhesive capsulitis, and patients do not necessarily follow these stages in a uniform fashion.⁹

Stage 1, which occurs during the first 2 to 3 months, is marked by acute synovial inflammation with limitation of shoulder movement due to pain. Stage 2 (*freezing stage*), which occurs from months 3 to 9, is characterized by decreased shoulder motion from capsular thickening and scarring, and chronic pain. In stage 3 (*frozen stage*), which occurs from months 9 to 15, the pain has diminished to a low level, but there is a more fibrotic and thick capsule and continued significantly decreased flexion, abduction, and internal/external rotation. Stage 4 (*thawing stage*), which generally occurs after 15 months, is associated with minimal pain and progressive improvement in the range of motion of the shoulder.⁹

Clinical Features

Pain is described typically as diffuse and aching, is poorly localized, and often extends down the upper arm. The pain is often described as worse at night and is also present at rest, especially in earlier stages. A painful stiffened shoulder is the hallmark finding on examination. Active and passive range of motion are limited, especially in abduction and in internal/external rotation. Disuse atrophy may be present. Pain is not usually reproducible by palpation, but is present at the limits of motion. Impingement testing is difficult due to restricted motion. Posterior glenohumeral dislocation must always be considered in the patient with restricted motion of the shoulder in an appropriate clinical scenario.

Radiographic Findings

There are no specific radiographic findings other than disuse osteopenia in long-standing cases. Radiographs should be ordered to exclude other disorders, such as posterior glenohumeral dislocation after trauma or seizure.

Emergency Department Treatment

The overall goals of treatment, regardless of stage, are to reduce pain and initiate restoration of motion and function. NSAIDs, analgesics, ice, and progressive range-of-motion exercises should be prescribed in the ED. Shoulder immobilization with a sling should be avoided unless absolutely necessary. If administered in those early stage 1 patients with severe pain, its use should be discontinued as soon as possible to prevent increased loss of motion due to further capsular restriction.

Follow-up should be provided with the primary care physician or orthopedist in 1 week for initiation of physical therapy and consideration of steroid injection.

DISORDERS OF THE BICEPS TENDON

Pathophysiology

Disorders of the biceps tendon can be a source of shoulder pain for patients and may result from progressive impingement or from isolated tendon inflammation or injury. The tendon of the long head of the biceps

lies anterior and superior to the humeral head as it courses through the bicipital groove before inserting into the superior aspect of the glenoid labrum (see Figures 283-2 and 283-3). The tendon may become inflamed, subluxed out of the bicipital groove, or rupture altogether. Acute traumatic ruptures of the bicipital tendon are discussed in Chap. 271.

Clinical Features

Bicipital tendinitis presents as acute, intense, localized pain at the anterior aspect of the shoulder. Palpation of the tendon within the bicipital groove reproduces the intense pain. Forearm supination, one of the main actions of the biceps, will also reproduce pain, especially when resistance is applied. *Speed test* identifies biceps tendon weakness or inflammation. A downward force is applied to the patient's forearm with the thumb in an upright position. The patient's shoulder is flexed 60 degrees and the elbow is fully extended. A positive result is indicated by palpable pain in the affected shoulder's biceps groove as the examiner resists forearm supination by the patient, although muscle weakness may also be elicited in cases of muscle injury or rupture. *Yergason test* (Figure 283-8) also may be used to diagnose biceps tendinitis. The examiner similarly resists patient forearm supination with the shoulder adducted and elbow flexed at 90 degrees. A positive test elicits pain at the proximal bicipital groove.

The tendon may sublux or momentarily dislocate from the bicipital groove if the transhumeral ligament, which forms the roof of the groove, tears from degeneration or acute trauma. Resisted forearm supination may cause subluxation that is palpable and accompanied by a painful popping sensation as the tendon subluxes.

Rupture of the biceps tendon is almost always proximal, and as with rotator cuff injury, is due to microtears and other age-related degenerative changes in this area of the tendon. In younger patients, mild trauma may cause complete rupture of the biceps tendon and is heralded by an audible snap or pop followed by severe pain. On examination, the classic finding is described as a "Popeye" deformity caused by distal contraction of the muscle belly. Supination is weak on muscle testing but elbow flexion remains strong because of the presence of other intact elbow flexors (short head of biceps and brachialis muscles).

Emergency Department Treatment

Tendinitis and subluxation are managed conservatively with brief use of a sling as needed for support and comfort. Analgesics and anti-

inflammatory agents may be used in conjunction with relative rest, use of ice for 10 to 15 min several times daily, and elevation to reduce swelling. Early mobilization with stretching exercises should be initiated with close follow-up scheduled with the patient's primary provider. Bicipital tendinitis usually resolves with conservative therapy. Follow-up with the primary provider within 1 week will suffice. Orthopedic consultation should be reserved for severe cases or those that fail to respond to a conservative treatment regimen. Decompressive surgery and biceps tenodesis are options for this subset of patients.¹ Bicipital tendon rupture often requires surgical repair so orthopedic referral in 24 to 48 h is best.

OSTEOARTHRITIS

Since the glenohumeral joint is non-weight-bearing, primary osteoarthritis is rare. When it does occur, presentation is similar to that of degenerative disease in other joints; the patient experiences gradual and progressive onset of pain, which is worse with motion and better with rest. This usually occurs concurrently with degenerative disease of the acromioclavicular joint.

Secondary osteoarthritis is more common and usually associated with a previous fracture, recurrent dislocations, or with an underlying rheumatologic, metabolic, or endocrinologic disorder. ED care of both primary and secondary arthritis includes analgesics, anti-inflammatory agents, and gentle exercises to preserve range of motion. Referral should be made for further evaluation of possible underlying rheumatologic or inflammatory conditions.

DIFFERENTIAL DIAGNOSIS OF SHOULDER PAIN

Although disorders of the rotator cuff and other intrinsic structures of the shoulder are the most common cause of shoulder pain, extrinsic conditions outside the shoulder complex can refer pain to the shoulder. The differential diagnosis includes disorders of the cervical spine, brachial plexus injuries, axillary artery thrombosis, suprascapular nerve injury, thoracic outlet syndrome, Pancoast tumor, and miscellaneous thoracoabdominal disorders.

The neck is the most common source of pain referred to the shoulder. Degenerative disease of the cervical spine, degenerative disk disease, and herniated nucleus pulposus can all refer pain to the shoulder. The patient with a C5-C6 herniated disk may present with pain very similar to that due to rotator cuff disease. Careful and thorough examination of the cervical spine and a complete neurovascular examination should be included in the evaluation of any patient with shoulder pain. See Chap. 281 for discussion of neck pain.

Brachial plexus injury can cause pain referred to the shoulder and can produce weakness and atrophy in the muscles of the shoulder within weeks of injury. Radiographic evaluation of the cervical spine should be included in the ED evaluation of patients with suspected brachial plexus injury or involvement. *Brachial plexus neuritis* is uncommon but can be very painful. It is presumed to be of viral origin. The inflammation of the brachial plexus can lead to weakness and atrophy of the muscles of the shoulder complex within weeks following the onset of pain. Brachial plexus neuritis is usually self-limiting. Referral to a neurologist should be arranged if this disorder is suspected.

The most serious vascular injury that can cause shoulder pain is *acute thrombosis of the axillary artery*. Repetitive mechanical trauma or explosive stress from lifting heavy objects can compress and contuse the intimal lining of the axillary artery, predisposing the artery to thrombosis.

Compression of the suprascapular nerve can cause shoulder pain. This nerve originates from the brachial plexus distal C5-C6 nerve roots and courses posteriorly to the suprascapular notch. It can become entrapped beneath the transverse ligament at the level of the suprascapular notch. Traction injuries from explosive movements can also injure the nerve. On examination, infraspinatus atrophy and associated

FIG. 283-8. Yergason test is used to identify bicipital tendinitis. With the patient's elbow flexed at 90°, the examiner palpates the bicipital groove as the patient attempts forearm supination against resistance. Pain or instability at the proximal bicipital groove indicates biceps tendinitis or tendon subluxation.

weakness and external rotation will typically be found. The initial treatment is conservative. Electromyographic and nerve conduction velocity studies will reveal the extent and location of nerve injury. Surgery for decompression is considered if conservative measures fail.

Compression of the brachial plexus and blood vessels proximal to the shoulder, the *thoracic outlet syndrome*, can cause shoulder pain. Women in the childbearing years are affected three times more commonly than men. The medial trunk of the brachial plexus is most commonly affected, and the symptoms usually involve pain that radiates through the shoulder to the medial forearm and occasionally to the small and ring fingers. Patients can usually identify motions that reproduce the symptoms. Radiographic evaluation may reveal evidence of a prior clavicle fracture with malunion, or the presence of a cervical rib band, which compresses the brachial plexus. Surgical decompression may be considered if the symptoms are debilitating or refractory to conservative measures.

Pancoast tumor may compress the brachial plexus against the chest wall and cause shoulder pain. The patient may experience local or radicular shoulder pain or sense a fullness in the supraclavicular fossa.

Finally, a large number of *thoracoabdominal disorders* can cause shoulder pain. These include myocardial ischemia and infarction, pneumonia, and pulmonary embolism and infarction. Any thoracic or abdominal disorder that irritates the diaphragm can also cause referred shoulder pain. Abdominal disorders that can cause shoulder pain include biliary tract disease, splenic injury or inflammation, perforated viscus, or ruptured ectopic pregnancy.

284 EMERGENCIES IN SYSTEMIC RHEUMATIC DISEASES Richard C. Chandler Mary Chester Morgan Wasko

Systemic rheumatologic diseases rarely cause life-threatening illness, and when they do, it usually results from internal organ damage, such as alveolar hemorrhage in SLE or aortic arch dissection in temporal arteritis.¹ Alternatively, life-threatening illness may be a complication of treatment itself, such as infection in the setting of immunosuppression, or gastrointestinal hemorrhage complicating nonsteroidal anti-inflammatory drug (NSAID) use. Either can lead to serious morbidity and increased mortality if not recognized and managed promptly.

This chapter discusses rheumatologic emergencies from an organ-system, rather than disease-oriented, perspective. Table 284-1 highlights emergent musculoskeletal complaints that warrant prompt evaluation, along with a differential diagnosis for each.

RHEUMATIC EMERGENCIES ASSOCIATED WITH RISK OF MORTALITY

The Airway and Respiratory System

Systemic rheumatologic diseases may cause life-threatening respiratory compromise by airway obstruction or respiratory failure (Table 284-2).² Relapsing polychondritis is an inflammatory disease affecting cartilage that usually begins with the abrupt onset of pain, redness, and swelling of the ears or the nose. The airway is affected in roughly half of patients, causing inflammation, destruction, and ultimate collapse of tracheobronchial cartilage with airway obstruction. Patients report throat tenderness over cartilaginous structures and hoarseness. Less commonly, they experience shortness of breath, cough, or stridor. Repeated exacerbations ultimately may cause asphyxiation. Patients should be hospitalized for careful observation and high-dose corticosteroids during acute exacerbations. In severe cases, emergency tracheostomy may be necessary.

Up to 25 percent of patients with rheumatoid arthritis (RA) may have cricoarytenoid joint involvement with associated pain which is aggravated by swallowing/speaking and which may be referred to the ear. Severe involvement of the cricoarytenoid joint may lead to hoarseness, stridor, and airway obstruction, mandating emergent laryngoscopy and/or tracheostomy.

In addition to airway obstruction, respiratory muscles may be impaired by inflammatory muscle disease, leading to respiratory failure. Patients with dermatomyositis and polymyositis may be too weak to generate intercostal retractions, so nasal flaring may be the only indi-

TABLE 284-1 Emergent Musculoskeletal Clinical Signs and Symptoms

Feature	Differential Diagnosis
History of significant trauma	Soft tissue injury, internal derangement, or fracture
Hot, swollen joint	Infection, systemic rheumatic disease, gout, pseudogout
Constitutional signs and symptoms (e.g., fever, weight loss, malaise)	Infection, sepsis, systemic rheumatic disease, malignancy
Weakness:	
Focal	Focal nerve lesion (compartment syndrome, entrapment neuropathy, mononeuritis multiplex, motor neuron disease, radiculopathy*)
Diffuse	Myositis, metabolic myopathy, toxin, paraneoplastic syndrome, degenerative neuromuscular disorder, myelopathy,* transverse myelitis
Neurogenic pain (burning, numbness, paresthesia):	
Asymmetric	Radiculopathy,* reflex sympathetic dystrophy, entrapment neuropathy
Symmetric	Myelopathy,* peripheral neuropathy
Claudication pain pattern	Peripheral vascular disease, giant cell arteritis (jaw pain), lumbar spinal stenosis

*Radiculopathy and myelopathy may be due to infectious, neoplastic, or mechanical processes.

TABLE 284-2 Respiratory Manifestations of Rheumatic Diseases

Disease	Common	Infrequent	Rare
SLE	Serositis, effusion	Infiltrate	Hemorrhage, "shrinking lungs," fibrosis
RA	Nodules, effusion	Pulmonary fibrosis	Cricoarytenoid obstruction
Spondyloarthropathies		Pulmonary fibrosis	Pulmonary infiltrates, ARDS
Relapsing polychondritis	Airway obstruction	Tracheobronchial collapse	
Polymyositis and dermatomyositis		Hypoventilation with hypoxemia, respiratory failure Interstitial pneumonitis	
Scleroderma	Pulmonary fibrosis	Pulmonary hypertension	
Vasculitides			
Wegener granulomatosis	Sinusitis, nasal ulcers, pulmonary nodules, infiltrate, bronchospasm, hemoptysis	Hemorrhage	
Polyarteritis nodosa		Peripheral infiltrate	Interstitial pneumonitis

Abbreviations: ARDS = acute respiratory distress syndrome; RA = rheumatoid arthritis; SLE = systemic lupus erythematosus.

cator of respiratory insufficiency. Unless aspiration pneumonitis is present, chest x-rays are usually normal or show a "high-riding" diaphragm. Admission for patients with inflammatory muscle disease and signs of respiratory distress is advised in anticipation of the possible need for intubation. The clinical course can be followed at bedside with measurements of peak inspiratory force and expiratory flow rate or volume. Respiratory failure is predictable with peak inspiratory effort of less than 30 percent of predicted or vital capacity of less than 50 percent of predicted.

Pleuritic chest pain is uncommon in RA, but in SLE up to 50 percent of patients have symptomatic pleurisy during the course of their disease.³ Pleural effusions are common across the spectrum of rheumatic disease. Rheumatic, infectious, and malignant effusions are often exudative and either polymorphonuclear or mononuclear cells may predominate. In the patient without renal insufficiency, NSAIDs (e.g., indomethacin 25 to 50 mg tid) usually prove beneficial. Prednisone 10 mg PO tid is useful for patients failing this regimen.

Other serious pulmonary complications may be associated with other rheumatologic diseases. Pulmonary hemorrhage can complicate Goodpasture disease, SLE, hypersensitivity vasculitis, and Wegener granulomatosis. Ankylosing spondylitis, scleroderma, and rarely RA and other rheumatic diseases can lead to pulmonary fibrosis. Patients may present with abrupt decompensation after a history of a well-tolerated slow decline. In polymyositis, however, interstitial pneumonitis may develop with quiescent muscle disease, progress rapidly, and result in fulminant respiratory failure. Patients with acute respiratory insufficiency should be hospitalized to exclude infection and be treated with aggressive immunosuppression.

Cardiac Diseases

Pericarditis is one of the most common cardiac disorders associated with rheumatic diseases, especially in RA and juvenile rheumatoid arthritis (JRA).^{4,5} SLE often causes symptomatic pericarditis, particularly in the elderly, and may be associated with symptoms of a flare such as a rash, oral ulcers, or joint pain. Symptoms tend to be consistent from one flare to the next, and therefore a thorough review of systems is important. The diagnoses of malignancy and infection should be considered in symptomatic pericarditis. Treatment with NSAIDs or indomethacin is similar to that for pleurisy. Complications of pericarditis, such as pericardial tamponade and constrictive pericarditis are uncommon in RA and SLE.

While therapy has greatly improved long-term survival in SLE, late mortality from premature atherosclerotic disease is increasing. Pre-

cordial chest pain in SLE is not always due to serositis or costochondritis, particularly with long-standing disease, and myocardial ischemia should always be considered in the differential diagnosis.

Myocardial infarction (MI) in rheumatic diseases is not usually related to underlying disease. The noteworthy exceptions are Kawasaki disease and polyarteritis nodosa (PAN). PAN is a form of vasculitis affecting small to medium caliber arteries of the skin (nodular, urticarial, or multiform rashes), gut (abdominal angina), and kidneys (hypertension, hematuria). Coronary arteries are commonly involved.

Acute rheumatic fever (ARF) remains an important cause of pancarditis. ARF follows group A streptococcal pharyngitis within a few weeks. It is heralded by fever and acute polyarthritis in adults or migratory arthritis in children. A few patients have a more insidious onset. Signs of ARF include the presence of subcutaneous nodules, chorea, or erythema marginatum, but only a third of patients will have one of these manifestations. Diagnosis is based on documenting the clinical involvement and antecedent streptococcal infection. The throat should be cultured and antistreptolysin O (ASO) or streptozyme titers determined at intervals to document a fourfold change in titer over a month. Other baseline tests include chest radiography, echocardiography, and ECGs to monitor the carditis; and acute phase reactants such as the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP). The fever and arthritis usually respond to salicylate therapy, but salicylates should be held until the diagnosis is clear. Patients should be placed at bed rest until clinical and laboratory parameters begin to normalize.

Other diseases are associated with migratory arthritis (Table 284-3). Bacterial endocarditis or septicemia due to common bacterial pathogens and the prodromal phase of pulmonary mycoplasma or fungal infections may cause migratory joint pain. Children with Henoch-Schönlein purpura and cefaclor serum sickness often have migratory articular and periarticular involvement. Stage II Lyme disease can be manifested by migratory articular involvement, with individual joints resolving over hours to days. Often young adults with polyarthritis are empirically treated with intravenous penicillin for disseminated gonococcus (GC). The arthritis of ARF does not respond to antibiotic therapy; therefore prompt improvement suggests the diagnosis of GC.

Valvular heart disease is a recognized extra-articular manifestation of the seronegative spondyloarthropathies, particularly in patients with HLA-B27-positive ankylosing spondylitis.⁶ Fibrotic changes of the aortic valve are usually asymptomatic, with dysfunction occurring more often in patients with longstanding, severe disease. Scar tissue also may impair cardiac conduction, leading to atrioventricular block. Relapsing polychondritis can result in aortic insufficiency and aortic

Lyme disease

aneurysm. Table 284-4 summarizes cardiac involvement in rheumatic diseases.

Adrenal Insufficiency

Patients with steroid-dependent rheumatic diseases are at risk for adrenal insufficiency either from unexpected medical or traumatic stressors, or from abrupt cessation of prescribed steroid medication. Common symptoms of acute adrenal insufficiency include hypotension, lethargy, mental status changes, and hypoglycemia (see Chap. 217). Patients known to be steroid dependent and exhibiting signs of acute adrenal insufficiency should be treated with IV NS solution, glucose, and hydrocortisone 100 mg IV unless diagnostic evaluation for another cause of adrenal insufficiency is necessary. In that case, dexamethasone 4 mg IV should be substituted for hydrocortisone as dexamethasone does not interfere with an ACTH suppression test or cortisol level. Rarely, patients treated with steroids in the past 18 months develop adrenal insufficiency. They may have early symptoms of weakness, depression, fatigue, and postural dizziness, or late life-threatening vomiting. The serum chemistries usually do not reveal hyponatremia or hyperkalemia in patients with adrenal insufficiency after prednisone withdrawal because that steroid has no mineralo-corticoid activity. If the diagnosis is uncertain, prior to steroid administration a cortisol level should be drawn in the ED. Under stress, normally-functioning adrenal glands generate a cortisol level in excess of 20 μ g/dL.

RHEUMATIC PRESENTATIONS WITH HIGH RISK OF MORBIDITY

The Cervical Spine and Spinal Cord

Cervical spine disease and its neurologic risk is well-recognized in rheumatoid arthritis and ankylosing spondylitis. In RA, pannus for-

TABLE 284-4 Cardiac Manifestations of Rheumatic Diseases

Disease	Common	Infrequent	Rare
Systemic lupus erythematosus	Pericarditis	Angina, myocarditis	Tamponade, constrictive pericarditis
Ankylosing spondylitis		Aortic stenosis/insufficiency, dissection	Drop attacks
Relapsing polychondritis		Aortic insufficiency, dissection	
Polymyositis and dermatomyositis		Arrhythmias, myocarditis	
Scleroderma		Fibrotic myocardial fibrosis, arrhythmias	Cor pulmonale
Vasculitides		Angina, myocardial infarction, pericarditis	

mation and destruction of ligamentous supporting structures may lead to atlantoaxial subluxation.⁷ An atlantodental distance in excess of the normal 3.5 mm seen in a lateral flexion view suggests instability (in children under 12, 4 mm of widening is normal). Cord compression may occur acutely following a trivial injury or be more insidious. Subtle clues include a change in bowel or bladder function, new weakness, numbness, or paresthesias. Instability may lead to posterior subluxation of the odontoid, causing vertigo or other complaints relating to vertebral insufficiency. Lhermitte sign, an electric shock sensation radiating down the back on neck flexion, is a classic indication of cervical spine instability. Strength may be difficult to assess in an RA patient, so subtle differences in reflexes are particularly informative. Plain films, cervical spine CT scan, or MRI are indicated depending on the clinical findings.

The ankylosed, inflexible cervical spine in a patient with a seronegative spondyloarthropathy (e.g., ankylosing spondylitis) is susceptible to fracture with minor trauma.⁸ A forcible blow from behind may result in new neck pain in an ankylosed area. The complaint of new neck pain requires a careful history and examination, with attention to possible trauma to the neck and evidence of peripheral nerve damage. Fractures are most commonly transverse through a disc space, leading to greater risk of dislocation and cord compression.

Intubation of patients with possible rheumatic cervical spine disease should be accomplished by the most experienced clinician available. Atlantoaxial instability should be assumed, and the neck stabilized during intubation.

Spinal cord injury can also be caused by transverse myelitis in SLE, or by an anterior spinal artery syndrome in patients with other rheumatic diseases.⁹ The anterior spinal artery is a direct branch of the aorta; dissection of the aorta, vasculitis, or embolism can impair blood supply to the anterior cord and produce a clinical picture distinct from transverse myelitis or metastatic tumor by sparing of posterior column function (position sense and vibration).

The Eye

Temporal arteritis (TA), also called giant cell arteritis (GCA), must be correctly diagnosed and promptly treated to prevent the complication of sudden and irreversible blindness.¹⁰ TA occurs in up to 30 percent of patients with polymyalgia rheumatica (PMR), a related systemic illness that affects middle-elderly aged individuals who usually present with unexplained anemia, fatigue, and proximal limb/girdle pain. TA is a granulomatous arteritis of the thoracic aorta and its branches; the vasculitis and ischemia in this distribution induce characteristic signs and symptoms: new headache, tender scalp, fluctuating vision, diminution or loss of a brachial pulse, jaw claudication while chewing or talking, and constitutional symptoms. The ESR is usually (but not always) elevated >50 mm/h, as is the CRP >2.45 mg/dL, and using both studies increases diagnostic specificity. Prodromal changes in vision almost always precede blindness. A high index of suspicion is critical when evaluating anyone older than 50 with a new headache, fluctuating vision, or jaw, tongue, or upper extremity claudication. The diagnosis of TA is established by temporal artery biopsy, but treatment with prednisone 60 mg/d should be instituted prior to biopsy if the diagnosis is likely. Immediate treatment of suspected TA may prevent blindness, yet does not seem to affect biopsy outcome if the biopsy is done within a week. Treatment of PMR requires lower doses of prednisone, in the 10- to 20-mg/d range.

Sjogren syndrome, a lymphocytic infiltration of the lacrimal and salivary glands causing dry eyes and dry mouth, may complicate many rheumatic diseases or occur independently.¹¹ It predisposes the patient to corneal irritation, ulceration, and superimposed infection.

In RA, a red eye requires careful evaluation.¹² Under bright natural light, examination can reveal the difference between episcleritis, which is usually self-limiting, and scleritis, which can be an emergency. Episcleritis is a painless injection of the episcleral vessels,

giving the eye a pink-red appearance; it rarely impairs vision. As it is self-limiting, no therapy is indicated. Scleritis causes exquisite ocular tenderness and the eye has a deep purplish discoloration. Visual impairment and scleral thinning with rupture are feared outcomes. High-dose steroids and intensive ophthalmologic management are required.

Hypertension

Hypertension is associated with PAN, Wegener granulomatosis, or SLE with renal involvement, as well as RA with drug-induced renal toxicity (e.g., nephritis, or renal papillary necrosis). Hypertension is a concerning complication of systemic sclerosis (scleroderma), and hypertensive renal crisis was the leading cause of death in scleroderma until the advent of angiotensin-converting enzyme (ACE) inhibitors.¹³ The most susceptible patients have rapidly progressive skin changes and present within the first few years of diagnosis with complaints related to hypertension. Laboratory studies reveal rapidly progressive renal insufficiency and frequently a microangiopathic hemolytic anemia and thrombocytopenia. Hypertension results from sclerosis and impaired renal glomerular perfusion, causing hyperreninemia. Dehydration from gastroenteritis or diuretics may precipitate the crisis. Patients should be hospitalized and promptly treated with captopril. Any intervention such as diuretics that might exacerbate volume contraction and the underlying pathophysiology should be avoided.

The Kidney

Most systemic rheumatic diseases can affect kidney function.¹⁴ Glomerulonephritis is a major determinant of morbidity in patients with lupus and Wegener granulomatosis. Urinalysis abnormalities (hematuria, proteinuria) and hypertension are apparent before serum creatinine rises. Patients with lupus and nephrotic syndrome can develop renal vein thrombosis due to urinary loss of antithrombin III; presenting with flank pain and proteinuria. In diffuse scleroderma, renal dysfunction secondary to hypertension and microangiopathy typically develops rapidly over days to a few weeks.

Occasionally, a patient with active polymyositis or metabolic muscle disease develops acute renal insufficiency due to rhabdomyolysis. In metabolic muscle disease, myalgias and muscle breakdown can be triggered by exercise. Myoglobinuria should be suspected when the urine is brown and the urinary dipstick detects hemoglobin but no red blood cells are seen on microscopic examination. In contrast to a hemolytic state, the serum is clear, creatine phosphokinase is elevated, and haptoglobin is normal. Patients should be hydrated with normal saline to restore intravascular loss that accompanies muscle necrosis. Furosemide and mannitol also are indicated to preserve urinary output (see Chap. 279).

A final consideration is medication nephrotoxicity. Patients, particularly the elderly, treated with nonsteroidal anti-inflammatory drugs can develop renal insufficiency and fluid retention on the basis of alteration in renal blood flow; this is mediated by prostaglandin inhibition (see Chap. 172). A decline in renal function in any rheumatic disease patient should prompt a search for remediable causes of renal dysfunction, either related to drug therapy or to the rheumatic disease itself.

NONTRAUMATIC DISORDERS OF THE HAND

Mark W. Fourné

HAND INFECTIONS

Infection is most commonly introduced by an injury to the dermis. The infection initially may remain superficial, as a cellulitis, or localized, as a paronychia or felon. Left untreated, infections ultimately will spread along anatomic planes or to adjacent compartments in the hand. Deeper injuries may directly seed underlying structures, giving rise to rapidly spreading infections such as those seen with closed-fist injuries or cat bites. Rarely, hematogenous seeding may be the source of hand infections.^{1,3}

A directed history should be obtained to delineate a likely cause of the infection. Patients who present with systemic symptoms secondary to a hand infection are seriously ill, and parenteral antibiotics with inpatient management is indicated. A history of chronic illness or immunodeficiency should alert the physician to the possibility of atypical pathogens.^{2,3}

Since hand infections tend to disseminate along anatomic compartments and planes, the physical examination should be directed at defining the anatomic limits of the infection. The examiner should document if the process involves the skin, subcutaneous tissues, fascial spaces, tendon, joint, or bone. If deep structures of the hand are involved, emergent consultation with a hand specialist is indicated because treatment likely will involve inpatient care and drainage in the operating room.

With the exception of superficial cellulitis, hand infections are surgical problems that must be managed using accepted surgical principles. First, if there is pus, drain it. Superficial and discrete infections, such as paronychia and felons, can be drained in the ED. All other infections involving deep structures in the hand should be treated in the operating room by a hand surgeon. Second, immobilize and elevate the extremity. This will rest the hand, reduce inflammation, avoid secondary injury, and limit anatomic extension of the infection. Immobilization is accomplished by applying a bulky hand dressing and splinting the hand in a position of function: the wrist at 15 to 30 degrees of extension, the metacarpophalangeal (MCP) joints at 50 to 90 degrees of flexion, and the interphalangeal (IP) joints at 5 to 15 degrees of flexion (Figure 285-1). The hand may be elevated on pillows or suspended using stockinet. Third, broad-spectrum antibiotics should be initiated (Table 285-1). Finally, serial examinations should be performed to ensure that an effective management plan has been instituted. If the

FIG. 285-1. Positioning the hand during immobilization. Top position is used when splints are applied in fractures or severe sprains. Bottom position is position of function used when applying a soft bulky dressing.

patient is not admitted to the hospital, timely and appropriate follow-up must be arranged by the emergency physician.

Pathophysiology

The bacterial etiology of hand infections depends on the source of the offending inoculum. Since *Staphylococcus* and *Streptococcus* species routinely colonize the skin, they are the bacteria most frequently isolated from hand infections. Polymicrobial infections, including anaerobes, are common.

Injection drug users typically present with abscesses or deep space infections secondary to *Staphylococcus aureus*. Infections are most commonly caused by direct introduction of a contaminated needle through inadequately cleaned skin, but hematogenous spread from bacterial endocarditis should also be considered. Paronychia and felons are commonly caused by minor trauma associated with chewing fingernails or exposing minor injuries to saliva. Most of these infections are polymicrobial in origin, with most harboring anaerobic bacteria.

Bacteria found in infections caused by animal bites reflect the oral flora of the involved species. This encompasses a broad range of bacteria, including gram-positive, anaerobic, and gram-negative organisms. In human bites, *Eikenella corrodens* is a common pathogen. *Eikenella* is sensitive to penicillin and ampicillin, but is relatively resistant to numerous antibiotics, including first-generation cephalosporins, nafcillin, and clindamycin. Therefore, an aminopenicillin with a beta-lactamase inhibitor or a first-generation cephalosporin in combination with penicillin is required for prophylactic antibiotic coverage for human bites and for treatment of hand infections caused by human bites (see Table 285-1). Cat and dog bites may harbor *Pasteurella multocida*, which typically produces an aggressive, rapidly spreading cellulitis that quickly becomes suppurative. *Pasteurella* is also sensitive to penicillin and ampicillin, and antibiotic coverage is the same as that indicated for human bites. Initial antibiotic coverage is reviewed in Table 285-1. For a complete discussion on animal bites, see Chap. 47.

Patients with diabetes or acquired immunodeficiency syndrome (AIDS) may harbor atypical infections caused by *Mycobacterium* or *Candida albicans*. Patients who are immunocompromised or asplenic may be at risk for rapidly progressive and fatal infections. Aggressive intervention is indicated in these settings.

Cellulitis

Cellulitis is the most superficial of hand infections and may be treated definitively with oral antibiotics if diagnosed early. Diagnosis is made by documenting erythema, warmth, and edema in the affected portion of the hand. The examiner must document lack of involvement of any deeper structures in the hand. Specifically, range of motion of the digits, hand, or wrist should not be uncomfortable for the patient, and palpation of the deeper structures of the hand should not produce any tenderness.

TABLE 285-1 Initial Antibiotic Coverage for Common Hand Infections

Infection	Initial Antibiotic	Likely Organisms	Comments
Cellulitis	first-generation cephalosporin (cephalexin) <i>or</i> antistaphylococcal penicillin (amoxicillin-clavulanate, dicloxacillin)	<i>S. pyogenes</i> , <i>S. aureus</i>	Consider vancomycin for intravenous drug abusers
Felon/paronychia	first-generation cephalosporin (cephalexin) <i>or</i> antistaphylococcal penicillin (amoxicillin-clavulanate, dicloxacillin)	polymicrobial, <i>S. aureus</i> , anaerobes	Antibiotics indicated for infections with associated localized cellulitis
Flexor tenosynovitis	aminopenicillin with a β -lactamase inhibitor (ampicillin/sulbactam) <i>or</i> first-generation cephalosporin (cefazolin) and penicillin	<i>S. aureus</i> , streptococci, anaerobes, gram-negatives	Parenteral antibiotics are indicated; consider ceftriaxone for <i>N. gonorrhoeae</i>
Deep space infection	aminopenicillin with a β -lactamase inhibitor (ampicillin/sulbactam) <i>or</i> first-generation cephalosporin (cefazolin) and penicillin	<i>S. aureus</i> , streptococci, anaerobes, gram-negatives	Inpatient management
Animal bites (including human)	aminopenicillin with a β -lactamase inhibitor (ampicillin/sulbactam) <i>or</i> first-generation cephalosporin (cefazolin) and penicillin	<i>S. aureus</i> , streptococci, <i>E. corrodens</i> (human), <i>Pasteurella multocida</i> (cat), anaerobes and gram-negatives	All animal bite wounds should receive prophylactic oral antibiotics
Herpetic whitlow	None, unless secondary bacterial contamination is present	Herpes simplex	Consider acyclovir, no surgical drainage is indicated

The most common offending organism is *Streptococcus pyogenes*, although *S. aureus* and other pathogens are identified occasionally. An antistaphylococcal penicillin or first-generation cephalosporin is recommended for initial treatment (see Table 285-1). For more extensive involvement, parenteral antibiotics should be instituted. Inpatient management should be reserved for patients who are immunocompromised or systemically ill and for rapidly spreading infections.

The hand should be immobilized in a position of function, and the patient should keep the hand elevated as much as possible. Finally, close follow-up should be arranged, with reexamination in approximately 24 h.

Flexor Tenosynovitis

Flexor tenosynovitis is a surgical emergency. Failure to accurately diagnose and manage flexor tenosynovitis will lead to loss of function of the digit and eventually loss of function of the entire hand. Diagnosis is made by recognizing the four classic clinical findings described by Kanavel: tenderness over the flexor tendon sheath, symmetric swelling of the finger, pain with passive extension, and a flexed posture of the involved digit at rest.³

The infection usually is associated with penetrating trauma of the affected area, although the patient may be unaware of this injury. *Staphylococcus* is the most common bacterium isolated; however, infections often harbor anaerobes and are routinely polymicrobial in origin. Suspect disseminated *Neisseria gonorrhoeae* in a patient with a recent history consistent with a sexually transmitted disease.

Initiate treatment with parenteral antibiotics (see Table 285-1). Vancomycin should be considered for injection drug abusers because they may harbor methicillin-resistant *S. aureus* (MRSA). Any spontaneous exudate from the infection should be sent for Gram stain and culture with sensitivities.

The hand should be immobilized and elevated, and a hand surgeon should be consulted from the ED. If the infection is identified early in its course, conservative (e.g., nonoperative) therapy may be indicated initially. The patient would then be treated with parenteral antibiotics, immobilization, elevation, and reevaluation within 24 h. The decision to manage the patient without operative intervention must be made in conjunction with the hand surgeon.

Deep Space Infections

The hand offers numerous compartments in which infections may propagate and migrate. The volar surface of the hand encompasses many potential spaces that may become infected by direct inoculation or spread from surrounding structures. These include the thenar space, the midpalmar space, the radial bursa, and the ulna bursa (Figures 285-2 and 285-3).

The volar aspect of the hand is covered by the tough and relatively fixed tissues of the palm; the veins and lymphatics course through the softer tissues on the dorsum of the hand; thus, regardless of the precise anatomic site of infection or inflammation, the dorsum of the hand will always swell whenever there is an inflammatory process. For this reason, a deep space infection initially may be misdiagnosed as a cellulitis over the dorsum of the hand if the practitioner does not obtain a thorough history and conduct a complete examination, including palpation of the volar surface of the hand to elicit tenderness, induration, or fluctuance, as well as doing a sensory evaluation. Since these compartments are contiguous with the flexor tendons of the hand, range of motion of the digits often produces significant pain for the patient.

Occasionally, infections will arise in the web space. These "collar button" abscesses present with pain and swelling of the web space, causing separation of the affected digits. Examination reveals induration or fluctuance in the dorsal and/or volar web space, along with erythema, warmth, and tenderness. *S. aureus* and *Streptococcus* species are the most common organisms isolated.³

FIG. 285-2. Anatomy. Flexor tendon infections may travel quickly along established anatomic planes and spread quickly to the ulnar and radial bursae.

Give parenteral antibiotics (see Table 285-1), and immobilize and elevate the hand. The patient likely will require analgesia while in the ED. Emergent evaluation by a hand surgeon is required because drainage of the infection should be undertaken in the operating room.

Infections from Closed-Fist Injuries

The most common human bite infection of the hand is the result of striking another individual's teeth with a clenched fist. Because of the

FIG. 285-3. Deep palmar spaces. The midpalmar and thenar spaces are deep structures of the hand. The proximity to vital structures necessitates an aggressive management course including parenteral antibiotics and referral to a hand surgeon for drainage.

force associated with the contact and the penetrating nature of the human incisor, these infections tend to occur on multiple planes, and infection spreads rapidly to adjacent compartments. Skin, extensor tendons, joint space, bone, and surrounding deep spaces often are involved because the inoculum of saliva may traverse all these structures.

The physical examination should document the extent of the infection. Hand x-rays are indicated because closed-fist injuries are often associated with fractures, or may contain tooth fragments. The most common organisms reflect the natural flora of the mouth and include *Streptococcus* species, *S. aureus*, anaerobes, *E. corrodens*, and *Neisseria* species. Antibiotics should be initiated in the ED and a hand surgeon consulted (see Table 285-1). The wound should be irrigated in the operating room and left open. The hand should be immobilized in the position of function and elevated.

Paronychia

Paronychia is an infection of the lateral nail fold or perionychium, occasionally extending to the cuticle or eponychium. It is usually caused by minor trauma such as nail biting, manicures, or hangnails. The infection starts as a small area of induration that may be erythematous and tender. Most paronychia contain both aerobic and anaerobic bacteria. *S. aureus* and *Streptococcus* species are the most common aerobic bacteria cultured. Chronic paronychia may occur, particularly in patients who are immunocompromised. Consider atypical bacterial or fungal infections such as with *C. albicans* in these cases.⁴

If no fluctuance is identified, the paronychia may be treated with warm soaks, elevation, and antibiotics (see Table 285-1). Early intervention may prevent the need for surgical drainage. After suppuration has occurred, the infection will exhibit either fluctuance or identifiable pus that will necessitate drainage. Minor infections can be treated with elevation of the perionychium or eponychium with a flat probe or no. 11 blade (Figure 285-4). This procedure sometimes can be performed without placing a digital block or providing analgesia.

FIG. 285-4. Paronychia. A. The eponychial fold is elevated using a flat probe or no. 11 blade in order to allow the wound to drain. B. Alternatively, for more extensive infections, a no. 11 blade may be used to incise the area of greatest fluctuation directly into the eponychium. The wound may then be gently probed with a small clamp to ensure drainage.

More extensive infections that do not communicate directly with the nail fold may require digital block and incision directly into the area of greatest fluctuance. Severe infections with pus beneath the nail require removal of a portion of the lateral or proximal nail to ensure adequate drainage. Rarely, a free-floating nail will be encountered on a bed of pus, necessitating removal of the entire nail.

Following incision and drainage, keep the hand elevated and immobilized. Warm soaks may be initiated to keep the wound open and clean. The patient should be scheduled for reevaluation in 24 to 48 h. If cellulitis is present, a short course of antibiotics should be prescribed.

Felon

A felon is a subcutaneous pyogenic infection of the pulp space of the distal finger or thumb. The septa of the finger pad produce multiple individual compartments and confine the infection under pressure. The patient presents with marked throbbing pain and a red, tense distal pulp space. Infection typically begins with minor trauma to the dermis overlying the finger pad. With time, the bacterial infection gradually spreads between septae, forming multiple compartmentalized abscesses. Left untreated, the infection may spread to the flexor tendon sheath and the interphalangeal joints, or eventually osteomyelitis may develop. Do not mistake a felon for pulp erythema secondary to a paronychia or herpetic whitlow.^{5,6}

S. aureus is the most common organism, but *Streptococcus* species, anaerobes, and gram-negative organisms are frequently encountered. A Gram stain and culture should be obtained because these infections may be difficult to eradicate, and chronic infections may be caused by atypical organisms. If osteomyelitis has developed, positive identification of the offending organism is necessary because long-term antibiotic therapy will be indicated.

If the finger pad is swollen and tense, or if there is any palpable fluctuance, drainage is necessary. A digital block using a long-acting anesthetic such as bupivacaine should be used because postoperative discomfort is considerable (see Chap. 37). Most felons can be drained adequately with a limited incision and drainage procedure.

A unilateral longitudinal approach is the most frequently used technique because it spares the sensate volar pad and achieves adequate drainage (Figure 285-5A). A no. 11 blade is introduced lateral to the felon and is directed across the finger until pus is encountered. The incision should be extended to ensure adequate drainage, although it should not extend to the distal interphalangeal (DIP) flexor crease. Also, the incision should not carry through the distal end of the finger pad because this would likely cause instability and loss of sensation to the distal fingertip. A small clamp may be used to bluntly dissect septa to ensure complete drainage. If the wound is large enough, a small wick may be placed to encourage continued drainage.

If the felon is pointing toward the volar fat pad, a longitudinal volar approach may be used, as depicted in Figure 285-5B. Care should be exercised to avoid extending the incision to the flexor crease of the DIP joint. More extensive incisions such as the fishmouth, hockey stick, and through-and-through incisions are rarely if ever indicated. These incisions are routinely associated with loss of sensation to the fingertip and instability of the finger pad.

Following drainage, the wound should be irrigated and then dressed with a dry, sterile dressing. The patient should be instructed to keep the extremity elevated, and the wound should be reevaluated in 24 to 48 h. Warm soaks may be initiated to keep the wound clean and promote continued drainage.

Most felons have significant associated cellulitis that should be treated with oral antibiotics. A first-generation cephalosporin or antistaphylococcal penicillin should be prescribed for 7 to 10 days or until the infection has abated. Felons not responding to treatments outlined above should be referred to a hand specialist for more definitive management and long-term follow-up.

FIG. 285-5. Felon. A. The unilateral longitudinal approach is the most frequently used method for draining felons. This approach minimizes interference with sensate areas of the finger pad. B. If the felon is pointing toward the volar surface of the finger pad, the longitudinal volar approach may be used.

Herpetic Whitlow

Herpetic whitlow is a viral infection of the distal finger caused by the herpes simplex virus, usually from contact with oral herpetic infections. Herpetic whitlow in children tends to be associated with gingivostomatitis and herpes simplex virus type 1 (HSV-1), whereas adults most commonly harbor herpes simplex virus type 2 (HSV-2). Health care professionals are at especially high risk for this infection.⁷

The patient will present with a burning, pruritic sensation similar to all herpes simplex infections. On examination, the lesion is erythematous and tender, with vesicular bullae (Figure 285-6). The finger may be indurated, but is not tense, as is seen in a felon. Do not mistake herpetic whitlow for a felon because incision and drainage may result in increased morbidity and prolonged failure to heal. If there is any question concerning the diagnosis of herpetic whitlow, a vesicle may be unroofed, and the drainage fluid may be used for a Tzanck smear to confirm the diagnosis.

Treatment consists of immobilization, elevation, and pain medication. Antiviral agents such as acyclovir or valacyclovir may shorten the duration and have been shown to prevent recurrent infections. The patient must be instructed in the management of the infection, and the finger should be kept in a clean dressing to prevent autoinoculation or spread of the herpes infection to other individuals.

NONINFECTIOUS INFLAMMATORY STATES OF THE HAND

Noninfectious inflammatory states of the hand often present as an acute exacerbation of symptoms related to recent overuse, either in the workplace or at home. Inflammatory states of joints and tendons can be markedly painful, and may be difficult to distinguish from acute septic arthritis or suppurative tenosynovitis. If the diagnosis is in doubt, treat for infection, and consult a hand specialist.

If an inflammatory state is confidently diagnosed, the patient initially should be treated with conservative measures. These include rest, immobilization, elevation, and initiation of anti-inflammatory agents.

FIG. 285-6. Herpetic whitlow. (Reproduced with permission from Domonkos AN: *Andrews' Diseases of the Skin*. Philadelphia: Saunders, 1971).

Tendinitis and Tenosynovitis

Inflammatory tendinitis may involve the flexor or extensor tendons of the hand. Most often, the patient is able to recount a history of repetitive motion directly affecting the inflamed tendon. Palpation of the tendon produces tenderness. Active or passive movement of the tendon produces significant pain.

Treatment is splinting in the position of function with elevation of the affected area, and nonsteroidal anti-inflammatory agents. Patients should be referred to their primary care physician or a hand surgeon for follow-up. The patient also should be directed to return to the ED for worsening pain, increased swelling, or any signs of infection, including fever and erythema.

Trigger Finger

Tenosynovitis can develop in the flexor sheaths of the fingers and thumb. Scarring or inflammation may cause the tendon to become nodular, which results in friction and catching between the tendon and its sheath, usually in the vicinity of the A1 pulley at the volar crease at the base of each digit. This is referred to as *stenosing tenosynovitis*, or *trigger finger*. The patient experiences binding of the tendon, usually as the finger extends, relieved by a painful "snap" as the tendon clears the obstruction. Occasionally, this condition may progress to the point that the finger locks, usually in flexion. Early stages of trigger finger have been treated successfully with depot steroid injection into the tendon sheath, although there may be recurrence. Surgical division of the A1 pulley is usually curative.

De Quervain's Stenosing Tenosynovitis

De Quervain's tenosynovitis is a common condition that occurs in patients who have experienced excessive use of the thumb. Often no plausible cause can be found. This is a tenosynovitis of the extensor pollicis brevis and abductor pollicis tendons, where they lie in the groove of the radial styloid.

The patient presents with pain along the radial aspect of the wrist that extends into the forearm. The definitive examination that confirms the diagnosis is the Finkelstein test (Figure 285-7), in which the patient grasps the thumb in the palm of the hand and the examiner ulnar deviates the thumb and hand. This produces sharp pain along the involved tendons.

The thumb and wrist should be immobilized with a splint. Instruct the patient to remove the splint briefly each day and perform range-of-motion exercises to prevent joint stiffness. Anti-inflammatory medication should be prescribed for 10 to 14 days. Recurrence of this condi-

tion is not uncommon, particularly when related to occupational stress. Persistent cases should be referred to a hand surgeon.

Carpal Tunnel Syndrome

Carpal tunnel syndrome is a peripheral mononeuropathy that involves entrapment of the median nerve in the carpal canal or tunnel, which is covered by the tense transverse carpal ligament. Whenever a condition causes swelling in the carpal tunnel, the median nerve is compressed, causing paresthesias that extend into the index and long fingers, the radial aspect of the ring finger, and along the palmar aspect of the thumb. The patient often complains of awakening at night with burning pain and tingling in the hand, or numbness when driving a car or maintaining the wrist in prolonged flexion.

Direct trauma to the wrist may exacerbate symptoms; however, a more common scenario involves overuse syndromes in which the patient recounts a history of repeated flexion and extension of the wrist that results in edema in the carpal tunnel. Edematous conditions such as pregnancy and congestive heart failure may acutely exacerbate symptoms in patients with a predisposition for carpal tunnel syndrome. It is also common in diabetes and rheumatoid arthritis.

Tinel sign may support the diagnosis and involves tapping the volar aspect of the wrist over the median nerve. A positive sign produces paresthesias that extend into the index and long finger. Phalen sign is more sensitive (50 percent) and specific (75 percent), and involves flexing the wrist maximally and holding it in this position for at least 1 min. The patient complains of tingling and numbness along the median nerve distribution. Both signs are subject to false-positive and false-negative results and electrodiagnostic techniques may be required to confirm the diagnosis.^{8,9}

The presence of median nerve motor deficit requires emergency hand consultation. Otherwise, initial treatment is a volar splint to maintain the wrist in neutral position, and nonsteroidal anti-inflammatory agents. Surgery may be needed if symptoms do not improve, so referral to a hand surgeon is needed.

Dupuytren Contracture

Dupuytren contracture is a poorly understood disorder resulting in fibroplastic changes of the subcutaneous tissues of the palm and volar aspect of the fingers. There appears to be a genetic component, and the condition is found most commonly in men of northern European descent. This process eventually may lead to tethering and joint contracture. Firm longitudinal thickening and nodularity of the superficial tissues usually are readily appreciated. The diagnosis is made by identifying a nodule in the palm, usually at the distal palmar crease of the ring or small finger, which is held in the classic flexion contracture. This condition should be referred to a skilled hand specialist because surgical excision of the fibrotic bands is usually palliative.

Ganglion Cysts

A ganglion or synovial cyst is a cystic collection of synovial fluid within a joint or tendon sheath. It is one of the most common conditions of the wrist and hand. Clinically, the patient presents with a tender cystic swelling over or near a tendon sheath. Common locations are the dorsal and volar wrist, flexor surface of the metacarpophalangeal joint, or the base of the nail. Involvement of the thumb may appear as generalized thumb pain, pain with movement, and edema. Treatment is pain control and nonsteroidal anti-inflammatory agents. About one-third of cysts resolve spontaneously. Referral to a hand surgeon is indicated for persistent or recurrent pain, or cosmetic deformity. Treatment options include cyst aspiration, corticosteroid injection, or occasionally, surgical excision.

FIG. 285-7. The Finkelstein test. The thumb is cupped in the closed fist and ulnar deviation reproduces pain along the extensor pollicis and abductor pollicis.

ACUTE DISORDERS OF THE JOINTS AND BURSAE

John H. Burton

Acute disorders of the joints affect a collection of patients with diseases that span a vast spectrum of age, acuity, and etiologies. Emergency physicians must differentiate conditions that require immediate attention from those that require less urgent therapy. A careful, methodical process utilizing certain unifying approaches within the clinical history, physical examination, laboratory evaluation, and radiographic assessment will lead to appropriate diagnosis, treatment, and disposition.

CLINICAL FEATURES

Many pathways provoke acute joint complaints: degradation and degeneration of articular cartilage (osteoarthritis), deposition of immune complexes or immune-system-related phenomena (rheumatoid arthritis, rheumatic fever, and gonococcal arthritis), crystal-induced inflammation (gout and pseudogout), seronegative spondyloarthropathies (ankylosing spondylitis and Reiter syndrome), and bacterial invasion (septic or Lyme arthritis) or viral invasion (viral arthritis). These processes impact joint capsules and surfaces, resulting in a cascade of reactive and inflammatory events.

The most useful tool for evaluation of joint disorders is evaluation of synovial fluid. Table 286-1 lists the diagnostic characteristics of

synovial fluid. However, joint aspiration may be difficult or impossible in smaller joints or those with minimal effusions. Identifying the distribution and number of affected joints is also useful for diagnosis (Table 286-2). A migratory pattern of joint involvement may be helpful as well (Table 286-3).¹

Patient age and gender are aids to diagnosis. Although no clinical pattern is diagnostic, certain general observations are helpful. Septic arthritis is important in infants and children,² with typical affecting organisms characteristic of age and development (Table 286-4). Additionally, a number of infectious and inflammatory processes are unique to childhood (see Chap. 136 for detailed discussion).² In teen and adult years, sexual activity results in an increase in prevalence of gonococcal arthritis and Reiter syndrome associated with chlamydial urethritis.³

Crystal-induced arthritides commonly affect middle-aged adults. Gout is the most common inflammatory joint disease in men over age 40.⁴ The classic gout patient is a middle-aged man with an acute monoarthritis. Women, however, are generally spared the onset of gout until later middle age but can develop polyarticular involvement.⁴

As age progresses, the incidence of rheumatoid and osteoarthritis increases. Whereas osteoarthritis is a disease of older adults (over age 60), rheumatoid arthritis tends to strike earlier with a predilection for women three to four times that of men.¹ Additionally, rheumatoid arthritis classically demonstrates a progressive course with additive, polyarticular involvement of symmetric joints.⁵

DIAGNOSIS

Examination of Synovial Fluid

Joint fluid should routinely be analyzed for culture, Gram stain, leukocyte count with differential, and a wet preparation for crystals.⁶ Glucose and lactate levels may be assessed as well. Cultures should include those for gonococci and anaerobes, when appropriate. Certain disease mechanisms are associated with classic joint aspirate findings (see Table 286-1).

Laboratory Tests

In the acute setting, few tests other than the joint aspirate contribute meaningfully to the diagnostic evaluation. Although the erythrocyte sedimentation rate (ESR) is frequently elevated in a number of acute inflammatory and reactive arthritides (septic, gonococcal, crystal-induced, spondyloarthropathies, and rheumatoid and Lyme arthritis),⁷ the ESR is neither specific nor sufficiently sensitive for disease or as a marker for disease progression. The most applicable use for ESR in children and young infants in whom ESR sensitivity has been reported as 90 percent in the face of septic arthritis.⁸

TABLE 286-1 Examination of Fluid

	Normal	Noninflammatory	Inflammatory	Septic
Clarity	Transparent	Transparent	Cloudy	Cloudy
Color	Clear	Yellow	Yellow	Yellow
WBC/pX	<200	<200-2000	200-50,000	>50,000
PMNs (%) [*]	<25	<25	>50	>50
Culture	Negative	Negative	Negative	>50% positive
Crystals	None	None	Multiple or none	None
Associated conditions		Osteoarthritis, trauma, rheumatic fever	Gout, pseudogout, spondyloarthropathies, RA, Lyme disease, SLE	Nongonococcal or gonococcal septic arthritis

The white blood cell count (WBC) and percent polymorphonuclear leukocytes (PMNs) are affected by a number of factors, including disease progression, affecting organism, and host immune status. The joint aspirate WBC and PMNs should be considered part of a continuum for each disease, particularly septic arthritis, and should be correlated with other clinical information. RA = rheumatoid arthritis; SLE = systemic lupus erythematosus.

TABLE 286-2 Classification of Arthritis by Number of Affected Joints

Number of Joints	Differential Considerations
1 = Monoarthritis	Trauma-induced arthritis Infection/septic arthritis Crystal-induced (gout, pseudogout) Osteoarthritis (acute) Lyme disease Avascular necrosis Tumor
2–3 = Oligoarthritis	Lyme disease Reiter syndrome Ankylosing spondylitis Gonococcal arthritis Rheumatic fever
>3 = Polyarthritis	Rheumatoid arthritis Systemic lupus erythematosus Viral arthritis Osteoarthritis (chronic)

Conversely, the white blood cell count (WBC) also has poor sensitivity and specificity for septic arthritis. Notably, in pediatric septic arthritis, the total WBC is reported as 30 to 60 percent sensitive, with a left shift of the differential approaching 66 percent sensitivity.⁸ Similar findings have been described in the adult population.⁹

Blood cultures have limited utility although they are routine for possible septic arthritis. Cultures should be drawn prior to antibiotic therapy. Blood cultures have demonstrated sensitivities of 23 and 40 percent, in adults and children, respectively.^{9,10}

Additional laboratory assessment may be required for follow-up, including Lyme titer, rheumatoid factor, antinuclear antibodies, anti-neutrophil cytoplasmic antibodies, HLA-B27 tissue typing, lupus anticoagulant, and repeat synovial fluid analysis.

Radiology

Radiographs of an inflamed joint should be obtained when trauma, tumor, ankylosing spondylitis, avascular necrosis, or osteomyelitis are in the differential diagnosis. Radiographic evidence of osteomyelitis has been noted to follow symptom onset by 7 to 14 days.¹ Radioisotope scanning is not usually required for emergency department diagnosis, but can be useful to detect osteomyelitis, occult fracture, avascular necrosis, or tumor.

ARTHROCENTESIS

Accurate diagnosis of articular problems often depends on aspiration and examination of synovial fluid from the affected joint(s) (see Table 286-1).

Technique for Preparation of Selected Arthrocentesis Site

The skin overlying the affected joint should be free of cellulitis or impetigo in order to avoid contamination of the joint space during arthrocentesis. Other relative contraindications to joint aspiration are co-

TABLE 286-4 Commonly Encountered Organisms in the Septic Arthritis Patient

Patient/Condition	Expected Organisms	Antibiotic Considerations
neonates and infants	<i>taphylococcus</i> , gram-negative bacteria, group B <i>Streptococcus</i> , <i>Candida</i>	afcillin* plus aminoglycoside or third-generation cephalosporin, ampicillin-sulbactam
Children <5 years	<i>taphylococcus</i> , <i>Streptococcus</i> , <i>Haemophilus influenzae</i>	afcillin* plus cefuroxime, ampicillin-sulbactam
Older children and healthy adults	<i>taphylococcus</i> , <i>Neisseria gonorrhoeae</i> , <i>Streptococcus</i>	afcillin* plus third-generation cephalosporin, ampicillin-sulbactam
Involvement of the foot	<i>taphylococcus</i> , <i>Pseudomonas</i>	afcillin* plus ceftazidime or aminoglycoside
Intravenous drug users	<i>taphylococcus</i> , gram-negative bacilli	afcillin* plus aminoglycoside, ampicillin-sulbactam
Immunocompromised patients	<i>Salmonella</i>	iprofloxacin, ofloxacin, or ceftriaxone

*First-generation cephalosporin may be substituted for penicillinase-resistant penicillin. Vancomycin should be employed for treatment of suspected methicillin-resistant staphylococci.

agulopathy, hemarthrosis in hemophilic patients before factor replacement, and the presence of a prosthetic joint. However, if the concern for septic arthritis is high, arthrocentesis may be performed in these settings after consultation.

The technique for preparation of any selected joint begins with overlying skin preparation and proper anesthesia. A large area overlying and adjacent to the affected joint is cleansed with povidone-iodine solution. After air drying, the skin is cleaned with an alcohol wipe to remove the povidone-iodine solution from the skin surface. This prevents the introduction of the povidone-iodine antiseptic into the joint, which can result in chemical irritation, or sterilization of the aspiration sample. Sterile drapes are then placed over the site.

Anesthesia is accomplished with infiltration of a local anesthetic by using a 25- to 30-gauge needle. Intra-articular injection of anesthetic should be avoided, because it can inhibit bacterial growth and may result in a spuriously negative culture in an early septic joint.⁹

A large-bore needle (18 or 19 gauge) should be used for aspiration of the joint. Smaller joints may require a smaller-bore needle to enter the joint space. The anticipated volume of fluid within the joint space should direct the selection of syringe size. As much synovial fluid should be removed as possible to optimize diagnosis and relieve pain from joint capsule distention. Aspirated fluid should promptly be sent for appropriate studies, including culture, Gram stain, leukocyte count with differential, and crystal analysis.

Recent reports have documented ultrasound-assisted arthrocentesis by emergency physicians.¹¹ Ultrasound should not be utilized to determine if arthrocentesis is indicated, but rather as an adjunct to assist localization and aspiration of joint fluid.

Shoulder

ANTERIOR APPROACH Insert the needle just lateral to the coracoid process. This technique is performed with the patient sitting in an upright position, facing the examiner. The needle is directed posteriorly between the coracoid process and the humeral head. Because of the difficulty in locating the coracoid process, a posterior approach to the glenohumeral joint may be preferable in some patients.

POSTERIOR APPROACH Sit the patient upright with his or her back toward you. The spine of the scapula is palpated to its lateral limit: the acromion. The posterolateral corner of the acromion is located. The point for needle insertion lies 1 cm inferior and 1 cm medial to the posterolateral corner of the acromion (Figure 286-1). A 1½-in. needle is directed anterior and medial toward the presumed position of the coracoid process. The glenohumeral joint is located at a depth of approximately 1 to 1½ in.

Elbow

A lateral approach to the elbow is used. Place the elbow in 90 degree flexion, resting on a table, with the hand prone. Locate the radial head, lateral epicondyle of the distal humerus, and the lateral aspect of the olecranon tip. These three landmarks form the anconeus triangle. The center of this triangle is the site for needle entry into the skin. The needle should be directed medial and perpendicular to the radius (Figure 286-2).

Wrist

Landmarks for wrist arthrocentesis are palpable with the wrist in a neutral position. Noted landmarks are the radial tubercle of the distal radius, the anatomic snuff-box, the extensor pollicis longus tendon, and the common extensor tendon of the index finger (Figure 286-3). The needle should be inserted perpendicular to the skin slightly ulnar to the radial tubercle and the anatomic snuff-box between the extensor pollicis longus and the common extensor tendons.

Hip arthrocentesis may be performed via an anterior or medial approach. Due to the belief that patients, particularly children, with a

FIG. 286-2. Arthrocentesis of the elbow.

septic hip should undergo open surgical assessment and drainage, an orthopedic consultant will generally perform this procedure.² Controversy exists regarding the utility of ultrasound, bone scan, or magnetic resonance imaging as a screening test prior to open surgical evaluation.^{13,14} Immediate consultation with orthopedics is therefore desirable when a diagnosis of septic hip arthritis is considered.

Knee

The knee joint can be entered either medial or lateral to the patella. With the patient supine, the knee should be fully extended and the quadriceps muscle relaxed. The midpoint of the patella is identified. The insertion point of the needle is located approximately 1 cm inferior to the patellar edge, either lateral (Figure 286-4) or medial (Figure 286-5) to the middle of the patella. The needle should be directed posterior to the patella and horizontally toward the joint space. Compression applied over the joint

FIG. 286-1. Arthrocentesis of the shoulder, posterior approach.

FIG. 286-3. Arthrocentesis of the wrist.

FIG. 286-4. Arthrocentesis of the knee, lateral approach.

space or "milking" of the bursae, on the patellar side opposite the needle insertion site, may facilitate aspiration.

Ankle

Ankle arthrocentesis may be performed at either the subtalar joint (lateral approach) (Figure 286-6) or the tibiotalar joint (medial approach) (Figure 286-7). The subtalar joint is entered just below the tip of the lateral malleolus with the foot perpendicular to the leg. The needle should be directed medially toward the joint space.

The tibiotalar joint is approached with the patient supine and the foot initially perpendicular to the leg. This position facilitates the location of a sulcus lateral to the medial malleolus and medial to the tibialis anterior and extensor hallucis longus tendons (see Figure 286-7). The foot is then plantar flexed with the needle entering the skin over-

FIG. 286-5. Arthrocentesis of the knee, medial approach.

FIG. 286-6. Arthrocentesis of the ankle, lateral approach.

lying the sulcus. The needle should be angled slightly cephalad as it passes between the medial malleolus and the tibialis anterior tendon.

SPECIFIC CONDITIONS

Traumatic Arthritis

Traumatic hemarthrosis has a high association with ligamentous injury or an intra-articular fracture. Effusions following trauma may range from small to large, painful fluid collections that impede range of motion. Aspiration of very large traumatic effusions will provide pain relief and increase range of motion. Treatment of traumatic hemarthrosis consists of immobilization, ice, and elevation of the affected joint. In the absence of a fracture or significantly unstable joint requiring immediate orthopedic evaluation, follow-up is needed for possible ligamentous and articular injuries.

Spontaneous hemarthrosis usually indicates underlying systemic illness and should trigger a search for primary or secondary coagulopathies. Hemophiliacs should receive specific clotting factor replacement (see Chap. 220), and joint aspiration for acute hemarthrosis in hemophilia is controversial, but recommended by some for large bleeds if done during the first 12 h.¹⁵ Follow-up and/or consultation should be provided with hematology and orthopedics.

Nongonococcal Septic Arthritis

Three mechanisms can lead to septic arthritis: (1) hematogenous spread of bacteria, (2) migration of bacteria from a focus contiguous to a joint, and (3) direct inoculation of bacteria into the joint.

Septic arthritis is a medical emergency. A rampant bacterial infection with a normal inflammatory response can destroy a joint within days. The involved joint can become exquisitely painful over a few hours. On examination, effusions may be scant, with significant splinting and resistance to movement.

FIG. 286-7. Arthrocentesis of the ankle, medial approach.

Although the classic bacterial arthritis patient is described as febrile with chills and rigors, a 10-year retrospective review of 43 adult patients noted presence of fever or rigors in only 40 and 21 percent of patients, respectively.⁹ Thus the absence of constitutional symptoms should not preclude a septic arthritis diagnosis. A suspicion for a bacterial infection should always guide clinical decision making when approaching patients with monoarthritis.

After joint aspiration, if septic arthritis cannot be excluded, the patient should be admitted for pain control and parenteral antibiotics until synovial culture results are available. Consultation with orthopedics or infectious disease is desirable. Repeat closed-needle aspiration, arthroscopy, or open surgical drainage may be required, depending on a number of factors, including consultant preference, patient age, affected joint, and likelihood of septic source.

Gonococcal Arthritis

Gonococcal arthritis is the most common cause of septic arthritis in adolescents and young adults.² Joint infection will typically have a prodromal phase in which migratory arthritis and tenosynovitis predominate before pain and swelling settle on one or more septic joints. Vesiculopustular lesions, especially on the fingers, may be found.

Synovial fluid cultures are often negative in gonococcal arthritis, with only 25 to 50 percent of cases yielding positive identification of the organism. Cultures of the posterior pharynx, urethra, cervix, and rectum prior to antibiotic treatment may increase the culture yield.²

Treatment for gonococcal arthritis follows the same principles as treatment for nongonococcal septic arthritis. *Neisseria gonorrhoeae*,

in the setting of arthritis, remains sensitive to penicillin, and extended antibiotic coverage is typically not required following identification of the organism.

Crystal-Induced Synovitis (Gout and Pseudogout)

Crystal-induced synovitis is primarily an illness of middle-aged and elderly adults. Uric acid (gout) and calcium pyrophosphate (pseudogout) are the two most common crystalline agents, with gout representing the most common form of inflammatory joint disease in men older than age 40.⁴ Patients typically present with joint pain that acutely evolves over hours, as in acute gout attack, or over a single day, as in pseudogout. An acute gout or pseudogout attack often follows trauma, surgery, a significant illness, or change in medications that results in an abrupt change in uric acid levels. Crystalline involvement of joints has a predilection for the lower extremities. Although the first metatarsophalangeal joint is a classic focus for acute gout, no joint is the exclusive site of involvement for either crystal.

The diagnosis of a crystal-induced synovitis is by joint aspiration and identification of crystals through a polarizing microscope. Uric acid crystals appear needle-shaped and blue when the source of light is perpendicular to the crystal. Calcium pyrophosphate is yellow in this alignment, with a rhomboid shape. Crystals should be located within phagocytes from aspirates of synovial fluid or inflamed tissues adjacent to the affected joint.

Serum uric acid levels have limited utility in diagnosis, as up to 30 percent of patients will have normal uric acid levels during an acute gout attack.⁴ The joint aspirate WBC is often high with gout, approaching 100,000/xL in some cases.⁴ However, the presence of crystals, absence of findings on Gram stain or culture and frequently, the dramatic response to nonsteroidal anti-inflammatory drugs (NSAIDs) will clarify the diagnosis. When the diagnosis of a septic joint cannot be excluded, hospital admission until cultures and/or clinical response clarify the diagnosis is the safest course of action.

When the diagnosis of gout or pseudogout is established, an NSAID, such as indomethacin, is standard first-line therapy. All NSAID dosing should be adjusted for renal function and continue for approximately 1 week. For patients with normal renal function, the initial dose of indomethacin is 50 mg. Therapy is continued three times a day for 3 to 5 days. Substantial pain relief typically occurs within 2 h of NSAID administration.¹⁶ Additional treatment for pseudogout is typically not required.

Colchicine, although not often necessary, may also be employed as an alternative in the treatment of acute gout. Oral colchicine is typically administered at a dose of 0.6 mg/h until intolerable side effects (vomiting or diarrhea) or efficacy ensues. Intravenous administration of colchicine can be associated with serious side effects, with risks such as bone marrow suppression, neuropathy, myopathy, and death. Consequently, intravenous colchicine is limited to a single dose of 1 to 2 mg administered slowly over 1 h in an established intravenous line.¹⁷

Patient disposition is determined by consideration of effective analgesia and the inclusion or elimination of septic arthritis as a diagnosis in the patient evaluation. Once the symptoms of an acute crystal-induced synovitis episode have resolved, long-term control may be achieved with reduction or elimination of gout-inducing agents (diuretics, aspirin, or cyclosporine) and treatment with prophylactic drugs, such as allopurinol or probenecid.

Lyme Disease

The arthritic manifestations associated with Lyme disease occur in the weeks, months, or years following the primary, stage I infection. Typically, a monoarticular or oligoarticular, asymmetric involvement of joints is noted, with brief exacerbations followed by complete remission. Large joints are most often affected.¹⁸ A migratory pattern of oligoarthritis may be noted, in addition to brief attacks of bursitis and tendonitis.

Arthrocentesis yields an inflammatory synovial fluid, usually with negative cultures.¹⁸ The diagnosis of Lyme arthritis is initially suspected in patients residing in, or with a recent visit to, an endemic area. A history of tick bite or erythema chronicum migrans (ECM) rash is helpful but often absent. In patients with no history of rash, tick bite, or endemic location, a constellation of characteristic stage II and stage III findings—such as fatigue, neurologic abnormalities, and/or cardiac conduction disturbances—may be helpful in establishing the diagnosis. Ultimately, definitive diagnosis requires the history or presence of the ECM rash, multi-organ system involvement, or laboratory confirmation through enzyme-linked immunosorbent assay, immunofluorescent antibody titer, or isolation of the *Borrelia burgdorferi* spirochete from a clinical specimen.

Given the difficulty of making a definitive diagnosis in many patients, treatment of suspected Lyme arthritis is often initiated on the grounds of high clinical suspicion. Treatment is administered for 3 to 4 weeks, with a number of antibiotics recognized as effective, including doxycycline, penicillin G, amoxicillin, or ceftriaxone. Intravenous antibiotic therapy is reserved for those patients with more severe presentations.

Rheumatoid Arthritis

Rheumatoid arthritis is distinguished by its symmetric, polyarticular involvement, with noted sparing of the distal interphalangeal (DIP) joints. Patients will describe stiffness of the joints occurring after prolonged periods of inactivity (morning stiffness). Multisystem involvement is characteristic, and depression, fatigue, and generalized myalgias are also common. Extra-articular symptoms and signs include pericarditis, myocarditis, pleural effusion, pneumonitis, and mononeuritis multiplex syndrome.

Articular involvement is noted for symmetric, painful, tender joints. A "boggy," slightly edematous synovium may be palpated. Sparing of the DIP joints is the rule, with an additive involvement of affected joints during the course of the illness. Arthrocentesis of synovial fluid is typically noted for an inflammatory profile.

Treatment during an acute exacerbation is directed at reducing pain and inflammation. Salicylates or other NSAIDs are the cornerstone of treatment, with immobilization providing added relief from joint movement pain. Corticosteroids may be utilized for brief periods, with long-term therapy using agents such as antimalarials, gold, and methotrexate.

Osteoarthritis

Osteoarthritis is distinguished from rheumatoid arthritis by a lack of constitutional symptoms and/or multisystem involvement. Destruction of joints in osteoarthritis may involve the DIP joints, with less dramatic symmetric, polyarticular exacerbations. Although osteoarthritis is a chronic, polyarticular disease, patients may present with an acute monoarthritis exacerbation, typically of the knee. Effusions are small and difficult to aspirate. If fluid is aspirated, it is noninflammatory.

Radiographs contribute to the diagnosis of osteoarthritis, demonstrating characteristic joint space narrowing due to destruction of articular cartilage. Treatment, as in rheumatoid arthritis, involves rest of affected joints and the use of salicylates or NSAIDs. Because of the noninflammatory and destructive nature of osteoarthritis, corticosteroids are not used in the disease. Disease progression often necessitates total joint replacement.

Reiter Syndrome

Reiter syndrome, or reactive arthritis, is a seronegative spondyloarthropathy characterized by an acute, asymmetric oligoarthritis preceded 2 to 6 weeks earlier by an infectious illness. **The classic triad of Reiter syndrome is arthritis, urethritis, and conjunctivitis. A history of all three components is not necessary for diagnosis.** *Chlamydia* or *Ureaplasma* are common inciting infectious agents, particularly with regard

to a precipitating urethritis. Diarrhea has also become recognized as an entity that may precipitate a reactive arthritis. A history of recent diarrhea or enteric infection while traveling abroad may suggest a recent *Salmonella* or *Shigella* infection as an inciting factor for the disease.³

Joint involvement is typically found in the lower extremities, particularly the heels of the feet. A diffuse swelling of an entire digit (sausage digit) may be found as well, but is not specific to Reiter syndrome alone.¹ Synovial fluid aspirates demonstrate an inflammatory profile. Treatment is supportive with emphasis on pain control and NSAID therapy. Antibiotics have not been found to be useful.

Ankylosing Spondylitis

Another of the seronegative spondyloarthropathies—ankylosing spondylitis—demonstrates an arthritic predilection for the spine and pelvis. Ankylosing spondylitis is similar to rheumatoid arthritis in its association with morning stiffness and multisystem involvement with constitutional symptoms such as malaise, weakness, and fatigue. However, ankylosing spondylitis is clearly differentiated in its association with hereditary factors, particularly the HLA-B27 antigen and negative rheumatoid factor.

Ankylosing spondylitis is suspected in individuals younger than age 40 who note insidious onset of symptoms that improve with exercise, are associated with morning stiffness, and last longer than 3 months. Radiographic findings, in addition to genetic predisposition, are helpful in the diagnosis of ankylosing spondylitis. Squaring of the vertebral bodies (bamboo spine) and sacroiliitis are some of the more classic findings. Treatment consists of pain control with short-term and long-term management with NSAIDs.

BURSITIS

The term *bursitis* refers to any acute or chronic inflammatory process involving one of the more than 150 bursae identified throughout the human body.¹⁹ Bursitis is classified by etiology, body location, and presence of infection. Etiologic entities include trauma, crystal-induced, rheumatoid, and idiopathic forms. Presence of infection is noted by classification as septic or nonseptic. *Staphylococcus aureus* accounts for the majority of identified infectious agents, but *Staphylococcus epidermidis* and *Streptococcus* species are also encountered.

Bursitis is a relatively common condition, due to the number of bursae and the minimal trauma required to initiate a clinically evident process. The affected site is determined by the activity precipitating the event and/or the relatively superficial location of many bursae. Certain entities are frequently associated with occupations or activities that precipitate their occurrence: "carpet layer's knee" (prepatellar bursitis) or "student's elbow" (olecranon bursitis).

General principles of management include restraint from further trauma/injury, elevation, and a compressive dressing. Drag therapy with NSAIDs is the primary pharmacotherapeutic intervention. Injection of the affected bursa with steroids is controversial and should be avoided when septic bursitis cannot be excluded.

Septic bursitis generally responds well to oral antibiotics, with emphasis on coverage of *Staphylococcus* and *Streptococcus* species. Selected patients will require more aggressive interventions, including admission to hospital, administration of parenteral antibiotics, incision and debridement, and open irrigation. These patients typically have more advanced, purulent infection within the bursa, extensive spread of infection/cellulitis to surrounding soft tissues, suspected joint involvement, or failure to respond to oral antibiotics and outpatient interventions.

Specific Conditions

OLECRANON BURSITIS The olecranon bursa overlies the olecranon process on the extensor surface of the elbow. Patients with olecranon bursitis present with a tense, edematous bursa that is often ten-

der to palpation. Pain elicited with range of motion at the elbow is minor until the motion tightens and compresses the distended overlying bursa. The bursa is frequently erythematous and warm.

Distinguishing nonseptic bursitis from the septic and crystal-induced forms is a clinical challenge. Patients with crystal-induced bursitis will often demonstrate gouty tophi overlying the elbow extensor surface. Presence of crystals in bursal fluid analysis is diagnostic.

Septic bursitis and nonseptic bursitis are difficult to distinguish. No definitive conclusion can be reached solely on the basis of physical examination findings or history, although one report has noted the utility of surface temperature comparison of the affected bursa with the unaffected side.¹⁹ These authors reported a temperature difference exceeding 2.1°C to be highly predictive of a septic bursal fluid aspirate.

Most authors advocate the importance of aspirating bursal fluid,^{19,22} which is performed both for diagnostic and therapeutic purposes. Bursal fluid, like joint aspirates, demonstrates characteristic findings (Table 286-5). The utility of any one finding is limited, however, and the culture represents the definitive test for presence or absence of infection.

Aspiration of olecranon bursitis fluid is undertaken by means of a lateral approach to the affected bursa. As in joint aspirates, a sterile technique should be utilized, with evacuation of as much fluid as possible.

Management of patients with olecranon bursitis follows the aforementioned general bursitis management principles. When a septic bursitis is definitively excluded, a steroid injected into the bursa may expedite resolution of inflammation.²² However, a septic process usually cannot be excluded during the initial evaluation of an acute olecranon bursitis. As a consequence, utilization of steroid injection should be approached with caution.

Antibiotic treatment is usually effective with a 14-day course of oral antibiotic therapy.^{19,21} Selected patients who may require parenteral therapy or operative management are generally distinguished by their toxic appearance, systemic signs of infection, extensive cellulitis to surrounding tissues, failure of outpatient interventions, or immunocompromised host status.

PREPATELLAR BURSITIS Prepatellar bursitis may affect any of the four bursae surrounding the extensor aspect of the knee. As in other bursitis conditions, a history of overuse or trauma to the prepatellar area is often elicited.¹⁹ Clinical findings are consistent with those of olecranon bursitis.

TABLE 286-5 Characteristics of Bursal Fluid in Patients with Septic and Nonseptic Olecranon and Prepatellar Bursitis

	Septic	Traumatic and Idiopathic	Crystal-induced
Appearance	purulent; may be straw colored or serosanguineous	straw colored, serosanguineous, or bloody	Straw colored to bloody
Leukocytes/ μ L	500-300,000; mean 75,000	0-11,000; mean 1100	1000-6000; mean 2900
Differential count	redominantly PMNs	redominantly mononuclear	Highly variable
Ratio bursal fluid to serum glucose	<50%	>50%	Unknown
Gram stain	Positive in 70%	Negative	Negative
Crystals present	No	No	Yes
Culture results	Positive	Negative	Negative

Source: From McAfee and Smith,¹ with permission.

Aspiration of prepatellar bursal fluid should be accomplished using either a medial or lateral approach to the affected bursa. Treatment emphasizes conservative management and occasionally requires antibiotic therapy or admission following the same approach as outlined for patients with septic olecranon bursitis.

SOFT TISSUE PROBLEMS OF THE FOOT

Frantz R. Melio

Foot problems are common human afflictions. This chapter discusses the common foot disorders that are likely to present to the ED. Patients with chronic or complicated foot problems generally should be referred to a dermatologist, orthopedist, general surgeon, or podiatrist, depending on disease and local resources.

CORNS AND CALLUSES

Pressure or irritation causes focal hyperkeratotic lesions of the skin of the foot. The cause of these lesions can be external (poorly fitted shoe) or internal (bunion). These areas of epidermal accumulation are called *calluses*. Calluses serve a protective function and should not be treated if they are not painful. Calluses grow outward but are soon pushed inward by continued pressure and become corns. Corns also develop in areas of scarring and between toes. Corns are classified as hard or soft. Hard corns are seen over bony protuberances where the skin is dry. Soft corns are seen between toes where the skin is moist. Corns may be painful or painless, but pressure on the corn usually produces pain. Corns interrupt the normal dermal lines and can thus be differentiated from calluses. Hard corns may resemble warts; however, when pared, warts bleed and corns do not. Soft corns resemble tinea, which often leads to misdiagnosis and mistreatment.^{1,2}

Treatment of symptomatic lesions consists of paring with a no. 15 blade scalpel and application of a pad on or around the lesion to relieve pressure. Avoiding constrictive footwear is also important. The use of keratolytic agents is controversial. Patients should be referred to a podiatrist, since therapy includes repeated paring and possibly surgery to correct any underlying source of pressure.^{1,2}

Keratotic lesions may be an indication of more severe underlying disease, deformity, local foot disorder, or mechanical problem. Other causes of keratotic lesions include syphilis, psoriasis, arsenic poisoning, rosacea, lichen planus, basal cell nevus syndrome, and rarely, malignancies.²

PLANTAR WARTS

Plantar warts are caused by the human papillomavirus. These warts are fairly common and contagious. They may be painful and are usually found over bony prominences. Single lesions are endophytic and hyperkeratotic. A mother-daughter wart is similar to a single lesion except for a small vesicular satellite lesion. Mosaic warts are often painless, closely grouped, and may coalesce. Diagnosis is usually made clinically. There are many therapeutic options. Treatment is complicated by the fact that many of these lesions will resorb spontaneously within 2 years. Plantar warts may require prolonged treatment so referral to a dermatologist or podiatrist is best.^{1,3}

TINEA PEDIS AND ONYCHOMYCOSIS

Tinea pedis and onychomycosis are discussed in Chap. 248, "Disorders of the Hands, Feet, and Extremities."

ONYCHOCRYPTOSIS (INGROWN TOENAIL)

Ingrown toenails occur when a segment of the nail plate penetrates the nail sulcus and subcutaneous tissue. Curvature of the nail plate is the most common predisposing factor. The lesion usually occurs as a result of external trauma or self-treatment. Onychocryptosis is characterized by inflammation, swelling, and infection of the medial or lateral aspect of the toenail. The great toe is the most commonly affected. Protracted infection may result in periungual ulcerative granulation. In patients with underlying diabetes or arterial insufficiency, cellulitis, ulceration, and necrosis may lead to amputation if treatment is delayed. If infection is not present at the time of presentation, simple elevation of the nail with placement of a wisp of cotton between the nail plate and the skin, daily foot soaks, and avoidance of pressure on the nail is usually sufficient treatment. Another option, if no infection is present, is to remove a small spicule of the offending nail. A digital block is placed (see Chap. 37). The area is cleaned, and the skin is prepared for surgical procedure. An oblique portion of the affected nail is trimmed about one- to two-thirds of the way back to the posterior nail fold. The nail groove should then be debrided, and a nonadherent dressing placed^{2,4} (Figure 287-1).

FIG. 287-1. Partial toenail removal.

If granulation or infection is present, then partial removal of the nail plate is indicated. This is performed by first placing a digital block, and preparing the area for a surgical procedure. The entire affected area, one-quarter or less of the nail plate, is cut longitudinally (base to tip), including the portion of the nail beneath the cuticle. English anvil scissors or a nail splitter are the optimal instruments for cutting the nail. The affected cut portion of the nail is then grasped with a hemostat and, using a rocking motion, removed from the nail groove. The nail groove is then debrided⁴ (Figure 287-2). Once the procedure is completed, a nonadherent gauze or antibiotic ointment should be placed on the wound. A bulky dressing should then be placed on the toe. The wound should be checked in 24 to 48 h.⁴

OTHER NAIL LESIONS

Other common toenail afflictions include paronychia and subungual hematoma, which are treated similarly to when they occur in the fingers. Hyperkeratotic toenails can be a problem in the elderly. These may become so severe as to affect gait and cause ulcerations and infections. Patients with these lesions require referral for repeated trimming or nail plate removal.²

BURSITIS

There are many bursae in the foot, all of which may become a source of pain. Pathologic bursae can be divided into noninflammatory, inflam-

FIG. 287-2. Partial toenail removal (infection present).

matory, suppurative, and calcified. Noninflammatory bursae are usually pressure-induced and are found over bony prominences. Inflammatory bursae are commonly due to gout, or rheumatoid arthritis. Suppurative bursitis is due to the invasion of the bursae, usually from adjacent wounds, by pyogenic organisms (primarily staphylococcal species). Acute bursitis can lead to the formation of a hygroma or calcified bursae. In severe cases, pressure on bursae can lead to fistula and ulcer formation. Diagnosis of these lesions is dependent on analysis of bursal fluid, which can be obtained by large-bore needle aspiration. Fluid should be sent for cell count; protein, glucose, and lactate (elevated in septic bursitis) levels; crystal analysis; and Gram stain as well as culture (since initial Gram stains are often negative). Treatment of the bursitis depends on its cause. In all cases one should avoid further pressure to the area by instructing the patients to avoid putting weight on the affected foot. Septic bursitis should be initially treated with a penicillinase-resistant semisynthetic penicillin while awaiting culture results. Repeated aspiration or incision and drainage may become necessary.⁵

PLANTAR FASCIITIS

Plantar fasciitis is an inflammation of the plantar aponeurosis. The plantar fascia's main function is to anchor the plantar skin to the bone, thus protecting the longitudinal arch of the foot. The cause of plantar fasciitis is usually overuse in the physically active patient or in the patient unaccustomed to activity. Other causes include abnormal joint mechanics, tightness of the Achilles tendon, shoes with poor cushioning, abnormal foot position and anatomy, and obesity. In the younger patient, autoimmune and rheumatic diseases can lead to this entity. Patients present with pain on the plantar surface of the foot that is worse on arising and after physical activity. Examination usually reveals a point of deep tenderness at the anterior medial aspect of the calcaneus, the point of attachment of the plantar fascia. Ultrasound and magnetic resonance imaging (MRI) may aid in diagnosis. Plantar fasciitis is generally a self-limited disease. Short-term treatment consists of rest, ice, nonsteroidal anti-inflammatory drugs (NSAIDs), heel and arch support shoe inserts, and dorsiflexion night splints (molded ankle-foot orthosis that holds the plantar fascia and Achilles tendon stretched). Patients should be taught Achilles tendon stretching exercises and be told to avoid walking barefoot on hard surfaces. In severe cases, a short-leg walking cast may be applied to unload and rest the plantar fascia. Glucocorticoid injections are associated with plantar fascia rupture, and are usually best left to the orthopedist.¹⁶ Patients should be referred to a podiatrist, orthopedist, or primary care physician for follow-up care.¹⁶

TARSAL TUNNEL SYNDROME

Tarsal tunnel syndrome is a compression neuropathy of the posterior tibial nerve that causes foot and heel pain. After coursing inferiorly to the medial malleolus, the posterior tibial nerve enters the tarsal tunnel. The plantar aspect of the tarsal tunnel is bound by the talus and calcaneus bones, and by the tibialis posterior, flexor hallucis longus, and flexor digitorum longus. The dorsal aspect is bound by the inelastic flexor retinaculum, which extends from the medial malleolus to the calcaneus to the abductor hallucis muscle.

Nerve compression may be intrinsic or extrinsic. In the setting of overuse, running and activities requiring restrictive footwear (e.g., ski boots, skates) have been implicated. The edema of pregnancy, post-traumatic fibrosis, ganglion cysts, osteophytes, and tumors may also be a precipitant. Hyperpronation (inward rotation) while running makes the nerve more vulnerable both to direct trauma from stretch and to indirect trauma from inflammation of the surrounding structures resulting in compression.⁷

Pain or dysesthesia is noted at the medial malleolus, the heel (calcaneal branch), and sole (medial or lateral plantar branch), depending on the site and severity of compression. Distal calf pain may result due

to retrograde radiation (Valleix phenomenon). Similar to carpal tunnel syndrome, the pain is often worse at night. More advanced disease may result in weak toe flexion. Tinel sign is positive inferior to the medial malleolus. Simultaneous dorsiflexion and eversion of the ankle exacerbates symptoms. Diagnosis is aided by nerve conduction studies or MRI.

The differential diagnosis includes plantar fasciitis and, if limited to the heel, Achilles tendinitis. Plantar fasciitis will cause point tenderness over the plantar heel and worse pain upon morning standing. Tarsal tunnel syndrome causes greater medial heel and arch pain, due to involvement of the abductor hallucis muscle. Tarsal tunnel pain worsens with ambulation throughout the day. In addition, tarsal tunnel syndrome may produce distal calf pain, whereas fasciitis does not.

Initial treatment includes avoidance of the exacerbating activities and use of NSAIDs. If there is no improvement or symptoms recur after a few weeks, then orthopedic evaluation and treatment, which includes electromyographic studies, steroid injection, orthotic devices, or surgery, are recommended.⁷

GANGLIONS

A ganglion is a common benign synovial cyst. Ganglions are often clinically asymptomatic. Ganglions are 1.5 to 2.5 cm in diameter and are often attached to a joint capsule or tendon sheath. Although ganglions typically occur in the wrist or hand, they may also occur in the foot. These lesions typically arise in the anterolateral aspect of the ankle, but can occur in many areas of the foot. The pathogenesis of these lesions is unknown. The two most popular theories are (1) that they are produced by herniation of the tendon sheath, and (2) that they arise from focal myxomatous degeneration of collagenous tissues caused by trauma. Ganglions may appear suddenly or gradually, may enlarge and diminish in size, and may be painful or asymptomatic. On examination one notes a firm, usually nontender, cystic lesion. Diagnosis is usually made clinically, although ultrasound and MRI are useful if there is any question of the diagnosis. Aspiration and instillation of glucocorticoids by an orthopedist leads to the complete resolution of ganglions in some cases, with surgical excision required for persistence.⁸

TENDON LESIONS

Tendon lesions usually require referral and/or consultation with a podiatrist or orthopedist to aid in treatment decisions (Figures 287-3 and 287-4). Tenosynovitis and tendinitis may occur in the foot, usually due to overuse. Patients present with pain over the involved tendon. The flexor hallucis longus, posterior tibialis, and Achilles tendon are most commonly involved. Treatment consists of rest, ice, and oral NSAIDs.⁹

Tendon lacerations are usually traumatic. The usual mechanism of injury is a cut to the dorsal or plantar aspect of the foot. Tendon lacerations should be explored and repaired if the ends of the tendon are visible in the wound. The foot should be casted in dorsiflexion after the repair of extensor tendons, and in equinus after repair of flexor tendons. Unfortunately, tendon repairs in the foot have a relatively high complication and disability rate. Specialty consultation is appropriate.⁹

Spontaneous rupture of the Achilles, tibialis anterior, and posterior tibialis tendons is fairly common. Diagnosis and proper treatment of tendon ruptures is aided by ultrasound or MRI studies. Orthopedic consultation should be obtained to aid in proper therapeutic decisions. Achilles tendon ruptures are usually due to forceful dorsiflexion and occur more commonly in males. Patients present with pain, a palpable defect in the area of the tendon, and inability to stand on tiptoes. Squeezing the calf of the prone patient whose knee is flexed at 90° will normally cause the foot to plantar flex (Thompson test). This response will be absent in patients with Achilles tendon ruptures. Treatment is generally surgical in younger patients and conservative (casting in equinus) in older patients.⁹

FIG. 287-3. Tendons of the foot, anterior view.

Ruptures of the anterior tibialis tendon are rare. These usually occur after the fourth decade and are not excessively painful. Patients present with varying degrees of foot drop and a palpable defect distal to the ankle joint in the area of the tendon. In most cases, disability is minimal and surgery is not necessary.⁹

Spontaneous ruptures of the posterior tibialis tendon also occur after the fourth decade. Two-thirds of these cases occur in women. The presentation is usually chronic and insidious. Patients notice a gradual flattening of their arch, with modest discomfort and swelling over the medial ankle. Examination reveals absence of the tendon's normal prominence and weakness on inversion of the foot. Patients find it impossible to stand on tiptoes. Treatment may be conservative or surgical, depending on the duration of the tear and activity of the patient.⁹

Flexor hallucis longus tenosynovitis classically affects ballet dancers, but can also be seen in runners and nonathletes. Presentation is similar to plantar fasciitis and tarsal tunnel syndrome. Posteromedial ankle pain, medial arch pain, and a positive Tinel sign are seen. Management is often surgical. Flexor hallucis longus rupture presents as a loss of plantar flexion of the great toe. This lesion must be repaired in ballet dancers but not in the nonathlete.⁹

Disruption of the peroneal retinaculum can occur as a result of direct trauma during dorsiflexion of the foot. Besides pain localized to the peroneal tendon behind the lateral malleolus, the patient complains of a clicking when walking as the tendon subluxes. Peroneal tendon injuries may lead to lateral ankle instability. Treatment is generally surgical repair.⁹

PLANTAR INTERDIGITAL NEUROMA (MORTON NEUROMA)

Neuromas may form in a plantar digital nerve, usually proximal to its bifurcation. These neuromas may occur in any of the digital nerves but are most common in the third interspace. The cause of these lesions is thought to be local irritation of the nerve due to entrapment, usually from tight-fitting shoes. Women between the ages of 25 and 50 years are the most commonly affected group. Patients present with pain located in the area of the metatarsal head. The pain is described as burning, cramping, or aching. Pain is worsened by ambulation and resolved by rest and removal of shoes. The pain may radiate to the affected toes, and patients may note numbness in the toes. Pain is usually easily reproduced upon palpation of the area, and at times a mass is felt. Diagnosis is usually made clinically, but nerve conduction studies,

A Lateral

B Medial

FIG. 287-4. Tendons of the foot, posterior view.

electromyograms, ultrasounds, and MRI may be helpful at times. Conservative treatment consists of wearing wide shoes with good metatarsal head supports and metatarsal head off-loading inserts. Local glucocorticoid injections can sometimes be curative. Conservative therapy is often unsuccessful, and patients may ultimately require neurolysis or surgical intervention.¹⁰

COMPARTMENT SYNDROME

Compartment syndromes have been more commonly described to affect the arms and legs (see Chap. 278 for further discussion). Nine compartments have been identified in the foot. Compartment syndrome occurs when an elevation of tissue pressure within one of these nonyielding fascial compartments impedes vascular flow. In the foot, the cause of compartment syndrome is usually a high-energy injury associated with multiple fractures. Crush injuries are more likely to cause compartment syndrome than are penetrating injuries. Compartment syndromes have been reported in association with foot and ankle fractures, burns, contusions, bleeding disorders, postischemic swelling after arterial injury or thrombosis, venous obstruction, exercise, and prolonged pressure to the affected area. There have also been reports of chronic compartment syndromes due to overuse. Patients typically present with severe acute pain that is worsened on active or passive movement, swelling, paresthesias, and neurovascular deficits. The only reliable method to diagnose compartment syndrome is by obtaining intracompartmental pressures. Once the diagnosis is made, fasciotomy should be performed emergently. The sequelae of compartment syndrome range from transient neurologic compromise to complete myoneural necrosis, fibrosis, and ischemic contractures. The prognosis of compartment syndrome is directly related to the time delay in diagnosis and treatment.¹¹

PLANTAR FIBROMATOSIS

Plantar fibromatosis, or Dupuytren contracture of the plantar fascia, does not occur as commonly as in the hand. Plantar fibromatosis is a disorder of fibrous tissue proliferation, which slowly invades the skin and soft tissues. Presentation is generally in adolescence or young adulthood. Patients present with small (0.5 to 1.0 cm), asymptomatic, palpable, slowly enlarging, fixed, firm masses on the plantar aspect of one or both feet. These lesions tend to be in the non-weight-bearing areas of the foot. Toe contractures do not occur. Lesions have a tendency to reabsorb spontaneously. Diagnosis is aided by the use of MRI. Treatment is conservative, and only rarely is surgery indicated. Patients should be referred to the appropriate consultant for continued

FOOT ULCERS

Foot ulcers can generally be classified as neuropathic or ischemic by the predominant etiologic factor and clinical features. Infection can be a complicating factor in either type of ulcer. Diabetics are prone to both types of ulcers and in addition are more apt to develop infections. It has been estimated that proper foot care in diabetics (including prophylaxis and treatment of foot ulcers) could reduce the number of lower limb amputations by 44 to 80 percent.¹³

Venous stasis ulcers of the lower extremity are discussed in Chap. 247. The following sections discuss ischemic and neuropathic ulcers of the feet.

Ischemic ulcers are secondary to vascular compromise, usually due to atherosclerosis of larger vessels. Ulcers rarely develop due to problems with the microcirculation. These ulcers are seen in the setting of a cool foot, dependent rubor, pallor on elevation, atrophic shiny skin, and diminished pulses. Patients may complain of symptoms of intermittent claudication and leg or foot pain in the supine position, relieved by dependency. If the underlying vascular disease is corrected, these ulcers usually heal quickly. Without reconstructive surgery, the prognosis is poor and amputation is often inevitable.^{13,14}

Neuropathic ulcers are essentially pressure ulcers. Patients at risk are those with absent or distorted foot sensation. These include patients with diabetes, leprosy, tabes dorsalis, and other congenital or acquired neuropathies. Their feet are prone to ischemia from pressure by ill-fitting shoes, foreign bodies, abnormal bony prominences, and most commonly from the daily stresses of walking. The ulcers are usually well circumscribed with surrounding white callus-like material. The foot (if there is no underlying vascular disease) has normal temperature, color, and pulses. Defects in touch, pressure, or proprioception are noted on examination. Motor weakness and muscular atrophy may also be present. These changes can lead to abnormal gait and foot anatomy. Autonomic neuropathy leads to dry, cracked and callus skin from decreased perspiration. Disruption of the protective skin barrier may lead to infection.^{13,14}

Once an ulcer becomes infected, two aspects of therapy are essential for healing: thorough debridement and complete pressure relief. Debridement must be aggressive; wet-to-dry dressing changes are not sufficient. Once debridement is completed, the role of wet-to-dry dressing is controversial. These dressings may promote drying of the ulcer and eschar formation. Foot soaks have not been shown to be of benefit. Relief of pressure is accomplished by either complete bed rest or by total contact casting.^{13,15}

Antibiotics and often admission are warranted for the treatment of infected ulcers. Infections can be categorized as non-limb-threatening, limb-threatening, and life-threatening. Non-life-threatening infections can usually be treated in an outpatient setting. These infections are superficial infections with purulent drainage and minimal (less than 2 cm extension from the portal of entry) or absent cellulitis. There are no signs of systemic toxicity. Limb- or life-threatening infections require hospitalization. Limb-threatening infections involve ulceration

into the deep tissues, extensive purulent drainage, advanced cellulitis, lymphangitis, and systemic toxicity. Significant ischemia and gangrene may be present. Life-threatening infections have the same findings as limb-threatening infections, but in addition are accompanied by septic shock, bacteremia, osteomyelitis, or marked gangrene and necrosis.

Infections are usually polymicrobial. The most common organisms of non-limb-threatening infections are *Staphylococcus aureus* and group A and B streptococci. Limb-threatening and life-threatening infections are often due to *S. aureus*, *Streptococci*, *Enterococcus*, Gram-negative bacilli (including *Proteus* spp., *Klebsiella* spp., *E. coli*, and *Pseudomonas* spp.), and anaerobic organisms (particularly *Bacteroides* and *Peptostreptococci*). Superficial cultures of infected ulcers are unreliable. Cultures should be obtained of any purulent drainage and of aspirates from fluctuant areas. Antibiotics should initially be broad-spectrum to cover the wide variety of possible infective organisms. Choices depend on the severity of infection (Table 287-1). Abscesses should be incised and drained. X-rays should be considered if there is any suspicion of subcutaneous gas, foreign body, osteomyelitis, and Charcot foot. MRI and bone scan may be indicated to determine the presence of osteomyelitis. Palpation of bone in the depths of infected pedal ulcers has been shown to strongly correlate with osteomyelitis.

With diabetics, a serum glucose level should be obtained, as it is often elevated. Patients with nonhealing foot ulcers should be referred for evaluation and treatment. The underlying etiology of the ulcers include vascular, diabetic, or other systemic disease, including malignancies. Recent advances in the treatment of foot ulcers include recombinant human growth factor (becaplermin gel), granulocyte colony-stimulating factor, platelet releasate, and human skin equivalents. Hyperbaric oxygen has been advocated by some as beneficial in the treatment of both infected and noninfected foot ulcers.^{13,16}

MALIGNANT MELANOMA

The incidence of malignant melanoma is increasing, thus making consideration of this disease process important. Malignant melanoma of the foot accounts for up to 15 percent of all cutaneous melanomas. Melanomas can present as an atypical, pigmented, or nonhealing lesion of the foot, including the nail. These malignancies often imitate more common foot disorders such as fungal infections and plantar warts. Since prognosis is directly related to early diagnosis, a high index of suspicion must be maintained. Acral lentiginous melanoma is

TABLE 287-1 Selected Empirical Antimicrobial Regimens for Foot Infections in Patients with Diabetes Mellitus*

Non-limb-threatening infection: Oral regimen	
	Cephalexin or other first-generation cephalosporin
	Clindamycin
	Dicloxacillin
	Amoxicillin-clavulanate
	Extended-spectrum fluoroquinolone (e.g., levofloxacin)
Limb-threatening infection: Parenteral regimen	
	Ampicillin-sulbactam
	Ticarcillin-clavulanate
	Piperacillin-tazobactam
	Cefoxitin or cefotetan
	Extended-spectrum fluoroquinolone + clindamycin
	Aztreonam + clindamycin Life-threatening
infection: Parenteral regimen	
	Imipenem-cilastin or meropenem or trovafloxacin + vancomycin
	Metronidazole + aztreonam + vancomycin

*These regimens may require adjustment if the patient has a history of allergies or if there are clinical or epidemiologic factors suggesting unusual pathogens. Doses should be commensurate with the severity of infection, with adjustment for renal or hepatic dysfunction when indicated. Source: From Temple¹⁴ and Gilbert,¹⁶ with permission.

SECTION 24 • NONTRAUMATIC MUSCULOSKELETAL DISORDERS

an aggressive malignant tumor that more commonly affects noncaucasians. This tumor has a predilection for the plantar surface of the foot. It may present with atypical features leading to a delay in diagnosis and poor outcome. All skin lesions that are either atypical or not healing despite treatment should be referred for biopsy.¹⁷

PSYCHOSOCIAL DISORDERS

BEHAVIORAL DISORDERS: CLINICAL FEATURES Douglas A. Rund

Estimates of the proportion of emergency department patients who present with a psychiatric disorder range from a few percent to over a third. This variability is due in part due to differences in patient population and the community's use of alternatives for psychiatric crisis intervention.

When patients are screened for mental disorders including substance abuse, many have unrecognized psychopathology that is relevant to their assessment and treatment in the emergency setting. Subgroups of the emergency patient population at higher risk for psychiatric disorders include those who are self-referred for nonurgent, nonspecific, vague medical or social problems, and the "after midnight" group of emergency department patients who have been shown to have a higher prevalence of psychiatric illness than those presenting during the daytime. Sometimes, psychiatric disorders clearly make up the primary reason for an individual's presentation to an emergency department. In other cases, psychiatric disorders lead to injury and illness.¹ In contrast, psychiatric disorders may form part of the current or past medical history of a patient, yet possess little importance for the immediate clinical condition.

In studies that report categories of psychiatric illness seen in the emergency department, the most prominent diagnoses are substance abuse, affective disorders, anxiety disorders, antisocial personality disorder, and severe cognitive impairment. Among repeat users of the emergency department, persons with schizophrenia are overrepresented.

DIAGNOSIS

In the assessment of patients presenting with psychiatric symptoms, as with other medical conditions encountered in the emergency department, promptly stabilize the patient's acute psychiatric condition and evaluate the major complaint.² Formulating a specific diagnosis is not as important as determining if the patient is harmful to him- or herself or others and needs hospitalization. The determination that an individual is suicidal and in need of protection and hospitalization, for instance, is more important than deciding whether that person suffers from schizophrenia or psychotic depression.

Nevertheless, provisional psychiatric diagnoses can be made in the emergency department. Recognition of specific behavioral syndromes can assist in evaluating the presenting complaint, pursuing associated symptoms, and determining treatment and disposition. Emergency physicians should be sufficiently familiar with commonly seen psychiatric illnesses to describe their predominant clinical features.

Structured Diagnostic Criteria

The current official diagnostic nomenclature, most recently published in 2000 by the American Psychiatric Association, is the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (text revision), commonly known as *DSM-IV-TR*.³ A copy of *DSM-IV-TR* should be available for reference in the emergency department, because it contains the list of criteria for each disorder and additional material on demographics, associated symptoms and syndromes, and differential diagnosis.

Multiaxial Diagnostic System

The *DSM-IV* diagnoses are made on a multiaxial system in which each axis refers to a different domain of information. This system aids

in making a comprehensive assessment, organizing complex clinical information, and communicating between professionals. Axis I disorders comprise the clinical syndromes of mental disorders. Conditions listed under axis II are the personality disorders and developmental disorders, including mental retardation, which may underlie the more florid axis I syndrome. Axis III concerns general medical conditions. Axis IV consists of psychosocial and environmental stressors or problems. Axis V relates global, overall functioning (Table 288-1). Knowledge of this multi-axial system may facilitate an understanding of medical records, psychiatric consultants' notes, and interaction with consulting psychiatrists or psychosocial personnel. For instance, a patient with previous medical records containing *DSM-IV* diagnoses of axis I (alcohol intoxication), axis II (antisocial personality disorder), and axis III (scalp laceration) should be recognized as likely to display features of the axis II personality disorder, although the patient's chief complaint may be a new problem.

PSYCHIATRIC SYNDROMES (AXIS I DISORDERS)

The major categories of axis I disorders covered in this chapter are listed in Table 288-2. A useful strategy for making a *DSM-IV* diagnosis is to classify the primary feature into a major category, consider possible nonpsychiatric etiologies for the complaint, and then use the decision trees in Appendix B of *DSM-IV* to identify the appropriate diagnosis. The decision trees guide the clinician who is unfamiliar with the intricacies of the criteria within a category to identify the features that distinguish closely related conditions. An example of the decision tree for evaluating acute psychosis is shown in Figure 288-1.

Delirium, Dementia, Amnestic, and Other Cognitive Disorders

This group of syndromes is characterized by a clinically significant deficit in cognitive or memory function due to a general medical condition. There are several distinct and common causes of organic brain syndromes in which the causative factor is known, for example, vascular dementia and alcohol withdrawal delirium. In these cases, the specific diagnosis is listed in *DSM-IV*. In other cases, the etiologic factor should be specified with the descriptor "due to [general medical disorder or substance]," for example, "delirium due to hepatic encephalopathy."

DEMENTIA The essential clinical feature of *dementia* is a pervasive disturbance of cognitive functioning in several areas, including memory, abstract thinking, judgment, personality, and other higher cortical functions such as language. If clouding of consciousness is present, then the patient does not have solely a dementing illness but has *delirium* or intoxication. The presence of global cognitive impairment may be detected by a bedside cognitive examination, such as the Mini-Mental Status Examination⁴ (see Chap. 289), and additional confirmatory history should be gathered from an informant, such as a family member. Memory disturbance is usually the earliest sign to be apparent to others, and, unless it is very mild, it can be easily identified by examination. Such an examination asks the patient to retain, recall, and register information such as a list of words. The examiner may ask the patient to remember three words (*tree*, *pen*, and *book*) and repeat them back immediately and in 5 min.

Patients with dementia may be brought to the emergency department after having been found wandering away from home or an institution. Because the onset of most forms of dementia is slow and gradual, presentation to the emergency department often occurs only when some acute

Axis II	Personality disorders and mental retardation
Axis III	General medical conditions Medical conditions that are relevant to the understanding or management of the case
Axis IV	Psychosocial and environmental problems
Axis V	Global assessment of functioning

Source: Adapted from the American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. Washington, D.C., American Psychiatric Association, 2000.

worsening of mental status occurs, which may be the result of a superimposed medical illness, adverse drug effect, or environmental change. The demented patient's diminished intellectual and physiologic resources allow abrupt worsening of function with the addition of such stressors.

Early in the course of dementia, anxiety, depression,⁵ or psychosis may dominate the clinical picture and obscure cognitive dysfunction. **For this reason, a high degree of clinical suspicion of dementia should be maintained when evaluating an elderly patient with no prior psychiatric history who presents with new psychiatric problems.** Demented persons are also prone to unrecognized physical illness, because of inability to perceive or describe symptoms. Careful examination and appropriate laboratory testing are always indicated in the initial and ongoing evaluation of such patients.

Dementia is not synonymous with the previous designation of "chronic organic brain syndrome," which implies irreversibility. Common causes of potentially reversible dementia include metabolic and endocrine disorders, polypharmacy, and depression. Often, especially in elderly patients, depression may present with prominent cognitive impairment, a condition erroneously labeled "pseudodementia," but more accurately called *dementia of depression*. A relatively acute onset, prominent mood changes, and vegetative disturbances such as loss of appetite and weight, sleep disturbance, or expressions of guilt or suicidal ideation point to depression as the cause. In these situations, treatment of the mood disorder may lead to resolution of the cognitive impairment, although recent studies indicate that many such patients have evidence of brain dysfunction and only partial treatment response.

DELIRIUM Like dementia, *delirium* is characterized by global impairment in cognitive function but is distinguished from it in two major ways.⁶ **In delirium, the patient has clouding of consciousness, a reduction in the awareness of the external environment (manifest as difficulty sustaining attention), varying degrees of alertness ranging from drowsiness to stupor, and sensory misperception.**

The primary distinguishing feature of delirium is the course that is typically acute, with rapid deterioration in hours or days, rather than in months as with dementia. Also, the severity of delirium fluctuates over the course of hours; the patient may appear normal at one time and

wildly agitated a few hours later. Extreme changes in psychomotor activity, ranging from restlessness and hyperactivity to stupor, are frequent in delirium but uncommon in dementia except in the later stages when a delirious state may be superimposed. Hallucinations, often visual, are common in delirium. They typically have a vivid quality to which the patient reacts strongly. The hallucinations contrast with the visual hallucinations seen by psychotic patients, which often are described and experienced indifferently.

Substance-Induced Disorders

INTOXICATION When recent ingestion of a specific exogenous substance produces maladaptive behavior and impairment of judgment, perception, attention, emotional control, or psychomotor activity, and the patient does not display features of delirium, hallucinosis, or other organic brain syndromes, a diagnosis of *intoxication* is made. When the offending substance is known, it should be specified (e.g., alcohol intoxication or amphetamine intoxication). The specific features of intoxication syndromes commonly seen in the emergency department are described in greater detail in the section on toxicology.

As a general rule, the diagnosis of intoxication can be rather easy when laboratory analysis reveals the type and amount of intoxicant circulating in the system. The clinical features of alcohol intoxication are familiar to experienced emergency physicians and range from impaired judgment and coordination through ataxia, lethargy, and coma. When repeated episodes of intoxication occur within a brief period, the individual by definition has a substance abuse disorder, and the additional diagnosis is made. A urine toxicology screening test and a blood alcohol level are most useful in evaluating patients with new onset psychiatric symptoms and often are required as part of the evaluation assessment of patients admitted to psychiatric facilities.

WITHDRAWAL *Withdrawal* can follow cessation or reduction in use of a substance of abuse. The category signifies a syndrome characteristic of withdrawal from that particular drug, when the clinical syndrome does not satisfy the criteria for delirium or another organic brain syndrome. For example, mild forms of alcohol withdrawal would be classified here, but if the patient is confused, hallucinating, and agitated, a diagnosis of alcohol withdrawal delirium is indicated. The diagnosis is made by identification of the withdrawal syndrome and evidence of recent use of the substance in a pattern sufficient to produce withdrawal when the amount ingested is decreased. Specific withdrawal patterns depend on the agent customarily used.

Alcohol withdrawal, for instance, includes up to four stages: autonomic hyperactivity (sweating, tachycardia; 6 to 8 h after cessation of drinking), hallucinations (24 h after withdrawal), major motor seizures (1 to 2 days), and global confusion (3 to 5 days after last use of alcohol). Some withdrawal syndromes, particularly from alcohol or barbiturates, can be life-threatening.

Mental Disorders Due to a General Medical Condition

The *DSM-IV* has implemented a major change in the classification of psychiatric symptoms caused by medical conditions. The previous terminology of "organic brain syndrome" and the subtypes organic mood disorder and organic delusional disorder, for example, have been eliminated, because of the implication that the "functional" mental disorders are unrelated to biologic changes in brain function.

Using *DSM-IV*, when there is evidence that a psychiatric disturbance is a direct physiologic consequence of a general medical condition or substance, the mental disorder is specified as "due to" the medical problem, for example, "major depression due to hypothyroidism."

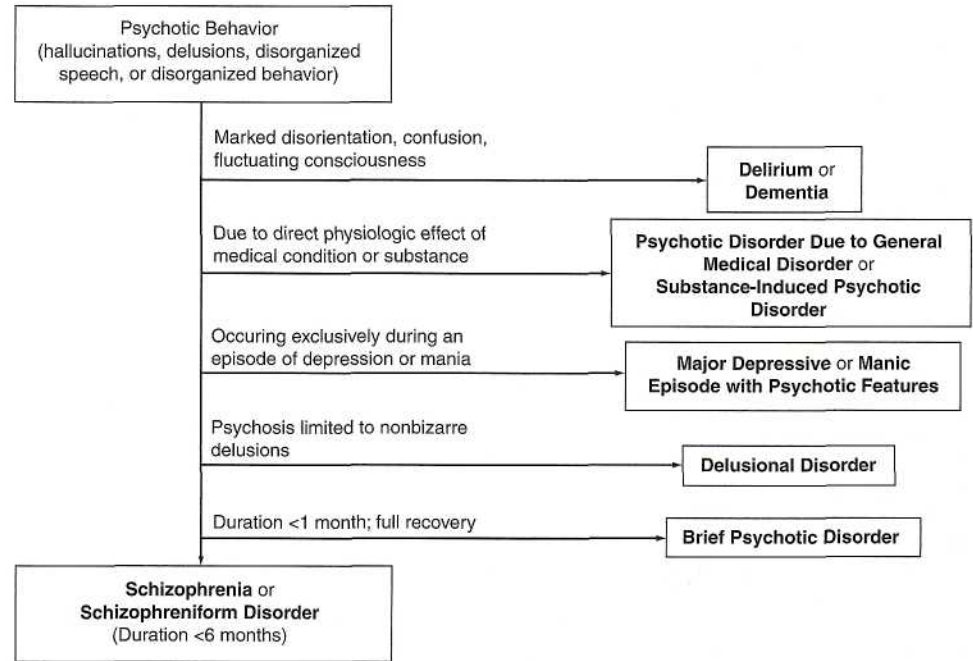

Schizophrenia and Other Psychotic Disorders

Schizophrenia and related disorders are marked by the presence of psychotic symptoms, primarily delusions and hallucinations. *Delu-*

FIG. 288-1. Decision tree for evaluating psychosis.

sions are defined as fixed false beliefs that are not amenable to arguments or facts to the contrary and that are not shared by others of similar cultural background. Common delusions are of several types. *Persecutory delusions* are those in which one believes that one is being attacked, followed, harassed, or conspired against. *Grandiose delusions* are those that involve themes of special powers or abilities. *Bizarre delusions* are those with patently absurd content, such as believing that one's thoughts are controlled by extraterrestrial beings. *Hallucinations* are false perceptions experienced in a sensory modality and occurring in clear consciousness. Auditory hallucinations are the most common, followed in order of prevalence by visual, tactile, olfactory, and gustatory; the presence of the latter, nonauditory hallucinations suggests a medical, not psychiatric, cause of psychosis (such as alcohol withdrawal). The most prevalent psychosis is *schizophrenia*, described in detail in the next section. The other psychotic disorders, discussed briefly, are less common. A decision tree helpful in evaluating psychotic symptoms is presented in Figure 288-1.

SCHIZOPHRENIA Schizophrenia is one of the most serious public health problems in the world, affecting just under 1 percent of the world's population. The essential features are a deterioration in functioning, characteristic active-phase symptoms (hallucinations, delusions, disorganized speech, disorganized behavior, and catatonic behavior), negative symptoms (blunted affect, emotional withdrawal, lack of spontaneity, anhedonia, or attentional impairment), cognitive impairment manifested by loose associations or incoherence for at least 1 month, and the relative absence of a mood disorder. Research has established the importance of genetic factors in its cause, and schizophrenia is most likely a group of disorders of different etiologies that shares a final common pathway, much as is the case with mental retardation. It is a brain disease, and there is no evidence that psychosocial stressors or poor parenting is responsible for the cause of the illness, although these may have a profound effect on the patient's adaptation to this usually chronic disorder.

Symptoms of schizophrenia usually begin in late adolescence or early adulthood, although the onset can occur at any age. The childhood history of schizophrenics often is marked by shyness, oddness or eccentric behavior, school difficulties, or paranoid behaviors, but such features are not always present. A prodromal phase, in which a gradual deterioration of function is noted, usually precedes the development of active delusions or hallucinations. Such deterioration usually includes the worsening of social withdrawal or the new onset of social

withdrawal, odd behavior or speech, and difficulty in functioning in school or work. Patients or their families rarely seek care until the onset of the active phase of psychosis. Schizophrenics seldom seek care at all, because they lack insight; they do not realize that their perceptions, thoughts, and behavior are abnormal.

Typical, or older, antipsychotic drugs (such as haloperidol) usually reduce the severity of positive symptoms (delusions and hallucinations). Other manifestations of schizophrenia less responsive to typical antipsychotics include negative symptoms (lack of volition, blunting of emotion, anhedonia, and inattention). Such symptoms result in lasting impairment in self-care, work, and social relations. Newer, "atypical," antipsychotic agents (such as risperidone, olanzapine, clozapine and ziprasidone) seem to have a greater effect in improving the negative and positive symptoms.

Disorganization of thinking and behavior characterizes schizophrenia. Disheveled appearance and grooming, bizarre behavior, poor judgment, and loosening of associations indicate such disorganization. *Loosening of associations* refers to a loss of the normal logical connections between one thought and the next; the schizophrenic patient's speech is often vague, rambling, disjointed, or nonsensical. Fantastic experiences and bizarre ideas are described in an indifferent manner and unchanging facial expression.

Common reasons for persons with schizophrenia to come to the emergency department include worsening of psychosis resulting from stress or noncompliance with medication, suicidal behavior, violence (often as a result of paranoid thinking), and extrapyramidal side effects of neuroleptic drugs. Schizophrenics constitute a large share of the chronic homeless population and may be brought in by authorities, in a confused state, obviously unable to attend to their basic needs. Their poor judgment and disorganization may lead to disregard for medical problems, so attention must be given to their physical status and the psychiatric problem.

SCHIZOPHRENIFORM DISORDER *Schizophreniform disorder* is diagnosed when the patient meets the criteria for schizophrenia but the symptoms have been continuously present for less than 6 months. A rapid onset over a few days and good premorbid functioning are more common than in schizophrenia.

BRIEF PSYCHOTIC DISORDER Some individuals may become acutely psychotic after exposure to an extremely traumatic life experience. If such a psychosis lasts for less than 4 weeks, it is termed a *brief*

psychotic disorder. Precipitants of the psychosis include the death of a loved one or a life-threatening situation such as combat or a natural disaster. Emotional turmoil, confusion, and extremely bizarre behavior and speech are common.

Mood Disorders

The mood disorders are the most prevalent of the major psychiatric disorders, affecting about 10 to 15 percent of the general population at some time in their lives. Depressive disorders are the major cause of completed suicide. An unsuccessful attempt may bring the patient to the emergency department. Mood disorders, substance abuse, and anxiety disorders are the most common psychiatric diagnoses in emergency patients.

Mood, or *affective*, disorders differ from the normal extremes of sadness and happiness in that characteristic clusters of psychological and vegetative symptoms (depressive or manic syndrome) are present, and functioning is impaired. Any of the features of schizophrenia such as delusions, hallucinations, or disorganization may be present, but if a full depressive or manic syndrome exists, a diagnosis of a psychotic mood disorder is required. Another important characteristic of affective disorders is that they tend to be episodic, with periods of remission and normal function.

MAJOR DEPRESSION The essential features of *major depression* are a persistent sad or depressed (dysphoric) mood or pervasive loss of interest in usual activities lasting for at least 2 weeks. Associated psychological symptoms include guilt over past deeds, self-reproach, feelings of worthlessness or hopelessness, inability to experience pleasure, and recurrent thought of death or suicide. "Vegetative symptoms" involve physiologic functioning and include loss of appetite and weight, sleep disturbance, fatigue, inability to concentrate, and psychomotor agitation or retardation. The depression may begin gradually or rapidly but usually will have been present for several weeks before the patient comes for treatment.

When the patient complains of the full spectrum of depression symptoms, the diagnosis of major depression is easy to make, but when the chief complaint is a single symptom such as insomnia or fatigue, it will be necessary to elicit the other symptoms of major depression to make the diagnosis. Somatic complaints such as vague pain or weakness may be part of major depression, as may generalized anxiety. A useful screening mnemonic is presented in Figure 288-2.

Major depression is more common in women, persons with a family history of depression or suicide, and individuals with medical or other psychiatric illnesses. When a medical disorder or drug produces a depressive syndrome through a presumed biologic effect on the brain, the diagnosis should be "depression due to [the offending condition]." Major depression is often superimposed on other mental disorders such as substance abuse, personality disorders, and anxiety disorders; and such conditions are frequently comorbid conditions. Depression in the elderly may go unrecognized by the emergency physician. Screening tools for depression recognition in the geriatric population can be helpful in diagnosis.

In	Interest

A	Activity
G	Guilt
E	Energy
S	Suicide

FIG. 288-2. In SAD CAGES. A screening mnemonic for major depression. (Reprinted with permission from Rund DA, Hutzler JC: *Emergency Psychiatry*. St. Louis, Mosby, 1983.)

Primary mood disorders tend to display more biologic features, are more familial, and respond better to somatic antidepressant treatment than do mood disorders due to medical disorders. The lifetime risk of suicide in patients with major depression is 15 percent, so prompt and aggressive treatment is strongly indicated. Major depression is often recurrent, so certain patients must be maintained on long-term treatment to prevent relapse.

BiPOLAR DISORDER Bipolar disorder, previously termed *manic-depressive illness*, is characterized by the occurrence of mania cycling with periods of depression. A full manic syndrome is one of the most striking and distinctive conditions in clinical practice. The essential disturbance in mood is one of elation or irritability. Manic patients feel "on top of the world," expansive, and energetic. The state is precarious, however, and the patient may quickly become argumentative, hostile, irritable, and sarcastic, especially when their plans are thwarted.

The vegetative signs of mania are a decreased need for sleep, increased activity, rapid pressured speech, and racing thoughts. Manics may have grandiose ideas, such as unrealistic plans to start a business or run for public office, and if the grandiosity reaches delusional proportions, such patients may believe themselves to be famous, fabulously wealthy, or blessed with special powers and abilities. Poor judgment in spending money and sexual behavior may lead to problems that prompt manics' families to seek treatment for them, because manics usually lack insight into their abnormal condition and deny that anything is wrong. For this reason, reports from informants such as relatives often reveal important information to substantiate the diagnosis. Because patients who have had a manic episode almost invariably have depressions at some time (the other "pole" of bipolar disorder), a history of depression also may help in diagnosis.

The disorder is equally common in men and women, and the onset is usually in the third and fourth decades. Complications include suicide, substance abuse (excessive alcohol use is common during the manic phase), and marital and occupational disruptions. The course of bipolar disorder is episodic, with the duration, frequency, and regularity of the episodes varying greatly. Depressive episodes are more frequent than manic episodes.

DYSTHYMIC DISORDER *Dysthymic disorder* is a more chronic and less severe form of depressive illness and was previously termed *depressive neurosis*. Depressed mood must have been present most of the day, more days than not, for at least 2 years. Psychotic features are not seen, and these patients often have a life-long gloomy, pessimistic outlook. Women are affected more often than men, and the onset is typically in childhood, adolescence, or early adulthood.

Associated personality disorders and substance abuse are common. When vegetative symptoms are present, they are usually less severe than with major depression. Major depression may be superimposed on dysthymia, often in association with stressful life events. When major depression complicates dysthymia, the patient may be brought in for evaluation, because of the severity of symptoms or treatment after a suicide attempt.

Anxiety Disorders

The *anxiety disorders* are mental disorders in which apprehension, fears, and excessive worry dominate the psychological life of the individual. Pathologic degrees of anxiety are accompanied by different degrees of autonomic activity (sweating, tachycardia, or dizziness) out of proportion to any real danger or threat. Because anxiety is a ubiquitous condition and frequently associated with medical illness, depression, neurologic syndromes, and psychoses, a diagnosis of a primary anxiety disorder should be made by exclusion of other causes.

Anxiety disorders are diagnosed in 4 to 8 percent of the general population and are diagnosed more often in women than in men. Because of the physical nature of certain symptoms associated with an-

xiety disorders, patients often seek treatment and evaluation in medical rather than psychiatric settings.

PANIC DISORDER Patients who experience recurrent attacks of severe anxiety are said to suffer from *panic disorder*. For detailed discussion, see Chap. 292. A panic attack consists of a sudden extreme surge of anxiety and dread accompanied by autonomic signs, including palpitations, tachycardia, shortness of breath, chest tightness, dizziness, sweating, and tremulousness. The symptoms develop over a few minutes at most and may be unprovoked or occur with a phobic stimulus, such as a crowded store. After the attacks begin, some patients start to avoid situations that seem to precipitate the panic (phobic avoidance). When activities are severely limited, the complication of *agoraphobia* is diagnosed. In agoraphobia, the patient tends to avoid situations where ready escape or assistance during an attack is not possible. The frequency and severity of panic attacks wax and wane, but the illness is generally chronic.

GENERALIZED ANXIETY DISORDER When anxiety attacks are absent but the patient complains of persistent worry, tension, or free-floating anxiety, a diagnosis of generalized anxiety disorder should be considered. This condition lasts at least 6 months and is characterized by apprehensive worrying, muscle tension, insomnia, irritability, restlessness, jumpiness, or distractibility. Muscle tension may be so severe that the patient actually experiences diffuse muscular pain. Associated autonomic symptoms include the cardiopulmonary, gastrointestinal, and neurologic symptoms seen in panic attacks. In generalized anxiety disorder, such symptoms occur more continuously and chronically than in panic disorder.

PHOBIC DISORDERS Phobic disorders, other than agoraphobia, are an unusual cause of self-referral to the emergency department. In phobias, the anxiety symptoms are recognized as excessive and occur when the patient is exposed to, or anticipates exposure to, a specific situation, which then leads to avoidance of the stimulus to a degree that it interferes with the patient's life. In social phobia, the situation involves having the attention of others drawn to the patient. Such activities as public speaking or meeting strangers create a fear that the patient will be embarrassed in some way. Specific phobias are quite common; they involve fear of a very specific stimulus, such as animals, heights, dark, or flying.

OTHER ANXIETY DISORDERS *Posttraumatic stress disorder* is an anxiety reaction to a severe psychosocial stressor, usually life threatening, such as military combat, fire, rape, or natural disaster. Symptoms involve repetitive and intrusive memories of the event, nightmares, emotional numbing, survivor guilt, and different degrees of depression and anxiety. Substance abuse appears to be a frequent complication.

Obsessive-compulsive disorder is a mental disorder in which the patient experiences intrusive thoughts or images that cannot be eliminated from the mind. Typical thoughts involve images of graphic violence to self or others, contamination, or perverse sexual behavior that the patient would not carry out but nevertheless obsessively fantasizes about. To control the obsessive thoughts, the individual may engage in compulsive behavior or rituals, such as excessive washing, repetitive checking, or counting. When the obsessions and compulsions occupy a great deal of time, the patient may become significantly disabled and seek psychiatric attention. The sense of helplessness and the impairment can lead to the development of depression, which also leads the patient to seek help.

Somatoform Disorders

Many patients have particular complaints or symptoms for which no medical explanation can be identified. When a physical cause has been

clearly eliminated, and the complaint is not delusional or occurring in the context of a depression or anxiety disorder, somatoform disorders may be considered. When the complaint involves a loss of function, usually in the neurologic system (e.g., paralysis, blindness, or numbness) and psychological factors are deemed etiologic, a *conversion disorder* may be present. Conversion disorders are much more common in culturally and psychologically unsophisticated persons. This diagnosis should be made with extreme caution, if at all, in the emergency department, because studies indicate that many patients diagnosed with conversion disorder eventually develop signs of a physical disorder explaining the symptom. For further discussion, see Chap. 293.

Some patients have a wide variety of complaints and long complicated histories of medical problems that have no apparent medical cause. Such individuals may have *somatization disorder*, a disorder beginning in the teens and twenties, usually in women, and leading to considerable unnecessary diagnostic and surgical intervention. The prototypical patient is a middle-aged woman who describes a "positive review of systems" in a dramatic and confusing way. As with conversion disorder, a firm diagnosis of somatization disorder should not be made on the basis of one visit to the emergency department, but the identification of somatizing behavior is useful for future reference, because patients frequently make repeated contacts with medical providers.

Hypochondriasis may be diagnosed when the patient is preoccupied with fears of serious illness, fears that persist despite appropriate medical evaluation and reassurance.

When pain is the sole complaint and the intensity and secondary disability are unexplained by a known physical ailment, a diagnosis of *pain disorder* may be considered.

Dissociative Disorders

The dissociative disorders comprise a group of uncommon and poorly understood conditions in which the central feature is a sudden alteration in the normal integration of identity and consciousness. The dissociation often occurs under severe stress and may or may not be recurrent, although it is rarely permanent. The forms of dissociative state relevant to emergency practice are *psychogenic amnesia*, a temporary loss of memory for important personal details that is not due to an organic cause, and *psychogenic fugue*, in which a similar loss of memory and assumption of new identity are accompanied by travel away from home. Dissociative disorders are difficult to distinguish from *malingering*, in which the individual in pursuit of a clear goal, such as avoiding incarceration or military duty, may consciously feign amnesia. As always, organic causes, such as drug intoxication, or loss of memory, such as that resulting from transient global amnesia, must be ruled out.

Other conditions in this category include *multiple personality disorder* and *depersonalization disorder*.

PERSONALITY (AXIS II) DISORDERS

Personality refers to an enduring pattern of perceiving, relating to, and reacting to one's environment and interpersonal relationships. When a pattern of behavior is lifelong, not limited to periods of illness, and causes significant impairment in social and occupational functioning or considerable distress, a *personality disorder* is present. Some individuals are painfully aware of the consequences of their behavior but are unable to alter these fundamental ways of dealing with their world. Most patients who are seen clinically in medical and psychiatric settings who are diagnosed with a personality disorder lack a clear awareness of how their behavior alienates others or aggravates their own stress. Even when such insight is possible, actual personality change is unlikely.

The patient presenting with a personality disorder often may be recognized by the characteristic effect the interaction has on the physician

TABLE 288-3 Behavioral Characteristics that Suggest Various Clusters of Personality Disorders

Behavior	Personality Disorder Group
Eccentric, odd, isolated, withdrawn, suspicious, inhibited, no friends, overly sensitive	Paranoid, schizoid, schizotypal
Emotional, dramatic, angry, seductive, impulsive, erratic	Antisocial, histrionic, borderline, narcissistic
Anxious, fearful, nervous, cautious	Dependent, avoidant, obsessive-compulsive

and medical staff. Antisocial patients, for instance, are disliked immediately; they seem to be in control of their behavior, unlike psychotic or depressed patients, but nonetheless have repeatedly engaged in maladaptive behavior. The patient may be seen as using the emergency department for some vague, or obvious, goal. These disorders are the most common secondary diagnosis in the malingeringer.

The emergency physician seldom needs to decide which of the personality disorders relates appropriately to the patient. General categories of personality disorders are grouped in Table 288-3. When such features are present and seem to be interfering with some important aspect of the patient's life, personality disorder can be suspected. The presenting complaint should be evaluated appropriately, because patients with well-established character disorders still develop bona fide medical illnesses.

The personality disorder that constitutes a disproportionate share of emergency visits is *antisocial personality disorder*. The patient shows a continuous pattern of maladaptive behavior displaying disregard for the rights of others in a variety of ways: criminal behavior, fighting, lying, abuse and neglect of dependents and spouses, financial irresponsibility, recklessness, and inability to sustain enduring attachments to others.

The sociopathic behavior begins before the age of 15 years, but the diagnosis may not be made until after the age of 18 years. Sociopathy is much more frequent in males, in lower socioeconomic classes, and in relatives of alcoholics and sociopaths. Alcohol and drug abuse, imprisonment, multiple divorces, traumatic injury, accidental and violent deaths, and poor medical compliance are common complications.

Management of the antisocial patient in the emergency department is often frustrating, but anger toward the patient can be minimized and the interaction hastened along by setting firm limits on behavior, focusing on the chief complaint, and providing the patient with necessary information about the medical problem at hand. No effective psychiatric intervention can be forced on the patient, although certain patients may benefit from substance abuse treatment, psychotherapy, or organized religion when motivated to make changes in their lives. Fortunately, the most violent and disruptive behavior of many antisocials seems to "burn out" in the late twenties or after, although their adjustment to society often continues to be marginal.

BEHAVIORAL DISORDERS: EMERGENCY ASSESSMENT

Douglas A. Rund Jeffery C. Hutzler

This chapter presents the principles of medical and psychiatric evaluation of patients with behavior disorders and reviews the management of suicidal and violent patients. The majority of psychiatric patient visits to emergency departments occur during the evening and at night when psychiatric services are limited; therefore, the hospital must be staffed at off-hours with adequate personnel adept at handling patients who are suicidal, violent, psychotic, or otherwise distraught.

Situations that require emergency stabilization include potential or actual homicidal or suicidal behavior,¹ or rapidly progressive medical conditions resulting in disturbed behavior (e.g., hypoglycemia, meningitis, or other causes of delirium).

A decision strategy for emergency psychiatric assessment should follow this sequence of questions: (1) Is the patient stable or unstable? (2) Does the patient have a serious medical condition that is causing abnormal behavior or thought processes? (3) If the cause of changes in behavior is not the result of an underlying medical condition, it will be primarily *psychiatric or functional*. What is the diagnosis and severity? (4) Is a psychiatric consultation necessary? (5) When should the patient be forcibly detained for emergency evaluation?

SAFETY ISSUES

Violent behavior demands immediate restraint. Hospital security forces and police are best equipped and best trained to subdue violent patients with the least chance of staff or patient injury. Further discussion of contemporary restraint practices is provided in Chap. 301. Pharmacological treatment of violent or agitated patients is discussed in Chap. 290.

Patients who are threatening or who demonstrate actual or potential violent behavior should be disrobed, gowned, and searched for weapons. Seemingly innocuous objects such as belts or belt buckles, which can be used to inflict self-injury or injury to others, should be removed.

Patients whose behavior suggests the potential for violence should be approached cautiously and with a nonthreatening attitude, with adequate security force nearby. The physician should also stay distant from the patient, avoid excessive eye contact, and maintain a somewhat submissive posture and tone of voice. Ideally, the physician should stand in a location that neither threatens the patient nor blocks the exit of the patient or the physician from the room. Allow the patient to ventilate feelings verbally. Setting limits on acceptable behavior and making neutral comments may diffuse a potentially violent situation. Adequate force nearby should be visible to the patient, and the patient should clearly be told that uncontrollable behavior will result in restraint. Patients who are actually or potentially dangerous to themselves or to others will generally need psychiatric admission.

A patient expressing suicidal ideation requires specific measures for protection. All dangerous objects are removed from the patient and the treatment room. Staff members, or a reliable family member, should accompany the patient if it necessary to leave the examining

room. Some institutions have members of the security staff available to provide supervision. Patients expressing suicidal ideation should not be allowed to leave the emergency department before medical or psychiatric evaluation.

History

The important elements of history taking include documentation of behavioral change, identification of important medical symptoms, determination of medical comorbidities, and medication/drug history.

The changed behavior is a good starting point for inquiry. Sudden onset of major changes in behavior, mood, or thought in a previously normal patient, or definite deterioration in a patient with a chronic behavioral disorder, should stimulate evaluation for an underlying medical or neurologic disorder. A sudden change in behavior, especially in a patient older than age 40 years, is an important indicator of a new and correctable disease process. The most important information about behavioral changes will come from the patient's family. If the family is unavailable, friends or coworkers should be contacted and questioned. The source may be able to report substance abuse or compliance with medication, and can describe the level of previous functioning. Family and social history may identify stressors in the patient's environment that are either a direct cause of changes in behavior or accentuate any responses to underlying disease. To help identify patterns of relapse, determine the history of previous psychiatric illness and treatment. All personal history should be corroborated by family members when possible. The physician should compare his or her own direct observations of the patient's behavior with reports from the patient's family and friends.

Neurologic symptoms associated with the behavioral changes should be explored. Such symptoms include fainting, dizziness, disorientation, impairment of speech, confusion, loss of consciousness, headaches, and difficulty performing routine tasks.

Medical comorbidities must be identified, as psychiatric patients often develop medical illnesses producing changes in behavior.

Specifically ask about fever, head trauma, human immunodeficiency virus (HIV) risk factors, and toxic ingestions or overdose.

Ask about the use of prescription and over-the-counter drugs, especially sedative-hypnotics, stimulants, psychotropic agents, anticonvulsants, anticholinergic agents, angiotensin-converting enzyme inhibitors, beta-blockers, corticosteroids, fluoroquinolone antibiotics, H₂-receptor blockers, opioids, salicylates, selective serotonin reuptake inhibitors, thiazide diuretics, and antiparkinsonian agents.² Over-the-counter analgesics or herbals containing salicylates, anticholinergics, antihistamines, or bromides may produce delirium or toxic psychosis. Alcohol³ and street drugs such as phencyclidine, lysergic acid diethylamide (LSD), mescaline, amphetamines, and cocaine can produce a toxic psychosis. Hypnotosedatives such as barbiturates and benzodiazepines may produce a confusional state or delirium both with intoxication and withdrawal.

Patients with chronic mental illness have a higher incidence of alcohol abuse than the general population. The syndromes associated with alcohol abuse which can result in altered behavior include intoxication, withdrawal, delirium, hallucinosis, alcohol amnestic disorder, paranoid behavior, and dementia. Alcohol screening tests are useful in disturbed patients even when the odor of ethanol is not present.

Mental Status Examination

The objective of the mental status examination is to distinguish psychiatric (functional) from medical (organic) disorders. A great deal of the information obtained in mental status examinations becomes evident through patient observation and the initial patient interview (Table 289-1). Important components of the mental status examination include level of consciousness, spontaneous speech, spontaneous behavior, physical appearance, the relaying of history information, attention, and language comprehension. Another tool to detect dementia

TABLE 289-1 Mental Status in the Emergency Department: An Outline

Behavior
What is the patient doing?
Affect
What feelings is the patient displaying?
Orientation
Does the patient know what is happening, where, and when?
Language
Is the patient understanding and being understood?
Memory
Can the patient recall historical details, recent and remote?
Thought content
Is the patient reporting beliefs that make little sense?
Perceptual abnormalities
Is the patient experiencing unusual sensory phenomena?
Judgment
Is the patient able to make rational decisions?

or delirium is the Mini-Mental Status Examination (MMSE), described in Chap. 307, Figure 307-2. An abnormal mental status examination suggests a medical (organic) basis for abnormal thought or behavior. Lability of affect, the necessity to repeat simple questions, irritability, disorientation, and lack of cooperation are some signs of organic dysfunction.

Documentation of the patient's orientation should include an assessment of attention, ability to concentrate on a specific task, and the traditional evaluation of person, place, and time. The patient should be asked the day, month, year, and place where he or she is presently being examined. Impaired language performance, including difficulty with speech, reading, writing, and word finding, may indicate a neurologic disorder. Memory is often divided into three categories: immediate, recent, and remote. Immediate memory is tested by asking a patient to repeat a series of digits (usually five) forward and backward. Recent memory can be tested by asking the patient to repeat three unrelated words (e.g., tree, apple, bicycle) immediately and then again after 3 to 5 min. The patient should be able to restate these after 3 to 5 min. The patient may also be asked about events that have occurred in the last few hours. Remote memory can be tested by asking about previous addresses, occupations, or historical events from an early period in the patient's life. Tests of memory should include details of significant personal, national, and international historical events. Investigation of higher cognitive functions includes assessment of a patient's general command of information; mental calculation, especially subtraction, such as serial sevens; and spelling of words forward and backward (such as world). Patients with organic disease often have difficulty spelling backward or performing serial calculation. The patient's affect or outward display of emotion should be evaluated for sadness, euphoria, and anxiety. This may help distinguish between cognitive disturbance induced by depressive disorders and dementia due to significant cerebral pathology. An examiner can draw some conclusions regarding a patient's thought processes during the patient's own telling of his or her history.

Disordered thought processes include paranoid or grandiose delusions, fixed false beliefs, and delusional denial of illness. Such beliefs should be compared with reports from family and friends.

Visual hallucinations do occur in functional psychotic illnesses (schizophrenia or affective disorder), but most often result from organic disease. A patient with visual hallucinations should always be assumed to have organic pathology until proven otherwise.

Judgment may be impaired in organic disease, and historical evidence of faulty judgment should be elicited. Insight about judgment can be gained by asking a patient how he or she would deal with day-to-day problems, such as finding the way home from the hospital.

Finally, the examiner should test for specific focal neurologic deficits, including apraxias, agnosias, right-left disorientation,

aphasias, and inability to follow complex spoken and written commands. Such signs may or may not occur in association with other localizing neurological signs, such as asymmetric reflexes, paresthesia, or hemiparesis. Ask the patient to "draw a clock face." The physician can draw a circle on a piece of paper and ask the patient to fill in the numbers on the paper to look like a clock face. If the patient can put in the numbers correctly in a clock face, he or she should then be asked to put the hands at the position to read a specific time (e.g., 10:30). If the patient cannot do these tasks, organic disease is present.

Accurately diagnosing and understanding behavioral emergencies in the elderly is difficult but important. Syndromes include confusion, agitation, psychosis, and behavioral regression. Detailed discussion is provided in Chap. 307.

Physical Examination

The objectives of physical examination are to identify medical disorders that may cause or have an impact on behavior and to identify the presence of medical problems that may need special care in, or are inappropriate for, management in a psychiatric setting. A limited physical examination should be conducted on every patient.⁴⁻⁷ Vital signs, including temperature, should be obtained on all psychiatric patients. Abnormal vital signs should not automatically be dismissed as secondary to anxiety or stress, but should be investigated.

The extent of the physical examination depends to some extent on the patient's age,^{8,9} the nature of the chief psychiatric complaint, psychosocial history, and the existence of medical comorbidities. Patients with abnormal vital signs, abnormal mental status examination, psychosis, mental retardation, and the elderly usually require a more complete physical examination, including assessment of chest, heart, and abdomen. Examine all patients for signs of trauma to the head, face, and neck, and carefully reconstruct the mechanism of injury. In the homeless, or in those with exposure, check extremities for frostbite. Examine for needle tracks. Neurologic examination typically includes an assessment of cranial nerves, gait, mental status, and general motor function and strength.

Laboratory Evaluation

Laboratory testing depends upon findings from the history, mental status examination, and physical examination.

A urine toxicology screen and blood alcohol level are two of the most commonly required tests for patients transferred to, or admitted to, psychiatric facilities from the emergency department. However, these tests may be most helpful when the cause of abnormal thought or behavior is unknown.

Consultation and Referral

In the ideal setting, all emergency departments would have psychiatric consultation available at all times. However, in many instances, the emergency physician will have to rely on more-limited resources. In many instances, following initial screening, disposition can be made to a variety of secondary sources of evaluation and treatment. Judgments regarding referral depend on assessment of a patient's likelihood of becoming violent toward self or others. Clues that suggest potential violence include hostile behavior, verbal aggressiveness, or statements about violent intent. Such patients need immediate hospitalization. Marked disorientation and confusion require evaluation for organic components. In the absence of such indications, referral can be made to a psychiatrist or a psychiatric facility. Results of the emergency department medical and psychiatric evaluation should be summarized in writing and provided to the consultant. The patient should receive clear discharge instructions and should have a follow-up interval for any medical or surgical disorders that were identified. Documentation of a thorough evaluation of these risk factors is important.

SUICIDE

Suicide continues to be a major cause of death throughout the world and a leading cause of death among the young. There seem to be epidemiologic differences between suicide attempters and suicide completers. Suicide completers, for instance, are more likely than attempters to be older, male, living alone, or physically ill. Such patients are at high risk and need to be carefully assessed. The ratio of attempted suicides to completed suicide is estimated to be approximately 40:1.

A suicide attempt is not a common accompaniment of the "downward" portion of the normal mood swings occasionally experienced by everyone. Only approximately 2 percent of the general population have seriously considered taking their lives and only approximately 1 percent have actually attempted suicide. Therefore, suicide attempters must be taken seriously. The attitude of the staff should be empathic; steps to insure patient safety in the emergency department should be instituted, including supervision and removal of potentially dangerous objects; and following medical management, the assessment of suicide risk should be carefully evaluated and documented.

Suicidal thinking is more frequent among women than among men and is associated with a clinical depression, social isolation, undesirable life events, and early parental loss. Suicidal thinking may precede an actual attempt by many months and may persist long after improvement in mental status and personal relationships.

Negative attitudes toward the suicide attempter have been documented among all types of emergency personnel: paramedics, nurses, and emergency physicians. A negative attitude intensifies a patient's already low self-esteem, thus increasing the risk of subsequent suicide and making it difficult to establish a therapeutic relationship.

Schizophrenia, substance abuse, and depression are psychiatric diagnoses that place a suicidal patient at relatively high risk. Personality disorder and adjustment disorder implying a transient situational disturbance are frequent diagnoses in suicide attempters and are generally associated with relatively lower completion risk than the major psychiatric illnesses noted previously. However, patients with these latter disorders still show a higher risk of completed suicide than the general population.

Drug overdose accounts for the overwhelming majority of all contemporary suicide attempts. Drugs used for suicide attempts tend to parallel prevailing prescribing patterns. Toxicity of the agent and the lethal intent of the patient help assess the relative risk. A patient taking a large dose of amitriptyline would be considered at greater risk than someone taking a few antihistamine tablets. Some patients may be relatively unaware of a drug's potential toxicity, however, and such knowledge and their continuing intent to die must be assessed by questions such as, "Were you surprised to find yourself alive after taking the overdose?"

Violent attempts (shooting, jumping, hanging) are generally considered serious and a high-risk factor for a future attempt. A number of reports have described a "wrist-cutting syndrome" in young, unmarried women whose self-mutilation, although repetitive, has traditionally been thought to be less serious in lethal intent than other situations. Such acts usually have been carried out in a state of mounting tension with depersonalization followed by relief after self-mutilation. A significant number of "wrist slashers," or self-mutilators, however, whose cases have been followed for 5 to 6 years, have committed suicide.

In determining suicide risk, a general rule is that the risk of a successful suicide rises with advancing age. Men are two to three times more likely than women to complete suicide, whereas women are two or three times more likely than men to attempt suicide. Patients who are single, divorced, separated, widowed, or unemployed are at higher risk than those who are married and employed.

A psychotic patient who attempts suicide requires careful observation, whatever restraint necessary, and evaluation by a psychiatrist. A

psychotic patient may respond unpredictably to distorted perceptions in a fearful or driven manner.

Secondary gain is a term that indicates that while the primary motive for a suicide attempt appears to be death, the attempt may meet another need such as attention or a plea for emotional help. When such needs are met by the attempt, a secondary gain is achieved and the risk of subsequent suicide attempt is lessened momentarily. It is dangerous, however, to assume that secondary gain is the cause of a suicide attempt with an initial evaluation in an emergency department. All suicide behaviors should be taken seriously.

Perhaps the most important part of the assessment of the suicide attempter is a determination of the patient's feelings and thoughts at the time of the interview.¹⁰ The patient who experiences helplessness, ex-

Disposition

haustion, overwhelming depression, and a clear expression of intent to die certainly remains at high risk. If a patient expresses continuation of such feelings at the time of the interview, the physician has sufficient evidence that the patient needs psychiatric consultation immediately. Some patients, however, seem to equate self-injury with other forms of emotional discharge, such as crying, talking to a friend, or becoming inebriated. They do not perceive the event as an attempt to end their life. When asked about their feelings at the time of the attempt, such patients may indicate that they were angry or vengeful. Attitudes and affect that generally indicate a good prognosis at the time of the interview are anger, remorse, or embarrassment. A patient who sits quietly, refusing to provide additional information to an examiner, should be considered at high risk. Feelings of hopelessness, helplessness, or exhaustion seem to be among the clearest indicators of long-term suicidal risk in patients hospitalized at one time for depression.¹¹

Patient disposition can be aided by estimating the lethality of the attempt and the likelihood of rescue. When there is a high likelihood of rescue and low lethality, a patient is considered at lower risk than in the reverse situation. A patient who makes a hanging attempt in a desolate wooded area is at greater risk than a person who takes a handful of relatively nontoxic pills in front of witnesses.

Patients who have made previous suicide attempts have traditionally been considered to be at greater risk for future suicide. Prior attempts seem a particularly ominous sign, particularly if the intensity and apparent lethality of the suicide attempts escalate with each subsequent attempt.

A "no harm contract"¹² is very useful in the emergency department in evaluating suicidal risk. The "no harm contract" is a verbal or written agreement, initiated by the emergency physician or psychiatrist, in which the suicidal patient is asked to agree not to harm or kill himself or herself for a particular period of time. This can be therapeutic, helping to reveal the intent of the patient and reduce it. It can also be diagnostic in assessing the nature and severity of a patient's suicidality. It can uncover specific issues precipitating suicidal thoughts and the ability of the patient to contract for safety. Such a contract has no legal implications, however. The most important aspect of the patient's record is the clear documentation by the physician that the patient is or is not an imminent risk to self or others, and why or why not. A very difficult decision in the emergency department is when to discharge a child or adolescent patient who has expressed suicidal thoughts or behavior. Consideration of the following criteria is suggested before discharging a child or adolescent patient¹³ with suicidal ideation or behavior from the emergency department:

1. The patient must not be imminently suicidal.
2. The patient must be medically stable.
3. The patient and the parents agree to return to the emergency department if suicidal intent recurs.
4. The patient must not be intoxicated, delirious, or demented.
5. Potentially lethal means of self-harm have been removed.
6. Treatment of underlying psychiatric diagnoses has been arranged.
7. Acute precipitants to the crisis have been addressed and attempts been undertaken to resolve them.

8. The physician believes that the patient and family will follow through on treatment recommendations.
9. The patient's caregivers and social supports are in agreement with the discharge plans. All of these conditions should be documented.

Adolescents who complete suicide are more likely to have had histories of substance or drug abuse, disruptive disorders, anxiety, mood disorder, or schizophrenia. Precipitating events are usually stressors such as disciplinary crises, being in trouble with the law or at school, or the loss of a relationship. Gender identity concerns are also a precipitant. Table 289-2 summarizes high-risk and low-risk suicide profiles.

High-risk patients whose suicide intent is strong and immediate require immediate psychiatric hospitalization. Moderate-risk patients are those who present in a serious suicidal crisis, but who, because of a positive response to initial intervention and favorable social support, are not judged to be in immediate danger. Hospitalization can often be avoided with such patients, provided practical outpatient treatment can be established immediately. Such determinations are most often made in concert with a

TABLE 289-2 Evaluation of Suicide Risk in Adults and Adolescents

Demographic and Social Profile	High Risk	Lower Risk
Gender	Male	Female
Marital status	Separated, divorced, or widowed	Married
Family history	Chaotic, conflictual Family history of suicide	Stable
Job	Unemployed	Employed
Relationships	Recent conflict or loss of a relationship	Stable relationships
School	In disciplinary trouble	No disciplinary problems
Religion	Weak or no suicide taboo	Strong taboo against suicide
Health		
Physical	Acute or chronic illness Excessive drug or alcohol use	Good health Little or no drug or alcohol
Mental	Depression (Sig ECAPS)* Schizophrenia or bipolar history Panic disorder Disruptive behavior Feelings of helplessness or hopelessness	No depression No psychosis Minimal anxiety Directable, oriented Has hope
Suicide ideation	Frequent, intense, prolonged	Infrequent, low intensity, transient
Suicide attempts	Repeated attempts Realistic plan High risk Guilt Continuing wish to die	No prior attempts No plan High likelihood of rescue Embarrassment about suicide ideation No continuing wish to die
Other	Lack of concern Unsupportive family Socially isolated	Good insight Concerned family Socially integrated

*Sig ECAPS is an aid to remembering 8 symptoms of depression: S-sleep disturbance; I-loss of interest; G-guilt; E-loss of energy; C-inability to concentrate; A-loss of appetite; P-psychomotor slowing; S-suicidal thoughts.

such as firearms or drug supplies, should be removed from the patient's access, and any psychotropic medication should be prescribed conservatively (usually no more than a 2-week supply). It is important to have a family member take charge of a patient's medications.

Before discharging a patient, the physician must be certain that the patient has a good social support system in place. The support system usually includes a place to live and family or friends who will support the patient emotionally, and that one or more of these people will be with the patient for the next 24 h.

Low-risk patients frequently present with suicidal threats or minor attempts that occur in the context of a clearly definable external crisis. Social support is usually available and responsive. However, because many attempts that appear trivial on first glance are found to have more serious implications on closer examination, all patients presenting following a suicide attempt should be carefully assessed. If there is any question about the safety of discharging a suicidal patient, and psychiatric consultation is not immediately available, the patient should be hospitalized.

PSYCHOTROPIC MEDICATIONS

Richard A. Nockowitz
Douglas A. Rund

The emergency physician should be familiar with the emergency indications, common side effects, toxic reactions, and common interactions of the psychotropic medications. Caution in prescribing is the rule. Patients with medical disorders, a history of serious side effects with psychotropic medication, or apparent need for more than one psychoactive medication usually require psychiatric consultation.

There are four major classes of psychotropic medications dealt with here: antipsychotics, anxiolytics/sedative-hypnotics, antidepressants, and mood stabilizers such as lithium and anticonvulsants. There

are multiple indications for several of these medications, particularly the antidepressants and anticonvulsants. However, only the antipsychotic and anxiolytic classes have undisputed emergency utility.

Antidepressants and lithium are rarely prescribed by the emergency physician, primarily because they have long latencies of action and multiple side effects and require careful long-term monitoring. Only in exceptional circumstances, in consultation with a psychiatrist who agrees to provide follow-up care, might the emergency physician elect to initiate antidepressant or lithium therapy. Extensive pretreatment evaluation and detailed patient education weigh heavily against prescribing lithium, monoamine oxidase inhibitors (MAOIs), or heterocyclic antidepressants in the emergency department.

ANTIPSYCHOTICS (NEUROLEPTICS)

Indications

Because antipsychotic medications are symptom-specific (not disease-specific), they are useful in nearly all psychoses, whether primary (a result of psychiatric illness) or secondary (substance-induced or because of a general medical condition). In the emergency setting, they are most often indicated to control agitated or psychotic behavior that constitutes an imminent danger to the patient or others.

A known allergy to a specific antipsychotic medication is a contraindication to its use and to use of other antipsychotic medications of the same class. Most patients who claim to be allergic to antipsychotic medications, however, actually describe a history of acute dystonic reactions when questioned more carefully.

Guidelines and Rapid Tranquilization

Low-potency antipsychotics (Table 290-1) such as chlorpromazine and thioridazine may cause significant hypotension and thus are rarely used in emergency medicine. High-potency antipsychotics such

TABLE 290-1 Commonly Used Antipsychotic Agents

		Approximate	
Generic Name	Brand Name	Equivalent Dose, mg	Relative Potency

Haloperidol	Haldol	2	High
Droperidol	Inapsine (for injection)	2	High

as haloperidol and fluphenazine have relatively few anticholinergic and alpha-blocking effects and are remarkably safe, even at high doses. They have traditionally been the emergency antipsychotic agents of choice.

Haloperidol is given IV but only the IM use is U.S. Food and Drug Administration (USDA) approved. One advantage of using haloperidol IV is the relatively low incidence of extrapyramidal side effects compared with the incidence seen with IM or oral routes of administration. The onset of action of IM haloperidol is typically 10 to 20 min. Haloperidol can cause extrapyramidal symptoms and signs and should not be given to those with Parkinson disease or other movement disorders, anticholinergic toxicity, or phencyclidine (PCP) overdose. It is not recommended in pregnant or nursing women. The initial dosage of oral or IM haloperidol ranges from 1 to 5 mg in adults. Lower initial doses are used if the patient is elderly, debilitated, brain injured or has AIDS.

Rapid Tranquilization

Rapid tranquilization is a method of pharmacologic management of acute agitation or psychosis using a high-potency neuroleptic such as haloperidol IV or IM (Table 290-2). The combination of a neuroleptic, haloperidol, and a benzodiazepine anxiolytic, lorazepam is often used and may be more effective in combination than either single agent used alone.¹ Oral dosing is acceptable and enables the patient to participate in the initial care plan. Parenteral administration may be the only available route, however, if the patient will not accept oral medication. For rapid tranquilization, certain target behavioral features such as agitation, violent behavior, or hostility are identified. An initial dose of 2 to 5 mg is given IM. Symptoms are reevaluated in 30 to 45 min and the dose may be repeated if target symptoms continue. The dosage may be repeated in another 30 to 45 min and symptoms reevaluated. Psychiatric evaluation and consultation should be obtained during the process. A general rule is that no more than six doses are given in the first 24 h of treatment.

Another technique for rapid tranquilization is to begin with haloperidol 2 mg in adults and double the dose every 45 min until the symptoms are controlled, the patient is calmed, or the behavior is stabilized. In this approach one does not think of the dosages as cumulative but rather determines the one single dose that effectively treats the symptoms. Once this is accomplished, use the particular effective dose on an "as needed" basis each time the patient's symptoms reappear.

Lorazepam is a benzodiazepine with a wide therapeutic index, rapid onset of action, and ease of administration by the parenteral or oral route. Lorazepam is the only benzodiazepine that can be reliably administered IM, and its oral and parenteral potencies do not greatly differ, allowing for ease in dosage calculation. Benzodiazepines are the preferred agents for the treatment of agitation associated with co-

caine intoxication and alcohol withdrawal. An initial dose of lorazepam 2 mg IM or IV is typically administered to adults and 1 to 2 mg is typically administered to the elderly. The dose can be repeated in a half hour. Lorazepam and haloperidol may be mixed in the same syringe (typically combined as lorazepam 2 mg and haloperidol 5 mg). There is a synergistic effect between the two medications. Additionally, the benzodiazepine may prevent the potential extrapyramidal problems that occasionally occur with neuroleptic use.

Droperidol is a butyrophenone derivative similar to haloperidol that has been used extensively in emergency department for the treatment of acute agitation and violent behavior. Traditional doses of droperidol range from 2.5 to 5 mg given IM or IV. Side effects include dystonia, akathisia, and hypotension, which are usually managed with IV fluids. Reports of QT prolongation and torsades de pointes resulted in official warning regarding its use, even though recent reports suggest safety and efficacy when used in appropriate dosages in the ED.^{2,5}

Side Effects

Antipsychotics block dopamine receptors throughout the central nervous system (CNS). Dopamine receptor blockade in the mesolimbic areas accounts for their antipsychotic properties. Dopamine blockade in the nigrostriatal tract is responsible for the majority of motor side effects, including acute dystonias, akathisia, and Parkinson syndrome.

ACUTE DYSTONIA Acute dystonias, which usually occur in young males during the trial phase of antipsychotic treatment, are probably the most common side effect of antipsychotic medications seen in the ED. Muscle spasms of the neck, face, and back are the most common dystonias, but oculogyric crisis and even laryngospasm may also occur. When a drug history is not carefully obtained, dystonias are often misdiagnosed as primary neurologic illnesses (seizures, meningitis, tetanus, etc.). Treatment with either benztropine 1 to 2 mg IV or diphenhydramine 50 to 100 mg IV rapidly corrects the dystonia. Dystonias often recur, however, even if the antipsychotic is decreased or discontinued, unless an antiparkinsonian drug such as benztropine, 1 mg PO two to four times daily, is administered over the next several days.

AKATHISIA Akathisia, a sensation of motor restlessness with a subjective desire to move, can begin several days to several weeks after initiation of antipsychotic treatment. Often misdiagnosed as anxiety or exacerbation of psychiatric illness, akathisia is aggravated by subsequent increases in antipsychotic dosage. Other coexisting extrapyramidal effects, such as cogwheel rigidity and shuffling gait, suggest antipsychotic effect, but these signs are not invariably present. Management can be difficult, but some useful strategies are known. If possible, the dosage of the antipsychotic should be decreased. The best treatment is probably administration of β -blockers. Propranolol 30 to 60 mg per d is a good starting dose. Some patients need 90 to 180 mg/d per d as blood pressure and heart rate allow. Antiparkinsonian or anticholinergic drugs such as benztropine 1 mg PO 2 to 4 times daily may also afford some relief. In refractory cases, the antipsychotic may need to be changed to an atypical agent, as discussed below.

PARKINSONISM Antipsychotic-induced Parkinson syndrome is particularly common in the elderly and usually begins in the first month of treatment. A complete Parkinson syndrome—including bradykinesia, resting tremor, cogwheel rigidity, shuffling gait, masked facies, and drooling—can occur, but often only one or two features of the syndrome are obvious. Antipsychotic dosage reduction and/or anticholinergic medication is usually effective.

Whereas antidopaminergic extrapyramidal side effects (EPS) such as acute dystonia, akathisia, and parkinsonism occur more often with high-potency neuroleptics, anticholinergic and antiadrenergic effects are more commonly seen with low-potency neuroleptics. Both anticholinergic and

TABLE 290-2 Management of Acute Agitation or Violent Behavior Using Rapid Tranquilization

1. Identify target symptoms to be brought under control: violent or agitated behavior, hostility, tension.
2. Identify contraindications to haloperidol (previous allergy, pregnancy, overdose with anticholinergics, Parkinson disease or other movement disorders, PCP toxicity).
3. If no contraindications, administer haloperidol IM (or IV)
Haloperidol: 1—2 mg in the elderly
5 mg in normal sized adult
Lorazepam: 1-2 mg in the elderly
2-4 mg in normal sized adult
4. Observe patient for 30-45 min for resolution of target symptoms and behavioral control.
5. Repeat dosing at 30-45 min if symptoms not under control.
6. Usually reassess after 3 doses of medication. Obtain psychiatric consultation. No more than 6 doses usually given in 24 h.

SECTION 25 • PSYCHOSOCIAL DISORDERS

alpha-blocking effects are dose-related and much more common in the elderly.

ANTICHOLINERGIC EFFECTS Anticholinergic effects range from mild sedation to delirium. Peripheral manifestations may include dry mouth and skin, blurred vision, urinary retention, constipation, paralytic ileus, cardiac dysrhythmias, and exacerbation of narrow-angle glaucoma. The central anticholinergic syndrome is characterized by dilated pupils, dysarthria, and an agitated delirium. Discontinuation of the antipsychotic and institution of supportive measures is the most prudent therapy.

CARDIOVASCULAR EFFECTS Cardiovascular side effects are seen almost exclusively with low-potency antipsychotics. The exception to this is the rare occurrence of torsades de pointes caused by high dosages of high-potency neuroleptics such as haloperidol and droperidol. The majority of reported cases occurred in the context of a prolonged QT_C interval (>500 ms) prior to starting the medicine or prolongation of the QT_C by greater than 25 percent consequent to initiating haldol or droperidol. Thus underlying presence of such QT_C prolongation should caution the physician about further use of the medicine. α -Adrenergic blockade and a negative inotropic effect on the myocardium may cause pronounced orthostatic hypotension and, rarely, cardiovascular collapse. Usually the hypotension can be easily managed with intravenous fluid. In severe cases, vasopressor support may be required.

NEUROLEPTIC MALIGNANT SYNDROME Neuroleptic malignant syndrome (NMS) is an uncommon idiosyncratic reaction to neuroleptic drugs manifested by rigidity, fever, autonomic instability (tachycardia, diaphoresis, and blood pressure abnormalities), and a confusional state. Elevation of creatinine phosphokinase, aldolase, the white blood cell count, and liver function tests are often seen. While high-potency antipsychotics may be more likely to cause the disorder, all antipsychotics are potential offenders. NMS is a medical emergency and has a mortality rate as high as 20 percent. Management includes immediate discontinuation of the antipsychotic medication, hydration, and meticulous supportive treatment in an intensive care setting. Anticholinergic medications are not helpful and may worsen the condition by further impairing centrally mediated temperature regulation. Medications such as dantrolene sodium or bromocriptine are sometimes used to relieve the rigidity. See Chap. 159 for a detailed discussion.

Overdose

While antipsychotics are rarely fatal when taken alone, overdose can present some unique management problems. With the exception of thioridazine (Mellaril), antipsychotics are potent antiemetics. Agents with μ -agonist activity such as isoproterenol are contraindicated for cardiovascular support because β -stimulated vasodilatation may worsen hypotension. Extrapyramidal effects may also be prominent in antipsychotic overdosage and are best treated with diphenhydramine (Benadryl) 50 to 100 mg IV

ATYPICAL AGENTS

Clozapine

Clozapine is an "atypical" antipsychotic medication in that it is preferentially more active at limbic than at striatal dopamine receptors and causes few or no EPS. Unfortunately, it may produce agranulocytosis, so its use is reserved for patients with schizophrenia unresponsive to standard agents and for those suffering from severe EPS or tardive dyskinesia with the standard agents. Use of clozapine requires weekly CBCs the first 6 months of use and then every 2 weeks after that. Any

white blood cell count less than 3500 requires closer monitoring, whereas a white blood cell count less than 2000 or absolute granulocyte count less than 1000 mandates immediate discontinuation of the drug and consultation with a hematologist. Fever may be a side effect during the first few weeks of therapy and should prompt an immediate CBC. If the CBC is normal, the fever will typically reverse. Clozapine is strongly sedating, strongly anticholinergic, and has considerable hypotensive effects. It also poses a substantial risk for inducing seizures, particularly when higher doses are used. Respiratory depression and arrest have been rarely reported, and there is a suggestion that coprescription of a benzodiazepine may increase the risk for this side effect.

Commonly reported features of overdose include altered sensorium (drowsiness, delirium, and coma), tachycardia, hypotension, respiratory depression and failure, hypersalivation, and seizures. Management, in addition to administration of activated charcoal, is symptomatic and supportive. Epinephrine and its derivatives should be avoided, as should antidysrhythmics such as procainamide and quini-dine. Close surveillance, including cardiac and vital sign monitoring, should continue for several days because of risk of delayed toxic effects. Fatal overdosages have been reported, usually at dosages greater than 2500 mg.

Risperidone

Risperidone is another "atypical" antipsychotic medication whose pharmacologic profile of potent serotonin (5-HT₂) antagonism and moderate dopamine (D₂) antagonism probably accounts for its relatively lower risk of EPS. Unlike clozapine, it does not have increased risk of agranulocytosis. Common side effects include sedation, insomnia, constipation, and weight gain. Cardiovascular effects may include small, short-term increases in heart rate, accompanied by reduced systolic/diastolic blood pressure, orthostatic hypotension, and QT-interval prolongation. Seizures have been reported in 0.3 percent of patients.

Features of overdose generally reflect exaggerated pharmacologic effects: drowsiness, sedation, tachycardia, hypotension, EPS, prolonged QT, widened QRS and, in several instances, seizure. Management is basically supportive. Cardiovascular monitoring is imperative. Should antidysrhythmic therapy be required, agents such as disopyramide, procainamide, and quinidine, which have the potential for QT-prolonging effects, should be avoided. As with more traditional antipsychotics, agents that may worsen effects of μ -adrenergic blockade, such as bretylium, epinephrine, and dopamine, should also be avoided. An IM preparation of risperidone is currently available for emergency use. Although proven effective for controlling acute agitation, it is this author's opinion that it is a second-line agent due to its cost. The inexpensive traditional neuroleptics described earlier are very effective and relatively safe, with potential side effects that are easily recognized and managed.

Olanzapine

Olanzapine has a chemical profile very similar to that of clozapine and thus causes little or no EPS. It also has the advantage of not being known to cause agranulocytosis and thus does not require monitoring of the white blood count. Its main adverse effects can include considerable weight gain, sedation, and mild anticholinergic activity. There is limited experience at this time about effects of overdose, but exacerbation of brain side effects such as somnolence and anticholinergic signs would be expected. At the time of this writing, an intramuscular form of olanzapine is about to come to market. There is an intramuscular preparation of olanzapine being tested at the time of this writing. Although likely to be effective for controlling agitation, the above comments for risperidone about its place in emergency medicine hold true for this medication as well.

Quetiapine

Quetiapine (Seroquel) is yet another atypical antipsychotic agent and, like the others, is characterized by a high 5-HT₂/D₂ binding ratio, responsible for its low incidence of EPS, while maintaining its antipsychotic effect. It has a high affinity for histaminic and α -adrenergic receptors, however, causing prominent adverse effects of sedation, orthostatic hypotension, and some dizziness. Again, experience is limited about effects of quetiapine in overdose.

Ziprasidone

Ziprasidone (Geodon), the most recent atypical antipsychotic available in the U.S. market, has similar receptor binding to risperidone. There is also an intramuscular preparation being used, which some say could eventually replace haloperidol as the agent of choice in the acute management of the agitated psychotic patient.^{6,7} Ziprasidone has a similar side effect profile to risperidone. Some advise that ziprasidone should be reserved for cases where a typical antipsychotic cannot be used. The initial dose of ziprasidone is 20 mg IM. A second dose of 20 mg can be given in 4 h raising questions about the emergency physician's ability to "titrate" the dose as one does with haloperidol.

The atypical agents also have the potential to cause QT_C prolongation and therefore carry the theoretical risk of related complications, as reported for the older agents.

ANXIOLYTICS

Indications

Severe emotional distress may indicate a need for psychotropic medication, even if the patient is not psychotic or an imminent threat to him- or herself or others. While not a substitute for psychotherapy, short-term anxiolytic therapy may be particularly beneficial in the anxious, agitated patient during a psychosocial crisis. Anxiolytics are also indicated for acute panic reactions unresponsive to reassurance.

Anxiolytics have utility in medical and surgical emergencies as well. Nonpsychiatric uses include facilitation of cooperation and muscle relaxation during painful procedures; controlling seizures; treating alcohol, sedative, or hypnotic withdrawal; and allaying anxiety when a painful procedure such as surgery has been delayed.

Benzodiazepines are contraindicated in patients with known hypersensitivity to benzodiazepines and in acute, narrow-angle glaucoma. Pregnancy, particularly in the first trimester, is a relative contraindication.

Guidelines

Before prescribing anxiolytics, the emergency physician should try to rule out any serious underlying psychiatric illness. Because agitation and anxiety may indicate incipient psychosis or major affective disorder, anxiolytics should be used with extreme caution in patients with a history of major psychiatric illness. The possibility that a patient may be feigning illness to procure controlled substances should also be considered.

Benzodiazepines are very effective anxiolytics with a high therapeutic index. Nonbenzodiazepine anxiolytics (e.g., barbiturates and propanediols) have low therapeutic indices and high addiction potential. Except in the rare case of an allergy to benzodiazepines, nonbenzodiazepine anxiolytics have little use in modern psychopharmacology. Buspirone hydrochloride (BuSpar), an atypical anxiolytic medication that does not interact with the benzodiazepine-7-aminobutyric acid (GABA) receptor complex, has a delayed onset of action of days to weeks, which makes it impractical for use in emergent situations. Because it does not have cross-tolerance with other sedative/hypnotics or alcohol, it is not useful in treatment of sedative/hypnotic or alcohol withdrawal.

Certain benzodiazepines have relatively long half-lives (Table 290-3), including diazepam, chlordiazepoxide, flurazepam, and prazepam. Agents with long half-lives gradually accumulate in the body and thus have a greater potential for causing sedation and confusion, particularly in the elderly. For short-term use, these agents may benefit the young, healthy person in crisis who complains of insomnia but who is also anxious during the day. A single bedtime dose both induces sleep and has a mild anxiolytic effect the following day. For the most part, however, with the exception of the use of diazepam in seizures, short-acting benzodiazepines such as lorazepam, oxazepam, and alprazolam are the preferred agents in emergency medicine. Alprazolam, 0.25 to 0.50 mg PO, is a particularly effective treatment in acute panic attack. Lorazepam, an agent with very low cardiopulmonary toxicity, is particularly well suited for emergency use. Dosages of 1 to 2 mg PO or IM are usually effective. Only midazolam, a very short-acting agent, and lorazepam have reliable intramuscular absorption. As with all benzodiazepines, dosage adjustments may be necessary: higher dosages may be required in patients with histories of alcohol or sedative/hypnotic abuse; lower dosages in patients with hepatic disease or severe debilitation. Because they potentiate other CNS depressants, benzodiazepines should be used with extreme caution in intoxicated patients. Benzodiazepines particularly suppress hypoxic respiratory drive and should be used with caution in patients with hypercarbia, especially if the patient is also receiving supplemental oxygen.

Side Effects

Benzodiazepine side effects are usually mild and easily treated. Drowsiness, decreased mental alertness, sedation, and ataxia are the most common side effects. Such effects can usually be managed conservatively by decreasing the dose and advising the patient to avoid potentially hazardous activities, such as driving or operating dangerous machinery. Excessive sedation and overdose can be reversed with flumazenil by giving 0.2 mg IV over 15 to 30 s and then 0.2 to 0.4 mg every 30 to 60 s up to 3 mg total dose, depending on the circumstances. Its use should be limited due to potential for significant adverse events. This is contraindicated, however, in mixed overdoses and chronic benzodiazepine use. Infrequent paradoxical responses to benzodiazepines of insomnia and agitation are more common in the elderly and require discontinuation of the medication. Because benzodiazepines have abuse potential and high street value, the emergency physician should never prescribe more than a week's supply.

TABLE 290-3 Commonly Used Benzodiazepines

			Usual Total
Generic Name	Brand Name	Approximate Half-Life, h	Oral Dose, mg
ANXIOLYTICS*			
Alprazolam	Xanax	12	1-6
Chlorazepate	Tranxene	48	15-60
Chlordiazepoxide	Librium	20	15-60
Diazepam	Valium	35	15-60
Lorazepam	Ativan	16	2-6
Midazolam	Versed	2	X
Oxazepam	Serax	15	20-60
Prazepam	Centrax	15t, 100t	20-60
HYPNOTICS			
Flurazepam	Dalmane	2t, V2f	15-30 qhs
Temazepam	Restoril	15	15-30 qhs
Triazolam	Halcion	2	0.125-0.5 qhs

*Anxiolytics are administered in divided doses, usually three or four times daily.

tFlurazepam and prazepam have active metabolites with long half-lives. JMidazolam is available for parenteral use only.

HETEROCYCLIC ANTIDEPRESSANTS

Although tricyclic antidepressants (named for their three-ring structure) were first synthesized in the nineteenth century, their antidepressant properties were not recognized until the late 1950s. Since that time, other "cyclic" antidepressant agents have been formulated thus creating need for the more general term *heterocyclic* (Table 290-4). The therapeutic effect of heterocyclic antidepressants (HCAs) is believed to be related to secondary downregulation of norepinephrine and serotonin postsynaptic receptors after initial blockade of presynaptic reuptake of norepinephrine and serotonin. HCAs are primarily indicated for major depression, but may also be effective for dysthymic disorder, panic disorder, agoraphobia, obsessive compulsive disorder, enuresis, and school phobia. As previously advised, initiation of HCA therapy in the emergency department is not routinely recommended.

Side Effects

HCAs have low therapeutic indices. Side effects are common and often occur with customary dosages, even though serum levels may be within the designated therapeutic range. The majority of side effects are either anticholinergic or cardiotoxic.

ANTICHOLINERGIC EFFECTS Anticholinergic side effects are the most common. They are particularly likely to occur with concomitant use of other drugs with anticholinergic properties, such as low-potency antipsychotics, antiparkinsonian agents, antihistamines, and over-the-counter sleeping remedies. Both peripheral and central effects may occur. Peripheral effects include dry mouth, metallic taste, blurred vision, constipation, paralytic ileus, urinary retention, tachycardia, and exacerbation of narrow-angle glaucoma. Central effects include sedation, mydriasis, agitation, and delirium. Mild to moderately severe anticholinergic effects may be managed by dosage reduction, change to a medication with fewer anticholinergic properties, or addition of urecholine, 10 to 25 mg PO three times daily. For acute urinary retention, urecholine, 2.5 to 5 mg may be given SC.

CARDIOVASCULAR EFFECTS Cardiac side effects of HCAs may include nonspecific T-wave changes, prolonged QT interval, varying degrees of atrioventricular block, and atrial and ventricular dysrhythmias. Orthostatic hypotension from α -adrenergic blockade may be significant, particularly in the elderly (see Chaps. 158 and 159).

HCA therapy may also be complicated by allergic obstructive jaundice, decreased seizure threshold (especially with maprotiline, clomipramine, and amoxapine), and, very rarely, agranulocytosis.

TABLE 290-4 Commonly Used Heterocyclic Antidepressants

Generic Name	Brand Name	Usual Dose mg/d
TRICYCLICS		
Amitriptyline	Amitril, Elavil, Endep	75-200
Amoxapine	Asendin	100-300
Desipramine	Norpramin, Pertofrane	75-200
Doxepin	Adapin, Curetin, Sinequan	75-200
Imipramine	Janimine, Presamine, SK-Pramine, Trofranil	75-200
Nortriptyline	Aventyl, Pamelor	40-150
Prisatriptiline	Vivactil	15-60
Trimipramine	Surmontil	75-200
OTHERS		
Maprotiline	Ludiomil	100-150
Trazodone	Desyrel	100-200

Trazodone has little in common with other HCAs. It lacks significant anticholinergic or cardiac conduction effects but may be associated with marked sedation, ventricular dysrhythmias, and significant orthostatic hypotension. It may also cause priapism.

MONOAMINE OXIDASE INHIBITORS

Monoamine oxidase catalyzes the oxidation of biogenic amines (tyramine, serotonin, dopamine, and norepinephrine) throughout the body. The therapeutic effect of MAOIs is probably related to their ability to increase norepinephrine and serotonin in the CNS. They are recommended for atypical major depressive episodes, characterized by hyperphagia, hypersomnolence, reversed diurnal variation (worse in the evening), emotional lability, so-called leaden paralysis (heavy leaden feelings in arms or legs), and rejection hypersensitivity. They are also occasionally useful in selected cases of HCA-refractory major depression and panic disorder. Only two agents in this class, phenelzine and tranylcypromine, are commonly used in the United States. As with HCAs, initiation of therapy in the emergency department is not recommended. The physician who initiates MAOI therapy must have firmly established an appropriate indication for use and provided the patient with extensive counseling about toxic interactions with numerous medications and foods.

Side Effects

In general, MAOIs have fewer side effects than do HCAs. Orthostatic hypotension, although occasionally severe, usually responds to supportive therapy. CNS irritability, including agitation, motor restlessness, and insomnia, is managed by dosage reduction or addition of a benzodiazepine. Occasionally, MAOIs, like other antidepressant medications, actually precipitate a manic episode. Autonomic side effects, such as dry mouth, constipation, urinary retention, and delayed ejaculation, sometimes occur but are usually mild.

MAOIs block oxidative deamination of tyramine and may precipitate a hypertensive crisis when certain drugs, such as sympathomimetic amines, levodopa (L-dopa), narcotics, or HCAs, or tyramine-containing foods are ingested. Common tyramine-containing foods include aged cheese, beer, wine, pickled herring, yeast extracts, chopped liver, yogurt, sour cream, and fava beans. The onset of the crisis is usually heralded by a severe headache. While hypertension is potentially the most serious effect, cardiac dysrhythmias, restlessness, diaphoresis, mydriasis, and vomiting may also occur. Beta-blocking agents are contraindicated, because they may intensify vasoconstriction and worsen hypertension. Although death may occur from hypertensive intracranial hemorrhage, the vast majority of patients recover completely from the hypertensive episode within a few hours. The MAOI can be restarted the following day after dietary counseling is reinforced.

Drug-drug interactions often complicate MAOI therapy. MAOIs potentiate the actions of sympathomimetics, anticholinergics, and oral hypoglycemics. They also inhibit metabolic degradation of alcohol, barbiturates, and narcotics. When combined with meperidine, MAOIs may cause a variety of adverse effects, including hypotension, hypertension, fever, and neuromuscular irritability. While the interactions listed are among the most common, the list is far from exhaustive. More comprehensive accounts may be found in standard references.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

Since the introduction of fluoxetine in 1988, the selective serotonin reuptake inhibitors (SSRIs) have become the most commonly prescribed antidepressants in the United States. Other SSRIs currently available include sertraline, paroxetine, fluvoxamine, citalopram, and escitalopram. SSRIs are primarily indicated for treatment of major depressive

episodes but are also useful in dysthymia and in anxiety disorders, including generalized anxiety disorder, panic disorder, and obsessive-compulsive disorder. Because of their favorable side effect profile and relative safety in overdose, some have argued that institution of an SSRI by an emergency department physician may occasionally be appropriate if (1) the patient can be assessed to rule out general medical causes for the depression, (2) ongoing substance abuse can be ruled out, and (3) the patient can be followed in the emergency setting until picked up by another health care provider. However, this rationale has rightly been questioned because of the concern over SSRIs and other antidepressants precipitating mania. The detection of bipolar disorder, because of its many variations and subtle forms, requires evaluation by an experienced psychiatrist. All antidepressants carry some degree of risk for precipitating a manic or mixed episode in a patient predisposed to bipolar illness.

Side Effects

SSRIs lack the anticholinergic and cardiac effects typical of the HCAs, although there are several reports of symptomatic bradycardia with fluoxetine. The side-effect profile of SSRIs reflect their potent serotonin antagonism. Among the most common side effects are headaches, dizziness, sexual dysfunction, nausea, diarrhea, insomnia, and agitation. Less-common side effects are akathisia and apathy syndrome. A significant advantage of SSRIs is their high therapeutic index and associated low lethality, even when large quantities are ingested acutely.

An SSRI discontinuation syndrome has become apparent, more commonly with agents having a shorter half-life (e.g., sertraline, paroxetine). It typically presents several days after cessation of one drug and is characterized by a flulike syndrome, including nausea, vomiting, fatigue, myalgias, vertigo, headache, insomnia, and sometimes paresthesias. Treatment is to reinstate SSRI therapy and taper more gradually.

A serotonin syndrome with SSRIs can occur when SSRIs are combined with other serotonergic medications such as the MAOIs. The syndrome is manifest by both CNS (restlessness, tremor, myoclonus, hyperreflexia, and seizures) and gastrointestinal (nausea, vomiting, diarrhea) irritability. Consequently, SSRIs or any medication that enhances serotonin levels should not be combined with MAOIs. Treatment of the serotonin syndrome consists of discontinuing the serotonergic agents and providing supportive care.

NEWER "COMBINATION" ANTIDEPRESSANTS

Whereas most tricyclic antidepressants enhance norepinephrine levels, SSRIs enhance serotonin levels, and psychostimulants (a category not discussed here) enhance dopamine levels. The newer antidepressants evidence "combinations" of these effects through various mechanisms. Examples of this include venlafaxine, bupropion, nefazodone, and mirtazapine.

Venlafaxine (Effexor)

Venlafaxine, which is structurally distinct from other antidepressants, is conceptually a combination of a tricyclic and an SSRI in that it enhances both serotonin and norepinephrine (as well as dopamine slightly) through reuptake blockade. Its advantages are relative freedom from medication interactions and no significant affinity for muscarinic, histaminic, and α -adrenergic receptors. Although lack of blockade for various receptors improves its side-effect profile somewhat, common complaints include agitation and insomnia, nausea, occasional dizziness, constipation, and sweating. Potential problems associated with venlafaxine include dose-related, sustained hypertension and the growing awareness of a significant discontinuation syndrome

requiring very slow tapering of the drug. The hypertension needs to be monitored and may require lowering of the medication. The discontinuation syndrome can be significant. It usually occurs within days to 2 weeks after lowering or stopping the drug and is similar to SSRI discontinuation symptoms. It can be treated with an SSRI or by increasing the venlafaxine and tapering it more slowly. Venlafaxine should not be used in combination with an MAOI.

Bupropion (Wellbutrin)

Bupropion is also structurally unique and works by initiating reuptake inhibition of both norepinephrine and dopamine, the former more than the latter. It also interacts with few other medications and has a favorable side-effect profile because of its minimal anticholinergic and antihistaminic effects. It is also being used as an aid in smoking cessation.⁸

Common side effects include some initial restlessness and insomnia that typically resolves within 2 weeks. It is noted for having the lowest incidence of sexual side effects, which are common with other antidepressants, including SSRIs. In fact, when bupropion is added for SSRI-induced sexual dysfunction, sexual functioning improves in many patients. One concern with this drug had been a dose-related increase in the incidence of seizures. However, further study has shown no higher incidence at usual therapeutic dosages compared with other antidepressants. Caution should be taken when using this drug in patients with bulimia or metabolic disturbances predisposing to seizures. Likewise, individual doses greater than 200 mg and daily dosages greater than 400 mg should be avoided. Combination with an MAOI is to be avoided as well. Bupropion may be the least likely of all antidepressants to precipitate a switch into mania.

Nefazodone (Serzone)

Nefazodone inhibits serotonin reuptake inhibitors and blocks postsynaptic 5-HT₂ receptors at the same time. It is similar chemically to trazodone but possesses less α -adrenergic blockade. Common side effects are dizziness, headache, dry mouth, and nausea. Some patients also have problems with orthostatic hypotension and drowsiness. Anxiety is less of a problem with this drug than with SSRIs, and sexual side effects are less common. It may be particularly useful for depression-associated insomnia.

Mirtazapine (Remeron)

Mirtazapine antagonizes inhibitory norepinephrine autoreceptors and heteroreceptors, causing increased release of norepinephrine and serotonin. The main side effects are somnolence, increased appetite, weight gain, and dizziness. Although serotonin enhancement is one of this drug's end results, it is via a very different mechanism, and the typical SSRI side effects are usually minimal. Given the limited clinical experience with this relatively new medication, effects of overdose are not well known.

MOOD STABILIZERS

Although lithium has been the mainstay of bipolar disorder (manic depression) treatment for years, anticonvulsants such as carbamazepine, oxcarbazepine, valproic acid, gabapentin, lamotrigine, tiagabine, and topiramate have come to play an increasingly important role in the management of this and other neuropsychiatric disturbances.

Lithium

Lithium carbonate is indicated for both acute mania and maintenance therapy in bipolar disorder. It is also useful in some cases of major depression (both unipolar and bipolar), and in some disorders characterized

by episodic explosive outbursts or self-mutilation. Its mechanism of action is not exactly known, although it may relate to reducing dopaminergic function, enhancing serotonergic function, or reducing "excessive signaling" by the phosphatidylinositol system. The extensive pretreatment evaluation and long latency of action preclude the use of lithium as an emergency psychotropic medication. The emergency physician should be aware, however, of its side effects and signs of toxicity (see Chap. 162).

SIDE EFFECTS Patients vary widely in susceptibility to lithium side effects. While most of the serious adverse effects are associated with toxic serum levels, mild side effects such as gastrointestinal distress, dry mouth, excessive thirst, fine tremors, mild polyuria, and peripheral edema are often seen even when serum levels lie within the designated therapeutic range. This is particularly common during the first few weeks of therapy. Many of the more chronic side effects, including polyuria, nephrogenic diabetes insipidus, benign diffuse goiter, hypothyroidism, skin rashes and ulcerations, psoriasis, and leukocytosis without a left shift, appear unrelated to serum lithium levels. Underlying neurologic illness, dehydration, salt-restricted diets, and childbirth predispose to both minor and major side effects.

TOXICITY AND OVERDOSE The severity of lithium toxicity is related to both the serum lithium level and the duration of the elevated level. Even in acute overdose, symptoms may not be fully apparent for up to 48 h. As a general rule, lithium toxicity is rare at serum levels of less than 2 mEq/L. Early signs of toxicity include nausea and vomiting, dysarthria, lethargy, and a coarse hand tremor. As toxicity worsens, neurologic symptoms increase. Ataxia, myasthenia, incoordination, hyperreflexia, muscle fasciculation, blurred vision, and scotomas may develop. Eventually, confusion, choreoathetosis, myoclonus, and seizures occur, and the patient may finally become comatose. Cardiovascular toxicity is unusual at serum levels of less than 4 mEq/L. In addition to nonspecific T-wave changes, high lithium levels may be associated with hypotension, atrioventricular conduction defects, ventricular tachydysrhythmias, and eventually complete cardiovascular collapse.

Because lithium toxicity may result in permanent neurologic sequelae, it should be considered a medical emergency. Chap. 162 discusses management of lithium overdose.⁹

Anticonvulsants

These drugs all act through different mechanisms, such as enhanced GABA inhibitory function or decreased glutamate and aspartate excitatory release, all of which ultimately result in neuronal relaxation or stabilization. They have come to be used for mood stabilization in rapid-cycling, cyclothymic, and mixed states of bipolar illness. Recent studies demonstrate the superiority of anticonvulsants over lithium for such indications. Other uses are for impulsive aggression, behavioral disturbances in head-injured patients and in patients exhibiting self-injurious behavior, and even for the irritability commonly seen in severe personality disorders. The side effects of carbamazepine and valproic acid are well known from their use as anticonvulsants.

Gabapentin is well tolerated, has few drug interactions, and does not need blood-level monitoring. It may be titrated quickly and may be useful for patients already on multiple medications or with hepatic impairment. The main disadvantages are drowsiness, ataxia, and nausea at high dosages.

Lamotrigine is also well tolerated, with few adverse behavioral or cognitive effects. It does have some drug interactions (carbamazepine, valproate) and risk of potentially severe and fatal rash such as Stevens-Johnson syndrome and toxic epidermal necrolysis. The rash is more common in children and seems to be related to starting at too high a dosage, titrating too rapidly, and concomitant valproate therapy. Such a rash dictates immediate cessation of the medication in almost all cir-

cumstances. There may be additive toxicity with carbamazepine as well, causing more ataxia and dizziness than when used alone.¹⁰

At the time of this writing, experience is growing with the various anticonvulsants for anxiety, mood, behavioral, and other psychiatric issues.

ANOREXIA NERVOSA AND BULIMIA NERVOSA

Alexander H. Sackeyfio Susan J. Gottlieb

Anorexia nervosa and bulimia nervosa have reached epidemic proportions in the last 10 years. These diseases were once viewed as purely psychological in nature. However, increasing evidence has confirmed that both disorders involve physical complications, and knowledge of and ability to treat the medical complications that accompany eating disorders are crucial for the patient's well-being.

In the United States, eating disorders affect approximately 5 to 10 percent of adolescent girls and young women, and up to 1 percent of males. Eating disorders are now recognized across all socioeconomic and racial groups, in patients between the ages of 8 and 80 years.¹ The onset of anorexia is usually between 12 years of age and the mid-thirties, with a bimodal distribution of ages 13 to 14 and 17 to 18. Bulimia usually begins between the ages of 17 and 25. The onset of both disorders has been reported in older persons.

Anorexia, with its resulting starvation syndrome, is more likely to be recognized than the commoner bulimia, which is frequently concealed from both family and physician. Table 291-1 lists the signs and symptoms that suggest a diagnosis of anorexia, and Table 291-2 lists the signs and symptoms of bulimia.

TABLE 291-1 Clues to Undiagnosed Anorexia Nervosa

Unexplained growth retardation
Unexplained primary amenorrhea
Weight loss of unknown origin
Unexplained hypercholesterolemia or carotenemia in a thin person
Exercise abuse
Membership in a vulnerable vocation group (see Table 291-2)

TABLE 291-2 Signs and Symptoms of Bulimia in Adolescents and Young Adults

Hypokalemia of unknown cause or complications of hypokalemia
Metabolic acidosis, related to laxative abuse/excessive exercise
Parotid gland or submandibular gland enlargement; esophagitis; esophageal bleeding or rupture
Large unexplained weight fluctuations or weight loss
Unexplained elevations of serum amylase
Unexplained secondary amenorrhea
Extensive loss of dental enamel or severe caries onset ⁷
Scars on the knuckles of the hand from induced vomiting ¹⁵
Juvenile diabetes mellitus
Other disorders of impulse control (alcoholism, drug abuse, borderline personality)
Member of predisposed vocational group: models, ballet students or professionals, wrestlers, jockeys, athletes ¹⁶

Source: Wells LA, Sadowski CA: Bulimia nervosa: An update and treatment recommendations. *Curr Opin Pediatr* 13:591, 2001.

Anorexic patients² may present with one or all of the following:

1. Refusal to maintain body weight over a minimum normal weight for age and height; for example, weight loss or failure to make expected weight gain during a period of growth, leading to body weight 15 percent below normal.
2. Intense fear of becoming obese even when underweight.
3. Disturbance in the way in which body weight, shape, or size is perceived. For example, the obviously underweight or even emaciated patient may complain of being fat, or may believe that one area of the body is "too fat."
4. Absence of at least three consecutive expected menstrual cycles (primary or secondary amenorrhea).

A diagnosis of bulimia² is suggested by the following:

1. A minimum average of two episodes of binge eating (rapid consumption of a large amount of food in a short period of time) per week for at least 3 months.
2. During the eating binges, there is a feeling of lack of control over the eating behavior.
3. The individual regularly engages in self-induced vomiting, use of laxatives, strict dieting, fasting, or vigorous exercising in order to prevent weight gain.
4. Persistent overconcern with body shape and weight.

Another diagnosis² to be considered is *eating disorder, not otherwise specified*. It is characterized by:

1. For females, all criteria for anorexia except that the patient is still menstruating.
2. All criteria for anorexia except normal weight.
3. All criteria for bulimia but lower frequency or duration.
4. Regular use of compensatory weight control measures after eating a small amount of food.
5. Chewing/spitting out, but not swallowing, large amounts of food.
6. Binge-eating disorder.

The diagnosis of an eating disorder should be considered in a premenarchal patient who engages in potentially unhealthy weight-control practices and/or demonstrates obsessive thinking about food, weight, and height, especially if there is a delay in the maturation for gender and age.

ETIOLOGY

Anorexia nervosa and bulimia nervosa are found in societies that consider fat people as beautiful, attractive, and desirable, not just in societies that emphasize a drive for thinness and firm bodies. Etiologic

factors include biological vulnerability, family issues and societal pressures.³ There is an increased rate in monozygotic twins and in first-degree relatives.

Personality factors that increase susceptibility to anorexia nervosa and bulimia nervosa include perfectionism, obsessive-compulsive disorder, symmetry and exactness and harm avoidance.^{4,5} Dysfunctional family dynamics are more common in patients with eating disorders than in controls.

Other factors linked to increased incidence of eating disorders include early menarche, which is also associated with not living with biological father for more than 1 year during childhood. Trauma or stress in early life can increase sensitivity of the anterior pituitary and increased risk for depression and eating disorders.

Neurotransmitters and neuropeptides are also implicated in the predisposition and perpetuation of eating disorders. Serotonin, which is known to be involved in feeding, moods and obsessions, impulse control, and harm avoidance, has been extensively studied. Anorexia is seen as a hyperserotonergic state and bulimia as a hyperserotonergic state.

Anorexia most often begins during adolescence. Normal physiologic changes that are preparation for the reproductive function, namely an increase in total body fat (up to 200 percent in adolescent females) as well as the accumulation of fat around the chest and hips, are perceived as "fatness," and the adolescent begins to diet to lose the unwanted weight. Various reasons have been proposed for the progression of "normal" dieting into an eating disorder. Some feel that for the anorexic, restriction of eating serves as a part of a general need to control impulses and disturbing feelings. Others have suggested that the central problems might be an avoidance of adulthood, an emergent panic related to the challenge of late adolescence and the loss of the security enjoyed by the child and early adolescent.^{3,4}

Bulimics have an intense need for approval, a high self-expectation, and a poor body image. Bingeing provides escape from boredom, anger, and loneliness, and is sometimes a preferred social experience, especially when interpersonal intimacy has been elusive. Purging only adds to an already negative self-image. Binge eating in bulimics almost always begins as a response to hunger from dieting and weight loss. Late in the syndrome, binge eating becomes generalized to deal with emotional distress.^{3,4}

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes both psychiatric and medical disorders. Schizophrenics can present with an aversion to eating and sometimes with eating and purging. In depressive illness, anorexia and hyperphagia can be part of the presenting symptoms. Hysterics, inadequate personality disorders, and patients with borderline personality disorders may also exhibit eating disorders.

A number of medical disorders should be considered, including superior mesenteric artery syndrome, inflammatory bowel disease, chronic hepatitis, Addison's disease, diabetes, hyperthyroidism, hyperemesis gravidarum, tuberculosis, and malignancy. Eating disorders may coexist with other conditions, such as adolescent diabetes.

PATHOPHYSIOLOGY

Eating disorders are associated with a number of physiologic changes (Tables 291-3 and 291-4).

Cachectic patients are relatively well adapted to their chronically deprived, mildly catabolic state. The hypothalamus is affected by low fat intake and that disturbs the reproductive, metabolic, growth and neurohypophyseal hormones. There is an associated fall in metabolic rate, protein levels are preserved and cell-mediated immunity tends to be normal.⁶

Self-induced vomiting results in various disorders. Dental problems⁷ are caused by gastric acid regurgitation into the oral cavity. In

TABLE 291-3 Physiologic Changes Associated with Eating Disorders

Hematologic
Normochromic normocytic anemia
Leukopenia with relative lymphocytosis
Low sedimentation rate
Reduced C3 complement
Biochemical
Hypokalemia
Hyponatremia
Hypomagnesemia
Hypocalcemia
Hypophosphatemia
Osteoporosis
Carbohydrate metabolism
Lower serum insulin levels
High serum glucagon levels
Starvation ketosis and hypoglycemia
Abnormal glucose tolerance as a consequence of fasting
Hypercholesterolemia
Endocrine
Normal T4, low T3
Elevated serum cortisol without diurnal variation
Lower serum LH, FSH, and estradiol
Low total urinary estrogens
Increased growth hormone
Pseudo Bartter syndrome (laxative and diuretic abusers)
Decreased ADH secretion (diabetes insipidus)
Decreased peripheral adrenergic activity with normal adrenomedullary function
Cutaneous ¹⁵
Xerosis
Cheilitis
Hypertrichosis
Alopecia
Dry scalp hair
Acral coldness or cyanosis
Periungual erythema
Gingivitis
Brittle nails
Hand calluses
Bruising

Abbreviations: ADH = antidiuretic hormone; FSH = follicle-stimulating hormone; LH = luteinizing hormone.

addition, the oral hygiene of most anorexics is poor, and the vigorous brushing often done by bulimics aggravates dental problems. Poor oral hygiene, together with dietary deficiencies and dehydration of the soft tissue of the mouth, can cause gingivitis and dental erosion.

Parotid and submandibular gland enlargement is often seen. Oral lacerations and contusions, and callous formations on knuckles from stimulating the gag reflex, are common. Dysphagia, hematemesia, and, rarely, rupture of the esophagus, subcutaneous emphysema, or pneumomediastinum can occur following excessive purging. Easy bruising because of loss of bile salts and poor absorption of vitamin K is another complication. Severe hypokalemia and hypovolemia often accompany recurrent vomiting. Ipecac abuse can cause dermatomyositis-like syndrome and cardiomyopathy. Hyperamylasemia, probably of salivary gland origin, is associated with purging episodes.

Laxative abuse produces weight loss mainly by dehydration and hypokalemia. Common nonspecific complaints of laxative abuse include constipation, diarrhea, abdominal cramping, and bloating. Severe potassium depletion as a result of chronic laxative abuse and intense physical exercise may contribute to rhabdomyolysis. Specific effects include melanosis coli and cathartic colon. In cathartic colon, the colon is converted into an inert tube incapable of propelling the fecal stream without large doses of laxatives. This condition is not entirely reversible and may require colectomy. Brownish gray hyperpig-

TABLE 291-4 Clinical Effects of Eating Disorders

Cardiac: arrhythmias, cardiac arrest, orthostatic hypotension, Q-T prolongation, ¹⁷ nonspecific electrocardiogram changes
Gastrointestinal: constipation, ileus, exacerbation of hepatic encephalopathy
Metabolic: glucose intolerance, hypokalemic metabolic alkalosis
Neuromuscular/orthopedic: hypo- or areflexia, paralysis, peripheral neuropathy, respiratory depression, rhabdomyolysis, weakness, pathologic fractures ¹⁸
Renal: decreased urinary concentrating ability; polyuria and polydipsia, nephropathy; myoglobinuria (caused by rhabdomyolysis)

mented areas on the skin are reported as complications of phenolphthalein-containing laxatives (Correctol, Ex-Lax).

Diuretic abuse results in dehydration and multiple serum abnormalities including hypokalemia, hypercalcemia, hyperuricemia, hypomagnesemia, and hyponatremia.

Binge eating after a period of starvation can result in acute gastric distention and/or pancreatitis. Postbinge pancreatitis has a reported 10 percent mortality rate.

Periods of starvation result in hypoglycemia, which is a poor prognostic indicator. Hypoglycemia is often associated with hypothermia, coma, and infections, and may be fatal. Starvation leads to low insulin levels that are insensitive to both glucose and amino acid infusion. Gastric distention and reduced gastric emptying produce enhanced satiation and prolonged intermeal intervals. Food has been demonstrated to remain in the stomachs of anorexics for up to 24 h.

Starvation causes a decreased hypoxic ventilatory drive, decreased vital capacity, tidal volume, and minute ventilation. In addition, the surfactant pool is reduced, resulting in "stiffer" lungs with a greater tendency to collapse. The muscles of ventilation are affected by starvation, causing reduced diaphragm mass and respiratory muscle weakness.

Cardiovascular changes include brady- and tachyarrhythmias caused by cardiomyopathy or electrolyte abnormalities. ST-T wave changes, and Q-T interval prolongation, may be evident. Decreased peripheral adrenergic activity with normal adrenomedullary function results in bradycardia and orthostatic hypotension.

Dermatologic changes include pedal or pretibial edema, with or without hypoalbuminemia; excessive loss of subcutaneous fat; brittle hair and nails; pellagra or scurvy; and petechiae or purpura.

Peripheral neuropathy, most likely a product of chronic malnutrition, is a notable complication. Localized compression neuropathies secondary to subcutaneous tissue loss can also develop. Some patients experience paresthesias of the fingers and toes. Deep tendon reflexes may be diminished, and gross motor coordination may be impaired.

Anorexics are especially likely to be compulsive exercisers. Stress fractures⁸ in the feet, march hemoglobinuria, and various musculoskeletal overuse syndromes have been identified in our institution as complications of compulsive exercise.

Osteoporosis is common in anorexics. It usually affects the femur, radius, and spine in decreasing frequency. Estrogen deficiency is not a major causative factor. Any patient with an eating disorder who has been amenorrheic and low in weight for more than a year should undergo bone density studies. We have seen a femur fracture in a young anorexic who tripped on a rug.⁸

Adolescent diabetics induce ketosis by skipping insulin for a day or two to lose weight; sometimes they overeat and increase insulin in compensation. The abuse of insulin and food can lead to severe metabolic consequences. Young diabetics with frequent hospitalizations should be evaluated for a coexisting eating disorder.

PSYCHOLOGICAL PRESENTATIONS

In addition to the presenting physical symptoms, psychological manifestations may also be detected on emergency evaluation. Depression, including suicidal ideation, is the primary psychological complication

of eating disorders. Other psychological manifestations include obsessive-compulsive personality traits, with rumination about food, calories, and weight. Ritualistic eating and exercising behavior are also evident. Perfectionistic striving often results in deterioration of friendships and leisure activities.

Impulse control disorder is a psychological complication of eating disorders more commonly seen in bulimics than anorexics. Other behavioral manifestations include shoplifting and stealing, sexual promiscuity, drug and alcohol abuse, and self-mutilation.

PROGNOSIS

As with most mental illnesses, the earlier the onset, detection, and treatment the better the prognosis. There is a large variation in outcome. Some studies report longer term improvement in 30 to 50 percent of patients,^{9,10} but in most, it is a chronic disorder. Eating disorders can have potentially irreversible effects on the physical and emotional growth in adolescents. There is evidence suggesting improved outcome with early treatment and therefore the threshold for intervention should be lower than in adults. Behaviors may remain constant or the patient may improve briefly and return to the eating disorder during stressful times. Psychological immaturity persists in approximately 50 percent of the patients, with difficulties in social adjustment, and one-third of patients continue to have problems with eating. Chronicity increases the risk of morbidity.

In spite of the advances in the understanding of anorexia and bulimia nervosa, eating disorders are still associated with significant long-term morbidity and mortality. Mortality figures range from 2 to 5 percent to a high of 18 percent. Abnormally low albumin levels and low body weight (≤ 60 percent ideal body weight) best predicts a lethal course. High creatinine and uric acid levels predict chronicity in anorexics.¹¹ Death may result from suicide, starvation, metabolic catastrophe, infection, and cardiac insufficiency. Agents used to induce weight loss may lead to fatal complications.

TREATMENT

Emergency management of the patient with an eating disorder consists of volume repletion and correction of electrolyte imbalance. Fluid and nutritional replacement should be gradual. Cachectic patients do not secrete inducible enzymes, such as lipase or lactase. They have reduced gastric emptying and atrophy of small intestinal villi. Aggressive refeeding can lead to hypertonic dehydration, hyponatremia, prerenal azotemia, and refeeding pancreatitis. Caloric requirements should be advanced slowly. The refeeding syndrome, with severe cardiopulmonary and neurologic complications, has been described in anorexics and is associated with rapid electrolyte shifts, hypophosphatemia, hypokalemia, and hypomagnesemia. Anorexics usually present with bradycardia and the pulse rate may be the simplest noninvasive way to monitor fluid replacement. Closely monitor the electrocardiogram, serum and urine electrolytes, phosphorus, and magnesium. Hospitalization is suggested for the following conditions:

1. Weight loss greater than 30 percent over 3 months
2. Severe metabolic disturbance
3. Depression severe enough to be at risk for suicide
4. Severe bingeing and purging
5. Failure to maintain outpatient weight contract
6. Psychosis
7. Family crisis
8. Need to confront patient and family denial
9. Need for initiation of therapy (individual, family, and/or pharmacotherapy)
10. Complex differential diagnosis

A period of about 48 h in an inpatient setting is essential to determine the extent and severity of the illness and its complications. An eating

disorders unit or medical floor with involvement of a multidisciplinary psychiatric and internal medicine team is advised.

A variety of medications have been used in eating disorders, including H₂ antagonists (ciproheptadine), selective serotonin reuptake inhibitor and cyclic antidepressants, and atypical antipsychotics (olanzapine).¹²⁻¹⁴ The sense of bloating or uncomfortable fullness as anorexics begin refeeding is usually related to delayed gastric emptying and can be helped by taking metoclopramide before meals.

The selective serotonin reuptake inhibitors are the mainstay of pharmacologic treatment in bulimia. Naltrexone and odansetron have been reported as useful in some cases.

A trial of outpatient psychological treatment can be attempted if food restriction and weight loss are of less than 3 months' duration, and if there is a very positive family support system. Referral to a local health professional who specializes in the treatment of eating disorders or to a self-help group can be obtained by contacting the following national organizations:

PATHOPHYSIOLOGY

The etiology basis of panic disorder is unknown. It is most likely multifactorial in origin, with genetic, behavioral, and biological underpinnings.¹⁰

Genetic or Familial

First-degree relatives of patients with panic disorder have a four- to sevenfold increased risk of developing the disorder,⁶ and monozygotic twins have a higher concordance than dizygotic twins for panic disorder.^{7,11}

Behavioral

Cognitive-behavioral theorists have proposed that panic disorder is a learned response to interoceptive cues. Heightened awareness of body functions and/or cognitive misinterpretation of these cues are postulated to trigger a conditioned fear response.¹² Anticipatory anxiety and agoraphobia develop as a person begins to associate panic attacks with a particular place or situation.

Biological

Neurobiological research into the etiology of panic disorder uses two main approaches: studies that use provocative ("panicogenic") substances and studies that use known pharmacologic treatments. These approaches have implicated multiple neurotransmitters or neuropeptides, including norepinephrine, serotonin (5-hydroxytryptamine), 7-aminobutyric acid (GABA), and cholecystokinin (CCK), among others.

NOREPINEPHRINE Panic disorder patients are generally hypersensitive to carbon dioxide inhalation.¹³ One model has been proposed that carbon dioxide stimulates the locus ceruleus, which contains noradrenergic neurons, and induces panic by stimulating norepinephrine release.¹⁴ In addition, there is some evidence for impaired receptor sensitivity in panic disorder.¹³

SEROTONIN Two agents have been reported to provoke panic attacks via effects on serotonergic receptors. Fenfluramine and *m*-chlorophenylpiperazine cause panic in challenge tests.¹³ Theories that have attempted to explain the results of these tests and incorporate the known efficacy of serotonergic agents in treating panic disorder include the following hypotheses: increased sensitivity of postsynaptic receptors, decreased or increased central nervous system serotonin activity, and interactions between serotonin and norepinephrine, GABA, or CCK.¹³

CHOLECYSTOKININ Recently, much attention has been given to the neuropeptide, CCK, as an important mediator in panic disorder. It is present in many of the neuroanatomic areas thought to be involved in panic disorder, including the cerebral cortex, hippocampus, and brainstem. A tetrapeptide form of CCK causes panic when administered to panic disorder patients and its effects are attenuated by imipramine, a tricyclic antidepressant with efficacy in treating panic.¹⁵ There are also close interactions between CCK and GABA, between serotonin and dopamine, and between endogenous opioids and the excitatory amino acid, glutamate.¹⁵

The mechanisms by which the provocative agents sodium lactate, yohimbine, and caffeine, which reproducibly induce panic in patients with panic disorder, cause panic attacks are not known.

CLINICAL FEATURES

The cardinal features of panic disorder are recurrent, unexpected panic attacks and persistent worry about having another attack and/or its potential implications, such as heralding a serious medical illness. Panic

PANIC DISORDER

Linda M. Nicholas

Ann E. Maloney

Susan L. Siegfried

Panic disorder is a common, often chronic, condition characterized by recurrent, spontaneous panic attacks. Panic attacks are short-lived episodes of anxiety or intense fear, accompanied by a range of somatic symptoms, which may include tachycardia, tachypnea, dyspnea, chest tightness, weakness, nausea, dizziness, and paresthesias. Panic disorder may occur with or without agoraphobia, a condition typified by avoidance of places or situations associated with anxiety. Panic disorder with agoraphobia may be severely disabling, because patients may be incapable of functioning socially or occupationally.

Because many of the symptoms of panic overlap with those of acute medical illness, the first point of contact for patients with panic disorder is often the emergency room.

When compared with patients who had other psychiatric or medical problems, patients with panic disorder had the highest rates of use of emergency department services.¹ Increased use can precede the diagnosis of panic disorder by up to 10 years.² Although progress is made in diagnosis and treatment, as many as 50 percent who have the disorder are undiagnosed.

EPIDEMIOLOGY

Panic disorder is relatively common, with national lifetime and 12-month prevalences of 3.5 and 2.5 percent,³ respectively, and a cross-national lifetime prevalence of 1.6 to 2.2 percent.⁴ The age of onset is usually from late adolescence to the mid-30s. The incidence may have a bimodal distribution, with the first peak in late adolescence, followed by a second, smaller peak in the mid-30s.⁵

Women are two to three times more likely than men to develop panic disorder. There is some evidence that panic attacks may remit during pregnancy, only to be exacerbated in the postpartum period.^{6,7} Cultural factors may play a role in the presentation of panic disorder. Sleep paralysis and hypertension are common symptoms of panic disorder in the African American population.⁸ *Ataque de nervios* is an anxiety syndrome in Hispanic cultures that, at times, has a similar presentation to panic disorder.⁹

attacks are of sudden onset and include feelings of apprehension, fear, and discomfort; these attacks are relatively brief in duration, with a peak within about 10 min and resolution within 1 h. The attacks are accompanied by characteristic somatic and/or cognitive symptoms.⁵ Somatic symptoms are referable to the major organ systems in the body. Cardiovascular complaints include palpitations and tachycardia or chest pain and discomfort. Respiratory symptoms of shortness of breath or the sensation of being smothered are common. A choking sensation, nausea, and gastric distress comprise most gastrointestinal complaints. Neurologic symptoms include dizziness, unsteadiness, lightheadedness, faintness, trembling, shaking, or paresthesias. Sweating, hot flushes, or chills are also common. Cognitive symptoms include feelings of unreality about or being detached from one's environment (derealization) or one's self (depersonalization) and the fear of going crazy, losing control, or dying.⁵ Some patients alter their behavior to minimize their risk of having more panic attacks, even to the point of becoming fearful of leaving their home and being in places or situations where escape or finding help would be difficult if a panic attack occurred (agoraphobia).⁵

DIAGNOSIS

For a diagnosis of panic disorder, the patient must have recurrent, unexpected panic attacks followed by at least 1 month of persistent fear of having additional attacks, worry about the implications or consequence (e.g., going crazy, having a heart attack), or a significant change in behavior.⁵ The panic attacks must not be better accounted for by another psychiatric or medical disorder (Table 292-1). The patient's age, presenting symptoms, time course of symptom development and resolution, and lack of other identifiable medical causes are often helpful in considering the differential diagnosis of a panic attack.¹⁶ Care must be taken to identify victims of domestic violence, who often present with psychiatric complaints. When screening suggests domestic violence, safety planning and referrals for counseling should be provided.

Psychiatric Differential Diagnosis

A panic attack is an episode of intense fear that develops abruptly and reaches a peak within 10 min. During a panic attack, at least 4 of 13 characteristic symptoms must be present, as listed in Table 292-2. Panic attacks are characterized in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, as unexpected (uncued), situationally bound (cued; i.e., always occurring with exposure to a specific trigger), or situationally predisposed (i.e., likely to occur with exposure to a given situation). Situationally bound or predisposed panic attacks may occur in association with a wide range of psychiatric disorders, including social phobia, specific phobia, acute or posttraumatic stress disorder, separation anxiety disorder, obsessive-compulsive disorder, and depressive disorders. The occurrence of spontaneous or unexpected panic attacks is necessary for a diagnosis of panic disorder. The patient always should be questioned about situations triggering the attacks. It is often useful to ask patients if their panic attacks occur "out of the blue" or to inquire if they are ever awakened by panic attacks.

Medical Differential Diagnosis

A patient presenting to the emergency department with multiple somatic complaints consistent with a panic attack, even if they are known to have panic disorder, should have a thorough history, physical examination, and, when indicated, other specific tests performed to rule out medical causes. The differential diagnosis is quite extensive, and panic disorder is often a diagnosis of exclusion.

The clinician should carefully review the patient's concurrent medical problems and prescribed and over-the-counter medications, because some medical conditions and/or treatments can provoke anxiety and overt panic attacks. Substance intoxication and withdrawal states

also may induce panic. A history of caffeine use is important, because panic patients often are exquisitely sensitive to methylxanthines. A brief psychosocial history should include questions regarding substance use and recent or ongoing psychosocial stressors that may be exacerbating or precipitating panic attacks. Table 292-1 contains a partial list of medical diagnoses and substance-induced states that may present with symptoms similar to those of panic disorder.

Physical examination findings in panic patients most commonly are transient tachycardia and mildly elevated systolic blood pressure. Laboratory findings, when present, are most consistent with hyperventilation with low levels of sodium bicarbonate. In general, most patients with panic disorder will have a negative medical workup.

ASSOCIATIONS

Panic disorder is closely associated with other psychiatric and medical conditions. Comorbid psychiatric disorders include depression in up to

TABLE 292-2 Symptoms of a Panic Attack

Somatic Symptoms	Cognitive Symptoms
Palpitations, pounding heart or tachycardia	Fear of losing control
Sweating	Fear of dying

Feeling dizzy, unsteady, lightheaded, or faint	
Paresthesias	
Chills or hot flashes	

50 to 65 percent, other mood disorders, substance abuse and dependence, other anxiety disorders, and personality disorders.⁵ Certain medical conditions have been associated with panic disorder but are unrelated to its etiology. Panic disorder has well-documented associations with mitral valve prolapse and asthma.⁵ Other medical conditions, such as idiopathic cardiomyopathy, hypertension, atypical chest pain without evidence of coronary artery disease, irritable bowel syndrome, chronic obstructive pulmonary disease, Parkinson disease, and migraine headaches, have been associated with panic attacks.¹⁷

COURSE

The course of panic disorder is variable in frequency and severity. Some patients suffer only intermittent attacks, whereas others have attacks almost continuously. In general, the course of the illness is chronic, with a pattern of waxing and waning. Panic disorder patients also can have situationally predisposed attacks when exposed to certain cues or triggers, limited symptom panic attacks in which fewer than 4 of the 13 recognized diagnostic somatic or cognitive symptoms occur, and nocturnal panic attacks. A 4- to 6-year follow-up study of patients from a tertiary care setting after treatment showed that 30 percent were asymptomatic, 40 to 50 percent were improved, and 20 to 30 percent remained the same or were worse.¹⁸ Lifetime rates of suicide attempts are similar for patients with uncomplicated panic disorder and uncomplicated major depression (7 and 7.9 percent, respectively), whereas rates for patients with comorbid panic disorder and depression were 19.5 percent.¹⁹

Patients with panic symptoms should always be asked about suicidal feelings. It is imperative that panic disorder be diagnosed and appropriately treated to prevent significant morbidity and mortality.

TREATMENT

Treatment of panic disorder starts with recognition of the illness. Balenger proposed that the following screening question be used in patients for rapid identification: "Have you experienced brief periods for seconds or minutes of an overwhelming panic or terror which was accompanied by racing heart, shortness of breath or dizziness?"²⁰ Once a diagnosis of panic disorder is made, the next step is to educate patients while providing reassurance that they are not dying or going crazy and emphasizing that it is an illness that can be treated effectively. Instruction on avoidance of triggers for panic attacks can reduce the long-term sequelae.²¹

Cognitive behavioral therapy (CBT) and pharmacotherapy are effective treatment modalities for panic disorder.²² Choice of treatment

is based on an individual assessment of risks, benefits, efficacy, availability, acuity, and patient preference. Cognitive behavioral therapy and pharmacotherapy, with the exception of benzodiazepines, take at least 4 weeks for most patients to notice significant benefit. If there is no improvement within 6 to 8 weeks of a particular treatment, often a different treatment is required or combined CBT and medication is used.

Cognitive Behavioral Treatment

Cognitive behavioral therapy involves education about the disorder, symptom and thought records, learning anxiety management skills (e.g., breathing retraining), changing cognitions associated with panic attacks (cognitive restructuring), and exposure (with response prevention) to feared situations, usually by using a hierarchy created by the patient and therapist.²²

Medications

Four classes of drugs have been found to be effective in treating panic disorder: selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants (TCAs), monoamine oxidase inhibitors (MAOIs), and benzodiazepines. Tables 292-3 through 292-6 list some of the advantages and disadvantages of each class. Drugs found to be ineffective include bupropion, Ludiomil, deprenyl, buspirone, **p** antagonists, and barbiturates.

ANTIDEPRESSANTS Antidepressants are considered by many to be the mainstay of treatment for panic disorder, because the potential complications of abuse, dependence, and withdrawal are not associated with their use. In addition, antidepressants may be beneficial in treating comorbid mood and anxiety disorders, including posttraumatic stress disorder and premenstrual dysphoric disorder. Due to safety considerations and side-effect profiles, SSRIs are considered the drugs of choice. Although sexual side effects may be problematic with these antidepressant classes, SSRIs lack the anticholinergic side effects, cardiovascular effects, and toxicity in overdose associated with TCAs or MAOIs.

When initiating treatment with SSRIs and TCAs, the starting dose should be lower than that used to treat depression, because panic disorder patients often are extremely sensitive to side effects. It is helpful to advise patients that they may temporarily notice some increased anxiety or activation when initiating treatment or increasing the dose. Patients also should be told that it might take several weeks before there are noticeable benefits.

Monoamine oxidase inhibitors are used much less frequently now and are reserved as second-line treatment due to the dietary restrictions and risk of hypertensive crisis.²² Reversible monoamine oxidase inhibitors, which do not require adherence to a tyramine-free diet, are effective for treating panic and phobic symptoms.^{23,24} However, reversible monoamine oxidase inhibitors are not currently approved for use in the United States.

TABLE 292-3 Selective Serotonin Reuptake Inhibitors

Advantages	Disadvantages
Single daily dose	Delayed onset
Antidepressant effects	Early anxiogenic effect
Safety	Sexual side effects
Benign side-effect profile	Requires dose titration
No abuse potential	
Effective	

TABLE 292-4 Tricyclic Antidepressants

Advantages	Disadvantages
Single daily dose	Delayed onset
Antidepressant effects	Anticholinergic effects
Well studied	Postural hypotension
Generics available	Sexual side effects
No abuse potential	Weight gain
Effective	Initial stimulation
	Dangerous in overdose

TABLE 292-6 Benzodiazepines

Advantages	Disadvantages
Rapid onset	Discontinuation reactions
Effective	Sedation
Well tolerated	Multiple daily dosing
General antianxiety effects	Abuse potential
Relatively safe in overdose	Fall risk
Generics available	Cognitive slowing risk
Tolerance rare for panic effects	Dose escalation by patient
	Disinhibition (paradoxical reaction) in some patients

BENZODIAZEPINES For patients in whom more rapid control of panic symptoms is necessary, such as those who are unable to fulfill expected major psychosocial obligations (work, school, etc.), benzodiazepines may be the drug of choice. Alprazolam has been the most extensively studied benzodiazepine and is currently the only one approved by the U.S. Food and Drug Administration for treatment of panic disorder. It may be initiated at a dose of 0.5 mg qid. In double-blind studies, alprazolam, in the 5- to 6-mg per d dosage range, reduced panic attack frequency, anticipatory anxiety, phobic avoidance, and disability.²² Studies suggested that diazepam, lorazepam, and clonazepam in equivalent doses also may be effective in treating panic disorder (i.e., clonazepam 0.25 to 0.5 mg by mouth twice daily, with most patients responding well to 1 to 3 mg per d).

Benzodiazepines also may be administered acutely for a patient who is having a panic attack, regardless of the etiology of the panic. These drugs should be used with caution in patients with a respiratory disorder or who have a history of substance abuse or dependence. Caution also should be used in the elderly in whom there is concern for falls, cognitive slowing, or drug interactions due to polypharmacy.

It may be beneficial to initiate treatment with an antidepressant and a benzodiazepine, with the goal to later taper or minimize the benzodiazepine dose as the antidepressant begins to control symptoms. Tapering is required, because abrupt withdrawal can lead to seizures or delirium. A controlled trial of alprazolam as an adjunct to imipramine during the first 4 to 6 weeks of treatment demonstrated that patients receiving both drugs have a more rapid therapeutic response.²⁵ However, 10 of 17 patients were unable to discontinue the alprazolam in 2 weeks after the treatment period. Thus, the benefits of a rapid response must be weighed against the risk of difficulty in discontinuing the benzodiazepine.

Selective serotonin reuptake inhibitors and CBT are currently the treatments of choice for panic disorder, whereas benzodiazepines are extremely effective for short-term relief.

Cognitive-behavioral therapy and pharmacologic treatment, with

the exception of benzodiazepines, take at least 4 weeks for most patients to notice significant benefit. If there is no improvement within 6 to 8 weeks of a particular treatment, often a different treatment is required, or combined CBT and medication is used. Acute treatment usually lasts at least 12 weeks. If medication is being used, often a taper and discontinuation is attempted after 1 year of maintenance treatment. It is unclear whether further CBT sessions ("booster sessions") are beneficial in prevention of relapse. Relapse is treated with CBT and/or medication.

DISPOSITION

Usually, treatment for panic disorder can be initiated in an outpatient setting. If a patient is already being treated for panic disorder, it is optimal to consult with the treating physician before initiating or changing medication. The clinician may wish to seek a psychiatric consultation while the patient is in the emergency department or refer the patient to the primary care physician or a psychiatrist for follow-up care.

Patients who are suicidal or who are so incapacitated that they cannot care for themselves require psychiatric hospitalization. In such cases, a psychiatric evaluation is necessary to determine the extent of dangerousness and need for inpatient treatment.

CONVERSION DISORDER

Gregory P. Moore Kenneth C. Jackimczyk

For a diagnosis of conversion disorder to be made, the following five criteria must be met:¹

1. A symptom is expressed in which there is a change or loss of physical function suggesting a physical disorder.
2. The patient has experienced a recent psychological stressor or conflict.
3. The patient unconsciously produces the symptom.
4. The symptom cannot be explained by a known organic etiology or culturally sanctioned response pattern.
5. The symptom is not limited to pain or sexual dysfunction.

PATHOPHYSIOLOGY

An illustrative example involves the case of a young wife who is scheduled to visit her debilitated father in the hospital. His recent diagnosis of cancer has left her distraught, and the sight of him depresses her greatly. On the morning of her visit, she suddenly becomes blind.

This example typifies a conversion disorder in which conflict is caused by the patient's intense, but psychically unacceptable, urge to avoid a required action (in this case, visiting her father). The physical symptom (blindness) allows expression of the urge (how can she drive there if she is blind?) without consciously confronting the feelings that led to the wish. At the same time, the symptom imposes morbidity as a punishment for the wish. Often, the presenting symptom will have a symbolic relationship to the conflict, but this is not always the case. In this case, the sight of her father is distressing, and therefore loss of sight is the chief complaint.

Conversion disorders are often thought of as nonverbal exertions of control on the environment. Two mechanisms are responsible for the symptoms. The first is *primary gain*, in which the symptom allows patients to avoid confronting their uncomfortable feelings. The second is *secondary gain*, in which uncomfortable situations are avoided and support is given that might not normally be available. In our example, secondary gain would occur if the patient's husband then stayed home from work to tend to his "blind" wife.

Conversion disorders are described as rare, with an annual incidence in outpatient psychiatric settings of 0.01 to 0.02 percent. An incidence of 5 to 16 percent among inpatients with psychiatric consultations has been noted. Most agree that the incidence is declining. Cases predominantly involve neurologic and orthopedic manifestations and are seen in the military during times of war, in victims of industrial accidents, and in victims of violence. Conversion disorders are much more frequent in women, accounting for up to 80 percent of cases in some series, than in men. The most common ages of presentation are adolescence or early childhood, although other age groups are affected. Conversion disorders are more prevalent in rural, lower socioeconomic, and less educated populations. Other predisposing factors include medical illness, depression, anxiety, schizophrenia, somatization disorder, dependent personality disorder (5 to 21 percent of patients), borderline personality disorder, and passive aggressive personality disorder.^{2,3}

CLINICAL FEATURES

Conversion disorders usually present as a single symptom with a sudden onset related to a severe stress. Precise history taking should focus on how the problem affects the patient and the surrounding events at time of onset. It may be necessary to interview the patient and family separately to confirm diagnostic suspicions. The most reliable diagnostic criterion for conversion disorder is a history of the disorder or a somatization disorder (each found in one-third of cases). Symptoms may vary in cases of recurrence.^{2,4} Motor complaints, usually involving voluntary muscles, are more common than sensory complaints.^{2,4}

Classic symptoms of conversion disorders include paralysis, aphonia, seizures, coordination disturbances, akinesia, dyskinesia, blindness, tunnel vision, anosmia, anesthesia, and paresthesia. Pseudo-seizures represent 10 to 40 percent of conversion disorders referred to psychiatrists. Patients may describe their condition with surprising lack of concern, considering the severity of the symptom (*la belle indifférence*). This was previously thought to be a hallmark of the disorder, but it is absent in about half of cases and is found just as often in patients with organic disease. It is no longer considered diagnostic.^{2,5}

Diagnosis is made first and foremost by ruling out organic pathology. Absence of a medical condition does not necessarily support the diagnosis of conversion disorder, because the appropriate psychological criteria also must be met. Suspicion for the disorder should arise when no physical findings related to the symptom are found or the examination is not consistent with known anatomic or pathophysiologic states. Several techniques that can be used in the physical examination are helpful in testing for true neurologic deficits (Table 293-1). Appropriate laboratory and ancillary studies should be ordered to confirm suspected organic disease. However, it is important to remember that organic disease may be present concurrently with conversion disorder.⁶

DIFFERENTIAL DIAGNOSIS

Careful history taking and physical examination should be used to rule out neurologic disease. A high index of suspicion should be maintained for physical disorders that have a vague onset, such as systemic lupus erythematosus, multiple sclerosis, polymyositis, Lyme disease, and drug toxicity or poisoning. Schizophrenia and depression may have associated conversion disorders. In somatization disorders, the symptoms are more chronic and involve multiple organ systems. With

TABLE 293-1 Physical Examination Techniques Used to Distinguish True Neurologic Deficits and Conversion Disorder

Function	Technique
Sensation	
Yes–no test	Patient closes eyes and responds <i>yes</i> or <i>no</i> to touch stimulus. <i>No</i> response in numb area favors conversion disorder.
Bowlus and Currier test	Patient extends crossed arms with thumbs pointed down and palms facing together. Fingers (but no thumbs) are interlocked, and then hands are rotated inward toward chest. The distortion of body position makes false responses to sensory stimuli difficult.
Strength test	Patient closes eyes. Test “strength” by touching finger to be moved. True lack of sensation would not allow patient to ascertain finger to be moved.
Pain	
Gray test	With abdominal pain due to psychological factors, the patient will close eyes during palpation. In pain of organic basis, the patient is more likely to watch the examiner’s hand to anticipate pain.
Motor	
Drop test	When a patient with paralysis of nonorganic etiology lifts a thumb, the affected limb will drop more slowly or fall with exaggerated speed as compared with the unaffected limb. In addition, an extremity dropped from above the face will miss it.
Stretch reflex test	Patient contracts a muscle at maximum strength while counteraction is provided. The examiner suddenly jerks the muscle into extension. This will produce a stretch reflex that reveals the patient’s true muscle strength.
Thigh adductor test	Examiner places hands against the inner thighs of the patient who is told to adduct the normal leg against resistance. With pseudoparalysis, the other leg will adduct.
Hoover test	Examiner’s hands cup both heels of the patient who is asked to elevate the normal leg. With pseudoparalysis the other leg will push downward. Absence of downward pressure of the normal leg when the patient is instructed to lift the weak leg indicates noncompliance.
Sternomastoid test	Patient with conversion hemiplegia cannot turn head to the weak side.
Coma	
Corneal reflex	Corneal reflexes remain intact in an awake patient.
Bell phenomenon	Eyes divert upward when lids are opened, whereas eyes remain in neutral position in true coma.
Lid closing	In true coma, lids when opened close rapidly initially and then more slowly as lids descend. Awake patients will have lids stay open, snap shut, or flutter.
Seizures	
Corneal reflex	Usually intact in pseudoseizure.
Abdominal musculature	Palpation of abdominal musculature reveals lack of contractions with pseudoseizure.
Blindness	
Opticokinetic drum	Rotating drum with alternating black and white stripes or piece of tape with alternating black and white sections pulled laterally in front of a patient’s open eyes will produce nystagmus in a patient with intact vision.

hypochondriasis, patients are usually without loss of function and display the conviction that some terrible undiscovered illness is present. Hypochondriacal patients will be overly concerned with symptoms. In cases of factitious symptoms, usually associated with malingering, patients will consciously complain about symptoms to get out of an undesirable duty or to receive sympathy or undeserved compensation. Such patients rarely have neurologic complaints. Amobarbital interviews have been used to diagnose conversion disorder and coexisting diagnoses. The interviews also may be therapeutic.⁷

TREATMENT AND PROGNOSIS

The patient is devoid of insight that the symptoms have no organic cause. Confronting the patient and insisting that nothing “real” is wrong is not helpful in alleviating symptoms and may worsen the patient’s condition. The symptoms should be neither trivialized nor reinforced. If the precipitating factor is identified, correction of the situation should be attempted. Meanwhile, the patient should receive reassurance that no serious medical problem has been identified. If the results of initial testing and the examination are negative, it should be suggested to the patient that the symptoms will resolve. Nonspecific supportive therapy should be prescribed. For instance, in the example cited at the beginning of this chapter, it could be suggested that the patient visit her father less often, call daily instead, and have her husband accompany her to the hospital. She should expect the blindness to resolve if she follows this course.²⁸

Referral is mandatory. Patients with conversion disorders may need repetitive reassurance and suggestions that symptoms will resolve before returning to full function. Periodic follow-up is also important to monitor for subtle organic disease. Between 25 and 50 percent of patients diagnosed with conversion disorders later develop serious organic conditions.²⁹ A recent study of 85 patients with a diagnosis of conversion disorder found that 12 percent had a neurologic problem.¹⁰ Factors that increased the likelihood of an organic etiology were older age, longer symptoms, suspicion of a neurologic problem, and use of medication.¹⁰ Other investigators, in reporting six cases of severe neurologic pathology in patients diagnosed as having conversion disorder, highlighted six errors in evaluation of conversion disorder patients (Table 293-2).¹¹ Use of magnetic resonance imaging led to the correct diagnosis in five of those cases.¹¹ Most conversion disorders are brief and quickly resolve. Favorable prognostic factors are lack of other psychiatric disorders, sudden severe stress as a precipitating cause, and absence of medical problems. Some cases are resistant and require hypnosis or amobarbital interview for resolution. The interview should be coordinated by the primary care provider. Lorazepam has been found to be helpful in the management of this condition. Approximately 25 percent of patients will have another episode over the ensuing 1 to 6 years, which may involve the same or a new symptom complex.²⁹

Some patients develop a chronic form of the disorder with complications, including contractures and atrophy of muscle groups. In addition, unnecessary diagnostic tests may lead to iatrogenic complications.

TABLE 293-2 Errors and Cautions in the Diagnosis of Conversion Disorders**Errors**

- A finding in the evaluation is "unbelievable"
- A finding has "never been seen before" by the examiner
- A finding is nonanatomic
- The examination is inconsistent, effort is poor, classic feigning signs are present (see Table 293-1) The patient exhibits *la belle indifférence* There is an "obvious" psychological explanation
- Cautions**
 - Neurologic symptoms can be bizarre
 - A physician's "neurologic clinical experience" may be limited A physician may be unfamiliar with true anatomic pathology There are many reasons for inconsistent effort, including neurologic pathology and examiner input *La belle indifférence* may be the expression of neurologic problems or due simply to individual variation Physicians often fall into the trap of jumping to a psychological explanation for a confusing entity

NOTIFYING THE LIVING OF DEATH

James Brown Glenn
Hamilton

Of the 90+ million ED visits in 1995, a total of 339,000 (0.4 percent) deaths occurred in the department.¹ The timing and nature of death are often unexpected and traumatic to the survivors. In one study, 65 percent of ED deaths were considered unexpected versus 7 percent of inpatient deaths. Compounding this difficult, acute situation is the fact that the ED staff generally have no prior relationship with the patient or the family.

Death notification training is deficient throughout medical education. Medical students question how well they are prepared to tell a family about death. One-half of emergency physicians report training in death notification during medical school and only one-third during

residency. Seventy percent of ED physicians find death notification to be emotionally draining. Without proper training, this role is even more difficult.² Educational programs involving videotaping of death notifications and role playing can assist physicians in developing the necessary skills.^{3,4} The ED staff can become desensitized or preoccupied with moving on to the living patients who are waiting. One-fourth of families describe the ED staff as cold, unsympathetic, and not reassuring.⁵

PREPARING FOR NOTIFICATION

An organized approach is essential (Table 294-1). A secluded area close to the ED should be available for the family and friends. This area should include a telephone with long-distance access to allow the contact of relatives and friends. If the family arrives while resuscitation efforts are continuing, a physician or trained member of the hospital staff should inform them of the resuscitation and its progress. Families who wish to be present at the resuscitation should be allowed to be (see below, and Chap. 17). Updates should be given frequently (every 5 to 10 min) until the effort concludes.⁶ Sharing information and empathy during this time allows family members to become knowledgeably prepared for the potential outcome.

After leaving the resuscitation room, the physician must mentally "change gears" within 15 to 30 s. It is important to collect one's thoughts and organize the presentation. If clothing is soiled, it should be changed before the notification. An appropriate amount of time for family discussion is allotted. Other tasks in the department are delegated to others, or families are informed of the reason for delay. Advance information about which family members are present and their preparation is obtained whenever possible. It is best not to go alone. If clergy or social services support is not present or will not be available in a timely fashion, the nursing staff can be enlisted.

TELLING THE SURVIVORS

It is the physician's responsibility to inform family members of the death.⁷ Upon entering the room, the physician should introduce the team to the patient's family. The leading family member is identified, and all parties, including the physician, are seated, if possible. Sitting minimizes the chance of trauma occurring from fainting or falling and signals the family that the physician will remain as long as necessary. The deceased should be addressed by name. The family is then given a very brief summary of the patient's response to treatment, if any. This should be done in plain language, without medical jargon. Providing unnecessary or lengthy detail before announcing the death can rouse false hopes and cause extreme anxiety.

After these few brief phrases, the family is told that the patient has died and sympathy is expressed. To avoid confusion, terms such as *passed on* or *no longer with us* should not be used. Once the initial statement is made, allow a brief period for the initial grief response (30 to 60 s). The physician may give physical comfort to the family if the physician is comfortable doing so.

After the initial pause, asking the most stable survivor for a perception of the event allows the initial presentation of information to conclude. Families may receive some comfort from statements that the patient suffered no pain (if appropriate) and that everything possible was done. They are told that the coroner or medical examiner and their private physician will be contacted. They are also told that the physician will return to answer any questions they may have.⁸

GRIEF REACTION

Individual responses to the death of a loved one vary greatly. The initial response has been described as a "psychic pain spike." It lasts only a brief period, usually 5 to 15 min. During this period, the family can make no decisions. Once this period of acute grief has ended, the fam-

TABLE 294-1 Sequence of Events

Preparation	Private area or room is prepared. The family is gathered. The family advised of ongoing efforts, if any. Social services or the chaplain is contacted. The physician prepares mentally and physically.
Notification	Introduce yourself and identify family members. Sit down with the family. Give a brief synopsis of events to date.. Tell the family that the patient has died.
Grief response	Give physical comfort, if able. Do not move away. After the initial response, ask a question about the patient. Reassure the family that no suffering was involved, if appropriate. Support other physicians and emergency medical service personnel when possible. Stand up. Advise the family that you will contact the family physician and coroner. Leave the room.
Viewing the body	Allow the family to view the deceased. Do not force a viewing. The body is prepared before viewing. A staff member accompanies family.
Concluding process	Express condolences. Ask family members whether they have questions. Inquire about an autopsy and organ donation. Sign papers. Identify those at risk for pathologic grief. Avoid prescribing sedatives. Arrange follow-up as appropriate. Tell the family when to leave.

Sources: Hamilton GC: Sudden death in the ED: Telling the living. *Ann Emerg Med* 17:382, 1988; Walters DT: Family grief in the emergency department. *Emerg Med Clin North Am* 9:189, 1991.

ily members will progress through other reactions: denial, anger, and/or guilt.⁹

Denial may be expressed as disbelief. The family may insist on viewing the deceased, and this should be done when possible.⁹ Denial may be a protective mechanism, giving the mind time to absorb the situation. It is accepted and tolerated patiently, allowing the bereaved some time to adjust.

Anger may be directed at the physician or staff. Accusations of negligence or statements about what should have been done may be made. Although difficult to accept, the physician must see these as expressions of grief. This anger is often misplaced guilt at causing or failing to prevent the death. Unconscious frustration with the deceased for abandoning the bereaved can find its outlet in anger directed at others. A defensive posture on the part of the physician is counterproductive. Reflecting the family members' feelings back to them and not taking the outbursts personally is the best response. Eventually the anger will dissipate, allowing the family to move on with their grief. The physician's handling of this immediate response is an important step in facilitating grief.

Guilt is nearly universal. There may be issues between the deceased and the bereaved that can no longer be resolved. It is important to intercept the survivor's self-accusations and to address the components of the survivor's guilt when possible. Exoneration by the physician can be very comforting.

The emotional response depends on the cultural background of the bereaved. Responses vary from hysterical crying to cold distraction. Regardless of the initial response, the bereaved must be allowed to express their feelings. The physician's response to these expressions is one of calm and silence. If possible, gently touching the bereaved can be more important than any words. Cliches such as "It's God's will" or "Life must go on" should be avoided.⁹

Normal grieving lasts 6 to 8 months. Physical symptoms include headache, irritability, fatigue, insomnia, restlessness, dyspnea, or anorexia. Emotional symptoms include guilt, denial, anger, depression, difficulty concentrating, lack of organization, and preoccupation with the deceased. These symptoms become pathologic grief if they persist over a prolonged period or with heightened intensity. Other manifestations of pathologic grief may include an exacerbating or remitting pattern of grief or signs of physical disability. Pathologic grief can be seen with multiple symptoms, including apathy, panic attacks, overactivity, hostility with paranoia, suppression of hostility with resultant flat affect, depression, or symptoms resembling those of the deceased.

Recognition of survivors at risk for or manifesting pathologic grief allows for early intervention. Risk factors for pathologic grief include sudden or unexpected death; death of an infant, child, or spouse; death involving suicide or homicide; or death where the survivor contributed to it. A surviving spouse with children may not have time to mourn appropriately. Those spouses with a high-conflict relationship, long duration of marriage, or a dependent relationship on the deceased are

particularly at risk. In the 2 years after losing a spouse older than 50 years, the risk of the survivor dying is increased over fourfold.

Physicians may be asked to provide sedatives, tranquilizers, or sleeping medications for the bereaved. The grieving process requires active work on the part of the bereaved. The survivors must learn to adjust to the absence of the deceased, form new relationships, and live in their environment without their loved one. This process is delayed by tranquilizing medications. Their use is to be avoided except in cases of pathologic grief and then only as part of comprehensive psychotherapy. Requests for medication should be countered with empathy and reassurance.

VIEWING THE BODY

After the initial grief reaction, the family should be offered an opportunity to view the body of the deceased, without pressuring them to do so. Failure to view the body may prolong the process by not permitting the survivors to believe the person is really dead. Whereas most find viewing the body to be a helpful experience, those who do not express no regret about their decision.⁵

The body is prepared before viewing. Blood and body secretions are cleaned off. The eyes are closed, and the body is covered except for the hands and face. If permitted by the circumstances and local protocol, tubes and catheters are removed. If disfigurement has occurred, these areas are bandaged. The family is warned about the temperature and color changes of the deceased. The body is placed in a smaller room, away from the treatment area, to give the mourners more privacy. The physician, clergy, or nursing staff accompanies the family to provide support or answer questions. The family is encouraged to speak to and touch the deceased, if they wish. A family member may wish to be alone with the deceased. This is permitted in appropriate circumstances; a staff member should remain close by for support. The deceased should be referred to by name or "him" or "her" and never by "it" or "the body."^{7,9}

CONCLUDING PROCESS

Even after the family has an opportunity to view the body, several important processes remain. Now is the time to make requests for autopsy and organ donation. Any signing of papers is done at this time, and copies are given to the family. Any further questions are addressed at this time. Arrangements for funeral home and release of the body are made. The family is told that the patient's private physician will be contacted.⁷ The physician and staff should be sympathetic but not apologetic. Families may misinterpret such expressions as an admission of guilt. Expressions such as, "You have my sympathy," or "I know this is very hard for you," are superior to, "I'm sorry."⁷

As in any other emergency encounter, follow-up arrangements conclude the visit. The survivors are educated about common grief symptoms. They are told to expect these as a normal part of grieving. At the

minimum, the family should have the name and number of a staff member who can provide further information or answer questions that may arise.⁷ Most researchers recommend a follow-up phone call or letter within 1 week and again in 2 months. One facility has established a program in which the staff sends a sympathy card, phone calls are made periodically during the year after the death, and the attending physician sends a letter explaining the autopsy findings.²

Finally, the family is told that it is time to leave. Survivors are frequently so overwhelmed with events that they do not know when to leave. They are escorted to the door and again given reassurance. Suggestions are made about contacting other friends or family for notification and funeral preparations.

SPECIAL CONSIDERATIONS

Long-Distance Notification

Telephone death notification is never ideal. If the survivors have not been notified of their family member's arrival in the ED, then initiate telephone contact. The caller should identify him- or herself and establish the identity of the survivor. The survivor is told that the relative or friend is severely injured or ill and that he or she must come to the hospital immediately. Instruct the survivor to drive carefully.⁹

There are times when distance, environmental, or other factors make physical notification inadvisable. One study showed that many survivors prefer to be notified by telephone if the driving time exceeded 1 h. Notification should not be rushed but should proceed in the same fashion as if done in person. The notification should not be forced; if the family member seems unprepared, offer to speak with another family member in the home or another relative. After the notification is made, if the survivor is alone, offer to contact some supporting person. If the survivor appears suicidal, local police may need to be contacted. If no adult is present, ask the oldest child how to contact an adult relative. Assure the child that an adult will be in contact shortly. Depending on the circumstances (distance, time of day, weather), the survivor should be instructed to come to the hospital driven by some supporter.

Coroner's Cases

In most states, the coroner and/or medical examiner has the responsibility to investigate the cause of death within a particular jurisdiction. Cases the medical examiner may choose for further investigation include those of a sudden, mysterious, unusual, or unnatural nature. Deaths with a possible public health danger, deaths in police custody or in prison, or violent death (including those resulting from motor vehicle crashes) are also cases for the medical examiner. Autopsy is usually performed in these cases, and the family is informed. Organ donation may still be possible, in consultation with the medical examiner.⁷ Before viewing of the body by the family, resuscitative lines and tubes must be left in place. Except in very unusual circumstances, such as homicide, the viewing of the deceased can take place.

Autopsy

Autopsy rates have continued to decline in the United States, for a number of reasons. The Joint Commission on Accreditation of Hospitals eliminated its minimum autopsy rate of 20 percent in 1971.

Findings from autopsies can clarify premortem diagnoses or aid in the diagnosis of new diseases. Autopsies can assist in the grieving process by demonstrating to the family that they did not contribute to the death. Despite physicians' fears that the autopsy will lead to increased liability exposure, postmortem examinations are used more often as a defense.

Public misperceptions concerning autopsy abound. Some of the misperceptions are that diagnostic tests are infallible; autopsy disturbs

the patient's "peace"; bodily mutilation occurs; funeral arrangements will be delayed; it is too late to accomplish anything positive; there are religious prohibitions; the family never gets the results; and if an autopsy is necessary, one will be requested.

The most senior physician involved with the case should approach the family with the request for autopsy. Specific points to be discussed include that the autopsy is done by specialists in pathology (an analogy to surgery may be helpful); specific determination of cause of death may help to dispel any doubt the family has; funeral arrangements will not be disturbed; and no mutilation occurs. If the family is concerned about religious prohibitions, they can be reassured that autopsy is not prohibited by most major religions and can be encouraged to consult with the chaplain. The physician requesting the autopsy must be aware of local and institutional policies regarding billing and payment for autopsies. Many teaching institutions consider the autopsy as part of comprehensive care and do not submit a charge. However, there is great variation in policies in community, state, and municipal hospitals, and insurance policies may not pay for an autopsy, so the patient's family should be informed about possible costs when they make their decision.⁷

Organ Donation

Although actually harvesting organs in the ED is a rare event, many organs can be harvested up to 24 h after death, if the body is refrigerated within 4 h of death. These harvestable organs include tissues such as cornea, bone, skin, tendon, fascia, cartilage, saphenous vein, and heart valves. Contraindications to donation include age older than 80 years, death from infectious disease, cancer (although corneas may still be donated), or toxic exposure.¹⁰ Organs have been harvested successfully despite fatal exposures to cocaine, ethanol, carbon monoxide, lead, and barbiturates. Consultation with a toxicologist is recommended in these circumstances.^{7,11}

There are several barriers to tissue procurement in the ED. One study showed that only 43 percent of families were approached, with a successful donation rate of 12 percent. Reasons given for not approaching families included a coroner's investigation (35 percent), family not available (20 percent), family too upset (18 percent), deceased medically unsuitable (14 percent), and no patient identification (12 percent). Time constraints are another barrier to successfully obtaining donation. Limited time to develop rapport with families and to allow them to come to terms with the death, along with a busy staff, have been cited as reasons for unsuccessful donation efforts.¹⁰

The appropriate time to make a request for organ donation is after the family has viewed the body. At this point, an interval has occurred from the actual notification, and the bereaved have had time to come to accept the death as real. A premature request for organ donation may leave the family with doubts about the resuscitative efforts. The family is informed that they are not charged for any procedures related to the donation and that no alteration in the appearance of the deceased occurs.

Viewing Resuscitation
