The fractional excretion of sodium ($Fe_{Na} = U_{Na}/P_{Na} \cdot r U_{Cr}/P_{Cr}$) is another test that is commonly used to identify hypovolemia as the cause of ARF, but it has a few limitations. For example, in the setting of intrinsic renal failure in which tubular concentrating capacity is retained, as in the case of glomerulonephritis, the Fe_{Na} may be depressed, just as it will be in the setting of normal kidneys under a prerenal stress. In the setting of tubular injury, such as ischemic or toxic ATN the loss of concentrating ability results in a dilute urine, with an Fe_{Na} above 1 percent (Table 92-7).

Microscopic examination of urine is very useful in establishing the differential diagnosis of ARF (Table 92-7). In the setting of acute glomerulonephritis, red blood cells enter the filtrate at the glomerulus and, on the urinalysis, appear as casts and dysmorphic cells due to the increased tonicity of the renal medulla. In the setting of ATN, the tubular epithelium breaks down and there is significant protein leak into the filtrate and tubular epithelial cells in the sediment.

Cast formation is a common feature in many causes of ARF, and the composition of the casts offers clues to the cause. Hyaline casts are common in prerenal failure, whereas pigmented granular casts are common with ischemic or toxic tubular injury. Brown granular casts are a common finding in the setting of pigment nephropathy (e.g., hemoglobin or myoglobinuria). Crystals may be seen on conventional urinalysis but are best seen with polarized light microscopy. An "active sediment," with red cell casts and proteinuria, should prompt investigation of a primary glomerulonephritis or some underlying autoimmune disease.

Renal Biopsy

Renal biopsy should be considered in all causes of intrinsic ARE, especially in the estimated 10 to 25 percent of patients with ARP in whom the cause cannot be clinically diagnosed. Retrospective studies have shown that the results of the renal biopsy significantly changed the diagnosis and management of ARF in 40 percent of cases. The most common complication of renal biopsy is hematuria, which occurs in almost all patients. Serious complications, defined as the need for blood transfusion, nephrectomy, puncture of other organs, or perinephric hematomas, occur at a rate of 2 percent. Overall mortality for renal biopsy is 0.1 percent.

TREATMENT

Fluid Administration

Patients with ARF present challenging fluid-management problems. Hypovolemia potentiates and exacerbates all forms of ARF. The reversal of hypovolemia by rapid fluid infusion is often sufficient to treat and/or ameliorate many forms of ARF, but rapid fluid infusion can result in life-threatening fluid overload in patients with ARF. Accurate determination of these patients' volume status is essential and often requires invasive hemodynamic monitoring, particularly in the setting of cardiac dysfunction. Crystalloids are the resuscitation fluid of choice, and, among colloids, albumin should specifically be avoided, because of the possibility of additive renal injury.¹⁴

Medications

Because patients with nonoliguric as opposed to oliguric ARF have improved mortality and renal function recovery rates, many investigators recommend diuretics in an effort to "convert" oliguric to nonoliguric ARF. However, randomized double-blind controlled trials have failed to show a benefit in administering diuretics to patients with ARF.¹⁵ These studies concluded that diuretics are useful only in the management of volume-overloaded patients, a setting in which venodilators and dialysis may be more effective. The prevalence of prerenal physiology in the ED and the association of high-dose furosemide with long-term hearing deficits also should be considered before using diuretics.

Renal vascular vasodilators in ARF have theoretical and experimental support. Low ("renal")-dose dopamine (1 to 5 μ g/kg per min) was widely used for many years to treat ARF. In this setting, dopamine does increase urine output, but there is no evidence that dopamine

TABLE 92-7 Urine Findings in Conditions That Cause Acute Renal Failure

Condition	Dipstick Test	Sediment Analysis	Urine Osmolality (mOsm/kg)	Fractional Excretion of Sodium (%)
Prerenal azotemia	Trace to no proteinuria	A few hyaline casts possible	>500	<1
Renal azotemia				
Tubular injury				
Ischemia	Mild to moderate proteinuria	Pigmented granular casts	<350	>1
Nephrotoxins	Mild to moderate proteinuria	Pigmented granular casts	<350	
Acute interstitial nephritis	Mild to moderate proteinuria; hemoglobin, leukocytes	White cells and white cell casts	>1 <350 >1	
Acute glomerulonephritis	Moderate to severe proteinuria; hemoglobin	casts; eosinophils and eosinophil casts; red cells		
Postrenal azotemia	Trace to no proteinuria; can have hemoglobin and leukocytes	Red cells and red cell casts; red cells can be dysmorphic Crystals, red cells, and white cells possible	>500 <350 >1	<1

produces a significant improvement in either renal recovery or mortality.¹⁶ Dopamine is pro-arrhythmic, and its diuretic effect may come at the cost of increased medullary oxygen consumption without increased oxygen delivery.

In animal models, calcium channel blockers are protective against ARF if given before the renal insult. In humans, their major benefit has been in preventing ARF in renal transplant patients taking cyclosporine, but they have not found wider use.

There are no controlled studies of mannitol showing benefit in patients with established ARF. In fact, mannitol, given in high doses, has been identified as a cause of ARF. There are also significant risks of fluid overload and hyperkalemia associated with administering large doses of mannitol to ARF patients.

In the setting of pigment nephropathy (myoglobinuric ARF), early large-volume crystalloid infusion is the cornerstone of treatment. Mannitol is also routinely recommended in this setting, in which it may have rheologic and dilutional effects. Sodium bicarbonate dosed to accomplish urine alkalization is also recommended. Tubular acidosis has been shown to be a potent cofactor in the tubular toxicity of myoglobin.

Urinary pH plays an important role in most drug-associated crystal nephropathies, and alkalization is used for some of them. Even though some crystal nephropathies theoretically could benefit from urine acidification, the risks associated with acid infusion outweigh its benefit, even in this setting. Volume resuscitation and discontinuation of any offending medication are most important.

Several interventions have been shown to be useful in the prevention of radiocontrast nephropathy. Acetylcysteine reduced the rate of ARF in a high-risk population, from 21 to 2 percent.¹⁷ Fenoldopam reduced the incidence of ARF by almost half in patients with CRI undergoing angiography.¹⁸ Crystalloid infusion also may reduce the risk of this common complication of radiocontrast administration.

Although there has been no demonstration that interventions directed toward prevention or arrest of the pathophysiology of ischemic ATN improve outcomes, growing understanding of these mechanisms continues to increase the hope that such interventions will soon be available. Strategies directed toward interrupting the ischemic or inflammatory cascade at multiple steps may prove more effective than more focused interventions. Specific strategies may include arginine-glycine-aspartic acid peptides, antioxidants, phosphodiesterase inhibitors, growth factors, adenosine receptor antagonists, and targeting of cell-to-cell adhesion molecules.

Renal Replacement Therapy

The advent of renal replacement therapy (RRT) has had a significant impact on the treatment of life-threatening fluid and electrolyte complications of ARF. It is not clear, however, whether it plays a role in renal recovery, whether the timing of initiation affects outcome, or which of several methods is best in ARF. In recognition of the fact that there is little evidence on which to base guidelines regarding RRT in ARF, several notable contributors to this literature started the Acute Dialysis Quality Initiative in 2000 to guide future research and develop evidence-based practice guidelines.

The principal methods of RRT are intermittent hemodialysis (IHD), continuous venovenous hemofiltration (CVVH), and peritoneal dialysis. Each has advantages and limitations. Intermittent hemodialysis is widely available, has only moderate technical difficulty, and is the most efficient way of removing volume or solute from the vascular compartment quickly. Unfortunately, dialysis-associated hypotension may adversely affect remaining renal function, particularly in the critically ill. Continuous venovenous hemofiltration is more expensive and not universally available but, in addition to avoiding hypotension, is believed to achieve better control of uremia and clearance of solute from the extravascular compartment. Because it continues around the clock, CWH is able to remove larger fluid vol-

umes, which is a significant advantage with critical care patients on parenteral nutrition and multiple infusions. Continuous venovenous hemofiltration also may better preserve cerebral perfusion pressure. A theoretical but contested advantage of CVVH is the clearance of mediators of the inflammatory cascade. Several studies have sought to directly compare CVVH with IHD; none has found a convincing advantage for one therapy over the other. Nevertheless, many authorities assert that the choice of IHD over CVVH in the setting of shock would be inappropriate and unethical. Peritoneal dialysis is inexpensive, widely available, and does not result in hypotension. However, it cannot remove large volumes of fluid or solute. Its use may be most common in children.

Indications for and timing of initiation of RRT are also important, if somewhat controversial, subjects. Widely accepted indications for initiation of RRT include volume overload, hyperkalemia ($K^+ > 6.5$ or rising), acid-base imbalance, "symptomatic uremia" (pericarditis, encephalopathy, bleeding dyscrasia, nausea, vomiting, or pruritus), uremia (BUN > 100), and dialyzable intoxications. Severe dysnatremia (<115 or > 165) and dysthermia also may be appropriate indications for RRT. Significant intoxications with a dialyzable agent (e.g., methanol, ethylene glycol, theophylline, aspirin, and lithium) may be the strongest indication for emergent dialysis, because there are other effective temporizing therapeutic interventions for most other complications of ARF. Volume overload can be treated with nitrates and phlebotomy; hyperkalemia can be treated with calcium, insulin, glucose, bicarbonate, binding resins, and (3-adrenergic agonists).

The timing of initiation of RRT in the absence of these indications is more controversial, although there may be growing consensus that RRT itself contributes to the resolution of ARF. Intensity of RRT is another area of active controversy and research; two recent studies have suggested that more is better. In a study of CVVH intensity in which patients with ARF were randomized to standard or supernormal levels of ultrafiltration, the patients with more intense RRT had significantly lower mortality.¹⁹ Another randomized trial compared daily with traditional every-other-day IHD in ARF patients and found that mortality (28 vs. 46 percent) and speed of renal recovery (9 vs. 16 days) were significantly improved.²⁰

DISPOSITION

Patients with ARF require admission to the hospital, often to an intensive care setting, where their fluid and medical management can be monitored on an hour-to-hour basis. An appropriate specialist (nephrologist, intensive care specialist, or internist) should be consulted early.

deaths, with malignancy accounting for another 1 to 4 percent. Approximately 20 percent of dialysis patients withdraw from therapy before death. Patients older than 65 years have the highest withdrawal rate (25 percent). The increasing incidence of withdrawal with age is linked to progressive severity of comorbid conditions affecting patients' quality of life on RRT.

PATHOPHYSIOLOGY OF UREMIA

In 1840, Piorry was the first to use the term *uremia*, contamination of the blood with urine, to describe the clinical syndrome from ESRD. The concept that uremia is from an excretory failure resulting in toxin accumulation is reinforced by the continued use of the term *azotemia*, the buildup of blood nitrogen.

Excretory Failure

Excretory failure leads to elevated levels of more than 70 chemicals in uremic plasma, leading to the hypothesis that these toxins, individually or in combination, cause uremic organ dysfunction and produce the symptoms of uremia. For more than 100 years, limiting protein intake markedly has been noted to improve the symptoms of uremia. Urea, the major break-down product of proteins, reproduces a few of the neurobehavioral uremic symptoms, but only at very high concentrations. Other potential uremic toxins include cyanate, guanidine, polyamines, and p₂-microglobulin.

Although toxins from ESRD excretory failure are definitely a factor in uremia, they cannot explain all its clinical features. In addition, if uremia were simply a toxidrome, then dialysis would reverse all its untoward effects. Because many uremic organ dysfunctions persist after dialysis, other processes are clearly important.

Biosynthetic Failure

Biosynthetic failure refers to the aspects of uremia from loss of the renal hormones 1,25(OH)₃ vitamin D₃ and erythropoietin. The kidneys are primarily responsible for the secretion of erythropoietin and 1- α -hydroxylase, which is necessary to produce the active form of vitamin D₃. Because 85 percent of erythropoietin is produced in the kidneys, ESRD patients have depressed levels, thereby contributing to anemia. Vitamin D₃ deficiency results in decreased gastrointestinal (GI) calcium absorption, thereby inducing secondary hyperparathyroidism, which is responsible for the development of renal bone disease.

Regulatory Failure

Regulatory failure results in an over-secretion of hormones, leading to uremia by disruption of normal feedback mechanisms after renal failure. In response to the accumulation of ions and other waste products with ESRD, the maintenance of internal homeostasis depends on a variety of extrarenal processes. These homeostatic responses, although adaptive to one toxin, may have untoward effects outside the system they are attempting to regulate. The "tradeoff" hypothesis, first proposed by Bricker,² was initially postulated to explain how hyperparathyroidism in ESRD was a tradeoff for the beneficial effects of high parathyroid hormone (PTH) levels on controlling phosphate levels. The tradeoff for the maintenance of normal calcium and phosphate levels is hyperparathyroidism, which causes increased bone turnover and leads to renal bone disease. Bricker extended this tradeoff hypothesis to sodium regulation in ESRD. As the glomerular filtration rate (GFR) decreases in ESRD patients, increasing fractional sodium excretion prevents salt retention. Bricker postulated that the tradeoff for this natriuretic factor is a generalized inhibition of sodium transport, which explains many aspects of uremic organ dysfunction.

Although Bricker's tradeoff hypothesis is still controversial, sodium transport abnormalities have been well documented in uremia.

93 EMERGENCIES IN RENAL FAILURE AND DIALYSIS PATIENTS Richard Sinert Mark Spektor

End-stage renal disease (ESRD) is the irreversible loss of renal function, resulting in the accumulation of toxins and the loss of internal homeostasis. Uremia, the clinical syndrome resulting from ESRD, is universally fatal without some form of renal replacement therapy (RRT). At present, RRT consists of two basic modalities: renal transplant and dialysis therapy. This chapter discusses the pathophysiology and clinical features of uremia and the specific techniques and complications related to hemodialysis (HD) and peritoneal dialysis (PD).

EPIDEMIOLOGY

The 2001 annual report of the United States Renal Data System (USRDS) noted that, for 1999, there were 89,252 new cases of ESRD, with 424,179 patients being treated for ESRD.¹ End-stage renal disease is a disease of the elderly, with patients older than age 65 years comprising 47.9 percent of new cases of ESRD and accounting for 37.2 percent of all living patients with ESRD. Diabetes mellitus is the most common disease (42.8 percent) responsible for ESRD, followed by hypertension (25.9 percent), glomerulonephritis (9.0 percent), cystic kidney disease (2.3 percent), and other causes (20.0 percent). The USRDS projects a 6 to 7 percent growth per year in the incidence of ESRD. An expanding incidence and life span will result in an expected increasing prevalence of ESRD of 8 to 9 percent per year.

The use of RRT for ESRD is divided into 70.1 percent on dialysis therapy and 29.9 percent with renal transplants. Of the patients on dialysis, 89 percent are on HD and 11 percent are on PD. Pediatric patients (ages 0 to 19 years) have higher rates of renal transplantation (77.7 percent) and PD (12.1 percent) than do other age groups.

One-, two-, and five-year survival rates (adjusted for age, race, sex, and primary disease) for ESRD are 79.6, 64.9, and 34.4 percent, respectively. Cardiac causes account for approximately 50 percent of all cases of ESRD death. Infectious causes of death occur in 10 to 25 percent of patients. Cerebrovascular events make up 6 percent of ESRD

$\text{Na}^+\text{K}^+\text{ATPase}$ activity is reduced in the red blood cells, leukocytes, intestinal epithelium, cardiac muscle, and skeletal muscle in uremic patients. Inhibition of $\text{Na}^+\text{K}^+\text{ATPase}$ activity results in partial cellular depolarization and increased calcium entry, which are linked to the high prevalence of hypertension and heart failure in ESRD. Recently, an endogenous dialyzable digitalis-like inhibitor of $\text{Na}^+\text{K}^+\text{ATPase}$ activity has been isolated in uremic plasma. This defect in $\text{Na}^+\text{K}^+\text{ATPase}$ activity is reversed by dialysis.

The uremic state produces excess free oxygen radicals, which react with carbohydrates, lipids, and amino acids, to create advanced glycation end products (AGEs), which have been linked to atherosclerosis and amyloidosis in ESRD patients.³ Unfortunately, AGEs are largely protein bound and not cleared by dialysis, which may explain the progressive nature of atherosclerosis and amyloidosis seen in ESRD patients.⁴

CLINICAL FEATURES OF UREMIA

Uremia should be viewed only as a clinical syndrome; no single symptom, sign, or laboratory test is reliable in diagnosing all aspects of uremia. Although a correlation exists between the symptoms of uremia and low GFR (8 to 10 mL per min), available laboratory tests (e.g., determinations of serum urea nitrogen and serum creatinine) are inaccurate markers of the clinical syndrome of uremia. The decision to start chronic dialysis should be a clinical one based on the symptoms of uremia (Table 93-1).

Neurologic Complications

Subdural hematoma occurs in approximately 3.5 percent of HD patients, presumably related to head trauma, bleeding dyscrasias, anticoagulants, excessive ultrafiltration, and hypertension. Bilateral subdural hematomas commonly present without focal neurologic deficits and should be considered in the differential in any ESRD patient with a change in mental status.

TABLE 93-1 Clinical Features of Uremia

Neurologic
Uremic encephalopathy: cognitive defects, memory loss, decreased attentiveness, slurred speech, reversal of sleep-wake cycle, asterixis, seizure, coma, symptomatic improvement with dialysis
Dialysis dementia: progressive neurologic decline, fatal, fails to improve with dialysis
Subdural hematoma: headache, focal neurologic deficits, seizure, and coma
Peripheral neuropathy: singultus (hiccups), restless leg syndrome, sensorimotor neuropathy, autonomic neuropathy
Cardiovascular
Coronary artery disease
Hypertension: essential hypertension, glomerulonephritis, renal artery stenosis, fluid overload
Heart failure: high-output AV fistula, uremic cardiomyopathy, fluid overload
Pericarditis: uremic, dialysis-related, pericardial tamponade
Hematologic
Anemia, decreased red blood cell survival, decreased erythropoietin levels
Bleeding diathesis
Immunodeficiency (humoral and cellular)
Gastrointestinal
Anorexia, metallic taste, nausea, vomiting
GI bleeding
Diverticulosis, diverticulitis
Ascites
Renal Bone Disease
Metastatic calcification (calciophylaxis)
Hyperparathyroidism (osteitis fibrosa cystica)
Vitamin D ₃ deficiency and aluminum intoxication (osteomalacia)

Abbreviations: AV = arteriovenous; GI = gastrointestinal.

Uremic encephalopathy is a constellation of nonspecific central neurologic symptoms associated with renal failure that respond, in large part, to RRT. Uremic encephalopathy should remain a diagnosis of exclusion after structural, vascular, infectious, toxic, and metabolic causes of neurologic dysfunction have been investigated. Objective findings of uremic encephalopathy include a significant increase in slow delta waves on the electroencephalogram and consistently low scores on psychometric testing. Magnetic resonance imaging may reveal increased signal intensity bilaterally in the cortical and subcortical areas of the occipital and parietal lobes.⁵

The objective findings of neurologic dysfunction have been linked to inhibition of $\text{Na}^+\text{K}^+\text{ATPase}$ activity and increases in brain calcium from elevated PTH levels or abnormal calcium transport in uremic brains. Symptomatic and objective neurologic findings of uremic encephalopathy improve with dialysis and can be followed to judge the adequacy of RRT.

Dialysis dementia is similar to uremic encephalopathy, consisting of a nonspecific set of neuropsychiatric dysfunctions that, unlike uremic encephalopathy, are progressive and eventually fatal. This disorder usually becomes evident after at least 2 years on dialysis and fails to respond to increases in dialysis frequency or renal transplantation. Electroencephalographic findings can differentiate uremic encephalopathy from dialysis dementia. High brain aluminum levels from oral ingestion of aluminum or high levels of aluminum in dialysate water have been correlated with the development of dialysis dementia. Some improvement with desferrioxamine binding of aluminum has been demonstrated.

Peripheral neuropathy is one of the most frequent neurologic manifestations of ESRD, occurring in more than 50 percent of HD patients. The symptoms of peripheral neuropathy generally respond poorly to dialysis but can be reversed by renal transplantation. Failure of vibration sense usually is the earliest clinical manifestation. Patients can have asymmetric (mononeuropathies) and symmetric (polyneuropathies) peripheral deficits. Another common deficit is "glove-and-stocking" sensory involvement, presenting with pain or anesthesia affecting the most distal nerves. Electrophysiologic testing of patients with uremia shows depression of motor and sensory nerve conduction. No single pathologic correlate has been identified for peripheral uremic neuropathy, although inactivation of axons by long-term exposure to toxins and subsequent "dying back" phenomenon has been postulated.⁶

Autonomic dysfunction as demonstrated by impotence, postural dizziness, gastric fullness, bowel dysfunction, and reduced sweating are common complaints in many ESRD patients. Objective testing for autonomic dysfunction in ESRD has found reduced heart rate variability and baroreceptor control impairment. Autonomic dysfunction does not seem to explain intradialytic hypotension,⁷ but it is common in a subset of chronically hypotensive ESRD patients whose blood pressures do not respond to volume challenges.⁸ Hemodialysis does not seem to improve autonomic dysfunction.⁹

Cardiovascular Complications

The prevalence of cardiovascular disease (CVD) is significantly greater in ESRD patients than in the general population. Coronary artery disease, left ventricular (LV) hypertrophy, and congestive heart failure (CHF) are estimated to occur in 12, 20, and 5 percent, respectively, in the general population. In dialysis patients, these prevalences increase to 40, 75, and 40 percent.¹⁰

The etiology of CVD in ESRD patients is multifactorial, related to pre-existing conditions (e.g., hypertension, diabetes, etc.), uremia (e.g., uremic toxins, hyperlipidemias, homocysteine, hyperparathyroidism, etc.), and dialysis-related conditions (e.g., hypotension, dialysis membrane reactions, hypoalbuminemia, etc.). In addition, increased levels of AGEs represent a unique risk for advanced atherosclerosis in ESRD patients.¹¹

The diagnosis of ischemic CVD in ESRD patients often has been clouded by the misconception that the traditional serum protein markers of myocardial damage (creatinine protein kinase and troponin) are unreliable in dialysis patients. Creatinine protein kinase and MB, troponin I, and troponin T are not significantly elevated in ESRD patients undergoing regular dialysis and have been shown to be specific markers of myocardial ischemia in these patients.^{12,13}

Hypertension is present in 80 to 90 percent of patients starting dialysis. Hemodynamic profiles of hypertensive ESRD patients show that maintenance of hypertension depends on increases in total peripheral resistance. The etiology of the increase in total peripheral resistance appears to be multifactorial. Increases in blood volume, the vasopressor effects of native kidneys, the renin-angiotensin system, and the sympathetic nervous system have been shown to play roles in ESRD hypertension.

Management of hypertension in ESRD patients should begin with the control of blood volume. If that is unsuccessful, most patients' hypertension can be controlled with adrenergic-blocking agents, angiotensin-converting enzyme inhibitors, or vasodilating agents, such as hydralazine or minoxidil. Bilateral nephrectomy is rarely necessary for blood pressure control.

Congestive heart failure occurs for many of the same reasons in ESRD patients as in other patients; hypertension is the most common cause of CHF in ESRD patients, followed by coronary artery disease and valvular defects. Causes of CHF unique to ESRD include uremic cardiomyopathy, fluid overload, and arteriovenous (AV) fistula-related high-output failure (see Complications of Vascular Access).

Uremic cardiomyopathy should be a diagnosis of exclusion when all other causes of CHF have been ruled out. In most uremic patients, LV dysfunction is related to ischemic heart disease, hypertension, and hypoalbuminemia rather than to a uremic toxin. Dialysis rarely improves LV function in uremic patients with CHF. However, PTH has been linked to decreased LV function in uremia by studies showing marked improvement of LV function after parathyroidectomy.

Pulmonary edema in ESRD patients is commonly ascribed to fluid overload, but other differentials should always be investigated. Acute myocardial ischemia can cause depressed LV function, causing pulmonary edema even in patients at or below their postdialysis ("dry") weight.

Management of pulmonary edema in ESRD patients is generally similar to treatment in non-ESRD patients. Cornerstones of therapy in both types of patients include oxygen, nitrates, angiotensin-converting enzyme inhibitors,¹⁴ and morphine. **Diuretics, such as furosemide, are still effective in treating CHF in ESRD patients, even with minimal urine output.**¹⁵ In pulmonary edema, intravenous furosemide in doses of 60 to 100 mg provides pulmonary vasodilatation, thus improving oxygenation. Preload reduction in ESRD patients also can be accomplished by inducing diarrhea with sorbitol and by phlebotomy. Although not a first-line therapy, phlebotomy of as little as 150 mL of blood is safe and effective in treating pulmonary edema.¹⁶ For example, phlebotomy of 150 mL in a patient with a hematocrit of 20 percent results in the loss of 120 mL of plasma and 30 mL of packed red blood cells (10 g of hemoglobin). The improved oxygenation by phlebotomy will more than offset the decrease in oxygen-carrying capacity due to the decrease in hemoglobin. Phlebotomized blood should be collected in transfusion bags, enabling plasma to be extracted by the blood bank and transfusion of red blood cells later during dialysis. Hemodialysis is the ultimate treatment for fluid overload in ESRD patients. Peritoneal dialysis does not remove volume fast enough to have a significant impact on pulmonary edema.

Cardiac tamponade is the main concern in all patients with pericarditis and should be considered in the differential diagnosis of any critically ill ESRD patient. **Patients with ESRD and tamponade rarely present with the classic signs of Beck's triad.** Instead, ESRD patients may present with changes in mental status, hypotension, or shortness of breath. Increased interdialytic weight gain, increased

edema, and intradialytic hypotension suggest the early diagnosis of tamponade. Two other findings include moderate hypotension and an increasing heart size on chest radiograph. Echocardiography can detect the pericardial effusion and may detect evidence of tamponade. Hemodynamically significant pericardial effusions require pericardiocentesis under fluoroscopic or ultrasonographic guidance. Pericardiocentesis, because of its high complication rate, should be used only in hemodynamically unstable patients.

Pericarditis in ESRD patients is usually due to uremia, but patients should be evaluated carefully for other causes. Approximately 20 percent of uremic patients requiring chronic dialysis develop uremic pericarditis or dialysis-related pericarditis.

Uremic pericarditis is more common of the two and represents approximately 75 percent of cases. Uremic pericarditis is most common when the other symptoms of uremia are most severe. The etiology of uremic pericarditis has been linked to fluid overload, abnormal platelet function, and increased fibrinolytic and inflammatory cell activities. Pericardial contents are sterile unless infected and are abundant with fibrin and inflammatory cells.

Uremic pericarditis causes pericardial friction rubs, which are louder than in most other forms of pericarditis, often palpable, and frequently persist for some time after metabolic abnormalities have been corrected. Serum urea nitrogen is nearly always over 60 mg/dL. One of the unique features of uninfected uremic pericarditis is that the inflammatory cells do not penetrate into the myocardium, so typical electrocardiographic changes of acute pericarditis are absent. Most often, the ECG may demonstrate associated abnormalities, such as LV hypertrophy, ischemia, and metabolic abnormalities (e.g., hyperkalemia and hypocalcemia). When the ECG is typical of acute pericarditis, infection should be suspected.

Dialysis-related pericarditis also seems related to the general uremic milieu. This form of pericarditis is most common during periods of increased catabolism (trauma and sepsis) or inadequate dialysis due to missed sessions or vascular access problems. The pathophysiology of dialysis-related pericarditis has been linked to the buildup of middle molecules and hyperparathyroidism.

Dialysis-related pericarditis is more common during HD than during PD and fortunately is becoming less frequent because of improved dialytic techniques. Constitutional symptoms, such as fever, are more common and severe than in uremic pericarditis. Effusion, with and without hemorrhage, is the most important complication and tends to be recurrent. Due to the recurrent nature of dialysis pericarditis, adhesions and fluid loculations are more common, which complicate echocardiography and other imaging modalities.

Mortality rates for ESRD patients with pericarditis are as high as 8 percent, and average survival without dialysis is approximately 1 month. Management of uremic and dialysis-related pericarditis in hemodynamically stable patients is by intensive dialysis therapy. Hemodialysis is preferred over PD because of its higher clearance rates but the risks of heparin and rapid fluid shifts precipitating tamponade must be taken into account. This therapy is effective in more than 50 percent of cases of dialysis-related pericarditis, usually after 10 to 14 days. Indomethacin and steroids are of questionable value for ESRD pericarditis. If pericardial effusion persists for more than 10 to 14 days with intensive dialysis, the treatment is considered a failure. Most centers now recommend anterior pericardectomy as the treatment of choice in this condition. Total pericardectomy is reserved for constrictive pericarditis.

Hematologic Complications

Anemia in ESRD patients is of multifactorial origin, secondary to decreased erythropoietin, blood loss from dialysis, and decreased red blood cell survival times. In addition, wide fluctuations in plasma blood volume seen in dialysis patients often cause factitious anemia. Without treatment, the hematocrit in ESRD patients usually will stabilize at 1

to 20 percent, with normocytic and normochromic red blood cells. Bone marrow will show erythroid hypoplasia, with little effect on leukopoiesis or megakaryocytopoiesis. Management of anemia is by the infusion of human recombinant erythropoietin on a regular basis. Erythropoietin replacement therapy has markedly improved the quality of life for ESRD patients by increasing exercise capacity and tolerance.

The *bleeding diathesis* seen in ESRD patients produces increased risks of GI tract bleeding, subdural hematomas, subcapsular liver hematomas, and intraocular bleeding. Abnormal hemostasis in ESRD is multifactorial in origin. Several mechanisms, including decreased platelet function, abnormal platelet-vessel wall interactions, altered von Willebrand factor, anemia, and abnormal guanidinosuccinic acid-dependent production of nitric oxide, are contributors to uremic bleeding.

The skin-bleeding test is the best predictor of clinically important defects in hemostasis. Improvements in bleeding times can be obtained by infusion of desmopressin, conjugated estrogens, and erythropoietin (see Chap. 219 for further discussion). A 6-day course of oral tranexamic acid also has been shown to result in significant shortening or normalization of bleeding time in 67 percent of uremic patients.

Immunologic deficiency in ESRD patients produces a high mortality rate from infectious diseases. Leukocyte chemotaxis and phagocytosis are depressed in uremic patients secondary to anemia, malnutrition, and zinc, selenium, and vitamin deficiency. Increased intracellular calcium concentration and low- and high-molecular-weight uremic toxins also have been proposed as a cause for impaired function.¹⁷ Abnormal T-cell activation also has been noted in ESRD patients secondary to reduction in interleukin-2 production.

Dialysis therapy does not appear to improve the immune function of leukocytes or T cells. In fact, HD may even exacerbate immunodeficiency by complement activation after exposure to the HD filter membrane. However, addition of Vitamin E to the membrane reduces complement activation.¹⁸ Parathyroid hormone has been proposed as the culprit in increasing the intracellular calcium concentration in uremia. Calcium channel blockers interfere with the effect of PTH on polymorphonuclear leukocytes and have been associated with improvement in metabolism and phagocytosis in neutrophils.¹⁹

Gastrointestinal Complications

Anorexia, nausea, and vomiting are common symptoms of uremia and often are used as an indication to initiate dialysis and to follow the adequacy of RRT. There is an increased incidence of gastritis and upper GI bleeding in ESRD patients, but the incidence of gastric and duodenal ulcers is similar in ESRD patients and the general population. The increased incidence of GI bleeding and re-bleeding and the higher mortality rates from GI hemorrhage in ESRD patients are functions more of the bleeding dyscrasias than of a primary GI disease. In addition, ESRD patients are at increased risk from bleeding from angiodysplasias. Successful prevention of recurrent bleeding from GI angiodysplasias has been obtained by use of tranexamic acid and conjugated estrogens, which decrease bleeding time.

Chronic constipation is common among ESRD patients secondary to decreased fluid intake and the use of phosphate-binding gels. End-stage renal disease patients have an increased incidence of diverticular disease and colonic perforation, especially patients with polycystic kidney disease.

Dialysis-related ascites is an idiopathic form of ascites secondary to fluid overload, portal hypertension from polycystic liver disease, and osmotic disequilibrium. Treatment of refractory ascites is possible with peritoneovenous shunts.

Renal Bone Disease

SYSTEMIC CALCIFICATION As the GFR falls, phosphate excretion decreases, resulting in increased serum phosphate levels. When the

calcium-phosphate product [$\text{Ca (mg/dL)} \times \text{PO}_4 \text{ (mg/dL)}$] is greater than 70 to 80, metastatic calcification can ensue. Patients typically present with complaints of pseudogout secondary to metastatic calcification of synovial-lined joints. Metastatic calcification in small vessels results in skin and finger necrosis. Life-threatening calcifications can occur in the cardiac and pulmonary systems. An increased mortality rate has been observed in ESRD patients with a calcium-phosphate product greater than 72. Treatment consists of the use of low-calcium dialysate and phosphate-binding gels.

HYPERPARATHYROIDISM (OSTEITIS FIBROSA CYSTICA) As ESRD progresses, the combination of calciphylaxis and vitamin D₃ deficiency results in depressed ionized calcium levels and stimulation of the parathyroid gland. The increased production of PTH results in high bone turnover. Patients present with weakened bones highly susceptible to fracture. In addition, patients with osteitis fibrosa cystica often complain of bone pain and muscle weakness. High alkaline phosphatase and PTH levels make the diagnosis. Treatment consists of control of serum phosphate with binding gels, vitamin D₃ replacement, and, if necessary, subtotal parathyroidectomy.

VITAMIN D₃ DEFICIENCY AND ALUMINUM INTOXICATION (OSTEOMALACIA) A subset of ESRD patients develops osteomalacia, a defect in bone calcification. Once vitamin D₃ replacement became universally available, aluminum intoxication became the major cause of osteomalacia in ESRD patients. Sources of aluminum are dialysate diluent and phosphate-binding gels. The signs and symptoms are weakened bones, bone pain, and muscle weakness, similar to those for hyperparathyroidism. Osteomalacia has low-to-normal alkaline phosphatase levels and low PTH levels. Elevated serum aluminum and bone aluminum levels are useful for confirming the diagnosis. Treatment with desferrioxamine has been shown to be effective in aluminum bone disease.

p₂-MICROGLOBULIN AMYLOIDOSIS Dialysis-related amyloidosis, or p₂-microglobulin amyloidosis, is seen commonly in dialysis patients older than 50 years and on dialysis for more than 10 years. Advanced glycation end products appear central to the chronic inflammatory condition leading to amyloidosis in ESRD patients. Amyloid deposits are found in the GI tract, bones, and joints. Complications include GI perforations, bone cysts with pathologic fractures, and arthropathies, including carpal tunnel syndrome and rotator cuff tears. Patients with amyloidosis have significantly higher mortality rates than do those without this disorder.

HEMODIALYSIS

HD in humans was made possible by the invention of the rotating-drum artificial kidney by Kolff and colleagues in 1943. Access to the patient's bloodstream was not practical until the development of the external AV shunt by Scribner in 1960. Brescia and Cimino in 1966 developed the subcutaneous AV fistula, which made HD safer and more acceptable. Renal replacement therapy became widely available after 1973, when the U.S. Congress authorized Medicare funding for the treatment of ESRD.

Technical Aspects of Hemodialysis

The nephron removes toxins and maintains internal homeostasis through an elegant combination of glomerular filtration followed by selective reabsorption and secretion of water and solutes. Hemodialysis uses the brute force techniques of ultrafiltration and clearance to replace the functions of the nephron. Hemodialysis substitutes a hemodialyzer filter for the glomerulus to produce an ultrafiltrate of plasma. Adjustment of the pressure gradient across the hemodialyzer filter during HD controls the amount of fluid removal (ultrafiltration).

Solute removal (clearance) during HD depends on the filter pore size, the amount of ultrafiltration (solute drag), and the concentration gradient across the filter (diffusion). Solute diffusion of chemical gradients from the blood to the dialysis fluid (dialysate) determines their final blood concentration. Because hemodialyzer pore size prevents the filtration of proteins, dialysate consists only of electrolytes (Na^+ , K^+ , Cl^- , HCO_3^- , Ca^{2+} , and Mg^{2+}) and glucose, whose concentrations are varied to control their clearance.

During HD, blood is removed from the vascular access site by large-bore needles (typically 15 gauge), circulated through the dialysis machine at rates of 300 to 500 mL per min, and returned to the patient. The dialysate usually flows at a rate of 500 to 800 mL per min through the dialysis filter in the direction opposite to blood flow. Small amounts of intravenous heparin, 1000 to 2000 units, are typically used to prevent thrombosis at the vascular access site. HD sessions typically take 3 to 4 h.

Complications of Vascular Access

Long-term successful HD depends on reliable access to the patient's circulation. In cases in which a native artery or vein are not suitable for fistula creation, an interposing vascular graft made of an autologous vein, polytetrafluoroethylene, or bovine carotid artery must be used for vascular access. These grafts generally have a higher complication rate and shorter functional life expectancies than do natural AV fistulas. The third form of vascular access for HD is tunnel-cuffed catheters (e.g., Hickman, Neostar, Quinton) placed using a surgically created tunnel. The most common site for tunnel-cuffed catheter placement is the right internal jugular vein. Because of the cuff, these catheters cannot and should not be removed by pulling. Vascular access is the Achilles heel of HD, and complications of the vascular access account for more inpatient hospital days than do any other complication of HD.

Thrombosis and stenosis of the vascular access are the most common complications. Grafts generally have a higher rate of stenosis, secondary to endothelial hyperplasia, than do fistulas. Stenosis or thrombosis presents with loss of bruit and thrill over the access. Stenosis and even thrombosis are not emergencies and can be treated within 24 h by angiographic clot removal or angioplasty. Thrombosis of vascular access can also be treated with direct injection of alteplase 2.2 mg into the access.

Vascular access infections occur in 2 to 5 percent of AV fistulas and about 10 percent of vascular grafts over their functional lifetime. Patients with an infected access often present with signs of systemic sepsis, such as fever, hypotension, or an elevated white blood cell count. Classic signs of pain, erythema, swelling, and discharge from an infected vascular access are often missing. The most common organism is *Staphylococcus aureus*, followed by gram-negative bacteria. Patients with access infections usually require hospital admission. Vancomycin is the drug of choice (1 g IV), because of its effectiveness in methicillin-resistant organisms and long half-life (5 to 7 days) in dialysis patients. An aminoglycoside (gentamicin 100 mg IV initially and after each dialysis) is usually added empirically to cover gram-negative organisms.

Hemorrhage from a vascular access can produce life-threatening blood loss. Hemorrhage can result from aneurysms, anastomosis rupture, or over-anticoagulation. Bleeding that requires the patient to come to the emergency department should immediately be controlled with digital pressure at the puncture sites for 5 to 10 min, and the patient should be observed for 1 to 2 h thereafter. Continued or life-threatening hemorrhage may require the placement of a tourniquet proximal to the access. A vascular surgeon should be consulted if bleeding cannot quickly be brought under control. If over-anticoagulation is a concern, the effects of heparin can be reversed by protamine given at a dose of 0.01 mg/units heparin dispensed during dialysis. If the dose of heparin is unknown, protamine, 10 to 20 mg, will be suf-

ficient to reverse heparin, 1000 to 2000 units. If bleeding stops, the patient should be observed for 1 to 2 h for rebleeding or thrombosis. Occasionally, a newly inserted vascular access will continue to ooze at the insertion despite pressure. Small pieces of gelfoam soaked in reconstituted thrombin can be placed onto oozing sites. Desmopressin acetate (0.3 $\mu\text{g/kg}$ IV, maximum dose 20 mg) can be administered as an adjunct. If the emergency physician is unfamiliar with the use of desmopressin acetate in this situation, the nephrologist should be consulted.

Vascular access aneurysms result from repeated puncturing, leading to bulging of the wall. True aneurysms are very rare, occurring in fewer than 4 percent of fistulas or grafts. Most aneurysms are asymptomatic, with patients occasionally complaining of pain or an associated peripheral impingement neuropathy. Aneurysms rarely rupture.

Vascular access pseudoaneurysms result from subcutaneous extravasation of blood from puncture sites. Patients commonly present with bleeding and infections at access sites. Bleeding from the puncture site is usually controlled by digital pressure or a subcutaneous suture carefully placed at the puncture site. Vascular surgery may be required for continued bleeding or infection.

Vascular insufficiency of the extremity distal to the vascular access occurs in approximately 1 percent of all patients. The so-called "steal syndrome" is the result of preferential shunting of arterial blood away from nutrient arteries to the low-pressure venous side of the access. Patients present with exercise pain, nonhealing ulcers, and cool, pulseless digits. Steal syndrome is diagnosed by Doppler ultrasound or angiography and is repaired surgically.

High-output heart failure can occur when greater than 20 percent of the cardiac output is diverted through the access. Branham sign, a drop in heart rate after temporary access occlusion, is useful for detecting this complication.²⁰ Doppler ultrasound can accurately measure access flow rate and establish the diagnosis. Surgical banding of the access is the treatment of choice to decrease flow and treat heart failure.

Complications During Hemodialysis

Hypotension is the most frequent complication of HD, occurring during 10 to 20 percent of treatments (Table 93-2). Fluid removal during HD averages 1 to 3 L over a 4-h session, but removal of up to 2 L per h is possible. Maintenance of a normal blood pressure during ultrafiltration depends on cardiovascular compensatory mechanisms and refilling of the vascular space by fluid shifts from the interstitial and intracellular compartments. Excessive ultrafiltration from underestimation of the patient's ideal blood volume (dry weight) is the most common cause of intradialytic hypotension. In fact, dry weight is often clinically defined when hypotension prevents further fluid removal.

Cardiac compensation for fluid loss often is inhibited by diastolic dysfunction common in ESRD patients. Myocardial dysfunction from ischemia, hypoxia, arrhythmias, and early pericardial tamponade also should be included in the differential of intradialytic hypotension. Abnormalities of vascular tone during HD may occur in patients with

TABLE 93-2 Differential Diagnosis of Peridialytic Hypotension

Excessive ultrafiltration
Clearance simultaneous with ultrafiltration
Predialytic volume loss (GI losses, decreased oral intake)
Intradialytic volume loss (tube and hemodialyzer blood losses)
Postdialytic volume loss (vascular access blood loss)
Medication effects (antihypertensives, opiates)
Decreased vascular tone (sepsis, food, dialysate temperature $>37^\circ\text{C}$ or 98.6°T)
Cardiac dysfunction (LVH, ischemia, hypoxia, arrhythmia)
Pericardial disease (effusion, tamponade)

Abbreviations: GI = gastrointestinal; LVH = left ventricular hypertrophy.

sepsis, overproduction of nitric oxide, and antihypertensive medications. Refilling of the vascular tree can be inhibited by hypoalbuminemia and concurrent removal of solutes with ultrafiltration. Vascular refilling can be enhanced by improved nutrition, performing ultrafiltration before dialysis, and increasing the sodium concentration of the dialysate solution.

The timing of intradialytic hypotension is often helpful in the differential diagnosis. Hypotension early in the dialysis session is usually due to pre-existing hypovolemia. Predialysis losses should be suspected when the patient starts HD below their dry weight and is usually due to GI bleeding, sepsis, vomiting, diarrhea, or decreased intake of salt and water. Intradialytic blood loss can occur from blood tubing or hemodialyzer filter leaks. Hypotension near the end of dialysis is usually the result of excessive ultrafiltration, but pericardial or cardiac disease is still a possibility.

Intradialytic hypotension produces nausea, vomiting, and anxiety. Orthostatic hypotension, tachycardia, dizziness, and even syncope may occur. Treatment of intradialytic hypotension includes halting HD and placing the patient in the Trendelenburg position. If hypotension persists, the patient is given salt by mouth (broth) or NS, 100 to 200 mL IV. If these conservative measures fail, excessive ultrafiltration is very unlikely, and a more extensive evaluation is justified. These patients are commonly transferred to the ED for further evaluation.

The emergency physician should focus on immediate and potential life threats. The patient should be evaluated for adequacy of volume status, impairment of cardiac function, pericardial disease, infection, and GI bleeding. All of these entities may be producing or contributing to hypotension. Remember that estimation of the patient's blood volume by clinical criteria has already failed in the dialysis unit. The decision to undertake further volume expansion or administer vasopressors to support blood pressure may require invasive hemodynamic monitoring in an intensive care setting.

Dialysis disequilibrium is a clinical syndrome occurring at the end of dialysis and is characterized by nausea, vomiting, and hypertension, which can progress to seizure, coma, and death. This syndrome should be distinguished from other neurologic disorders, such as subdural hematoma, stroke, hypertensive crisis, hypoxia, and seizures. Dialysis disequilibrium is produced when large solute clearances occur during HD, as during the patient's first dialysis session or in hypercatabolic patients. The cause of dialysis disequilibrium is believed to be cerebral edema from an osmolar imbalance between the brain and the blood. During high solute removal, the blood has a transiently lower osmolality than the brain, favoring water movement into the brain and causing cerebral edema. This condition can be prevented by limiting solute clearance when initiating HD. Treatment consists of stopping dialysis and administering mannitol IV to increase serum osmolality.

Air embolism is always a risk when blood is pumped through an extracorporeal circuit. The clinical presentation depends on the patient's body habitus at the time of the air embolism. If the patient was sitting, air will pass retrogradely through the internal jugular vein to the cerebral circulation, causing neurologic symptoms due to increase intracranial pressure. In a recumbent position, air will go into the right ventricle and pulmonary circulation, causing pulmonary hypertension and systemic hypotension. The passage of air through a right-to-left (e.g., patent foramen ovale) creates an arterial air embolism, which can lodge in the coronary or cerebral circulation, causing myocardial infarction or stroke.

Patients with an air embolism typically present with symptoms of acute dyspnea, chest tightness, and unconsciousness, sometimes progressing to full cardiac arrest. Physical examination may show cyanosis and a churning sound in the heart from air bubbles in the blood.

Treatment consists of clamping the venous bloodline and placing the patient supine. Traditional recommendations have often included the Trendelenburg position with the left side down, presumably to favor air trapping in the right ventricle. However, experimental and anecdotal clinical evidence does not indicate any special benefit of this position. Oxygen, administered by 100 percent non-rebreather

mask, should be applied to aid reabsorption of the air. Other suggested therapies for vascular air embolism include percutaneous aspiration of air from the right ventricle, intravenous steroids, full heparinization, and hyperbaric oxygen treatment.

Electrolyte abnormalities can occur from errors in mixing the dialysate concentrate with water, resulting in rapid osmolar shifts and hemolysis. In some communities, water contains high concentrations of calcium and magnesium and produces a final dialysate high in these minerals. This dialysate can result in the "hard water syndrome," characterized by clinically significant hypercalcemia and hypermagnesemia in HD patients. These patients present with nausea, vomiting, headaches, burning skin, muscle weakness, lethargy, and hypertension. Treatment consists of properly filtering the dialysis water to lower calcium and magnesium concentrations.

Hypoglycemia has been reported in diabetic and nondiabetic ESRD patients. In addition to drug-induced hypoglycemia, malnutrition and sepsis are important causes of hypoglycemia that carry significant mortality.²¹

Evaluation of Hemodialysis Patients

Patients on HD may present to the ED for complications related to their ESRD or HD, or these conditions may be incidental to the reason for the visit. The medical history is very important in HD patients, because many of the same diseases that caused ESRD (e.g., hypertension, diabetes, etc.) persist after the patient's kidneys have failed. Questions should be asked about the patient's ESRD and HD (Table 93-3). Repeated episodes of intradialytic hypotension may provide important early clues to pericardial tamponade or myocardial ischemia. Repeated access infections may represent a worsening immunologic status.

Patients should be asked about their HD schedule. Most HD patients in the United States are on an every-other-day schedule (Monday, Wednesday, and Friday or Tuesday, Thursday, and Saturday), with each session lasting approximately 4 h. Certain centers have begun using high-flux HD machines with higher blood flows, allowing shorter HD sessions. The physician should document all recent missed sessions and the patient's explanations for missing them. Such history taking may provide important clues concerning worsening medical or social issues that need to be addressed outside the patient's chief complaint.

Dialysis patients are often quite knowledgeable about their dry weights and baseline laboratory test results. If the patient is not forthcoming with these data, the emergency physician can contact the HD center and ask about the dry weight, average interdialytic weight gains, and any recent HD complications. In addition, the dialysis nurses and technicians are very devoted to their patients and can provide a great deal of "soft data" concerning the patient. Query the patient in detail with regard to uremic symptoms as markers of inadequate HD. Patients should be asked whether they retain their native kidneys, which can be continued sources of hypertension, infection, and nephrolithiasis.

The physical examination of HD patients should always include a careful examination of the vascular access (Table 93-4). The vascular

access is the patient's lifeline and Achilles heel, complications of which are responsible for the majority of ESRD inpatient days. Flow through the access can be established by the presence of a bruit and thrill over the access site. The classic signs of infection, erythema, swelling, tenderness, and purulent discharge, are commonly limited until the infection is far advanced. The bedside Branham sign may detect patients with CHF due to high-output fistula-related heart failure. The cardiac examination of HD patients deserves some special attention. Signs of CHF, such as peripheral edema, HJR, and JVD, may misleadingly suggest the diagnosis of fluid overload when pericardial tamponade is present. A loud cardiac murmur in HD patients may just represent increased flow secondary to anemia or the AV access. Neurologic dysfunction in HD patients is generally diffuse and nonfocal. Any findings suggestive of a focal neurologic deficit should be investigated for structural, vascular, and infectious causes. Rectal examination to detect GI bleeding is always recommended.

PERITONEAL DIALYSIS

Ganter accomplished the first PD in 1923. Practical long-term RRT with PD did not become available until 1976, when Popovich and Moncrief worked out the basic concepts of continuous ambulatory peritoneal dialysis (CAPD). Their work was significantly aided by the development of a practical silicon rubber catheter by Tenckhoff in 1968, which is still in use today. Because of its simplicity, PD is the most common form of RRT used outside the United States and Canada,

Technical Aspects of Peritoneal Dialysis

Similarly to HD, PD relies on the separate processes of clearance (solute removal) and ultrafiltration (fluid removal) to replace the functions of the nephron. In PD, the peritoneal membrane serves as the blood-dialysate interface. Most solute removal occurs via diffusion down chemical gradients established by altering dialysate electrolyte concentrations. The amount of ultrafiltration is determined by osmotic pressure differences between the blood and dialysate, which are manipulated by changing the dialysate glucose concentration. Dialysate is supplied in a 1.5 or 4.25 percent glucose formulation, which can be alternated to increase or decrease ultrafiltration.

Typical CAPD regimens use four exchanges daily, with 2 L of dialysate infused and left in place for several hours before draining. During the day, approximately 8 L is infused and about 10 L is drained, for a removal of approximately 2 L per d of fluid. Peritoneal dialysis can be accomplished in an acute setting, chronically via exchanges of solution throughout the day (CAPD), or through multiple exchanges at night while the patient sleeps (continuous cyclic peritoneal dialysis).

Complications of CAPD

Peritonitis is the most common complication of PD. The incidence of peritonitis is about one episode every 15 to 18 patient-months. Mortality rates with peritonitis have been reported as between 2.5 and 12.5 percent, depending on the center studied. Symptoms and signs of peritonitis in PD patients are no different from those for other patients with peritonitis: fever, abdominal pain, and rebound tenderness. Cloudy effluent suggests the diagnosis of peritonitis. Patients often will bring in a sample of the cloudy dialysate fluid, which should be

sent for cell count, Gram's stain, and culture. The cell count in PD-related peritonitis is usually more than 100 leukocytes, with more than 50 percent neutrophils. Results of the Gram stain are positive in only 10 to 40 percent of cases of culture-proven PD-related peritonitis. Organisms isolated in PD-related peritonitis are *Staphylococcus epidermidis* (about 40 percent), *S. aureus* (10 percent), *Streptococcus* species (15 to 20 percent), gram-negative bacteria (15 to 20 percent), anaerobic bacteria (5 percent), and fungi (5 percent).

Empiric therapy should begin with a few rapid exchanges of fluid lavaged quickly in and out to decrease the number of inflammatory cells in the peritoneum. The addition of heparin (500 to 1000 U/L dialysate) will decrease fibrin clot formation. Empiric antibiotics are selected to treat the expected gram-positive and gram-negative organisms. Peritonitis related to PD can be treated with antibiotics added to the dialysate; parenteral administration is not required. A first-generation cephalosporin (e.g., cephalothin) can be mixed with the dialysate, 500 mg/L with the first exchange and 200 mg/L with subsequent exchanges. In penicillin-allergic patients, vancomycin can be substituted, with an initial dose of 500 mg/L and maintenance doses of 50 mg/L per exchange. Gentamicin can be added, with a loading dose of 100 mg/L and maintenance doses of 4 to 8 mg/L per exchange. Most protocols recommend treating for 7 days after the first negative culture results, usually for a total of 10 days. The decision to admit these patients or treat them as outpatients is a clinical decision based on how ill the patient appears.

Infections around a PD catheter are much less well defined than peritonitis. Patients present with pain, erythema, swelling, and discharge around the catheter exit site. The most common bacteria are *S. aureus* and *Pseudomonas aeruginosa*. Empiric therapy consists of a first-generation cephalosporin or ciprofloxacin for outpatient therapy. Patients should be referred back to their CAPD centers for follow-up the next day.

Abdominal wall hernias occur in 10 to 15 percent of PD patients. The literature recommends immediate surgical repair of pericatheter hernias, which have the highest risk of developing an incarceration.

Evaluation of Peritoneal Dialysis Patient

When a PD patient arrives in the emergency department, certain historical elements are important (Table 93-5). As with HD patients, the disease that caused the renal failure frequently persists. The type of PD and the person who performs the daily care may provide information about the risks of infection. The date of the patient's last episode of peritonitis should be ascertained; frequent relapses may signify a fungal etiology or tunnel infection. The patient should be asked about baseline weight and laboratory values; PD patients are selected for their knowledge about their condition and their ability to perform the procedure and monitor their care away from professional supervision. Weight gain may signal heart failure from ischemia or pericardial effusion. Weight gain also may be from ultrafiltration failure, a late sign of peritonitis.

The physical examination of PD patients should focus on the abdomen. The physician should focus on signs of infection of the peritoneum, tunnel, and exit site (Table 93-6).

URINARY TRACT INFECTIONS

David S. Howes

Mark P. Bogner

Urinary tract infection (UTI) is defined as significant bacteriuria in the presence of symptoms, such as painful urination (dysuria), hematuria, increased urinary frequency, urgency, hesitancy, suprapubic discomfort, and costovertebral angle (CVA) tenderness. Uncomplicated acute UTI in otherwise healthy, nonpregnant, nonobstructed young females is generally regarded as a benign illness if treated appropriately. Conversely, there can be very significant long-term sequelae of UTI, in particular recurrent or obstructive UTI, in pregnant patients, children, older patients, and patients with significant comorbidities (e.g., human immunodeficiency virus and acquired immunodeficiency syndrome [HIV/AIDS], diabetes mellitus, or other chronic illnesses). In the elderly population, UTI is a major cause of nosocomial gram-negative sepsis, with a significant associated mortality rate.

Many classification schemes exist and are used to describe UTI. As the above discussion suggests, one practical scheme is to divide UTI into two major categories, complicated and uncomplicated. The distinction is clinically useful, because extensive testing and anatomic evaluation are rarely necessary in cases of uncomplicated UTI. However, increasing resistance to traditional first-line antibiotics require attention to local resistance patterns when selecting antibiotics to treat uncomplicated UTI. Conversely, complicated UTI often poses significant challenges in diagnosis and treatment to account for other host factors and comorbidities contributing to the expected potential severity and sequelae of the infection.

EPIDEMIOLOGY

Urinary tract infection affects an estimated 20 percent of women at some point in their lives, and in the United States accounts for at least 1 million emergency department visits, 7 million office visits, and 100,000 hospitalizations every year. It is the second most common form of infection, representing up to 25 percent of all infections and more than 20 percent of all hospital acquired infections. The estimated U.S. annual cost of community-acquired UTI is approximately 1.6 billion dollars.¹

The epidemiology of UTI differs with age and sex. There are four groups at increased risk for infection: neonates, girls, young women, and older men. In neonates, a UTI occurs more often in males (1.5:1 male:female ratio) and is often part of the syndrome of gram-negative sepsis. The incidence of UTI in preschool children is approximately 2 percent, and the incidence in girls is at least 10 times greater than the incidence in boys. In school-age children, UTI incidence rises to 5 percent, almost exclusively occurring in girls. The incidence of infection in postmenopausal women also increases with age. The prevalence of bacteriuria among elderly women in nursing homes exceeds 40 percent.

Bacteriuria is rare in males younger than 50 years, and symptoms of dysuria or urinary frequency are usually due to a sexually transmitted disease-related infection of the urethra or prostate. However, in men older than 50 years, the incidence of UTI rises dramatically, because of prostatic obstruction or subsequent instrumentation. By their eighth decade over one-third of men will have had an episode of bacteriuria and one-fourth will have been diagnosed with prostatitis.²

Dysuria in females is a common symptom and usually due to infection. Urinary tract infection is a frequent problem in otherwise healthy young women, and the incidence of UTI in this population has been shown to increase as a result of the following risk factors: sexual activity, specifically increased intercourse frequency in the past month; spermicide and/or diaphragm use; a new sex partner within the past 12 months; age younger than 15 years at first UTI; and history of UTI in the patient's mother.³ Conversely, oral contraceptive use independent of sexual activity, personal hygiene habits, and postcoital

voiding have not been clearly demonstrated as significant risk factors for UTI.³ The relation between intercourse and UTI is sufficiently strong that recurrent UTI has been proposed as a possible marker for teenage sex.

The infecting organisms in UTI are generally those found colonizing the perineum. In women with a traditional "positive" culture of 10^5 colony-forming units (CFU) per milliliter of urine, *Escherichia coli* is responsible for approximately 80 to 90 percent of infections. However, up to one-half of cases of dysuria in young women is characterized by low bacterial concentration (10^2 to 10^4 CFU/mL), which has been termed the *acute urethral syndrome*. It is now believed that these patients have low-grade or early urinary tract infection due to *E. coli*, *Staphylococcus saprophyticus*, or *Chlamydia trachomatis*. The more than 10^5 CFU/mL definition for UTI was based on studies of upper urinary tract infection that established this degree of bacterial concentration as indicative of "significant bacteriuria." Subsequent research suggested that, with regard to lower urinary tract infections in the presence of symptoms, a colony count of at least 100 CFU/mL may represent significant bacteriuria and merit treatment.

Asymptomatic bacteriuria (ABU) is defined by the presence of more than 10^5 CFU/mL of one bacterial species on two successive urine cultures in a patient without symptoms. This requirement for two positive cultures is to eliminate those individuals with transient colonization of the urinary tract. Asymptomatic bacteriuria occurs in up to 30 percent of pregnant women and in up to 40 percent of female nursing-home residents. Asymptomatic bacteriuria is also common in patients with indwelling urinary catheters and disorders that prevent complete emptying of the bladder. In otherwise healthy, nonpregnant, sexually active women ages 18 through 40 years, the prevalence of ABU is approximately 5 percent.⁴ Persistence of ABU is uncommon; however, the presence of ABU is a strong predictor of subsequent UTI, which occurs within 1 week approximately eight times more frequently in patients with ABU than in those without ABU.⁴

Urinary tract infections in women recur because of relapse or reinfection. Relapse is caused by the same organism, and symptoms recurring within 1 month represent treatment failure. When symptoms recur in 1 to 6 months, it is generally due to reinfection. Reinfection is usually from a different enteric organism or a different serotype of the same organism, and may represent a defect in the defense mechanisms of the host. If a patient has a cluster of infections with more than three recurrences in 1 year, a more complete workup may be warranted to look for the presence of structural abnormalities, tumor, renal calculi, or associated systemic illness, such as diabetes mellitus.

Urinary tract infection during pregnancy poses special problems. If untreated, ABU may progress to symptomatic UTI or pyelonephritis, especially in the third trimester, and may lead to preeclampsia, sepsis, or miscarriage. This is the single setting in which treatment of ABU is definitely indicated.³

PATHOPHYSIOLOGY

Uncomplicated UTI is generally thought of as UTI occurring in otherwise healthy, young, female, sexually active but nonpregnant patients without an underlying defect in urinary anatomy or renal function.⁶ Most other cases will fall under the classification of complicated UTI: occurring in patients with underlying renal or neurologic disease, ureteral stone or other obstructive pathology; recurrent UTI history; pregnancy, advanced or very young age, impaired immune function (e.g., HIV/AIDS, chemotherapy patients), and other significant comorbidities. The most common urinary pathogen remains *E. coli* (Table 94-1). Uropathogenic organisms often have adhesins, fibrillae, or pili that allow for bacterial adherence to the uroepithelium. Anaerobic organisms do not grow well in urine and are rarely pathogenic. Whereas complicated UTIs can be caused by *E. coli*, they are more likely to be caused by unusual pathogens, such as *Pseudomonas* spp. or enterococcus.

TABLE 94-1 Etiologic Agents in Uncomplicated Urinary Tract Infection

Organism	Incidence
<i>Escherichia coli</i>	>80%
<i>Klebsiella</i> spp.	5-20%
<i>Proteus</i> spp.	5-20%
<i>Enterobacter</i> spp.	5-20%
<i>Pseudomonas</i> spp.	5-20%
Group D streptococci	<5%
<i>Chlamydia trachomatis</i> *	<5%
<i>Staphylococcus saprophyticus</i> *	<5%

*Much more common in the "dysuria pyuria" syndrome in which sterile or low colony count culture results are obtained. *Staphylococcus saprophyticus* may account for up to 15% of acute lower tract infection in young, sexually active females but rarely progresses to involve the upper tract.

Depending on its pH and chemical constituents, urine is generally a good culture medium. Factors unfavorable to bacterial growth are a low pH (≈ 5.5); a high concentration of urea; and the presence of organic acids derived from a diet including fruit juice and methionine, a breakdown product of ingested protein that enhances acidification of the urine. A thin film of urine remains in the bladder after voiding. An intact bladder mucosa removes organisms from the film, probably by the production of organic acids by the mucosal cells and not by antibody formation or phagocytosis. Incomplete bladder emptying renders this mechanism ineffective and is responsible for the increased frequency of infection in patients with a neurogenic bladder and in postmenopausal women with bladder or uterine prolapse. The latter group also has marked changes in vaginal micro flora due to lack of estrogen, with loss of lactobacilli and increased colonization by *E. coli*.

Frequent and complete voiding has been associated with the reduction in recurrence of UTI.⁷ Studies have found that the concentration of bacteria in the bladder may increase tenfold after sexual intercourse due to a "milking action" of the female urethra during intercourse. The use of a diaphragm and spermicide is also associated with recurrent UTI, probably because the spermicide enhances vaginal colonization with *E. coli*.^{8,9} It has long been recommended, although unproved, that prompt voiding after intercourse may lessen the frequency of UTI.⁷

Susceptibility to UTIs may have a genetic basis. Women who do not secrete blood group antigens (nonsecretors) have been shown to have a higher incidence of recurrent infection. This higher incidence appears to be due to the presence of specific uroepithelial cell *E. coli*-binding glycolipids that promote fecal coliform colonization of the vagina.⁶

Most UTIs occur as one of three clinical syndromes: acute cystitis, subclinical pyelonephritis, or acute pyelonephritis. The simplest and most common UTI is acute cystitis, in which infection is isolated to the bladder. Competent ureteral valves prevent ascent of the bacteria into the kidneys in most cases.

Subclinical pyelonephritis is characterized by bacterial infection in the upper urinary tract and detected by bladder washout techniques, selective ureteral catheterization, or the presence of antibody-coated bacteria in the urine. However, subclinical pyelonephritis is clinically indistinguishable from acute cystitis, and it has been estimated that approximately 25 to 30 percent of patients with the acute cystitis syndrome actually have subclinical pyelonephritis. Several epidemiologic factors correlate with increased risk for subclinical pyelonephritis: lower socioeconomic status; pregnancy; structural urinary tract abnormality; urinary stone; history of relapse after treatment for a UTI; prior history of acute pyelonephritis; frequent UTIs; symptoms lasting longer than 7 days; or diabetes or other immunosuppressing conditions.^{6,10}

Acute pyelonephritis is characterized by the presence of bacteria in the kidney with localized pain and CVA tenderness, with systemic symptoms of infection (fever, chills, nausea, vomiting, and prostration). The infective process of acute pyelonephritis can progress into three patterns of renal infection not commonly considered part of the UTI spectrum: acute bacterial nephritis, renal abscess, and emphysematous pyelonephritis.⁸ These tend to be diagnoses made on imaging studies performed on patients who have an inadequate or atypical response to treatment for presumed acute pyelonephritis. On ultrasound or computed tomography, acute pyelonephritis is seen as a diffusely enlarged kidney without focal abnormalities. Acute bacterial nephritis produces ill-defined focal areas, sometimes striated or wedge-shaped, of decreased density.⁸ Renal abscesses appear as well-defined areas of decreased density. Emphysematous pyelonephritis is a rare gas-forming infection within the kidney, nearly always occurring in diabetics (70 to 90 percent of patients).⁹ These patients usually have symptoms and signs of a severe infection, often with dehydration and pyelonephritis.⁹ Nephrectomy is required to adequately treat emphysematous pyelonephritis.

CLINICAL FEATURES

The presence of four specific symptoms and one sign has been shown to significantly increase the clinical probability of UTI: dysuria, frequency, visible (gross) hematuria, and CVA tenderness. Conversely, the probability of UTI is significantly decreased in the absence of dysuria and/or back pain, particularly if the patient complains of vaginal discharge or irritation or has vaginal discharge on physical examination.¹⁰ Self-diagnosis also has been shown to significantly increase the probability of UTI.¹¹

Unfortunately, the correlation between symptoms and the presence of infection is inexact, because only 50 to 60 percent of women with dysuria have significant bacteriuria. Internal dysuria, a burning suprapubic pain during urination associated with bladder tenderness, is more associated with UTIs than is external dysuria, the burning sensation as urine passes over inflamed perineal tissue. In females, external dysuria or a history of vaginal discharge or irritation more often is associated with vaginitis, cervicitis, or pelvic inflammatory disease than with a UTI. The presence of specific symptom combinations (e.g., dysuria and frequency) and the absence of vaginal discharge or irritation increase the probability of uncomplicated UTI in otherwise healthy, nonpregnant, sexually active young women to approximately 90 percent. It is important to note that, when a patient presents with one or more of these symptoms, further history, physical examination, and urinalysis cannot provide sufficient strength of evidence to lower the posttest probability of UTI to a point where it can be safely "ruled out." As such, these data support the case for empiric treatment of uncomplicated UTI in selected cases (discussed later).¹⁰

Flank pain, costovertebral angle tenderness, or specific renal tenderness to deep palpation may be associated with cystitis because of referred pain. However, when these findings occur in association with fever, chills, nausea, vomiting, and prostration, the clinical diagnosis is acute pyelonephritis.

In the male, dysuria with a urethral discharge indicates urethritis.^{1,6} Gram stain of the discharge may reveal gram-negative intracellular diplococci, which is virtually diagnostic of gonococcal urethritis. If Gram stain is inconclusive, the diagnosis is most likely nonspecific urethritis, which is mainly chlamydial or another sexually transmitted infection. In both cases, laboratory tests for gonorrhea and chlamydia should be obtained and possibly a serologic test for syphilis. It should be emphasized to the emergency department triage personnel that UTI in young adult males is extremely rare; therefore, a urine specimen should not be obtained until after examination by a physician. On the one hand, withholding urination may enhance the likelihood of a positive urethral swab in the male patient with minimal discharge. On the other hand, several investigators have demonstrated that the presence

of urinary leukocytes is more sensitive than urethral Gram stain in detecting patients who were later found to have chlamydial infection as confirmed by culture. If bacteriuria is present and not clinically associated with urethritis or prostatitis, then treatment, followed by urologic referral, is indicated.

DIAGNOSIS

Independent predictors of a UTI in a patient with dysuria include advanced age, history of a prior UTI, back pain, pyuria, hematuria, and bacteriuria.¹⁰ Among sexually active women, the incidence of symptomatic UTIs is high, and the risk is independently associated with sexual intercourse, use of spermicides and/or a diaphragm, and previous history of a UTI.^{3,4,7}

The first step in diagnosis is the careful collection of urine for a urinalysis and potentially for culture. The midstream voiding specimen is as accurate as urine obtained by catheterization if the patient is given and follows careful instructions. Instruct the woman to remove her underwear, sit facing the back of the toilet, spread the labia with one hand, cleanse from front to back with antiseptic towelettes or swabs, pass a small amount of urine into the toilet, and then urinate into a sterile cup. Instruct the man to carefully clean the urethral meatus, retract the foreskin if present, and obtain a midstream specimen, as described above.

If the sample is properly collected, it should contain no or few epithelial cells. The many sources of contamination include material in the collection bottle, menses, vaginal discharge, urethral or periurethral tissue, and organisms multiplying in the urine after collection. Bacteria in urine double each hour at room temperature; therefore, urine should be refrigerated if not sent directly to the laboratory. In addition to special care in cleaning, the use of a tampon helps women to obtain a clean-catch specimen if menstruation or profuse discharge is present.

Catheterization is indicated if the patient cannot void spontaneously, is too ill or immobilized, or is extremely obese. It also may be performed as part of a urologic evaluation and to relieve obstruction. Many researchers have promoted the ease and accuracy of "minicath" kits to obtain urine in women, especially with a vaginal discharge or bleeding. However, unnecessary catheterization should be avoided because 1 to 2 percent of patients develop UTI after one catheter insertion, especially if it is done just before delivery in pregnant patients.

Visual inspection or the smell of the urine is generally not helpful in determining infection. Cloudiness is usually not due to white blood cells (WBCs) or bacteria, but to large amounts of protein or amorphous phosphate crystals. Malodorous urine may be caused by diet or medications and is not a reliable sign of infection.

Current emphasis is on the detection of pyuria and bacteriuria in the initial examination of the urine to confirm the diagnosis of a UTI. However, the assessment of pyuria is imperfect. Variables include the specific gravity of the urine, method of centrifuging the specimen, the amount of supernatant in which the sediment is resuspended, and the final volume of urine under the coverslip that is examined. Laboratories that use a WBC counting chamber diminish some of this variability and increase accuracy in assessing centrifuged and non-centrifuged urine. When using a WBC counting chamber, abnormal pyuria can be defined as the presence of at least eight leukocytes per milliliter of non-centrifuged urine. This figure roughly corresponds to two to five leukocytes per high-power field (HPF; or 400X) from a centrifuged specimen.

Whereas some investigators feel that low-level pyuria (< 10 WBCs/HPF) is clinically important, others have suggested that pyuria in women is significant only if there are more than 10 WBCs/HPF, and only if bacteria are also present on the microscopic examination. Although the combination of pyuria and bacteriuria is likely to be true with typical coliform infection, lower degrees of pyuria with or without bacteriuria may be significant, especially with regard to infection with *Chlamydia*.

It is clear that women with symptoms and low-level pyuria (< 10 WBCs/HPF) do have significant infection that will symptomatically and bacteriologically respond to antimicrobial therapy. In the past, these women were not treated initially, and their cultures often did not contain more than 10^5 CFU/mL. Sensitivity to causes of lower UTI other than typical coliforms has brought the designation of the *dysuria-pyuria syndrome* (also referred to as the *acute urethral syndrome*), which almost always benefits from treatment.¹⁶ It is in this subgroup of women that the urinalysis may well be more useful than the urine culture. In addition, if the patient has dysuria-pyuria syndrome caused by *Chlamydia* infection, then the urine culture will be negative in any case.

In men, more than 1 to 2 WBCs/HPF can be significant in the presence of bacteria.²⁶ It must be remembered that urethritis and prostatitis are far more likely causes of pyuria in young males who are sexually active and complain of dysuria, regardless of the presence or absence of urethral discharge.

Bacteriuria is also felt to be a sensitive tool for detection of UTI in the symptomatic patient. **The presence of any bacteria on a Gram stain of non-centrifuged urine (more than one bacterium per oil-power field, or 1000X) is significant** and strongly correlates with culture results of more than 10^5 CFU/mL. For Gram-stained centrifuged specimens, more than 15 bacteria/oil-power field (1000 X) are significant. Both methods fail to detect low colony-count UTI or infection caused by *Chlamydia*. False-positive results can occur when vaginal or fecal contamination is present.

Several studies have evaluated urinary dipstick nitrite and leukocyte esterase tests in the diagnosis of UTIs and correlated the results with urinalysis.^{12,13} The urine nitrite reaction has a very high specificity (>90 percent), and a positive result is very useful in confirming the diagnosis of a UTI and is highly predictive of the absence of pure enterococcal bacteriuria.¹³ Unfortunately urine nitrite sensitivity is low (about 50 percent), rendering it much less useful as a screening examination, and a negative result does not exclude the diagnosis of a UTI. Initial reports of high sensitivity (nearly 88 percent) for leukocyte esterase as a screening tool for pyuria were obtained in symptomatic women with high levels of pyuria. Studies from the emergency department found a low sensitivity (48 percent) for leukocyte esterase with more common levels of pyuria (6 to 20 WBCs/HPF). Fortunately, specificity for leukocyte esterase is good (80 to 90 percent). In summary, a positive urinary dipstick nitrite or leukocyte esterase test supports the diagnosis of UTI, but a negative test does not exclude it.

Sometimes, women will have dysuria, without pyuria or demonstrable pathogen on culture, and will not respond to antimicrobial treatment. The absence of pyuria in these patients is useful, because it indicates that antimicrobial treatment is probably unnecessary. Presuming that vulvovaginitis or cervicitis (gonorrhea, chlamydia, and herpes) has been excluded, causes of dysuria may include inflammation of the urethra from physical trauma or due to the use of chemical agents, such as spermicides, cleansing douches, or other feminine hygiene products.

In a symptomatic patient who has fewer than 2 to 5 WBCs/HPF, other causes of false-negative pyuria should be considered, such as ingestion of large amounts of fluids, which washes out the bladder and produces a dilute urine; systemic leukopenia; or self-medication with consequent partly treated UTI-caused by patients often using old or leftover medications from previous UTIs or medications prescribed to another person. It should be remembered that pyuria may be intermittent or absent if the patient has an obstructed and infected kidney.

For the patient with typical symptoms of an uncomplicated UTI and a "positive" urinalysis evident as pyuria on microscopic examination, positive leukocyte esterase test, bacteriuria on Gram stain, and/or positive urine nitrite test, urine culture is not required. The vast majority of these patients respond to empiric therapy. In fact, a current trend in the diagnosis and treatment of uncomplicated UTI is to treat on the basis of history alone and without obtaining any urine tests, in

many cases by telephone management and self-diagnosis or "patient-initiated treatment" protocols, which have been shown to be at least as effective as traditional approaches, less expensive, more convenient for patients, and without deterioration in quality of care.^{14,15} Given the frequency of visits to clinics and emergency departments for UTI and the enormous cost of diagnosing and treating UTI, it seems worthwhile to consider these new approaches in managing acute, uncomplicated UTI with empiric treatment on the basis of history and perhaps limited physical examination when patients present to the ED.

Most investigators agree that a urine culture should be obtained in the following settings: acute pyelonephritis; patients with epidemiologic risk factors for subclinical pyelonephritis; any patient who needs to be hospitalized; those patients who have a chronic indwelling catheter; and all pregnant women, children, and adult males.^{1,2,5,10} If the patient is symptomatic, one positive culture is significant. For ABU, two or three positive cultures are necessary before treatment is undertaken, with the exception that treatment for ABU is always indicated in pregnancy.

In addition to urine cultures, blood cultures are commonly recommended in cases of acute pyelonephritis; and although they are positive in about 30 percent of patients, the results rarely change management.¹⁶ Renal imaging studies are not indicated in otherwise healthy patients with acute pyelonephritis that can be managed on an outpatient basis. Elderly, diabetic, or severely ill patients with acute pyelonephritis should be considered for imaging, particularly if there is a poor initial response to antibiotic therapy. The kidneys can be imaged with portable ultrasound at the bedside for the evaluation of obstruction and focal parenchymal abnormalities.⁸ Plain film radiology and ultrasound have poor sensitivity for detection of intrarenal gas formation in emphysematous pyelonephritis; in suspected cases (e.g., diabetic patients with fever and flank pain), computed tomography is the best imaging modality.^{8,9}

TREATMENT

Acute Cystitis

The selection of antibiotics depends on the suspected bacteriology of the infection, the patient's compliance, potential drug toxicity, and cost.¹⁷ In uncomplicated UTIs, *E. coli* is the offending microorganism in the vast majority of cases, and this and other typical coliform pathogens remain largely susceptible to a variety of agents, e.g., trimethoprim (TMP), TMP and sulfamethoxazole (TMP/SMX), nitrofurantoin macrocrystals, and the fluoroquinolones (Table 94-2). Most uncomplicated UTIs can be treated with a short (3 day) course of antibiotics.

Trimethoprim or TMP/SMX are still recommended as first-line agents in most cases, because these are inexpensive and effective.^{6,18,19} However, resistance to TMP/SMX has increased dramatically in recent years. There is wide regional variation in TMP/SMX resistance, and this must be considered when choosing TMP or TMP/SMX as an empiric treatment choice. Resistance to TMP/SMX has been reported at over 30 percent in the western United States, up to 14 percent in the mid-west, and around 7 percent in the east.²⁰ Currently, recommendations are to avoid TMP/SMX (unless treating on the basis of urine culture with sensitivities) as the first-line empiric agent of choice when local resistance exceeds 20 percent. It may even be prudent to do so when resistance gets above 10 percent. The cost of treatment failures when using TMP/SMX where resistance is known to exceed 10 to 20 percent probably obviates any savings from choosing to use TMP/SMX as a less expensive medication. The need for repeat visits, retesting, retreatment and, in most cases, longer treatment courses with more expensive agents, and potential development of complicated UTI and/or pyelonephritis possibly necessitating hospital admission are good

TABLE 94-2 Guidelines for Outpatient Management of Uncomplicated Urinary Tract Infection

Patient	UTI Type	Clinical Characteristics	Antimicrobial Regimens	Comments
Adult female	Lower	Uncomplicated UTI = not pregnant, few prior UTI episodes, brief duration of symptoms (<7 d), and no risk factors for subclinical pyelonephritis	TMP/SMX DS (160/800 mg) 1 tab bid X 3 d or Trimethoprim 200 mg bid X 3 d If community resistance to these agents is high (> 10-20%) or patient allergic, then Ciprofloxacin 250 mg bid X 3 d or Ofloxacin 200 mg bid X 3 d or Levofloxacin 250 mg qd X 3 d or Nitrofurantoin 100 mg qid X 5 d*	No initial culture is required. If using a short course regimen, good follow-up is important. TMP/SMX or TMP remains first line unless community resistance is high (> 10-20%). (3-Lactams and nitrofurantoin are less effective than others when used for only 3 d.
Adult female	Lower/upper	Risk of subclinical pyelonephritis: prolonged symptoms, relapse or recurrent UTI, diabetes mellitus, urinary tract abnormalities, recent pyelonephritis, indigent patients	Ciprofloxacin 250-500 mg bid or Ofloxacin 200-400 mg bid or Levofloxacin 250-500 mg qd If susceptibilities are known, consider: TMP/SMX DS (160/800 mg) 1 tab bid Nitrofurantoin 100 mg qid Amoxicillin/clavulanate 875/125 mg bid	Urine culture is advised. Coliforms are common. Treat for at least 10 (mild symptoms) or 14 (more severe symptoms) d. Admit if patient very ill or pregnant.
Adult male	Lower/upper	Suspect underlying anatomic abnormality; consider urethritis and prostatitis	Ciprofloxacin 250-500 mg bid Ofloxacin 200-400 mg bid or Levofloxacin 250-500 mg qd If susceptibilities are known, consider TMP/SMX DS (160/800 mg) 1 tab bid Nitrofurantoin 100 mg qid* Amoxicillin/clavulanate 875/125 mg bid	Urine culture is advised. Coliforms are common. Treat for at least 10 (mild symptoms) or 14 (more severe symptoms) d. Admit if patient very ill.
Adult female	Lower	Stuttering symptoms, new sexual partner or partner with urethritis, signs and symptoms of cervicitis, pyuria without bacteriuria	Ofloxacin 400 mg bid X 14 d or Levofloxacin 500 mg qd X 14 d (covers common pathogens, gonorrhea, and <i>Chlamydia</i> at this dose) Doxycycline 100 mg bid X 14 d (covers <i>Chlamydia</i> but not gonorrhea; thus, potential cost savings uncertain without culture and treatment failure rate is high) Erythromycin 500 mg qid X 14 d (if pregnant, will only eradicate <i>Chlamydia</i> , not gonorrhea)	Culture for gonococcus and chlamydia. Consider consultation with patient's obstetrician, if pregnant. Gonorrhea resistance to quinolones is rising.

Compliance falls with qid medications. Nitrofurantoin sustained release (Macrobid) is a bid alternative (no generic yet).

Abbreviations: DS = double strength; tab = tablet; TMP/SMX = trimethoprim/sulfamethoxazole; UTI = urinary tract infection.

arguments for considering other agents (e.g., fluoroquinolones such as ciprofloxacin) as first-line agents when resistance to TMP/SMX is known to be high. Many experts feel that TMP/SMX soon will be ineffective as a first-line agent for UTI in any part of the United States.^{8,18,20}

Nitrofurantoin is also a generally effective agent for treating UTI, although compliance with frequent dosing (qid) is a problem, and nitrofurantoin is not effective against *S. saprophyticus*. There is a twice-daily formulation of nitrofurantoin (Macrobid), but it is expensive and not currently available in generic form. It is a favorite antibiotic among obstetricians for ABU and otherwise uncomplicated UTI in pregnant patients.^{5,12} Nitrofurantoin has not been well studied in the many trials demonstrating the effectiveness of short courses of antibiotics for UTI (e.g., 3-day regimens), and what data there are suggest that nitrofurantoin may be less effective at eradicating bacteriuria and infection than TMP/SMX or fluoroquinolones when used in short courses.¹⁸

Nitrofurantoin does have a favorable resistance profile in many regions as compared with TMP/SMX, it is a generally safe alternative, and the brand name twice-daily form (Macrobid) is slightly less expensive than most fluoroquinolones. Because nitrofurantoin is not currently a proven agent for short course regimens, it should probably be used only when a longer treatment course is already indicated, when the patient is pregnant, or when urine cultures showing sensitivity to nitrofurantoin are readily available.¹⁸

Because of greatly increased bacterial resistance, extended-spectrum penicillins (e.g., amoxicillin and other p-lactams) and cephalosporins have become less acceptable alternatives. If cultures and sensitivities are available, these agents are reasonable choices, but this is rarely the case in the emergency department. Further, there is evidence that short course regimens using (3-lactams and cephalosporins have a higher failure rate as compared with TMP/SMX and fluoroquinolones.⁶

In cases of treatment failure, or in the host with a structural or immunologic defect, use of amoxicillin with clavulanic acid or one of the fluoroquinolones should be considered. Urine cultures with sensitivities should be obtained and used to guide treatment. Short course regimens are not an option in these cases. Concern about the emergence of resistant organisms and expense has and should continue to preclude indiscriminate use of fluoroquinolones. Nonetheless, where TMP/SMX resistance is known to be greater than 10 to 20 percent and empiric short course (3 day) therapy is indicated, fluoroquinolones are the only remaining reasonable first choice.²¹ Unfortunately, fluoroquinolone-resistant UTI is already becoming a problem and is expected to increase dramatically in the coming years.

In uncomplicated UTIs, the urine should be free of bacteria in 24 to 48 h, with substantial relief of symptoms within the same period. The offer of 1 to 2 days of an oral bladder analgesic, such as phenazopyridine, is considerate when urination is painful for the patient. Within the past decade, multiple studies of shorter treatment regimens for uncomplicated infections in nonpregnant adult women have been published, and 3-day regimens have become the recommended standard of care.⁶⁻¹⁷⁻¹⁸ Short duration treatment regimens offer a number of advantages: cost and side effects are substantially reduced, compliance improves, and the development of resistant strains of bacteria is less likely. However, 20 to 30 percent of patients given short duration therapy fail treatment and/or quickly relapse. In addition, 3-day regimens are not adequate for all patients, and a 7-day course is recommended for pregnant women, those with symptoms lasting longer than 1 week, patients with diabetes, individuals who had a previous, recent UTI, those who are older than 65 years, and women who use spermicides or a diaphragm.^{6,17,18}

The recommendations and increased use of 3-day treatment regimens have generated concerns that that an increased incidence of treatment failures would result because of unsuspected subclinical pyelonephritis. Several studies of patients with apparently simple cystitis exhibiting kidney involvement as demonstrated by the presence of antibody-coated bacteria did not respond to short-term therapy when compared with patients with antibody-coated bacteria who received 10 to 14 days of treatment. The current paradigm is to use short course treatment for apparently uncomplicated acute cystitis, with the expectation of cure in the majority. Those patients with recurrence of symptoms, pyuria, and bacteriuria will be promptly identified as having subclinical renal infection necessitating 14 days of subsequent therapy.^{6,18}

In ED settings serving indigent populations, in which there is delay in seeking care, the incidence of subclinical pyelonephritis may approach 70 percent of patients. In this circumstance, short course therapy is difficult to justify. Before the ED physician decides to use a 3-day course of treatment, the patient's ability to follow-up within 1 week or return if symptoms persist must be assessed. If follow-up compliance is not expected, or the epidemiologic risk of subclinical pyelonephritis is great, then the patient should be placed on a 10- to 14-day regimen of appropriate antibiotics.

One should be suspicious that *Chlamydia* is responsible for symptoms in the following settings: a woman with a new sexual partner; a partner with urethritis; examination findings of cervicitis; or when there is low-grade pyuria with no bacteria seen on urinalysis. Concurrent infection with gonorrhea is common with chlamydia infections. If the patient has UTI symptoms and suspicion of a chlamydia and gonorrhea infection (cervicitis and/or salpingitis), antibiotic treatment is more complex. If the patient is not sufficiently ill to require admission and is not pregnant, one initial treatment approach is to use ofloxacin, 400 mg bid for 14 days; ofloxacin effectively covers all common UTI pathogens, chlamydia and gonorrhea. If salpingitis is clinically evident, metronidazole 500 mg bid for 14 days, should complete treatment. This approach is expensive, but the cost of the medication should be balanced against the long-term costs of treatment failures and morbidity associated with untreated cervicitis and salpingitis.

When treating a young teenage patient with recurrent UTI, the emergency physician should take a sexual history and, if the patient is sexually active, consider counseling of the patient regarding contraception and prevention of sexually transmitted disease.¹⁰ Assistance from a social worker may be useful.

Recurrent infection is often due to a new serotype of *E. coli*, or it may be due to newly resistant organisms that develop as a result of antibiotics excreted into the gastrointestinal tract. If empiric therapy is considered for recurrent infections, it probably should use fluoroquinolones unless community resistance to TMP/SMX is known to be low. However, successful management in cases of recurrent UTI depends on urine culture and sensitivity testing.^{6,10,18} In addition to evaluation of the urinary tract, chronic suppressive therapy is usually instituted. Up to 80 percent of women who have had one UTI develop another one later on. Because many factors are involved in reinfection and some of these are correctable, appropriate referral is important in patients with recurrent UTIs.

In patients discharged from the ED with treatment plans for UTI, adjunctive therapy should include plenty of fluids to enhance diuresis, fruit juices containing vitamin C to acidify the urine, a proper diet, and frequent voiding (at least every 2 h) to diminish tissue contact with bacteria. The effectiveness of cranberry juice in preventing UTI is curiously controversial, and careful review of the literature provides rather weak support for promoting cranberry juice as a UTI prophylaxis. Nevertheless, many studies have suggested at least some benefit from cranberry juice in preventing UTI, and there is certainly no harm in drinking it.²² Women should be reminded that postcoital voiding also may be helpful in reducing recurrent infection. Although no panacea, these adjunctive measures have long been recommended by physicians and are loudly proclaimed as significant in popular women's magazines and Internet-based public health information sites. Because they are unlikely to cause harm, may help, and stating otherwise to patients is likely to create confusion and potential aggravation for the emergency physician, continuing to recommend these measures is reasonable.

Aggressive therapy is warranted for pregnant women with pyuria or bacteriuria, whether or not associated symptoms are present. Urine culture with sensitivities is always indicated in these patients. Most clinicians prefer nitrofurantoin or a cephalosporin for initial outpatient treatment. Trimethoprim and SMX may be considered except in the first trimester, when TMP is contraindicated, within 2 weeks of the estimated delivery date, and in those with glucose-6-phosphate dehydrogenase deficiency. Fluoroquinolones are contraindicated in pregnancy. Amoxicillin is generally safe, but resistance and, hence, treatment failure rates are high. All regimens should be continued for at least 7 days, and the patient should be referred to her obstetrician for follow-up within 48 h. If the patient is greater than 20 weeks' estimated gestation, the emergency physician should contact the patient's obstetrician to discuss treatment options, if possible. Inpatient management is stressed for suspected pyelonephritis, because the incidence is higher in pregnancy, with subsequent maternal and fetal morbidity.

Acute Pyelonephritis

Classically, acute pyelonephritis is characterized by shaking chills, fever, flank pain, and CVA tenderness after several days of dysuria and frequency.¹⁸ The urine often demonstrates WBC casts and clumps and bacteria. Sometimes the presentation may not be dramatic, and it might be difficult to distinguish lower from upper UTI.

Factors associated with an increased risk for pyelonephritis include advanced age, pregnancy, prolonged symptoms before seeking care, three or more UTIs in the past year, immunocompromised state, poor general health and comorbidities, morbid obesity, institutionalization, chronic indwelling urinary catheter or the need for self-catheterization,

and diabetes mellitus. Less often, the patient may have a congenital or acquired anatomic urinary tract abnormality, neurogenic problems that result in incomplete bladder emptying, recent urinary tract instrumentation, renal calculi and nephrocalcinosis, prostatic hypertrophy, or prostatitis as precipitating factors for acute pyelonephritis.¹⁸

Young, otherwise healthy females with uncomplicated acute pyelonephritis may be candidates for outpatient management.^{18,23} Conversely, oral outpatient treatment cannot be recommended for patients who are immunocompromised, pregnant, diabetic, or chronically ill. Although unproved, a popular regimen at many institutions is to treat the patient with antipyretics, intravenous fluids, analgesics, and the first dose of antibiotic (oral or parenteral) while undergoing a brief period of observation in the ED to ensure that further oral therapy will be tolerated, which is assessed by having the patient drink water. As compared with traditional inpatient treatment for pyelonephritis, outpatient therapy for selected patients (young, otherwise healthy, non-pregnant, able to keep down fluids and antibiotics) is equally safe and effective and considerably less expensive.^{6,10,18} Fluoroquinolones are now the recommended first-line agents for the outpatient management of acute pyelonephritis.^{18,23} If urine culture and sensitivity results are available and demonstrate sensitivity to other medications (e.g., TMP/SMX, P-lactams, cephalosporins, and nitrofurantoin), these also can be used safely. Treatment should be continued for 10 to 14 days. Patients should be instructed to return with increasing pain, fever, or vomiting. Prescriptions for analgesics (e.g., hydrocodone plus acetaminophen) should be provided. Overall, 80 to 90 percent of selected patients with acute pyelonephritis will respond well to outpatient oral therapy.²³

The decision to admit a patient with acute pyelonephritis is based on age, host factors, and response to initial emergency department interventions. Fluid replacement and parenteral antibiotics are necessary if the patient is vomiting or dehydrated and has unremitting fever and/or loss of vasomotor tone. In an otherwise healthy host with no prior or recent history of UTI, the typical infecting bacteria would be *E. coli* or another coliform bacteria. Acceptable first-line intravenous antibiotic regimens include a fluoroquinolone (ciprofloxacin, levofloxacin, or ofloxacin), ampicillin plus gentamicin, a third-generation cephalosporin (cefotaxime, ceftazidime, or ceftriaxone), or extended spectrum penicillin plus (3-lactamase inhibitor (ticarcillin plus clavulanate or ampicillin plus sulbactam)).¹⁷ Urine culture with sensitivities is mandatory in these cases. When selecting the antibiotic for administration, the physician also should consider cost differences and local sensitivity patterns. In most cases, single drug therapy with a fluoroquinolone is the best initial option.

Overall, about 1 to 3 percent of patients with acute pyelonephritis will die from the infection, with younger patients experiencing the fewest complications. Factors associated with an unfavorable prognosis are advanced age and general debility, renal calculi or obstruction, a recent history of hospitalization or instrumentation, diabetes mellitus, evidence of chronic nephropathy, sickle cell anemia, underlying carcinoma, and immunocompromised states (e.g., chemotherapy, HIV/AIDS). In patients with these factors, broad-spectrum antibiotic coverage to include *Pseudomonas* spp. should be provided. A fluoroquinolone is a good initial choice.

Dangerous complications of acute pyelonephritis include acute papillary necrosis with possible ureter obstruction, septic shock, perinephric abscesses, and emphysematous pyelonephritis. Imaging studies (usually computed tomography) are necessary to detect these complications. Adequate fluid resuscitation, pain and fever control, antiemetics, and early initiation of appropriate antibiotics are critical.

HIV/AIDS Patients

In patients with HIV/AIDS, TMP/SMX resistance is increased largely due to its use in *Pneumocystis carinii* prophylaxis. Fluoroquinolones

should be the initial antibiotic used in UTI with these patients, unless urine culture and sensitivity results are available to guide therapy. Most UTIs in HIV/AIDS patients are caused by typical pathogens or common sexually transmitted organisms. *Mycobacterium tuberculosis* is an infrequent cause of UTI in the HIV/AIDS population. Close outpatient follow-up and possible infectious disease consultation are warranted when treating UTI in this population.²⁴

MALE GENITAL PROBLEMS

Robert E. Schneider

One of the most anxiety-provoking problems presenting to an emergency department is the male with an acute genital disorders. Further, the extensive sensory innervation of this area can produce severe symptoms. The close relations of the abdominal and genital sensory afferent pathways in the male account for the common association of abdominal pain with some acute genitourinary disorders.

ANATOMY

Penis

The penis is composed of three cylindrical bodies: the two corpora cavernosa, which form the main bulk of the penis, and the corpus spongiosum, which surrounds the urethra (Figure 95-1). The corpora cavernosa are the major erectile bodies, extending distally from the pubic rami and capped by the glans penis. These two cylindrical structures are encased in a thick tunic of dense connective tissue, the tunica albuginea. All three cylinders are collectively covered by a thinner Buck's fascia, which fuses with Colles' fascia at the level of the urogenital diaphragm.

The blood supply is primarily from the internal pudendal artery, which branches to form the deep and superficial penile arteries. Lymphatic drainage is into the deep and superficial inguinal nodes.

Scrotum

The prepubertal scrotal skin is thin and thickens with subsequent hormonal stimulation. Immediately beneath the skin are the smooth muscle and elastic tissue layers of Dartos' fascia, similar to the superficial fatty layer (Camper's fascia) of the abdominal wall. The deep membranous layer (Scarpa's fascia) of the abdominal wall extends into the perineum, where it is referred to as Colles' fascia, and forms part of the scrotal wall (Figure 95-2). The blood supply is derived primarily from branches of the femoral and internal pudendal arteries. Lymphatics from the scrotum drain into the inguinal and femoral nodes.

Testes

The testes usually lie in an upright position, with the superior portion tipped slightly forward and outward. The average size is between 4 and

FIG. 95-2. Anatomy of the scrotum and the testis.

5 cm in length and approximately 3 cm in width and depth. The overall volume is about 25 mL. Each testis is encased in a thick fibrous tunica albuginea except posterolaterally, where it is in tight apposition with the epididymis. The enveloping tunica vaginalis covers the anterior and lateral aspects of the testes and attaches to the posterior scrotal wall. Superiorly, the testes are suspended from the spermatic cord; inferiorly, the testis is anchored to the scrotum by the scrotal ligament (gubernaculum). Maldevelopment with lack of firm posterior fixation of the tunica vaginalis leaves the testes and epididymis at risk for torsion. The posterior (visceral) leaf of the tunica vaginalis is adherent with the tunica albuginea of the anterior testicular surface. A potential space exists between this visceral leaf and the anterior (parietal) tunica vaginalis. Any traumatic or inflammatory event will impede the normal parietal tunica vaginalis from absorbing visceraally secreted fluid, resulting in a hydrocele (Figure 95-3).

The blood supply is by the internal spermatic and external spermatic arteries, which travel together in the spermatic cord. Venous return is primarily by the internal spermatic, epigastric, internal circumflex, and scrotal veins. The lymphatics drain toward the external, common iliac, and periaortic nodes.

The epididymis is a single, fine, tubular structure approximately 4 to 5 m long compressed into an area of about 5 cm. The function of the epididymis is to promote sperm maturation and motility. Vestigial embryonic structures, the appendix epididymis and the appendix testis, which have no known physiologic function, are often associated with the testes and epididymis. The appendix epididymis, a remnant of the epigenitales, is found attached to the head of the epididymis, or globus major. The appendix testis, a pear-shaped structure of Miillerian duct

of the penis.

FIG. 95-3. Embryonic retroperitoneal testis descends into the scrotum and invaginates into the tunica vaginalis, which anchors it to the posterior scrotal wall. Note the potential space in the tunica vaginalis for development of a hydrocele.

origin, is usually situated on the uppermost portion of the testis at the junction of the testis and the globus major of the epididymis.

The vas deferens, a prominent part of the adnexa of the scrotal contents, is a distinct muscular tube that is easily palpable within the scrotal sac. It extends cephalad in the spermatic cord from the tail of the epididymis (globus minor), traverses the inguinal canal, and crosses medially behind the bladder over the ureters to form the ampullae of the vas, where it joins with the seminal vesicles to form the paired ejaculatory ducts in the prostatic urethra.

Prostate

The prostate originates from the urogenital sinus at approximately the third month of embryonic life. It is continually enlarging and in the young male is approximately 10 to 15 g, often not definable on rectal examination. As a man matures, the prostate may enlarge dramatically, resulting in significant bladder outlet obstruction. The prostate is divided into five lobes: anterior, median, posterior, and two lateral lobes.

PHYSICAL EXAMINATION

Physical examination should be performed with the patient in the supine and upright positions in a well-illuminated, warm room. If the scrotum is contracted despite proper room temperature, a warm towel placed over the genitalia permits the scrotum to relax and the testes to descend and be comfortably examined.

Examination should always begin with visual inspection. In uncircumcised males, the foreskin should be fully retracted to inspect the glans, coronal sulcus, and preputial areas for ulceration or malignant lesions. The location of the urethral meatus and presence of discharge should be noted. The penile shaft should be carefully palpated for plaques, cysts, or early abscesses.

The supine or modified lithotomy (frogleg) position is more comfortable for the patient and the examiner and allows a more thorough examination of each testis, epididymis, the prostate, seminal vesicles, and rectal ampulla. During the critical evaluation of a scrotal mass, the patient's relaxation and cooperation in the supine position are paramount. Testicular nodularity or firmness should be considered carcinoma until proven otherwise. The epididymis usually lies on the posterolateral aspect of the testis and, if not inflamed or involved with other pathologic entities, has a soft, fleshy feel similar to that of the earlobe. Many males experience pain and tenderness with palpation of a normal globus major (head), body, and globus minor (tail) of the epididymis. All males experience some discomfort during palpation of a normal prostate. The supine position helps prevent an infrequent vasovagal response to the scrotal or prostate examination. The prostate has a heart-shaped contour, with its apex located more distally, abutting the urogenital diaphragm (anatomic soft spot). The consistency of the normal prostate has the same resiliency as the cartilaginous tip of the nose, whereas suspicious carcinogenic areas feel more like the bony prominence of the chin. The posterior lobe is small and thin, allowing palpation of the median raphe that distinguishes the two lateral lobes. A rectal prostate examination cannot assess the anterior or median lobes. The seminal vesicles, lying just superior to the prostate, cannot normally be distinguished unless there is inflammation, induration, or enlargement.

Examination of the inguinal canals for hernias and the scrotal spermatic cords for varicoceles is best done in the upright position, with the patient straining at the designated time. When the patient is upright, it should be determined whether the testes are aligned along a vertical or horizontal axis; horizontally aligned testes are at greater risk for torsion.

Some genital disorders may require urine collection and analysis. The uncircumcised male should retract his foreskin and wash the glans penis with cleansing towels before collecting a midstream specimen. Failure to do so will result in preputial contamination. The often described three-cup specimen used to localize male lower urinary tract infections is time consuming and requires the patient's compliance, factors that tend to limit its usefulness in the emergency department.

COMMON GENITOURINARY DISORDERS

Scrotum

Because the scrotal skin is loose and elastic, dramatic enlargement of the scrotum may occur secondary to scrotal or testicular pathology.

SCROTAL EDEMA Simple, isolated scrotal edema is uncommon. It usually occurs secondary to insect or human bites, contact dermatitis, or, in young boys, idiopathic scrotal edema. Contiguous scrotal and penile edema occurs in older men in conjunction with lower extremity edema in fluid overload states (congestive heart failure), hypoalbuminemia, and generalized anasarca. Idiopathic scrotal edema presents as unilateral pain with unilateral scrotal, perineal, and inguinal swelling and erythema in boys between 3 and 9 years.¹ Ultrasound findings include thickened scrotal wall, increased peri-testicular blood flow, and reactive hydrocele. Episodes resolve in 1 to 4 days, although recurrences occur in 10 to 20 percent of patients.

SCROTAL ABSCESS The important distinction with a scrotal abscess is whether the phlegmon is localized to the scrotal wall, i.e., simple hair follicle abscess, or involves, and even perhaps originates from, infection in one of the primary intrascrotal organs, i.e., testis, epididymis, or bulbous urethra. This distinction can be very difficult late in the course of the infective process, when a scrotal mass may be the only discernible finding.

A simple hair follicle scrotal wall abscess can be managed by incision and drainage. Oftentimes wound care can be simplified by circumferential excision of the entire roof of the abscess. This allows access for wound care and sitz baths and assures healing from the base outward. Antibiotics are rarely needed in an immunocompetent male.

Contiguous involvement of the scrotal skin by an inflammatory mass in the testis or epididymis is best evaluated by ultrasound. A retrograde urethrogram will delineate the integrity of the urethra. Definitive care of any complex abscesses should be referred to a urologist.

FOURNIER GANGRENE Fournier gangrene is a polymicrobial, synergistic, necrotizing infection of the perineal subcutaneous fascia and male genitalia that originates from the skin, urethra, or rectum. This infectious process typically begins as a benign infection or simple abscess that quickly becomes virulent, especially in an immunocompromised host, and leads to end-artery thrombosis in the subcutaneous tissue that promotes widespread necrosis of previously healthy tissue (Figure 95-4). The diabetic male seems to be most at risk. Prompt recognition of Fournier gangrene in its early stages should prevent extensive tissue loss that accompanies delayed diagnosis. Aggressive fluid resuscitation; gram-positive, gram-negative, and anaerobic antibiotic coverage; and wide surgical debridement sometimes in conjunction with pre- and postoperative hyperbaric oxygen therapy are the mainstays of treatment.² Overall mortality is about 20 percent. Urologic consultation is often required when periurethral abscess is the inciting event, or when other etiologies have secondarily invaded the urinary tract and suprapubic urinary drainage is needed. Emergency physicians should maintain a high index of suspicion for this entity in immunocompromised patients who present complaining of scrotal, rectal, or any genitalia pain out of proportion to their physical examination findings of infection (warmth, erythema, and swelling).

Penis

FIG. 95-4. A patient with Fournier's gangrene of the scrotum. Note the sharp demarcation of gangrenous changes and the marked edema of the scrotum and the penis.

inflammation of the glans and foreskin.³ When foreskin retraction is attempted, the glans and apposing prepuce appear purulent, excoriated, malodorous, and tender. **Recurrent balanoposthitis can be the sole presenting sign of diabetes.** Many cases are caused by infection, most commonly *Candida* followed by *Gardnerella* and anaerobes. Treatment consists of cleansing the area with mild soap, ensuring adequate dryness, application of antifungal creams (nystatin or clotrimazole), treatment with an oral azole (fluconazole), and possibly circumcision.⁴ Bacterial infection is suggested by warmth, erythema, and edema of the glans, foreskin, and penile shaft. If these signs are present, a broad-spectrum antibiotic, usually a first- or second-generation oral cephalosporin, should be prescribed. Cases that persist warrant culture for potential infective causes or biopsy.³

PHIMOSIS *Phimosis* is the inability to retract the foreskin proximally and posterior to the glans penis (Figure 95-5). Causes include infection, poor hygiene, or previous preputial injury with scarring. Scarring at the tip of the foreskin can occlude the preputial meatus, infrequently causing urinary retention. Hemostatic dilation of the preputial ostium can be done to temporarily relieve the urinary retention. Definitive treatment has traditionally been circumcision. Recently, topical steroid treatment (triamcinolone 0.025% bid, or betamethasone 0.05% qd) applied from the tip of the foreskin to the glans corona for 4 to 6 weeks has been shown to be 70 to 90 percent effective in treating phimosis to allow for some degree of foreskin retraction and avert circumcision.⁵

PARAPHIMOSIS *Paraphimosis* is the inability to reduce the proximal edematous foreskin distally over the glans penis into its naturally occurring position (see Figure 95-5). The resulting glans edema and venous engorgement can progress to arterial compromise and gangrene. Paraphimosis is a true urologic emergency.⁶ Paraphimosis often can be reduced by compression of the glans for several minutes to reduce edema and allow for successful reduction of the foreskin back over the now smaller glans. Tightly wrapping the glans with a 2-in. elastic bandage for 5 min is one method to reduce edema. Infrequently, several puncture wounds with a small needle (22 to 25 gauge) can help edema fluid be expressed out of the glans. A local anesthetic block of the penis is also helpful if the patient cannot tolerate the pain of compression. If these methods are unsuccessful, local infiltration of the constricting band with lidocaine 1 percent without epinephrine fol-

Phimosis

Paraphimosis

FIG. 95-5. Phimosis and paraphimosis.

lowed by superficial dorsal incision of the band will decompress the glans and allow foreskin reduction. In cases with impaired perfusion to the glans, an emergency physician should do this procedure unless a urologist is immediately available.

ENTRAPMENT INJURIES Various objects can be placed around the penis, initially occluding the venous, and subsequently the arterial, blood supply. String, metal rings, and wire have been wrapped around the penis for sexual, experimental, or accidental reasons. Removal of the offending object often requires ingenuity and care. One of the most insidious objects that can become entrapped behind the coronal ridge is human hair, usually found in young circumcised boys age 2 to 5 years, termed the *penile hair-tourniquet syndrome* (Figure 95-6). The child presents with swelling of the glans. The offending hair may be invisible within the edematous coronal sulcus. If the hair has been present for some time, the urethra and dorsal nerve supply of the penis may be partly or completely involved. In this case, urethral integrity (retrograde urethrogram) and distal penile arterial blood supply (Doppler) should be ensured before emergency department discharge. Despite the appearance, the consensus from the medical literature is that penile hair-tourniquet syndrome is not a sign of child abuse.

FRACTURE OF THE PENIS An acute tear or rupture of the corpus cavernosa tunica albuginea is an uncommon condition.⁷ The penis is acutely swollen but flaccid, discolored, and tender. The history is of trauma during intercourse or other sexual activity, when a sudden "snapping sound" occurs. Most patients are between 30 and 40 years.

FIG. 95-6. Hair is entrapped behind the coronal sulcus (arrow), constricting and progressively amputating the glans.

Even though the urethra is infrequently injured, a retrograde urethrogram may be necessary to assure urethral integrity. Surgical treatment consists of hematoma evacuation and suture apposition of the disrupted tunica albuginea.

PEYRONIE DISEASE Peyronie disease produces progressive penile deformity, typically curvature with erections, that is painful and may result in erectile dysfunction or preclude successful vaginal penetration during intercourse.⁸ Examination of the penile shaft will disclose a thickened plaque, typically on the dorsum, involving the tunica albuginea of the corpora bodies. Reassurance and urologic referral are warranted. Peyronie disease of the penis has been noted in association with Dupuytren's contractures of the hand.

PRIAPISM Priapism is a urologic emergency that presents as a persistent, usually painful, pathologic erection in which both corpora cavernosa are engorged with stagnant blood.⁹ Even though the glans penis and the corpus spongiosum are characteristically soft and uninvolved, urinary retention may develop. Impotence has been reported to occur in 35 percent of cases with sustained erections for prolonged periods; thus, expedient treatment and early urologic consultation are required. Many cases of priapism in adults are pharmacologically related to intracavernosal injection of vasoactive substances for impotence (pavarine, prostaglandin E₁) or use of oral agents for hypertension (hydralazine, prazosin, or calcium channel blockers) or mental disorders (chlorpromazine, trazodone, thioridazine).⁹ Most cases of priapism in children are due to hematologic disorders, usually sickle cell disease. Case reports have attempted to relate a variety of other drugs, metabolic conditions, and trauma to priapism, although the pathophysiologic mechanisms are speculative in most cases.

Priapism is classified into high-flow (nonischemic) priapism and low-flow (ischemic) priapism. High-flow (nonischemic) priapism is rare, most often nonpainful, and usually results from traumatic fistulae between the cavernosal artery and the corpus cavernosum. It is readily diagnosed by color Doppler ultrasound and successfully treated by embolization. Low-flow (ischemic) priapism is more common, is usually quite painful, and is diagnosed by the aspiration of dark acidic intracavernosal blood from the corpus cavernosum.

Adequate analgesia should be given. Regardless of specific etiology, initial therapy with terbutaline, 0.25 to 0.5 mg SC in the deltoid area, repeated in 20 to 30 min as needed, is the most effective therapy. Traditional therapies of sedation or ice water enemas are ineffective. Pseudoephedrine, 60 to 120 mg PO, has been reported as effective in some cases that present early (within 4 h). Priapism due to sickle cell disease is most consistently reversed by simple or exchange transfusion. Corporal aspiration followed by irrigation (with plain saline or α -adrenergic agonists, i.e., phenylephrine) is the primary treatment method for persistent priapism. The urologic consultant usually performs this procedure, but if one is not readily available, the emergency physician may need to intervene under the direction of a urologist. If medical treatment or phenylephrine infusion fails to produce detumescence, surgery may be required.

CARCINOMA Carcinoma of the penis is a rare disease occurring in about 1 of every 100,000 malignancies reported, usually appearing in the fifth or sixth decade in an uncircumcised male. Carcinoma may appear as a nontender ulcer or warty growth beneath the foreskin in the area of the coronal sulcus or glans penis and is often hidden by an inflamed phimotic foreskin.

Testes and Epididymis

TESTICULAR TORSION The differential diagnosis of acute scrotal pain includes testicular torsion, torsion of the testicular appendages, and epididymitis.¹⁰ Because of the potential for infarction and infertility, testicular torsion must be the primary consideration.¹¹ Although the peak incidence of intravaginal torsion occurs at puberty in conjunction with maximal hormonal stimulation, it may occur at any age.

Torsion of the testis or spermatic cord results from maldevelopment (usually bilateral) of fixation between the enveloping tunica vaginalis and the posterior scrotal wall. Characteristically, the at-risk testis is aligned along a horizontal rather than a vertical axis. The axis of alignment can be determined only with the patient in an upright position, and even then the determination may be difficult.

Frequently there is a history of an athletic event, strenuous physical activity, or trauma just before the onset of scrotal pain. However, a fair number occur during sleep, when unilateral cremaster muscle contraction results in testicular torsion. The pain usually occurs suddenly, is severe, and is usually felt in the lower abdominal quadrant, the inguinal canal, or the testis. Although the pain may be constant or intermittent, it is not positional in nature, because testicular torsion is primarily an ischemic event that becomes inflammatory only after the testis has infarcted.

On examination, the involved testis is firm, tender, and often higher in the scrotum when examined with the patient standing. The epididymis may be displaced and not found in its normal posterolateral position. The cremasteric reflex is typically absent. Exacerbation or relief of pain with elevation of the affected testicle (Prehn sign) cannot reliably distinguish torsion from epididymitis.

In obvious cases of testicular torsion, emergent urologic consultation and surgical exploration are recommended. The often quoted 4-h warm-ischemia time for greater than 90 percent testicular salvage comes from controlled animal studies and cannot be extrapolated to clinical medicine. There are no readily available clinical or laboratory parameters to judge the degree or duration of testicular ischemia.

Therefore, no matter how long the patient has been symptomatic and no matter what the presenting physical examination suggests, if testicular torsion cannot be excluded by history, physical examination, and imaging studies, emergency scrotal exploration is the definitive procedure of choice.

Color-flow duplex Doppler ultrasound and radionuclide scintigraphy are two imaging modalities used to evaluate patients with indeterminate clinical presentations.

¹ Both may be useful, but their routine clinical use is limited by timely availability and operator experience in interpreting the images. These studies are considered "positive" for testicular torsion when they demonstrate absent or clearly reduced intratesticular blood flow to the painful side when compared with the opposite testicle, and "negative" when flow is normal or increased. Both studies have nearly identical reported sensitivity (80 to 90 percent) and specificity (75 to 95 percent) for testicular torsion. Ultrasound has the advantage of demonstrating scrotal anatomy (which may indicate an alternative diagnosis) but has the disadvantage of the greater number of indeterminate results when compared with scintigraphy. Within these limitations, both modalities may be useful when promptly available for patients with unclear clinical presentations but should never delay attempted manual detorsion and scrotal exploration. For emergent or preoperative treatment, the emergency physician should consider manual detorsion of the affected testis.^{14,15} Most testes twist in a lateral to medial fashion; therefore, detorsion initially should be done in a medial to lateral motion. It must be explained to the patient that detorsion is a painful procedure and, although local anesthesia of the affected spermatic cord can initially make the patient more comfortable, it also removes an important end point of the detorsion maneuver, i.e., relief of pain. Detorsion is done in a manner similar to opening a book (Figure 95-7A). If one were to stand at the pa-

tient's feet, the patient's right testis would be rotated in a counterclockwise fashion and the patient's left testis in a clockwise fashion (Figure 95-7B). The initial attempt should include one and one half rotations (540°). Any relief of pain is a positive end point, and the success of the maneuver can be assessed with Doppler ultrasound demonstrating restoration of blood flow.¹⁵ An occasional patient will require manipulation beyond the initial one and one half rotations. A worsening of the patient's pain would dictate that detorsion be done in the opposite direction. Successful detorsion converts an emergent procedure to an elective one.¹⁴ The timing of the elective surgical correction should depend on the patient's compliance and responsibility.

Young boys may present to the ED with nonspecific abdominal pain suggestive of gastroenteritis only to return 1 to 2 days later with testicular torsion. Whether these patients had undisclosed testicular torsion at their initial evaluation is not known, but emergency physicians should think about testicular torsion in the differential diagnosis of any male presenting with a complaint of abdominal pain.

TORSION OF THE APPENDAGES The four testicular appendages, appendix testis, appendix epididymis, paradidymis (organ of Giraldes), and vas aberrans, have no known physiologic function. These pedunculated structures are, however, capable of torsion and, in prepubertal boys, probably twist more often than the testes. The appendix testes and appendix epididymis account for about 90 and 8 percent of appendage torsion, respectively. If the patient is seen early, the pain is more intense near the head of the epididymis or testis, and an isolated tender nodule can often be palpated.¹⁶ When the involved infarcted appendage is brought close to the thin, prepubertal, nonhormonally stimulated scrotal skin, a small dark or blue spot may be seen when light shines on or transilluminates the scrotum. This "blue dot sign" is pathognomonic of torsion of the appendix testis or epididymis. If the diagnosis can be assured and confirmed by color Doppler ultrasound showing normal intratesticular blood flow to the involved testis, surgical exploration is not necessary, and most appendages will calcify or degenerate over 10 to 14 days without causing harm. If late in the process and testicular swelling is present, or if the color Doppler ultrasound is equivocal, then urologic consultation and surgical exploration may be necessary to exclude testicular torsion.¹⁰

EPIDIDYMITIS The onset of pain in epididymitis or epididymo-orchitis is usually more gradual than that of testicular torsion because of its inflammatory etiology. Bacterial infection is the most common cause and tends to depend on age.¹⁷ In young boys, epididymitis or epididymo-orchitis is due to coliform bacteria, often with congenital anomalies of the lower urinary tract that promote urinary reflux into the globus minor (tail of the epididymis). In patients younger than 35 years, epididymitis is due primarily to sexually transmitted diseases (STD) or their complications, i.e., urethral stricture. In homosexual men with epididymitis or epididymo-orchitis, fungal infection of the lower urinary tract in addition to the more common STD organisms must be considered. In patients older than 40 years, epididymitis is caused by common urinary pathogens such as *Escherichia coli* and *Klebsiella*. These patients most often will have pyuria on urinalysis, but the absence of white cells or bacteria does not exclude the diagnosis. Older men with epididymitis due to infected urine must be evaluated for the cause of their lower urinary tract infection, i.e., benign prostatic hypertrophy or urethral stricture. Oftentimes the answer may be found by passing a 14- or 16-French Foley or Coude catheter into the bladder; easy passage precludes a stricture. Large residual urine should alert the physician to outlet obstruction as the cause of the patient's infection. Chemical epididymitis can occur due to reflux of sterile urine and should be considered when the patient has prolonged symptoms despite appropriate antibiotic treatment.

Epididymitis causes lower abdominal, inguinal canal, scrotal, or testicular pain alone or in combination. The retrograde progression of

View from below

FIG. 95-7. Testicular detorsion. This procedure is best done standing at the foot of or on the right side of the patient's bed. A. The torsed testis is detorsed in a fashion similar to opening a book. B. The patient's right testis is rotated counterclockwise, and the left testis is rotated clockwise.

infection from the prostatic urethra to the epididymis explains the location and progression of pain. Patients with epididymitis are more prone to lower urinary tract irritative voiding symptoms and may note transient relief of their pain in the recumbent position with scrotal elevation (positive Prehn sign). Initially, isolated firmness and nodularity of the affected globus minor are noted on examination. As the disease progresses, the sulcus between the epididymis and testis becomes obliterated, and the inflammatory epididymal mass may become contiguous with the testis, producing a large, tender scrotal mass (epididymo-orchitis) that may be difficult to differentiate from testicular torsion or abscess.

Urinalysis may show pyuria in about half of patients. Culture or DNA probe for gonorrhea and *Chlamydia* should be done if urethral discharge is present or in patients younger than 35 to 40 years. Urine culture should be done in children and older patients. Adjunctive diagnostic modalities such as color-flow duplex Doppler sonography or radionuclide scintigraphy will demonstrate increased or preserved blood flow to the testes. A reactive hydrocele may be seen on ultrasound.

Most cases of epididymitis can be managed as outpatient cases with oral antibiotics for 10 to 14 days¹⁸ (Table 95-1). Admission criteria for epididymitis include fever with elevated white blood cell count and subjective toxicity, which can be indicative of epididymal or testicular abscess formation. Inpatient management includes: (1) bedrest for the first 24 to 48 h, with scrotal elevation and ice application (10 to 15 min every 4 to 6 h) to the involved testis or epididymis; (2) nonsteroidal anti-inflammatory drugs; (3) intravenous antibiotics based on presumed etiology; and (4) opiates for pain control. The ambulatory patient should wear a scrotal supporter, being careful not to lift heavy objects or strain when having a bowel movement, both of which will increase intra-abdominal pressure and exacerbate the inflammatory cycle. A urologist will need to re-evaluate the patient in 5 to 7 days and then ultimately decide when the patient may return to work based on his job description, i.e., a sedentary worker would be able to return sooner than a laborer.

ORCHITIS Isolated orchitis, or inflammation of the testicle, is quite rare and usually occurs in conjunction with other systemic infections, such as mumps or other viral illnesses (coxsackie, Epstein-Barr virus, varicella, or echovirus). Mumps orchitis presents with unilateral involvement in 70 percent of cases, followed by contralateral involvement in 1 to 9 days. Bacterial orchitis is almost always associated with epididymitis. Immunocompromised patients have been reported to have orchitis due to mycobacteriosis, cryptococcosis, toxoplasmosis, or candidiasis. Patients with orchitis usually present with testicular tenderness and swelling over a few days' duration. History and physical examination are usually adequate for diagnosis, but ultrasound may be useful to exclude testicular torsion or abscess. Treatment is symptomatic and disease specific.

TESTICULAR MALIGNANCY Any asymptomatic testicular mass, firmness, or induration is the hallmark of testicular carcinoma. Ten percent of tumors will present with pain secondary to acute hemor-

rhage within the tumor. Metastatic testicular tumors can be insidious and must be suspected in any male with unexplained supraclavicular lymphadenopathy, abdominal mass, or chronic nonproductive cough from a lung metastasis; testicular examination may disclose a primary tumor. Although not a urologic emergency, any unexplained testicular mass must be approached as a possible tumor with urgent urologic referral.

Acute Prostatitis

Acute prostatitis is bacterial inflammation of the prostate gland. It is characterized by low back pain; perineal, suprapubic, or genital discomfort; obstructive lower urinary tract voiding symptoms: perineal pain with ejaculation; frequency or dysuria; and fever or chills. Risk factors include anatomic or neurophysiologic lower urinary tract obstruction; acute epididymitis or urethritis; unprotected rectal intercourse; phimosis; intraprostatic ductal reflux; and indwelling urethral catheter or condom drainage. The causative organism is *E. coli* in most cases, with *Pseudomonas*, *Klebsiella*, *Enterobacter*, *Serratia*, or *Staphylococcus* in the remainder.

Clinical findings include perineal tenderness, rectal sphincter spasm, and prostatic tenderness or boggy. The diagnosis is clinical as urinalysis and urine culture may or may not be positive. Prostatic massage is not necessary to make the diagnosis. Urethral cultures should be obtained to test for the presence of gonorrhea and chlamydia.

Favored initial treatment is ciprofloxacin 500 mg PO bid for 30 days. If drug cost is an issue, trimethoprim-sulfamethoxazole (TMP/SMX) DS one tablet PO bid for 30 days is an **alternative**, although cure rates are lower for TMP/SMX than for ciprofloxacin.

Most patients can be treated as outpatients, although if there is evidence of sepsis or other risk factors for sepsis such as diabetes or immunosuppression, admission will be necessary. Urologic follow-up should be provided for discharged patients, to ensure eradication of infection and to provide continuity of care in case of relapse.

Urethra

URETHRITIS Urethritis is characterized by purulent or mucopurulent urethral discharge. Diagnosis is clinical, although it can be confirmed by evidence of pyuria or bacteriuria in a first void urine specimen. Most cases are due to *N. gonorrhoeae* or *C. trachomatis*. HSV, *U. urealyticum*, or *Trichomonas vaginalis* are less frequent causes.

Physical examination should exclude other disorders such as epididymitis, disseminated gonococemia, or Reiter syndrome. Treatment is ceftriaxone 125 mg IM and azithromycin 1 g PO or doxycycline 100 mg PO bid X 7 d. Failure to respond suggests re-infection or re-exposure or infection with *T. vaginalis* or doxycycline-resistant *U. urealyticum*. For the former, metronidazole should be given, for the latter, azithromycin. See Chap. 141 for further discussion of STDs.

URETHRAL STRICTURE Urethral strictures are becoming more prevalent secondary to the rising incidence of STDs. Increasingly, in teenagers and young adults, gonococcal and chlamydial infections result in bulbous urethral strictures (Figure 95-8). Urethral strictures from trauma and instrumentation are less common and tend to be localized to areas where a traumatic event has occurred. In the older population, postendoscopy meatal stenosis or localized urethral strictures are more common.¹⁹

If a patient requires measurement of his residual urine, has difficulty voiding, or is in urinary retention, and a 14- or 16-French Foley or Coude catheter cannot be easily placed into the bladder, the differential diagnostic possibilities include urethral stricture, voluntary external sphincter spasm, bladder neck contracture, or benign prostatic hypertrophy. If time permits, retrograde urethrography can be done, which will define the location and extent of a urethral stricture. Only

TABLE 95-1 Empiric Outpatient Treatment of Epididymitis and Epididymo-Orchitis

Age <35-40 y: Treat for gonorrhea and <i>Chlamydia</i>
Ceftriaxone 250 mg IM, plus doxycycline 100 mg
PO bid X 10 d Ofloxacin 300
mg PO bid X 10 d
Age >35—40 y: Treat for gram-negative bacilli
Ciprofloxacin 500 mg PO bid X 10-14 d Levofloxacin 250
mg PO per d X 10-14 d Trimethoprim/sulfamethoxazole
160/800 mg (DS) PO bid X 10-14 d
Antibiotic treatment should be adjusted depending on culture results

Abbreviation: DS = double strength.

FIG. 95-8. Stricture of the bulbous urethra.

endoscopy can confirm a bladder neck contracture or the extent of an obstructing prostate gland. Suspected voluntary external sphincter spasm can be overcome by holding the penis upright and encouraging the patient to relax his perineum and breathe slowly during urinary catheter insertion.

When a urethral stricture is encountered, copious anesthetic lubrication is placed intraurethrally after the foreskin has been controlled with a folded 4X4. This latter maneuver is especially important in uncircumcised patients. A 12- or 14-French Coude catheter may negotiate the strictured area, because this catheter has an angled bend near its tip. If there are previous false passages from attempts at dilation or unsuccessful instrumentation, passage of the Coude catheter may be difficult. Further urethral manipulation may create new false passages, leading to unnecessary hemorrhage and possible gram-negative bacteremia. If two or three gentle attempts to pass the catheter fail, urologic consultation is indicated. A catheter guide or urethral sound should be used only by a urologist.

For emergency bladder decompression, a suprapubic cystostomy using Seldinger technique can be performed in the ED. The infraumbilical and suprapubic area is prepped with antiseptic (i.e., povidone iodine) solution. A 25- to 27-gauge spinal needle is used to locate the bladder. This step is especially important in cases of previous lower abdominal surgery in which normal anatomic relationships may be distorted. Alternatively, bedside ultrasound can be used to locate the bladder. Commercially available introducer cystostomy kits are readily available for temporary drainage. After the bladder has been accessed with a syringe and needle, the syringe is removed and a guidewire is passed through the needle into the bladder. The needle is then removed, and the fascial dilator with an overlying 14- to 18-French peel away sheath is passed over the wire into the bladder. The wire and dilator are then removed, leaving the hollow peel-away sheath. An appropriate-size Foley balloon catheter is passed through the peel-away sheath into the bladder, urine is aspirated from the catheter to ensure proper placement, and the balloon is inflated with water. The sheath is then removed from the bladder and peeled away, leaving the indwelling catheter, which should be withdrawn until it snugly approximates the cystostomy site. Appropriate urologic follow-up is necessary in 2 to 3 days.

URETHRAL FOREIGN BODIES Patients of all ages, but especially young children, may be victims of innocent urethral exploration or attempts to heighten sexual experiences by using a variety of foreign bodies such as bobby pins; long, thin paint brushes; or ball point pens.²⁰ Bloody urine combined with infection and slow, painful urination should suggest a possible foreign body in the lower urinary tract. An x-ray of the bladder and urethral areas may disclose the presence of a radiopaque foreign body.

Foreign bodies often require endoscopic removal or even open cystotomy. Occasionally a gentle milking action of the proximal end of the urethral foreign body by an experienced examiner will allow its retrieval from the distal urethral meatus. Even then, retrograde urethrography or endoscopic confirmation of an intact urethra is indicated.

Urinary Retention

Bladder outlet obstruction causes a variety of signs and symptoms; overt urinary retention represents one end of the spectrum, and symptoms of insidious overflow incontinence often will fool an unsuspecting examiner.²¹ Urinary retention may be suggested if chronic systemic medical illnesses or carcinomas that have as sequelae sensory or motor neurogenic side effects or complications are present. A detailed medication history, including over-the-counter cold and dietary medications, may reveal the ingestion of a sympathomimetic agonist that has secondarily caused outlet obstruction due to its muscle-constricting effect on the abundant a-agonistic fibers in the bladder neck. Inconvenient, and therefore infrequent, voiding during a prolonged car trip by a vacationing patient with borderline obstructive symptoms may be just enough to result in urinary retention. Mechanical causes of bladder outlet obstruction include meatal stenosis, urethral stricture, bladder neck stricture, and benign prostatic hypertrophy.

A voiding history begins with questions regarding problems holding or initiating the urinary stream, voiding completely with one continuous stream rather than starting and stopping of the stream, a feeling of complete bladder emptying as opposed to incomplete emptying and postvoid residual, and the relative frequency of nocturia. Most men do not void as well or completely empty their bladders when sitting down to urinate, which happens most often during the night. Infrequent ejaculation may lead to secondary prostatic congestion and subsequent spurious symptoms of irritation and outlet obstruction.

The most difficult evaluation involves the patient with silent prostatism. Historically, voiding symptoms have gradually worsened over the years, but at such a pace that the patient often makes adjustments and then perceives each worsening state as "normal" for him. The ultimate result is urinary retention, with a large palpable bladder and often 1600 to 2000 mL of residual urine upon urinary catheterization. An intact sensory examination, anal sphincter, and bulbocavernosus reflex differentiate chronic outlet obstruction from the sensory or motor neurogenic bladder.

Appropriate physical examination requires inspection of the meatus for stenosis; palpation of the entire urethral length for masses or fistulas consistent with urethral stricture disease or abscess formation; lower abdominal examination for palpation of a suprapubic mass; and rectal examination to evaluate anal sphincter tone and the size and consistency of the prostate. Outlet obstruction due to a large intravesical prostate can result in a palpably normal prostate on rectal examination. Similarly, rectal examination in a patient in urinary retention initially may reveal a spuriously enlarged, nodular prostate that will shrink considerably once bladder decompression is achieved. Bedside ultrasonography is a noninvasive, accurate way to determine bladder distention and significant postvoid residual.

Most patients with acute urinary retention are in distress, and passage of a urethral catheter using lubricant with Lidocaine (Lidocaine Jelly) alleviates their pain and urinary retention. If attempts at passage of a straight 16-French Foley catheter fail, a 16-French Coude catheter should be passed. The catheter should be passed to its fullest extent to

obtain a free flow of urine, and only then can the catheter balloon be inflated. This will prevent balloon inflation in the prostatic urethra. If the catheter drainage holes become obstructed with lubricating jelly, gentle irrigation with sterile saline or water will quickly establish urinary drainage. Spontaneous, complete drainage of a distended bladder can be accomplished rapidly without the need for repeated clamping of the catheter. Occasionally, when a bladder has been chronically distended, bladder mucosal edema develops. Rapid decompression after catheter placement may result in transient gross hematuria. The transient hematuria is usually self-limited, of little consequence, and responds to orally induced diuresis. Post-micturitional or bladder decompression syncope is rare and should be treated symptomatically.

The catheter should be left indwelling and connected to a portable leg drainage bag. The patient or his family must be instructed in the care and drainage of this simple device. Antibiotics should be initiated if there is evidence of urinary infection. The patient or a family member should be instructed on Foley balloon deflation in case emergent removal of the catheter is necessary.

If urinary retention has been chronic or insidious, postobstructive diuresis may occur secondary to osmotic diuresis or interstitial tubular dysfunction. Postobstructive diuresis may occur in the presence of normal serum urea nitrogen and creatinine levels and may become an emergency if the patient suddenly becomes hypovolemic or hypotensive without warning. Thus, close monitoring of urine output is essential, with appropriate fluid replacement. For these reasons, all patients with chronic or insidious obstructive voiding symptoms and urinary retention should be observed for 4 to 6 h or be admitted, with particular attention paid to hourly intake, urinary output, vital signs, and urine and serum electrolytes. Osmotic diuresis will dissipate or the dysfunctional tubules will recover within 24 to 48 h. In all cases of urinary retention, consultation and follow-up with a urologist for a genitourinary evaluation are necessary.

UROLOGIC STONE DISEASE

Rakesh Engineer

W. Franklin Peacock IV

RENAL AND URETERAL STONES

Epidemiology

Urologic stone disease is a common condition, with an incidence estimated as high as 12 percent.¹ Stones occur three times more often in males, usually in the third to fifth decades of life. Some hereditary diseases (e.g., renal tubular acidosis, hyperparathyroidism, and cystinuria) predispose patients to kidney stones.

Lifestyle factors can augment stone growth. Patients in mountainous, desert, or tropical regions and those in sedentary jobs have a higher frequency of stone disease.² There is also an increased incidence during the warmest 3 months of the year for any geographic location. Increased water intake is associated with a decreased incidence of calculi.¹

Some medications predispose to stone disease. The protease inhibitor, indinavir sulfate, used to treat the human immunodeficiency virus, is associated with a 4 percent incidence of symptomatic urolithiasis. Carbonic anhydrase inhibitors, triamterene, and laxative abuse also increase the prevalence of renal stones.^{2,3}

Children younger than 16 years constitute approximately 7 percent of all renal stone cases. Unique to children is a 1:1 sex distribution.⁴ The most common causes in pediatrics involve metabolic abnormalities (50 percent), urologic anomalies (20 percent), infection (15 percent), and immobilization syndrome (5 percent). The remainder are considered idiopathic.

In patients with a history of a renal stone, up to a third suffer recurrence within 1 year. The 5-year recurrence rate nears 50 percent, probably due to the persistence of the underlying abnormality creating the first stone.

Pathophysiology

Stone formation is a multistep process that begins with supersaturation of urine with urinary solutes.^{1,2} Crystals eventually precipitate out as more solute is added. Once crystals form, their growth into a stone is prevented by inhibitory substances (e.g., citrate and pyrophosphate) and, more importantly, the free flow of urine. Thus, stone formation requires three key elements: supersaturation, a relative lack of inhibitors, and stasis.^{1,2} Urinary stasis from physical anomaly, neurogenic bladder or catheter placement, and the presence of foreign bodies (e.g., surgical suture) may provide the environment for stone growth.

Approximately 75 percent of calculi are composed of calcium, occurring in conjunction with oxalate, phosphate, or a combination of both. These stones may develop as a result of increased urinary excretion of a given solute. Calcium excretion is elevated in conditions that include hyperparathyroidism, absorptive and renal hypercalciuria, and immobilization syndrome. Oxalate excretion is enhanced in patients with inflammatory bowel disease and as a result of small bowel

resection or jejunioileal bypass. Ten percent of stones are struvite (magnesium-ammonium-phosphate). These stones often are associated with infection by urea-splitting bacteria and are the most common cause of staghorn calculi, large stones that form a cast of the renal pelvis. Antibiotic penetration into staghorn calculi is poor, and the potential for urosepsis exists as long as the stones remain. Consequently, surgical treatment is recommended for staghorn calculi. Uric acid causes 10 percent of uroliths. Cystine and other uncommon minerals comprise the remainder. Certain groups of patients are identified as high risk for preventable stone formation secondary to their underlying medical illness (Table 96-1). With appropriate evaluation, 90 percent of patients will have a cause identified, and 85 percent of calcium oxalate stone recurrences can be prevented.³

Passage of stones through the urinary tract may be slowed or halted by areas of anatomic narrowing or bending. Progressing proximally to distally, common areas of impaction include the renal calyx, the renal ureteropelvic junction (UPJ), where the ureter passes over the pelvic brim and iliac vessels, and the ureterovesical junction (UVJ). The UVJ has the smallest diameter of the urinary tract and is a common location for impacted stones. Another location in women is the posterior pelvis, where the ureter is crossed anteriorly by the pelvic blood vessels and broad ligament.

With acute ureteral obstruction, after an initial rise of renal blood flow and intraureteral pressure, both parameters decline and glomerular filtration falls. Concurrently, there is a proportional increase in blood flow to the contralateral kidney. These effects are reversible if the obstruction is relieved. However, after prolonged obstruction (several weeks), irreversible renal damage occurs. Because the contralateral kidney usually can maintain excretory requirements, serum urea nitrogen and creatinine levels do not rise, even though there may be only one functional kidney.

The probability of spontaneous passage of stones is determined by multiple factors, including size, shape, location, and degree of ureteral obstruction (Table 96-2). Bizarre or irregularly shaped stones with spicules or sharp edges have a lower passage rate. With complete obstruction, there is a lower rate of spontaneous passage than if the blockage is partial.

Clinical Features

Uroliths may be asymptomatic until there is at least partial obstruction of the urinary tract. The typical episode occurs while the patient is sedentary or at rest. Ureteral distention and peristalsis cause the acute onset of remarkably severe, episodic visceral pain and little, if any, tenderness on examination. Although subacute presentations occur, the usual rapidity of symptom onset is in contradistinction to many other diagnoses that may mimic renal colic.

Typically pain originates in either flank, radiates anteroinferiorly around the abdomen, and progresses toward the ipsilateral testicle or labium majorum. The discomfort can be intense and may be associated with nausea, vomiting, or diaphoresis. Patients may be unable to find a comfortable position to relieve their symptoms. Consequently, they may be anxious, pacing, and reluctant to lie still on the examining table. The "writhing of renal colic" is a useful point in the construction of a differential diagnosis.

TABLE 96-1 Some Conditions at Risk for Preventable Renal Stone Formation

Hypercalciuria: absorptive, resorptive (primary hyperparathyroidism), renal leak
Hyperoxaluria: primary genetic disorder, malabsorption associated with chronic diarrhea or short bowel syndrome
Hyperuricosuria: gout
Cystinuria: primary genetic disorder
Struvite stones: infection

TABLE 96-2 Probability of Spontaneous Renal Stone Passage

Characteristic	Probability
Size <4 mm	90%
4-6 mm	50%
>6 mm	10%
Location in ureter at first diagnosis	20%
Proximal Middle Distal	50%
	70%

The characteristic radiating pattern of renal colic results from autonomic nerve fibers serving the kidney and ipsilateral gonad. Atypical presentations of pain referral to the hip, thigh, or knee are rarely reported. As a stone progresses to the mid-ureter, anterior abdominal pain may radiate back toward the flank. With passage near the bladder, the patient may develop urinary frequency and urgency. Symptoms can be remarkably episodic due to intermittent obstruction of the urinary tract. If the stone passes or the obstruction is temporarily relieved, the patient has immediate symptom relief. Patients are frequently cool and diaphoretic, and a history of fever is unusual. Fever should prompt an investigation for urinary tract infection or other causes of febrile illness.

In children, symptoms vary with age. Older children are more likely to present with typical adult symptoms. Younger children may have a more nonspecific presentation, such as abdominal or pelvic pain. Although renal colic is rare in infants, symptoms may be mistakenly attributed to intestinal colic.⁴ Overall, 20 to 30 percent of children may have only painless hematuria with urologic stone disease.

Patients with known stone disease may present after treatment with extracorporeal shock wave lithotripsy. Extracorporeal shock wave lithotripsy fractures stones into small particles with the use of focused sound waves. The resulting "sludge" is passed in the urine. When there are large fragments, an acute episode of renal colic occurs. The clinical presentation is identical to that of "de novo" renal colic.

Diagnosis

PHYSICAL EXAMINATION Special attention is given to the abdominal and cardiovascular examinations so that potential catastrophes mimicking acute renal colic can be excluded. Elevations of blood pressure and pulse secondary to severe discomfort are common. The presence of fever or hypotension suggests the possibility of concurrent infection or an alternative diagnosis.

The abdominal examination is extremely important. Auscultation of a bruit or palpation of a pulsatile mass suggests a rupturing or dissecting aortic aneurysm. Distal pulses in the extremities should be carefully examined; diminished, absent, or asymmetric pulses suggest a potential vascular emergency. However, lack of abnormal physical findings does not exclude aortic disease, and elderly, hypertensive patients without a prior history of renal colic should be considered at risk for an abdominal aortic aneurysm (AAA).

Mild tenderness may be noted over the site of an impacted stone. However, peritoneal findings (e.g., guarding or rebound) or abdominal distention is not a usual component of acute renal colic, but if present, other pathologies should be considered.

The genitourinary examination is also important. Costovertebral angle tenderness is not unusual but, if present with fever or other symptoms of urinary tract infection, suggests pyelonephritis. Pyelonephritis can occur simultaneously with stone disease. In addition, because the radiating pattern of discomfort in renal colic includes the testicle or labium majorum, these areas should be evaluated for a potential incarcerated hernia. In a male patient, the testicles should be examined to exclude torsion or infection. A pelvic examination is not

indicated in females with a consistent evaluation (typical flank pain, microscopic hematuria, and a "positive" imaging study), but should be considered when the diagnosis is unclear.

The general physical examination should address the cardiac, respiratory, musculoskeletal, and dermatologic systems. An abnormal chest examination may suggest an alternative diagnosis, such as lobar pneumonia or pulmonary embolus. Musculoskeletal complaints may result in flank pain similar to that with renal stones. The presence of a vesicular rash over a flank dermatome may represent herpes zoster.

LABORATORY TESTS A urinalysis should be performed in patients with suspected renal colic to identify hematuria or infection. The finding of hematuria supports the diagnosis of renal colic, but there is no correlation between the amount of hematuria and the degree of urinary tract obstruction. A few patients may demonstrate gross hematuria, and in up to 15 percent, microscopic hematuria is absent.⁵ A urine test strip detects hemoglobin, myoglobin, or porphyrins as blood. A microscopic urinalysis can confirm hematuria by demonstrating the presence of red blood cells. A urine culture and sensitivity should be obtained if the test strip is positive for leukocyte esterase or nitrates or if the microscopic urinalysis shows bacteria or pyuria. The presence of oxalate or urate stones on microscopic urinalysis can be an aid to identifying stone composition. However, because crystals may be seen without renal stones, their presence is not diagnostic and should be interpreted cautiously. An elevated urine pH (>7.6) is associated with infection and may indicate the presence of a urea-splitting organism. Alkaline urine is also seen in renal tubular acidosis or after ingestion of large amounts of alkali. Collected urine should be strained to detect any passed stones, and all collected stones should be retained for pathologic analysis.

A pregnancy test should be performed in women of reproductive age. A positive result suggests a possible ectopic pregnancy and affects the choice of imaging study to confirm a renal colic diagnosis. A complete blood cell count is not indicated in routine renal colic but should be considered if the presentation suggests the possibility of anemia, infection, or AAA.

Other laboratory testing can be individualized. Renal evaluation (e.g., blood urea nitrogen and creatinine) may be required in patients at risk for nephrotoxicity (the elderly and those with renal insufficiency, diabetes, or hypovolemia) if a radiocontrast media (RCM) study is planned. There is a higher incidence of RCM nephropathy in diabetics with serum creatinine levels above 1.5 mg/dL and in patients with chronic renal insufficiency and serum creatinine levels above 2.5 mg/dL. Diabetics also may require a serum glucose measurement, because the stress of renal colic may cause significant hyperglycemia or nausea, and vomiting may produce hypoglycemia.

DIAGNOSTIC IMAGING **Helical computed tomography (CT) is generally the preferred imaging modality to diagnose renal colic.**^{1,6} Ultrasound is preferred in pregnant women to minimize radiation exposure.^{1,2} Other modalities that may assist in the diagnosis include intravenous urography, radionuclide renal scan, and plain abdominal radiographs (Table 96-3).

Imaging confirms the presence of a ureteral stone, rules out other diagnoses, identifies complications, defines stone location, and assists with management if the stone fails to pass spontaneously.¹ It is unclear if all patients require ED imaging for suspected renal colic. For young, healthy patients in whom the diagnosis is clinically clear, imaging can be conducted later on an outpatient basis if symptoms dictate.⁷ In women, imaging can be helpful to exclude gastrointestinal or gynecologic disorders. In older patients, disorders such as renal cell carcinoma, acute appendicitis, or AAA can be excluded by proper imaging studies.

COMPUTED TOMOGRAPHY The noncontrast helical CT scan is sensitive and specific, with "diagnostic" positive and negative likelihood ratios for detection of renal stones⁶ (see Table 96-3). Images are obtained from the top of the kidney to the bladder base. Secondary signs of ureteral obstruction, such as ureteral dilatation, stranding of perinephric fat, dilatation of the collecting system, and renal enlargement, can be helpful in making the diagnosis. In combination, unilateral ureteral dilatation and perinephric stranding have a positive predictive value of 96 percent for stone disease.⁸ If both are absent, the negative predictive value is 93 to 97 percent.⁸

Noncontrast helical CT has advantages over other imaging modalities, including superior speed, the avoidance of RCM, and greater ability to identify other pathologies. However, because RCM are not used, the specificity and sensitivity for other diagnoses (e.g., AAA, appendicitis, or perinephric abscess) are not as great as with imaging protocols using contrast. The helical CT scan has a few disadvantages. Helical CT does not evaluate renal function or provide information on the degree of obstruction.

INTRAVENOUS UROGRAPHY Intravenous urography (or intravenous pyelogram) yields information on renal function and anatomy. It detects calculi with modest sensitivity but excellent specificity^{6,9} (see Table 96-3). When performing the study, maintaining adequate urine output by giving intravenous fluids before RCM infusion may decrease the risk of contrast-induced renal injury. An initial scout film is obtained, followed by RCM administration, with repeat films at 5, 10, and 20 min. The first and most reliable indication of ureteral obstruction is a delayed nephrogram. Because the ureter is peristaltic, it is usually not completely seen on one film. Visualization of the entire ureter is suggestive of obstruction.

TABLE 96-3 Ancillary Tests in Urologic Stone Disease

Test	Sensitivity	Specificity	LR(+)	LR(-)	Comments
Noncontrast computed tomography	94-97%	96-99%	24-∞	0.02-0.04	Advantages: speed, no RCM, detects other diagnoses Disadvantages: radiation, no evaluation of renal function
Intravenous urogram	64-90%	94-100%	15-∞	0.11-0.15	Advantage: evaluates renal function Disadvantage: RCM (allergy, nephrotoxicity, metformin)
Ultrasound	63-85%	79-100%	10-∞	0.10-0.34	Advantages: pregnancy, no RCM, no radiation, no known side effects Disadvantages: insensitive in middle third of the ureter, may miss smaller stones (<5 mm)
Plain abdominal radiograph	29-58%	69-74%	1.9-2.0	0.58-0.64	Advantage: may be used to follow stones Disadvantage: poor sensitivity and specificity
Urine test strip	80%	35%	1.2	0.57	Rapid screening test but can miss complete obstruction if hematuria is absent, provides additional information on the possibility of infection
Microscopic urinalysis >0 RBC/HPF	89%	29%	1.3	0.38	

Abbreviations: HPF = high-power field; LR(+) = positive likelihood ratio; LR(-) = negative likelihood ratio; RBC = red blood cell; RCM = radiocontrast media.

The location of a radiolucent obstructing stone often can be determined by a ureteral contrast column cutoff. Adjuncts to the diagnosis of renal colic include the presence of a prolonged nephrogram, renal enlargement, dilatation of the collecting system, and contrast extravasation.¹⁰ Extravasation suggests obstruction that decompressed into the perinephric tissue. Extra-urinary tract urine (urinoma) has the potential for infection and abscess formation.

A postvoid film can identify stones at the UVJ or distal ureter that are otherwise obscured by a full bladder. In patients with high-grade or complete obstruction, delayed films taken at 1- to 2-h intervals may be required to precisely determine the level of obstruction.

The advantage of intravenous urography over other imaging modalities is that it provides information on renal function. It can be an adjunct to CT if functional information and knowledge of the degree of obstruction are required. The main disadvantage of intravenous urography is the RCM administration, which has possible side effects of allergic reaction and nephrotoxicity. The patient should be closely questioned for possible allergy to contrast media, and appropriate material for managing acute anaphylaxis should be immediately available.

Radiocontrast media nephrotoxicity is seen in approximately 9 percent of patients with pre-existing renal insufficiency or diabetes mellitus¹⁰ (Table 96-4). With risk for nephrotoxicity, RCM administration should be deferred until normal blood urea nitrogen and creatinine are documented. Nonionic contrast agents may result in a lower rate of kidney damage. Radiocontrast media should be used with caution in patients on metformin, because this drug has been associated with severe lactic acidosis and RCM nephrotoxicity."

Other disadvantages of intravenous urography include time required to complete delayed films and the lack of bowel preparation, which may affect the final interpretation. A false-negative study can occur if the stone is small, radiolucent, partially obstructing, or if it passes into the bladder before the contrast is excreted by the kidneys. If this happens, the patient experiences nearly complete relief of pain. The intravenous pyelogram may show evidence of ureteral spasm after stone passage.

ULTRASOUND If patients are not candidates for CT or intravenous urography due to concerns of radiation (e.g., during pregnancy or in children), ultrasound can assist in the diagnosis.^{9,12} It is useful in the detection of larger stones; however, it may miss smaller (<5 mm in diameter) ureteral stones.¹² Ultrasound is helpful in diagnosing stones in the proximal and distal ureters but is insensitive for mid-ureteral stones. Overall, ultrasound has only modest sensitivity and specificity for detecting renal stones (see Table 96-3) but is 98 percent sensitive for detecting hydronephrosis. However, up to 22 percent of hydronephroses diagnosed by ultrasound do not represent obstruction.¹⁰ Causes of false-positive hydronephrosis include normal anatomic variation, full bladder, and renal cysts. Ultrasound studies provide information on renal size and, with Doppler scanning, renal blood and urine flow. Limited information may be obtained about other pathologic conditions mimicking urologic stone disease.

Ultrasound has many advantages: it is noninvasive, uses no dye or radiation, and has no known side effects. It may also be superior to intravenous urography for detecting UVJ stones. However, it is limited to

anatomic findings; and whereas the Doppler study provides information about renal blood flow, ultrasound yields no information on renal excretory function. In addition, accuracy is operator and equipment dependent. Obesity may interfere with obtaining good-quality scans, and ultrasound can miss early obstructive signs. Rapid bolus infusion of crystalloid can result in a false-positive finding of hydroureter.

PLAIN ABDOMINAL RADIOGRAPHS About 90 percent of urinary calculi are radiopaque because calcium phosphate and calcium oxalate stones have a density similar to that of bone. Magnesium-ammonium-phosphate (struvite) is slightly less radiodense, followed by cystine, which is only partly radiodense. Uric acid and matrix stones are essentially radiolucent, as are most stones associated with medications.¹³ Unfortunately, because of small size and overlapping soft tissue and bone shadows, urinary stones are visible much less frequently on plain films. Plain abdominal radiographs have poor sensitivity and specificity for detecting renal stones^{9,14} (see Table 96-3). The weak likelihood ratios indicate that plain radiographs are of little value in the diagnosis of renal colic. Although a plain abdominal radiograph can localize some large radiopaque stones, its greatest utility is exclusion of other conditions, and it may be used to follow known radiopaque stones.

Differential Diagnosis

Many diagnoses can be confused with renal colic (Table 96-5). History and physical examination can be difficult because the patient's discomfort may interfere with adequate information collection. The most critical diagnosis to consider is aortic dissection or ruptured AAA. Renal colic and AAA may have similar presentations. Focal abdominal tenderness, abdominal distention, pulse disparity, and hemodynamic instability are not found in renal colic and suggest a leaking or ruptured AAA.

Pyelonephritis may cause flank pain; however, the prodrome is less acute and the discomfort not as severe as with renal colic. Fever is not a finding with kidney stones. In renal colic, the patient is usually in-

Papillary necrosis presents similarly to renal stones. It is most frequent in sickle cell disease, diabetes, nonsteroidal analgesic abuse, or infection. The urinalysis may demonstrate hematuria and pyuria. Intravenous urography or CT can demonstrate the sloughed renal papillae as lucency within the renal pelvis. Urologic consultation and hospitalization are usually required.

Renal infarction, from vascular dissection or arterial embolus, may present with acute flank pain and hematuria. The noncontrast CT scan likely will show no abnormality. Diagnosis requires evidence of impaired excretion (intravenous urography) or diminished blood flow (Doppler ultrasound or renal angiography). In renal vein thrombosis, there is increased kidney size and decreased function with proteinuria and microscopic hematuria.

Other pathologic conditions may cause ureteral compression or obstruction, producing symptoms similar to renal colic. Any intra-abdominal mass can cause ureteral obstruction. If within the urinary system, it may cause obstruction and pain from expanding size or in association with hemorrhage or necrosis.

Patients with pain out of proportion to the findings on the physical examination raise suspicion of mesenteric ischemia. Other gastrointestinal conditions may mimic renal colic but usually have significant abdominal tenderness. Gynecologic disorders may mimic renal colic. Ruptured ectopic pregnancy can present with acute pelvic and flank pain. Salpingitis usually has a more insidious onset, with cervical motion tenderness and purulent discharge on the pelvic examination. Although renal colic can cause pain radiating to the testicle, the testicle itself is normal; the presence of testicular tenderness, redness, or swelling on examination should indicate another cause.

Drug seekers may present with factitious renal colic, they are remarkably inventive in the complexity of their ruse, and there is no specific method for detection. A history of multiple medical allergies to non-opiate analgesics and RCM is frequently given. They may report a known radiolucent stone and can simulate hematuria by placing blood in their urine. The vital signs may suggest this behavior if changes in blood pressure and heart rate do not match the extreme discomfort demonstrated. When the clinician is unsure, it is better to give analgesia than to deprive a patient suffering from renal colic.

Treatment

The mainstay of ED treatment is pain control. Because, in most cases, the diagnosis is clinical, a rapid urine test strip positive for blood may provide sufficient information, coupled with clinical findings, to start analgesics. **Pain medication should not be delayed pending test results.** Relief frequently requires multiple doses of intravenous opiates, titrated to the level of discomfort. Opiates may be accompanied by nonsteroidal anti-inflammatory drugs (NSAIDs). Because time of onset for NSAIDs is slower than that for intravenous opiates, they are not effective monotherapy. However, their use in combination with opiates may result in earlier ED discharge.¹⁵ NSAIDs should be used with caution in patients with suspected renal insufficiency (e.g., diabetics) so as not to precipitate or accelerate a decline in renal function. An antiemetic is helpful if there is emesis, or when nausea complicates opiate use. Intravenous fluids, usually NS, can be given for hypovolemia, vomiting, or if a RCM study is planned.

If there is evidence of associated infection, urine culture should be obtained and parenteral antibiotics given promptly, while the patient is still in the ED.

Disposition

Patients with infection and concurrent obstruction have the potential for severe systemic toxicity and represent a urologic emergency; urologic consultation and admission are required (Table 96-6). In addition, disposition should be discussed with a urologist if there is (1) renal

insufficiency, (2) severe underlying disease, (3) an intravenous urogram showing extravasation or complete obstruction, (4) multiple ED visits, (5) a large stone, or (6) sloughed renal papillae. Because of lower rates of spontaneous passage, patients with large (>5 mm), irregular, or proximal stones should be considered for admission. In severe concurrent underlying disease (e.g., angina or chronic obstructive pulmonary disease) or in the fragile elderly, who may be unable to tolerate the stress of renal colic, a lower admission threshold is indicated. Patients who return with continued pain require a careful history and physical examination to ensure the diagnosis is correct, but repeat imaging is probably unnecessary.

In most situations, excluding pain, unilateral renal obstruction has minimal acute or permanent effects. Discharge is appropriate in those with smaller, rounded stones; in the absence of infection; and when pain is controlled by oral analgesics.¹⁶ Patients should be given a urinary strainer with instructions to save any stones they pass for pathologic evaluation. Average time for stone passage varies according to size and location, but may range up to 7 to 20 days for stones 5 to 6 mm in diameter.¹⁷ Patients should be counseled to return promptly for fever, vomiting, or uncontrolled pain, and a prescription for an oral opiate and NSAIDs should be provided. There is limited evidence that the addition of sustained-release calcium channel blockers (nifedipine) and steroids (prednisone or deflazacort) added to standard outpatient treatment with opioids and NSAIDs enhances stone passage rate and reduces lost work days, repeat ED visits, and surgical interventions.^{17,18} Follow-up with a urologist within 7 days should be recommended.¹⁶

If the stone passes in the ED, no further treatment is required. Elective urologic consultation is recommended so that the etiology of the stone is evaluated and a prophylactic strategy can be arranged. Patients with hematuria, negative imaging studies, and no other attributable source require outpatient urologic follow-up to determine the cause of their hematuria.

Protease-inhibitor-induced urolithiasis management is similar to that with other causes of stone disease; however, adequate hydration is particularly important.¹³ In addition, discontinuation of the offending agent for a short period may be necessary. Such a decision should be made in consultation with a urologist and infectious disease specialist.

BLADDER (VESICAL) STONES

Vesical calculi account for about 5 percent of urinary calculi, and in developed countries usually are associated with bladder foreign bodies, bladder outlet obstruction, or infection.¹⁹ Bladder stones are endemic in some developing countries, and historically the vast majority occur in males and develop in early childhood. In developed countries, 90 percent occur in males, with 80 percent in those older than 50 years. Calculi are associated with outflow obstruction or neuropathic bladder disease in 70 percent of cases. Urinary tract infection, vesical diverticuli, and foreign body (e.g., sutures, catheters, or implants) predispose to bladder calculi. Consequently, bladder calculi are reported in children and adults as a urologic surgery complication.¹⁹ Calcium oxalate is the most common constituent of bladder stones, but urate and struvite stones also occur. Usually solitary, multiple bladder stones are found in 25 percent of cases.

Bladder calculi may be asymptomatic, especially in patients with underlying prostatic obstruction. Typical symptoms are intermittent dysuria and terminal hematuria. The greatest discomfort usually oc-

curs at the end of micturition, as the stone impinges upon the bladder neck. In bladder outlet obstruction, there is interruption of the urinary stream, with frequency and urgency commonly reported. There may be associated dull, aching, low abdominal pain unrelated to urination that is exacerbated by exercise and abrupt movement. Pain usually is referred to the penile tip or scrotum by the second and third sacral nerves. Occasionally pain is referred to the low back or heel.

Physical examination is of little diagnostic help. Rarely, exceptionally large stones are palpated during rectal, vaginal, or abdominal examination. Urinalysis may demonstrate hematuria, pyuria, or bacteriuria. Plain radiographs detect vesical stones in approximately 50 percent of cases. Although ultrasound may demonstrate bladder stones, cystoscopic examination is the most accurate detection method.

Other bladder pathology can mimic vesical stones, including foreign body, carcinoma, neurogenic bladder, bladder diverticula, or fistula. Complications include chronic bladder irritation, fistulas, and urethral obstruction. Pericystitis may develop, if chronic, and can result in adherence of the bladder to the adjacent pelvic fat. Bladder perforation is a rare complication.

Bladder calculi require emergency therapy when they result in urinary obstruction or with associated infection. Acute urethral obstruction requires stone removal or catheter placement. Very distal stones may be gently milked from the penis or removed by forceps. More proximal stones require emergency urologic consultation. If there is coexistent infection, antibiotics should be administered in the ED. Patients with symptomatic nonobstructing bladder stones may be discharged with urology referral, because most vesical calculi require cystoscopic removal.

HEMATURIA AND HEMATOSPERMIA

David S. Howes Mark
P. Bogner

HEMATURIA

Normal urine contains a small number of red blood cells (RBCs), usually too small to be detected by routine chemical test strip testing or microscopic urinalysis. Hematuria that should concern the clinician may be visible to the eye (gross or frank hematuria) or invisible (microscopic hematuria). Gross hematuria often motivates the patient to come to the ED while microscopic hematuria is usually detected in the course of evaluating other symptoms. Hematuria may be associated with pain during urination and often accompanies urinary tract infections. Painless hematuria is more often a result of neoplastic, hyperplastic, and vascular causes. Whether gross or microscopic, hematuria warrants an attempt at definitive diagnosis, because underlying disease can be found in a substantial percentage of cases. The emergency physician's task is to exclude a life-threatening cause, make a diagnosis if possible, initiate treatment, educate the patient, and ensure appropriate treatment, disposition, follow-up, and referral.

Epidemiology

Gross hematuria is easy to define: the urine appears red. However, other pigments, particularly myoglobin, may discolor the urine, or bleeding from a nonurinary source may contaminate the urine. It takes approximately 1 mL of whole blood per liter of urine to result in visible hematuria. Gross hematuria may also result in false proteinuria, because 1 mL of whole blood contains approximately 50 mg of albumin. This must be taken into account when protein-losing diseases (e.g., nephritic or nephrotic syndromes) are considered in the differential diagnosis. Approximately 3 percent of the general population reports at least one prior episode of gross hematuria.¹ The incidence is higher in women (because of urinary tract infections), older adults (because of neoplasia), and older men (because of prostatic hyperplasia). Microscopic hematuria is less-well defined. Approximately 1 million RBCs typically pass into the urine each day. This small amount will be reflected as 1 to 3 RBCs/high-power field (hpf) (400X) on microscopic examination of centrifuged urine sediment. The American Urological Association Best Practice Policy Panel on Asymptomatic Microscopic Hematuria (AMH) defines AMH as >3 RBCs/hpf from two of three properly collected urinalysis specimens. This definition allows for some degree of AMH in normal patients. A **practical definition of microscopic hematuria for use in the ED is >5 RBCs/hpf on a single sample**; avoiding impractical attempts at obtaining multiple urine samples on a single visit. Population-based studies of healthy young individuals have found at least one episode of transient microscopic hematuria in up to 40 percent of men and 13 percent of women.^{2,5} The incidence of microscopic hematuria in children and adolescents is up to 6 percent for one specimen and 1 percent to 2 percent for two positive specimens.^{6,7}

Pathophysiology

Any process that results in infection, inflammation, or injury to the kidneys, ureters, bladder, prostate, male genitalia, or urethra may result in hematuria (Tables 97-1 and 97-2).^{8,9} In false hematuria, the urine appears bloody, but dipstick test results are negative for blood, and there are no RBCs on microscopic evaluation (Table 97-3). Free hemoglobin, myoglobin, or porphyrins in the urine result in a positive urine test strip reaction for blood without RBCs on microscopic evaluation.

Clinical Features

It is useful to identify when the blood appears during micturition. Initial hematuria is the appearance of blood at the beginning of micturition, with subsequent clearing, and suggests urethral disease. Hematuria occurring between voiding and noticed only as staining of underclothes with blood, while voided urine is clear, indicates lesions at the distal urethra or the meatus. Total hematuria is visible throughout micturition and corresponds to disease of the kidneys, ureters, or bladder. Terminal hematuria, occurring at the end of micturition after initially voiding clear urine, occurs with disease at the bladder neck or prostatic urethra.

Gross hematuria more often indicates a lower-tract cause, while microscopic hematuria tends to occur with kidney disease. Brown or smoky-colored urine along with RBC casts and proteinuria suggest a glomerular source. Red, clotted blood in the urine indicates a source below the kidneys. Hematuria that varies with menstruation and is associated with severe dysmenorrhea may indicate endometriosis involving the urinary tract.

In younger patients, microscopic hematuria is most often caused by nephrolithiasis or urinary tract infection.¹ It is also important to consider such disorders as glomerulonephritis, immune complex disease, Goodpasture syndrome, Henoch-Schonlein purpura and Wilms tumor in children, and sickle cell anemia or trait. Poststreptococcal glomerulonephritis is more common in children and typically follows a throat or skin infection. Symptoms appear 7 to 14 days after the primary infection, and the subsequent findings can vary from isolated hematuria to severe nephritis. Treatment of the primary streptococcal infection with antibiotics does not reduce the incidence of poststreptococcal glomerulonephritis. IgA nephropathy develops several days after a viral respiratory infection and is often accompanied by proteinuria secondary to glomerular damage from immune-complex deposition.

In older patients, infections and nephrolithiasis remain common causes of hematuria. Nonetheless, hematuria in patients older than 40 years—even with a clear diagnosis of urinary tract infection or stone—warrants close follow-up and retesting of urine because renal, bladder, and prostate cancer increase in frequency and may coexist with urinary tract infection or kidney stone.¹⁰ Risk factors for uroepithelial cancer in addition to age greater than 40 years include excessive analgesic use, tobacco use, occupational exposures (e.g., to dyes, benzenes, or aromatic amines), pelvic irradiation, and cyclophosphamide use.¹⁰ Similarly, hematuria in a patient on oral anticoagulants should not be attributed to the anticoagulant alone, because the inci-

Abbreviations: AV = atrioventricular; IgA = immunoglobulin A; NSAID = nonsteroidal anti-inflammatory drug.

dence of underlying disease may be as high as 80 percent.¹¹ Expanding abdominal aortic aneurysms (AAA) may erode into the urogenital tract and produce hematuria.

Malignant hypertension, embolic renal infarction, and renal vein thrombosis (RVT) are other serious diagnoses that can cause hematuria. Pregnancy, dehydration, nephrotic syndrome, lymphoma, and renal cell or other types of carcinoma are all predisposing disorders for RVT. RVT is commonly asymptomatic, with minimal or no pain. Children with RVT are typically volume depleted and have some other cause of a hypercoagulable state. In adults with RVT, there is usually underlying nephropathy and obvious nephrotic syndrome. In pregnancy, hematuria can be associated with urinary tract infection, nephrolithiasis, or preeclampsia.

TABLE 97-1 Common Causes of Hematuria

Etiology	Associated Age
Infections	Any
Nephrolithiasis	Usually >20 years
Neoplasms	Typically >40 years (except Wilms')
Benign prostatic hypertrophy	Males >40 years
Glomerulonephritis	Mostly young patients and children
Schistosomiasis	Any; most common cause worldwide

TABLE 97-3 False Hematuria (Discolored Urine)**Medications**

Rifampin, phenazopyridine, phenolphthalein

Foods/dyes

Beets, berries, rhubarb

Disinfectants

Iodide, bromide

Abbreviation: NSAID = nonsteroidal anti-inflammatory drug.

The reported incidence of hematuria in HIV-infected patients is 18 to 50 percent.¹² Causes include subclinical viral renal infection, early glomerulonephritis, urinary tract infection, chlamydial and gonococcal urethritis, chronic hepatitis B infection, neurogenic bladder, thrombocytopenia, subclinical uroepithelial Kaposi sarcoma, and urethral trauma. However, up to 80 percent of HIV-positive patients with an episode of asymptomatic hematuria have no specific etiology found after complete urologic evaluation.¹²

Diagnosis

Potential causes for hematuria are sometimes suggested by considering the patient's age, gender, demographic characteristics, habits, potential risk factors for urologic cancer, recent genitourinary instrumentation, and comorbidity.^{3,8}

The symptom should be clarified: is the hematuria traumatic or atraumatic; gross or microscopic; initial, terminal, or total? When did it start? Are there associated symptoms, such as menstruation; flank, back, or abdominal pain; dysuria; nausea; or fever? Is the patient pregnant? Are there risk factors for cancer or RVT? Has the patient had a recent respiratory or other infection that might predispose to IgA nephropathy or poststreptococcal glomerulonephritis? Has the patient recently traveled outside the United States, particularly to the Middle East or Africa, raising the risk of schistosomiasis? Was there recent instrumentation of the urinary tract or urinary or renal disease? Are there comorbid conditions, such as diabetes, hypertension, sickle cell disease, HIV, tuberculosis, cancers, lupus, or other diseases associated with vasculitis? A complete medication history is important to identify the use of anticoagulants or nephrotoxic agents. Strenuous exercise is a common cause of benign hematuria in healthy young individuals.¹³

The physical examination should note the vital signs and the patient's appearance. A younger and otherwise healthy patient without fever, writhing in pain on the cart, unable to find a comfortable position, and complaining of severe flank pain radiating to the perineum most likely has nephrolithiasis. Hypertension and edema imply nephrotic syndrome. A new heart murmur (endocarditis) or atrial fibrillation increases the likelihood of embolic disease and renal infarction. Dysuria and suprapubic pain and tenderness with or without fever suggest hemorrhagic cystitis. Perineal pain, dysuria, and a tender, boggy prostate in older men indicate prostatitis. A nodular prostate suggests the possibility of cancer. Flank or back pain with fever and costovertebral angle tenderness suggests pyelonephritis. Flank or back pain without fever suggests nephrolithiasis, AAA, renal infarction, or obstruction secondary to tumor. In an older patient, the examiner should palpate for a pulsatile abdominal mass and listen carefully for bruits. Hematuria with rash, arthritis, and abdominal pain may be the result of Henoch-Schönlein purpura in children. Polycystic kidney disease or renal malignancy may result in a large, palpable kidney. External genitalia in males should be examined for obvious tumor or trauma. A pelvic examination should be performed to exclude a vulvar or vaginal source of hematuria.

A clean-catch midstream urine collection is appropriate for most patients. Catheter-collected specimens are recommended for women with a vaginal discharge, menstrual or vaginal bleeding, or perineal disease. While urethral catheterization may induce hematuria in approximately 15 percent of patients, the amount rarely exceeds 3 RBCs/hpf.¹⁴

Convenient, commercially available bedside urine dipstick and pregnancy tests provide useful initial screening examinations.⁸ A urine test strip test for blood can detect as little as 150 μ g/L of free hemoglobin, corresponding to 5 to 20 intact RBCs/fjil on microscopic analysis. False-negative results may be obtained with urine dipstick tests for blood if the urine has a high concentration of ascorbic acid (more than 5 mg/dL) or a high specific gravity. False-positive results occur when oxidizing agents are present (e.g., household bleach used in cleaning containers) and in the presence of free hemoglobin, myoglobin, or porphyrins. Povidone-iodine may also result in a false-positive urine dipstick test result for blood. The urine dipstick test also provides useful information regarding infection (positive leukocyte esterase or nitrite test results), proteinuria, glycosuria, and ketonuria.

When results of the initial urine test strip screening examination are positive or unavailable, or the clinical picture is highly suspicious for a urinary tract cause, a microscopic urinalysis is indicated. Abnormal RBC morphologic characteristics, RBC casts, and proteinuria suggest a glomerular source and the need for further nephrologic or hematologic workup.^{8,10} Such patients typically do not require emergent renal imaging. The finding of normal RBCs on microscopic examination of the urine together with bacteriuria and leukocytes in a young healthy patient supports urinary tract infection as the probable cause of hematuria. If leukocytes are plentiful [more than 20 white blood cells (WBCs)/hpf] and clumped, and the patient also has back pain and fever, then pyelonephritis is likely. The presence of normal RBCs without evidence of infection should prompt further urologic evaluation to determine the site of bleeding.

Strenuous exercise is a frequent cause of hematuria, and follow-up is recommended even in cases of prompt resolution.^{11,13} Patients taking anticoagulants should have appropriate coagulation studies performed in the ED with imaging studies indicated in follow-up for most older patients in order to exclude malignancy.^{10,11}

A minority of patients (5 to 15 percent) with acute symptomatic urinary lithiasis have no hematuria, as measured by a urine test strip or formal urinalysis.¹⁵ Thus, patients with a clinical picture indicative of nephrolithiasis but without hematuria still require further evaluation. Further laboratory examination depends on the results of the history, physical examination, and presumptive differential diagnosis.

Renal imaging is done with one of three complementary studies: intravenous pyelography (IVP), helical computed tomography (CT) scanning, or renal ultrasound.^{16,17} The advantage of an IVP is that this study clearly delineates most renal tumors, obstruction, or stones and their precise location.¹⁶ The disadvantage is the use of radiocontrast media with attendant risk. Serum creatinine should be measured in older patients, diabetics, and those with preexisting renal disease before administering radiocontrast. In addition, the IVP does not directly assess the aorta, retroperitoneum, and pelvis.

Helical (ultrafast) CT scanning without contrast material is highly sensitive and specific in identifying nephrolithiasis.¹⁷ In cases in which no stone is identified, intravenous contrast infusion may also be performed and other intra-abdominal or retroperitoneal structures evaluated at the same time; i.e., AAA and appendicitis can often be excluded simultaneously. Helical CT scanning with or without intravenous contrast is faster and simpler when compared to IVP. The amount of intravenous contrast used is less than with IVP, making helical CT more useful when renal function is suboptimal. These facts together with increased availability of helical CT scanners in hospitals and reduced costs have made it the initial study of choice in most cases, largely replacing IVP.

Renal ultrasound is useful when screening for obstruction, hydronephrosis, or AAA. It is the study of choice in pregnant patients with suspected nephrolithiasis.¹⁸ The presence of two kidneys can be confirmed, and they can be measured and screened for tumors or cysts. The pelvis, abdomen, and retroperitoneum can be scanned for free fluid, mass, or aneurysm. However, renal ultrasound rarely identifies or locates stones in the ureters that are not large enough to give findings

of obstruction. Renal ultrasound also does not provide any assessment of renal function—normal enhancing and excretion of contrast by both kidneys—whereas both helical CT with contrast and IVP do provide such important information.

Gross hematuria in patients with blunt or penetrating trauma to the abdomen, flank, or back warrants an aggressive approach to identify the source of bleeding and to guide management (see Chap. 261).¹⁹ Some trauma centers use the degree of hematuria, quantified as the number of red blood cells per high-power field, to decide which patients with posttraumatic microscopic hematuria to image. While such an approach is not universally accepted, the studies indicate that patients with relatively minor blunt trauma to the back or flank (e.g., punched, kicked, fall of less than 10 ft) with low levels of microscopic hematuria (less than 20 RBCs/hpf) rarely have significant urinary injury. If they are stable, such patients can be discharged with careful return instructions and referred for repeat urinalysis.

Treatment and Disposition

Treatment of hematuria is directed at the cause. Urinary tract infections should be treated with appropriate antibiotics. Nephrolithiasis should be treated with hydration and analgesics. Systemic diseases should be appropriately treated. Outpatient management and referral for follow-up are appropriate in hemodynamically stable patients without an apparent life-threatening cause of the hematuria. Patients who are discharged should have no or minimal symptoms; be able to tolerate oral fluids, antibiotics, and analgesics as indicated; and have no significant comorbid conditions. Discharged patients should not have significant anemia or acute renal insufficiency.

Patients younger than 40 years of age should be referred to a primary care physician for repeat urinalysis 1 to 2 weeks after treatment. Transient asymptomatic microscopic hematuria (AMH) is so common, particularly with increasing age, that it might be considered a normal variant unless it persists or is associated with other risk factors.⁸ Persistent hematuria warrants urologic evaluation. Stable patients older than age 40 years with risk factors for urologic cancer should be referred to a urologist for more expeditious outpatient workup.

In the general population, AMH alone is not associated with an increased risk of urologic malignancy, but it is associated with a twofold increased risk of later developing renal failure.⁸ A thorough investigation of AMH in high-risk populations, particularly older men, occasionally discovers malignancies, most commonly transitional cell carcinoma of the bladder.⁸ Proteinuria is a sign of prognostically significant glomerular disease. Consequently, any degree of proteinuria accompanying microscopic hematuria, regardless of age or other risk factors, requires further investigation within a reasonable time frame.⁸ Children with hematuria should have pediatric referral. HIV-positive patients with asymptomatic microscopic hematuria who have a benign urologic history and normal renal function can be safely referred for outpatient follow-up and repeat urinalysis.

Gross hematuria may lead to intravesical clot formation and bladder outlet obstruction. This is treated by placing a triple-lumen urinary drainage catheter and starting intermittent or continuous bladder irrigation with normal saline. Manual irrigation using a syringe may be initially necessary if the catheter does not drain after initial placement. Once drainage is present, irrigation using gravity is started to wash clots out of the bladder. The rate of irrigant flow is determined by the appearance of the output; the goal is clear to only slightly pink tinged drainage. If placement of the triple-lumen catheter is unsuccessful, cystoscopy may be required for clot removal.

Patients with intractable pain, intolerance of oral fluids and medications, significant comorbid illness, bladder outlet obstruction, evidence of hemodynamic instability, or possibly life-threatening causes of hematuria should be admitted. Patients with suspected or newly diagnosed glomerulonephritis are at high risk of developing complications, such as pulmonary edema, volume overload, azotemia, or hypertensive emergency, and should be admitted. In pregnant women, hematuria can accompany preeclampsia, pyelonephritis, or obstructing nephrolithiasis; consultation and admission are indicated.

HEMATOSPERMIA

Hemospermia, or hematospermia, is a disturbing symptom that produces extreme anxiety in sexually active males. Most seek medical attention after one or two occurrences. Any process that results in trauma or other injury (e.g., tumor with erosion), inflammation, or infection of the male ejaculatory system may result in bloody semen.²⁰ Two of the most common causes of hematospermia are iatrogenic trauma from instrumentation of the urinary tract or radiation therapy. In patients older than age 40 years, tumors of the prostate or elsewhere in the ejaculatory system and benign prostatic hypertrophy are considerations. In patients younger than age 40 years, common causes are infections and inflammatory conditions, including prostatitis, seminal vesiculitis, urethritis, sexually transmitted diseases, epididymo-orchitis, calculi with inflammation, and tuberculosis. Testicular tumors occur in the younger population. Vascular abnormalities and cysts causing ductal obstruction are less common causes. As with hematuria, systemic factors may cause hematospermia, including hemophilia, other coagulopathies, oral anticoagulation, severe hypertension, leukemia or other hematologic disease, lymphoma, and scurvy.

A careful history, including sexual history, recent urologic procedures, medications, and HIV and tuberculosis risk factors, should be obtained. The patient's general health and condition, vital signs, abdomen, external genitalia, and prostate should be examined. Because hematospermia may be the initial and only presenting complaint in underlying urologic disease, a urinalysis is generally warranted, and treatment and disposition are directed by the urinalysis findings.

Hematospermia has long been considered a benign condition and is usually diagnosed as idiopathic after a complete urologic evaluation. It is not uncommon after vigorous sexual activity. Infection, including sexually transmitted disease, should be treated appropriately. In the absence of other reasons for an expedited workup or admission, patients should be referred to a urologist for follow-up and further outpatient evaluation. Patients younger than age 40 years can be reassured that the vast majority of cases of hematospermia in their age group are benign, self-limited, and idiopathic. While all patients with hematospermia should be referred to a urologist, those older than age 40 years are at higher risk for cancer and should be strongly advised to seek further evaluation by a urologist, even when there is spontaneous resolution of hematospermia.

with computed tomography or ultrasound. Acute management may include fluid resuscitation, blood transfusions, analgesics, and antibiotics. Most patients are managed conservatively, with close monitoring of hemodynamic status and laboratory studies to assess for decreasing hematocrit and renal function. A urology consult should be obtained early on, because treatments, such as embolization and nephrectomy, may be required.^{1,2}

Steinstrasse ("street of stone") refers to the post-ESWL dispersal of stone fragments, usually within the ureters. When an accumulation of these calculi, or one large fragment, becomes lodged, flank or groin pain, urinary obstruction, and superimposed infection can ensue. Patients can be asymptomatic or may present with flank pain, nausea, vomiting, fever, hematuria, or dysuria. *Steinstrasse* can be visualized on plain abdominal radiographs. Treatment options may include conservative management, repeat ESWL, or percutaneous nephrostomy.²

There are some case reports of rare events in which ESWL caused injury to other abdominal viscera secondary to the high energy used and close proximity of the other organs to the kidney. Complications reported included bowel perforation, gastrointestinal mucosal erosions and hemorrhages, ureteric perforations, and splenic trauma in the form of rupture, hemorrhage, and abscess. Patients may present with abdominal pain, signs of peritonitis, and fall in hematocrit. Diagnosis usually requires imaging: computed tomography or ultrasound. Surgery and urology consultation should be obtained for definitive treatment.⁴

In managing all postprocedural complications of ESWL patients, supportive therapy is important: intravenous fluid hydration, antiemetics (if needed), analgesics, and antibiotic treatment, if indicated. In addition, prompt urologic consultation should be obtained, when there is concern regarding complicated *steinstrasse*, a renal hematoma, or in conjunction with the surgeon if there is suspicion that other abdominal organs may be involved.

VASECTOMIES

Vasectomies are often done in an outpatient setting. In general, this surgical procedure is a safe method of contraception, with a low failure rate and risk of side effects. However, acute postoperative complications that may present to the ED can include bleeding and scrotal hematoma, local wound infections (cellulitis and abscess), epididymitis, and painful sperm granulomas. Some patients may present months to years later with chronic complications, such as persistent testicular pain, or congestive epididymitis (pain and testicular tenderness on the affected side).⁵

In the ED, patients should receive appropriate pain management and antibiotics, when indicated, especially in cases of immunosuppression. When there is no evidence of bleeding or wound infection, treatment options for postvasectomy epididymitis include ice packs, scrotal support, and analgesia with nonsteroidal anti-inflammatory agents or opiates. For patients with suspicion of testicular abscess (diffuse pain and swelling, often with fever), a scrotal ultrasound should be used. An urologist should be consulted for testicular abscess or scrotal hematoma.

PROSTATE SURGICAL PROCEDURES

Prostate surgery is usually performed for benign prostatic hyperplasia or prostate cancer. Common surgical techniques include transurethral resection of the prostate, transurethral incision of the prostate, transurethral electrovaporization of the prostate, transurethral microwave thermotherapy of the prostate, transurethral needle ablation of the prostate, and visually assisted laser prostatectomy.^{6,7}

Surgical procedures of the prostate typically involve direct manipulation of the urinary outflow tract. Therefore, common complications include hematuria, urinary blood clots with subsequent retention and failure to void, urethral strictures, and urinary tract infections. Some

COMPLICATIONS OF UROLOGIC PROCEDURES AND DEVICES Elaine B. Josephson Jatinder Singh

Urologic surgical procedures are increasingly performed with outpatients or inpatients who are discharged from the hospital earlier in their postoperative course. Thus, patients often come to the ED with specific problems due to common urologic surgeries involving the renal or ureteral system, vasectomies, and the prostate. Similarly, because urologic devices, ranging from urinary (Foley) catheters, artificial urinary sphincters, nephrostomy tubes and stents, to objects used for erectile dysfunction and genital piercing, are in more widespread usage, complications arising from their presence also may bring patients to the ED. In general, a urology consult should be obtained for complications arising from urologic procedures and devices, and whenever possible, the urologist who performed the original operation should be contacted.

LITHOTRIPSY

Extracorporeal shock wave lithotripsy (ESWL) involves the use of high-intensity sound waves to break up calculi within the genitourinary system. The main advantage of this technique is to noninvasively treat a large obstructing calculus. Overall morbidity with ESWL is quite low. Typically patients with post-ESWL complications may come to the ED with the following signs and symptoms: abdominal and flank pain, nausea, vomiting (especially 48 h postprocedure), skin ecchymosis, or ureteral colic and fever. Hematuria is a common occurrence after lithotripsy but is generally self-limited (<24 h). Although symptomatic treatment is often required, it is important to note that these presenting complaints also may be the indication of more serious problems.^{1,2}

Potentially more serious post-ESWL entities, although rare, are the perinephric and renal hematomas (usually secondary to subcapsular renal hemorrhage). The diagnosis is suspected when there is significant and severe flank pain and evidence of hemorrhage (flank hematoma or fall in hematocrit). Patients also may present with hypotension or syncope secondary to the bleeding. The diagnosis is made

patients experience obstructive or irritative voiding symptoms that may include incontinence, hesitancy, dribbling, urgency, and frequency.⁶⁷

The overall rate of serious hemorrhage is low.⁶⁷ If bleeding is significant, patients should be evaluated for hemodynamic instability, intravenous fluids administered, and appropriate laboratory studies ordered (complete blood cell count, renal function from serum urea nitrogen and creatinine levels, and urinalysis). Outflow obstruction should be relieved by placing a urethral catheter (triple-lumen) and irrigating with saline to remove clots. If infection is present, antibiotics should be administered.

COMPLICATIONS OF URINARY CATHETERS

Urinary catheters are used for a multitude of indications. Short-term catheterization is initially done for patients with acute urinary retention, for hospitalized patients who have urologic surgery or spinal cord injuries, and for monitoring the urinary output in critical patients. Long-term catheterization (>30 days) is used for patients with bladder outlet obstruction not treatable otherwise, for severely incontinent patients who are terminally ill or cannot care for themselves, and for some patients with neurogenic incontinence. Such a prolonged form of catheterization is often used for chronically ill patients in nursing homes. Problems relating to the use of urinary catheters include infection, obstruction, and leakage, and traumatic complications that can occur during catheter placement.

Infection

Catheter-associated urinary tract infections (CAUTIs) are one of the most common causes of nosocomial infections. The risk of infection is related to a number of factors; chief among them are duration of catheterization and patient comorbid factors. Duration of catheterization is one of the more important predictors of risk of infection. The risk of infection is about 1 to 2 percent with a catheter in place for less than 24 h, with the prevalence of bacteriuria reaching almost 100 percent for long-term catheterization (longer than 28 to 30 days). There is about a 3 to 10 percent incidence of bacteriuria for each day the catheter is in place. Comorbid patient problems, which increase the risk of CAUTI, include female sex, men with obstruction secondary to an enlarged prostate, renal disease, diabetes, and those who are elderly and debilitated. Another important contributing risk factor for CAUTI is the use of unsterile techniques during initial insertion of the catheter and subsequent handling during its drainage.⁸

Microbial factors associated with an incidence of CAUTI include the source of the organisms, the specific bacteria, the route of invasion, and the duration of catheterization. The organisms may be part of the patient's endogenous intestinal flora or may be acquired from outside sources such as other patients, hospital personnel, or unsterile equipment. Bacteria may be able to gain access to the urinary tract through the catheter lumen (intraluminal) or along the catheter surface (extraluminal). An infection from the extraluminal route begins with the formation of a film on the catheter surface consisting of urinary electrolytes, host proteins, and other urinary substances. Bacteria adhere to this film and transform it into a biofilm formed of products of bacterial metabolism and urinary components. Bacteria become embedded within the biofilm and gain protection from antibiotics.⁸

The microbiology of CAUTI varies according to the duration of catheter placement. During short-term catheterization, infections are usually due to single organisms, most commonly *Escherichia coli*, followed by *Klebsiella*, *Pseudomonas*, *Enterobacter*, and gram-positive cocci such as staphylococci. With long-term catheterization, CAUTIs are usually polymicrobial from *E. coli*, *Proteus mirabilis*, *Pseudomonas*, and *Morganella morganii*, and *Candida* spp. These infections are usually difficult to treat due to antibiotic resistance by the infecting bacteria.⁸

Bacteriuria may be present without symptoms. Asymptomatic bacteriuria usually occurs with short-term catheterization, and removal of the catheter clears the bacteriuria. Antibiotic treatment of asymptomatic bacteriuria in a patient with a short-term indwelling urinary catheter is controversial: some argue that treatment only promotes resistance and some advocate a short course of antibiotics. However, bacteriuria with a fever and other signs of systemic illness in association with urinary catheters (especially long term) requires aggressive workup for the cause for the fever and early institution of antibiotic therapy. The most common location for CAUTI with fever is pyelonephritis; other sites include prostatitis, epididymitis, and scrotal abscess. Urine cultures should be obtained to guide antibiotic therapy, and blood cultures should be obtained if the patient is septic or immunocompromised. Antibiotics should be instituted promptly, because a delay in treatment can lead to the development of serious complications.⁸⁹

The duration of antibiotic therapy for CAUTI varies from 5 to 14 days. Most can be treated with a single agent. However, those with the possibility of polymicrobial infection or who are seriously ill should be started on a broad-spectrum agent, e.g., ampicillin plus an aminoglycoside, anti-pseudomonal penicillin, carbapenem, or a fluoroquinolone.⁹

Obstruction and Leakage

Urethral catheters can become obstructed for many reasons, most commonly from the formation of intraluminal encrustations during long-term placement. These concretions are composed of compounds, such as ammonium magnesium sulfate (struvite) and calcium phosphate (apatite), often with urease splitting organisms, such as *Protease* and *Morganella*. Such encrustations can increase the risk of formation of infectious stones and cause bladder trauma leading to blood clots. A catheter obstruction may lead to urinary leakage around the catheter and acute urinary retention. Management options include repeated bladder irrigations, methenamine treatment, and removal of the catheter if the other methods fail. Infections should be treated with antibiotics.⁹ Mechanical obstruction also can occur due to a nondeflation of the retention balloon on the catheter. Removal usually requires urologic intervention and potential cystoscopy.

Periurethral (or pericatheter) leakage can occur secondary to bladder spasms or catheter obstruction. The two can be differentiated by attempting to flush the catheter; if it does not flush, the catheter is probably obstructed. Treatment options include the use of antispasmodics, such as oxybutynin, flavoxate, and dicyclomine for bladder spasms and catheter irrigation and/or removal in case of obstruction.⁹

Traumatic Complications

Adequate lubrication and proper catheter size selection help to minimize the risk of trauma to the urethra during urinary catheter insertion. The urethra can be injured from inflation of the retention balloon within the urethra. Forceful attempts at catheter removal with an inflated balloon can cause edema and tears to the urethra. During insertion, a false lumen can be created, especially in patients with underlying urethral strictures or prostate enlargement, when excessive force is applied. Subsequently, the patient may develop bleeding, pain, and a lack of urine output from intraurethral clot formation or urethral disruption. Surgical intervention by the urologist may be required. To avoid possible traumatic complications, a Coude tipped or large-size catheter should be tried with less force when there is a problem with insertion in these patients. Although uncommon, bladder perforation should be suspected in patients with peritoneal signs, pyuria, hematuria, and diminished urine output. This warrants a diagnostic cystogram and urgent urologic consultation for definitive care, if the bladder is perforated.

Alternatives to Indwelling Catheters

Alternatives to long-term urethral catheters have a lower rate of complications and should be considered, if feasible. One option is the use of intermittent catheterization, which involves insertion and removal of a urinary catheter several times a day at periodic intervals. It is especially useful for patients with bladder emptying dysfunction and children with neurogenic bladders. For male patients, condom catheters are a noninvasive approach to incontinence with a lower risk of infection when compared with urethral catheters. Complications from condom catheters include penile skin erosion and penile strangulation.⁸

Suprapubic catheterization places a catheter directly into the bladder through the anterior abdominal wall. Compared with urethral catheterization, suprapubic catheterization is associated with a lesser incidence of bacteriuria, because the abdominal wall has a lower concentration of bacteria than the periurethral area. However, the suprapubic route carries risks of cellulitis, hematoma formation, and persistent leakage.⁹

COMPLICATIONS OF PERCUTANEOUS NEPHROSTOMY TUBES

Percutaneous nephrostomy is a urinary drainage procedure used for supravescical or ureteral obstruction secondary to malignancy, pyonephrosis, genitourinary stones, and ureteral strictures. It is also used as an adjunctive therapy with ESWL and ureteral stents. Nephrostomy tubes are also used for urinary diversion associated with vesical fistula, ureteral transection, and trauma. Patients may present to the ED from postoperative complications related to the procedure or days and months after the procedure. In general, the risk of complications is low and includes bleeding, infection, mechanical complications related to the catheter (dislodgement or obstruction), and accidental punctures of adjacent organs.

During insertion, injury can occur to the lungs (pneumothorax), liver, spleen, and the bowel (perforation). The risk may be higher in patients with an enlarged liver or spleen. The complication usually is clinically apparent during or immediately after the procedure, but recognition may be delayed a few days.¹⁰

Bleeding and hemorrhage can occur, especially if the patient has a coagulopathy. The hemoglobin, hematocrit, and renal function should be checked. Coagulation studies (prothrombin time, partial thromboplastin time, and platelet count) and type and crossmatch should be obtained if bleeding is excessive or the patient has a suspected coagulopathy. Most bleeding episodes are mild and can be managed with irrigation to clear nephrostomy tube blood clots. More severe bleeding can be handled by catheter tamponade, a procedure undertaken by the urologist and radiologist. Sometimes, bleeding can be severe enough to cause hemodynamic compromise. Severe hemorrhage occurs from vascular injury, such as laceration of an artery, formation of an arteriovenous fistula, or bleeding from a pseudoaneurysm, and may occur in the retroperitoneal space or perirenal areas. In such cases, fluid resuscitation and blood transfusion, in addition to more definitive interventions, are required. Angiographic studies with possible embolization may be needed to ascertain the site of bleeding and effect treatment.¹⁰

Infectious complications from nephrostomy tubes include simple bacteriuria, pyelonephritis, renal abscess, bacteremia, and urosepsis. The patient may present with fever, chills, rigors, pain, and purulent drainage at the site or from the tube. Urine and wound drainage (if present) cultures should be obtained, and antibiotics should be started in consultation with the urologist.¹⁰

Mechanical complications, such as catheter dislodgement and tube blockage, can occur with these devices. The risk of catheter dislodgement increases with increasing duration of the nephrostomy. Dislodgement occurring in the early postoperative period usually requires

creation of a new tract at a different site. Dislodgement occurring after some period may be treated by recannulation under fluoroscopic guidance. Tube blockage can occur secondary to encrustations and kinking. The urologist has several techniques available to re-establish access to an obstructed nephrostomy tube.¹⁰

COMPLICATIONS OF ARTIFICIAL URINARY SPHINCTERS

The artificial urinary sphincter (AUS) is a device used for urinary incontinence secondary to sphincter disturbance, postsurgical incontinence, neurogenic bladder and incontinence, trauma to the urethra, and congenital conditions associated with bladder dysfunction, such as meningocele, exstrophy, and epispadias. Many different models (the AMS 800, a current example) have been introduced over the years, with successive revisions. The basic principle of the AUS is to increase the resistance around the urethra and thus provide urinary continence. Mechanical parts of the AUS include a pump, an inflatable cuff that encircles the urethra, and a pressure regulating reservoir balloon. These are connected by a set of two tubes. Continence occurs when fluid is moved from the balloon to the cuff. To allow urination, the cuff is emptied of the fluid, which moves to the reservoir. Both activities are controlled by the pump, which is implanted in the scrotum of males or the pelvis of females.¹¹

Postoperative complications of the AUS device include bleeding, infection, and malfunctions. A common problem associated with AUS implantation is the formation of a hematoma. These hematomas usually occur in the scrotum or the labia and most resolve spontaneously. Larger hematomas may need to be drained to aid with the healing process.^{11,12}

Infections are the most serious complication of the AUS. Periprosthetic infection can present early or late after AUS implantation. Infections occurring early after implantation are usually due to skin flora. Later infections are usually due to gram-negative organisms of the urinary tract. Symptoms and signs of infection can range from pain, swelling, and induration of the site to localized erythema of the pump or cuff site. More serious infections can present with fever, local abscess formation, drainage from incision sites, and erosion of the pump or the cuff. Infections can cause the components (e.g., cuff) to externalize out onto the skin or erode the urethra.¹²

Treatment of periprosthetic infection requires antibiotics and removal of the sphincter. Patients with an AUS in place should get antibiotic prophylaxis when undergoing procedures that may cause hematogenous seeding of the device, such as dental procedures.^{11,12}

Retained air bubbles, fluid leaks, and tube kinking are some of the mechanical complications that can occur with the AUS. Design modifications over time have decreased some of the mechanical complications. Air bubbles can cause blockage of the pump, leading to filling defects and thus incontinence. Ineffective device functioning secondary to fluid leakage also can lead to sudden onset of incontinence. Tube kinking, a rare complication, can result in fluid blockage, thereby leading to urinary retention. A careful history may provide clues to malfunction. A pump that is difficult to squeeze implies blockage due to any cause, whereas a pump that remains compressed after squeezing signifies pressure loss or fluid leakage. Plain radiographs of the pelvis and other imaging studies are used to assess continuity of the mechanical components.¹¹

Urethral erosion secondary to infection or excessive cuff pressure around the urethra is another serious complication, and one that is seen most commonly 3 to 4 months after the implantation. Patients may present with pain, swelling along the urethra and in the perineum, urinary incontinence, bloody urethral discharge, and infection. Cystourethroscopy and cuff removal are necessary for management of erosions.¹¹

Recurrent incontinence after AUS placement can have many etiologies; infection, cuff erosion, fistulas due to surgical injuries, and

mechanical failure are the most common causes. Evaluation requires urodynamic studies to accurately define the cause. Acute urinary retention in a patient with an AUS implant may occur as a result of bladder neck contractures, urethral strictures, or cuff erosion. Evaluation usually requires imaging studies, such as cystourethrography and endoscopic viewing of the urinary system.¹²

Evaluation in the ED of complications related to the AUS requires a thorough history noting the model type and make and symptom assessment and a detailed physical examination, urinalysis, and appropriate imaging studies. **No attempt should be made to introduce a urethral urinary drainage catheter through an AUS.** A urologist should be consulted for further evaluation and management.

COMPLICATIONS OF URETERAL STENTS

Ureteral stents are used primarily in patients to relieve ureteral obstruction and maintain ureteral lumen patency. Obstruction to the ureter may result from causes such as stones, strictures, trauma, malignancies, or retroperitoneal fibrosis. Stents are also used during surgery involving the genitourinary tract to maintain urinary patency and drainage and as adjuncts to lithotripsy in the management of nephrolithiasis. The use of stents has increased during the past three decades, and more complications secondary to their use are being reported now. Side effects seen early (first week) after stent insertion include fever, infection, irritative bladder symptoms, and hematuria.^{13,14}

Many factors contribute to stent-related urinary tract infections. Stents induce a foreign body reaction, which increases the risk for infections. Encrustation of stents in the presence of infection with urea-splitting organisms also promotes infection. More serious infections, such as pyelonephritis and sepsis, can occur but are less common.

Most minor infections can be managed with outpatient antibiotics and do not require removal of the stent. If pyelonephritis or a systemic infection is suspected, intravenous antibiotics, imaging studies to determine the position of the stent, and urologic consultation are required. Stents usually can be visualized by plain abdominal x-rays due to the presence of radiodense marking imbedded within the catheters.¹⁴

Symptoms, such as mild flank pain, and signs suggestive of an irritative bladder, such as dysuria, urgency, frequency, and pain during voiding, occur commonly in patients with ureteral stents. Treatment options for these symptoms can include analgesics, anticholinergic medications, or, in severe cases, belladonna alkaloid and opioid suppositories. New complaints and symptoms, such as severe flank pain, require evaluation for stent migration, infection, or obstruction. Asymptomatic microscopic hematuria is usually of no clinical significance, whereas gross hematuria may indicate a more serious pathology, such as stent migration or erosion of the urinary tract, requiring imaging studies to locate the stent position.¹⁴

Serious problems, such as stent migration and stent fragmentation, are usually late complications seen with long-term stent placements. Stent migration can occur upward above the ureteropelvic junction or downward below this junction. Such migration can lead to obstruction and infections. These patients initially may present to the emergency department with new-onset abdominal pain, fever, and irritative bladder symptoms.^{13,14} Most serious complications require urgent consultation with a urologist.

COMPLICATIONS OF DEVICES USED FOR ERECTILE DYSFUNCTION

About 20 million American males suffer from erectile dysfunction. The most common causes are diabetes, medications, post-prostate surgery, spinal cord dysfunction, and psychogenic. Although oral medication therapy currently exists for erectile dysfunction, some patients with erectile dysfunction are treated with devices or procedures, such

as vacuum therapy, penile injections, external penile splints, and implantable penile prostheses.

Vacuum devices work by use of negative pressure and the use of a constriction ring to cause venous and arterial congestion, thus causing penile tumescence. The most common complaint reported is pain during application of the device and during ejaculation secondary to inappropriate pressure rise. Both symptoms can be resolved with proper use of device. Local skin cyanosis secondary to a drop in penile blood flow from the negative pressure may also be seen. Serious complications from the use of a vacuum device include penile skin necrosis, urethral bleeding, ischemia, and subcutaneous hemorrhage with ecchymosis. Peyronie disease and Fournier gangrene have also been reported.¹⁵

The external penile splint consists of two steel support rods in a silicone cover that have a support loop at the distal end, to loop around the subcoronal sulcus, and support rings at the proximal end, to position around the base of the penis. Aside from occasional dislodgement during sexual intercourse, these splints are relatively free of side effects.¹⁵

Two forms of injection therapy for erectile dysfunction are available: intracavernosal and intraurethral. The intracavernosal injections are given along the lateral aspect of the penis, directly into the corpora cavernosa. The basic mechanism involves vasodilation of arteries and veins leading to corporal smooth muscle relaxation and penile erection. Drugs used are papaverine, phentolamine, and alprostadil, a prostaglandin E₁ analogue, singly or in combination. Side effects include penile pain, prolonged erections (4 to 6 h), priapism (painful erection for longer than 6 h), and localized hematoma. Of these, priapism is the most urgent complication. Treatment includes the use of terbutaline, α -adrenergic agonists such as phenylephrine, and corporal aspiration of blood with emergent urology consultation.¹⁶

Intraurethral injections use alprostadil to produce penile tumescence. One marketed product, the MUSE (medicated transurethral system for erection), uses a medicated pellet via an applicator that allows insertion of the drug into the urethra. The basic mechanism of intraurethral administration is similar to intracavernosal injections; the drug is absorbed from the urethra and through the local communicating vessels and exerts its actions on the corpora. Side effects are few and can include penile pain, urethral bleeding, laceration of the cavernosal artery, and dizziness. Very rarely priapism can occur. Intraurethral administration is usually free of any major systemic side effects, but syncope secondary to a vasovagal reaction due to the anxiety of the injection and the vasodilatory effects of the drug can occur.¹⁶

Several different types of implantable penile prostheses are used: the rigid rod prosthesis, the malleable or semirigid device, and the inflatable device. The inflatable device is composed of a pair of inflatable cylinders inserted in the cavernosa, a scrotal pump, and an abdominal fluid reservoir. Infection is the most devastating of all penile prosthesis complications and usually occurs soon after the primary surgery for implantation. Late infections can occur years after the procedure secondary to seeding via the bloodstream. Infection usually occurs in the periprosthetic space, the area between the prosthesis and the secondary capsule formed around it, due to a foreign body type reaction of the body to the foreign material. The surface of the device is a site for bacterial adherence and the formation of a biofilm. This film allows bacteria to grow on the prosthetic surface and limit antibiotic penetration. Organisms causing penile prosthesis infection are *Staphylococcus epidermidis*, *Staphylococcus aureus*, and gram-negative bacilli. Infections present as pain along the device (e.g., in the scrotum or along the penis), erosion, and purulent urethral discharge. Treatment requires removal of the entire device by the urologist and antibiotics.¹⁷

Migration and erosion of the prosthesis occur most commonly due to infection. Migration may occur proximally or distally, presenting as extrusion through the urethral meatus. Migration most often requires removal. Penile ischemia and necrosis are rare but serious complications occurring mainly in patients with predisposing factors, such as diabetes and vascular disease. Mechanical failures, such as tubing

fracture, cylinder rupture, and reservoir leakage, have decreased over time due to device improvement. Evaluation of mechanical problems requires an assessment of the device by a urologist.¹⁷

COMPLICATIONS OF GENITAL PIERCINGS AND PENILE FOREIGN BODIES

Body piercing is the use of needles, rings, and other ornaments to pierce the skin for fashion and cultural practices. Although the earlobe traditionally is the most common site used, the piercing of other body parts, such as the navel and genitalia, are now becoming more prevalent in Western society. With this trend come risks of medical complications. In evaluating cases of genital piercings, information regarding where the procedure was performed and by whom, the composition of the jewelry used, the presence of comorbid conditions, and postprocedure care should be ascertained.¹⁸

Body piercing is not a benign procedure. Piercing can result in damage to deeper structures. Frequently, an unlicensed person who may use an unsterile technique or instruments, thus increasing the risk of infections, trauma, and other complications, performs the piercing.¹⁹ Sometimes, embarrassment about the use of piercing leads to delay in seeking medical attention for problems.

Complications from body and genital piercings have been described mostly in case reports; there are no prospective studies of the incidence or frequency of these events. Some complications are unique to the body part involved, e.g., paraphimosis or urethral injury from encircling penile foreign bodies. Local and systemic reactions can be related to the material in the jewelry used, e.g., contact dermatitis or asthma from metal allergies (most commonly nickel). Silver has been reported to produce localized argyria or systemic silver poisoning. Embedded jewelry and migration of jewelry are other problems that can occur after piercing procedures.¹⁸

Infections usually present with redness, swelling, and/or purulent drainage at the affected site. Infectious complications such as local cellulitis, sepsis, toxic shock syndrome, and endocarditis have been reported. An increased risk for infection occurs in immunosuppressed patients, such as those with diabetes or the human immunodeficiency virus. Similarly, patients with a history of valvular heart disease may be at increased risk of endocarditis. Most infections are bacterial and usually due to *Staphylococcus aureus*. Hepatitis B, C, and D have been reported after piercing. Treatment requires local wound care, antibiotic therapy, and, in some cases, removal of the piercing object.¹⁸

Because genital piercing is essentially an invasive procedure, trauma due initially to the procedure itself and later secondary to traction on the object can produce local edema, hematoma, tissue tearing, and bleeding. Urethral rupture, tears, and paraphimosis have been reported from penile piercing.¹⁸ Granulomatous reactions resembling sarcoid, hypertrophic scars, and keloids, and inguinal lymphadenopathy are delayed complications reported from piercing.¹⁹

Penile strangulation due to an encircling object, such as a ring or similar device, can lead to edema and vascular compromise, eventually causing ulceration, necrosis, and gangrene of the penis. Penile strangulation grades have been described: grade 1: distal penis edema, no skin ulceration or urethral injury; grade 2, distal penile edema with decreased sensation, skin injury and constriction of corpus spongiosum, no urethral injury; grade 3: loss of distal penile sensation, injury to skin and urethra, but no urethral fistula; grade 4: loss of distal penile sensation with complete division of the corpus spongiosum leading to urethral fistula and constriction of the corpus cavernosum; and grade 5: gangrene, necrosis, or complete amputation of distal penis. The relief of strangulation requires prompt removal of the device from the penis. Evaluation involves assessment of penile temperature, color, and sensation; ability to void; presence of pulses (Doppler ultrasound); and urethral integrity. Urologic consultation is indicated for evidence of penile ischemia, potential urethral injury, and when it is not possible to remove the object from the penis in the ED.

THE RENAL TRANSPLANT PATIENT

Richard Sinert Mert Erogul

Since the first transplantation of a kidney from one human to another in 1954, the procedure has evolved from the realm of experimental medicine to the routine. Renal transplantation has become the preferred treatment for end-stage renal disease. With more than 200,000 living kidney recipients, emergency physicians can expect to encounter these patients, and should become familiar with the issues regarding organ rejection and complications of immunosuppressive therapy. Special emphasis should be given to the evaluation of the renal transplant patient with infections and acute renal failure (ARF).

EPIDEMIOLOGY

Renal transplants account for the majority of solid-organ transplants in the United States; in 2001, there were 23,848 solid organs transplanted, of which 14,024 were kidneys.¹ At the same time, approximately 51,000 patients were waiting for a kidney transplant, and approximately 2900 patients died while on the waiting list.¹

Approximately 60 percent of kidneys are obtained from cadaveric donors, many of whom may be initially identified in an ED setting.¹ Traditionally, cadaveric donors have been victims of head injury or intracranial hemorrhage with unsurvivable neurologic injury, but do have preserved cardiovascular function. The "wet ischemia" time—that is, the time from cessation of circulation to removal of the organ and its placement in cold storage—should be no longer than 30 min. This reality, as well as other practical and logistical factors, stands in the way of using ED "code victims" as solid-organ donors. Absolute contraindications for organ donation include HIV, sepsis, and malignancy [with the exception of primary central nervous system (CNS) tumors]. Advanced age is a relative contraindication; most organ procurement organizations (OPOs) do not harvest solid organs from individuals older than 75 years of age. However, any questions concerning suitability for donation should be referred to the OPO representative.

While potential donors may be identified in the emergency department, the determination of neurologic death is usually not completed there. While there is still no global consensus on the definition of brain death, most accepted definitions require (1) the elimination of multiple masquerading conditions such as drug intoxication, hypothermia, and endocrinopathies, and (2) demonstration of complete and irreversible loss of brain and brainstem function, including cerebral unresponsiveness, brainstem areflexia, and apnea. Many definitions of brain death require a repeat assessment of the patient's neurologic status after a span of a number of hours.

Following brain death, a number of physiologic changes occur that necessitate intervention to preserve donor organ perfusion. Increasing cerebral edema after trauma or a cerebrovascular accident initially results in elevated catecholamine release and hypertension. With brainstem necrosis, catecholamine levels drop rapidly to 10 percent of normal values, causing hypotension that must be corrected with fluids and vasopressors as needed. Pituitary necrosis occurs in approximately 75 percent of organ donors, resulting in diabetes insipidus, which can cause significant hypovolemia if untreated. Antidiuretic hormone and free-water deficits should be rapidly replaced in these patients. Approximately 85 percent of donors become hypothermic from ischemia to their hypothalamus. Hypothermia has many detrimental effects on potential donor organs, including coagulopathy, shifting of the oxygen-hemoglobin dissociation curve, and hepatic and cardiac dysfunction. Potential brain-dead donors should be quickly admitted to an intensive care unit so that their cardiorespiratory status is maintained against the onslaught of physiologic insults that ensue once neurologic function has ceased.

Once an appropriate patient has been identified, consent must be obtained from the family. This is best done by an agent of the regional organ procurement organization, a list of which may be obtained from the American Association for Organ Procurement (www.aopo.org). Emergency physicians should be familiar with their departmental policies on brain death and organ procurement. Telephone and beeper numbers for the regional organ procurement organization should be readily available. OPOs should be notified early of potential organ donors, even before the formal declaration of brain death.

The Uniform Anatomical Gift Act of 1987 gives competent adults the legal authority to consent to organ donation after their death, often by simply signing a statement on the back of their driver's license. In practice, the OPO representative will often forego donation if a family opposes donation, even if the donor has provided consent prior to his or her death. The need to obtain consent from family members invariably comes at a time of great sadness and stress, and family members refuse approximately 50 percent of potential donations.² Experience shows that discussion of organ donation with the family is best done separately from discussion and acceptance of brain death. Once brain death has been declared, the OPO coordinator, who is highly trained for this delicate discussion, should broach the subject

of organ donation. For multiple reasons, families may perceive a mixed message if the physicians caring for their seriously ill relative also initiates discussion of organ donation before the patients are "officially dead." The emergency physician should focus on identifying possible donor candidates and giving the family a realistic prognosis for the patient.³ Consent rates for donation are highest when the family initiates the discussion of organ donation and are higher if the discussion about organ donation is decoupled from the explanation of brain death.

MORBIDITY AND MORTALITY

Renal Graft Prognosis

Graft prognosis is directly related to the source of the donor kidney: recipients of cadaveric kidneys generally have more episodes of rejection and lower graft survival rates. The graft survival rate for kidneys from living donors is approximately 95 percent at 1 year and 76 percent at 5 years, whereas the graft survival rate for kidneys from cadaveric donors is 89 percent at 1 year and 61 percent at 5 years.⁴ The major causes of morbidity after renal transplant are hypertension (75 to 85 percent of all renal transplants), hyperlipidemia (60 percent), cardiovascular disease (15.8 to 23 percent), diabetes mellitus (16.9 to 19.9 percent), osteoporosis (60 percent), and malignant neoplasm (14 percent).⁵

Recipient Prognosis

Predictably, recipients from living, related donors have lower mortality rates than recipients from cadaveric donors. This is likely related to fewer rejection episodes and thus lower immunosuppression requirements. Patients' survival rate after transplantation from a living donor is 98 percent at 1 year and 91 percent at 5 years, as compared to survival after cadaveric donation of 95 percent at 1 year and 81 percent at 5 years.⁴ Common causes of death include coronary artery disease (30.4 percent), sepsis (27.1 percent), neoplasm (13 percent), and stroke (8 percent).⁶ During the first year, most deaths are from infectious causes. Long-term mortality rates are more closely related to the development of coronary artery disease.

GRAFT FAILURE

Acute renal failure (ARF) in transplant patients is defined as a 20 percent rise from baseline serum creatinine levels, as opposed to a 50 percent rise in other patients with ARF. Causes of ARF range from graft rejection to nephrotoxicity from immunosuppressive agents such as cyclosporine and tacrolimus, urinary tract infection or obstruction, renal vascular stenosis or thrombosis, and recurrent renal disease from hypertension, diabetes, or other causes (Table 99-1).

Renal Vascular Stenosis and Thrombosis

Renal artery stenosis (RAS) is a treatable cause of graft failure that occurs in up to 12 percent of posttransplant cases from the second postoperative month onward, although usually after a year. It may arise because of stricture at the site of anastomosis or arteriosclerosis elsewhere along the course of the artery. RAS should be suspected in the patient who develops uncontrolled hypertension or whose renal function deteriorates, particularly after initiation of angiotensin-converting enzyme (ACE) inhibitors. *Renal artery thrombosis* is a very early complication thought to be associated with technical surgical considerations, while *renal vein thrombosis* generally occurs during the first month after transplant and may present to an ED setting.

TABLE 99-1 Differential Diagnosis of ARF Unique to Renal Transplant Patients

Complications of surgery
Renal artery stenosis or thrombosis
Urinary tract obstruction
Renal vein thrombosis
Rejection syndromes
Hyperacute rejection
Acute rejection
Chronic rejection
Cyclosporine and tacrolimus nephrotoxicity
Recurrent renal disease

Thrombosis of the artery or vein may be diagnosed by ultrasonography, although both are associated with poor outcome and often lead to transplant nephrectomy.

Transplant Rejection

Graft rejection occurs when the host immune system recognizes a donated organ as foreign and attacks it through both cellular and humoral immune pathways. From 30 to 50 percent of transplant recipients will experience an episode of rejection, and 15 to 20 percent will experience recurrent rejection episodes.⁷ Rejection episodes may be separated into hyperacute, acute, and chronic mechanisms.

Hyperacute rejection is a rare event that occurs within minutes to hours of transplantation and generally results in immediate transplant nephrectomy. It is caused by ABO incompatibility or by some other critical human leukocyte antigen (HLA) mismatch that went unrecognized during the pretransplant tissue typing.

Acute rejection occurs from days to decades after transplantation, but most commonly in the first 3 months. Rejection is related to activation of T cells, which, in turn, stimulate specific antibody production against the graft. The clinical presentation of acute rejection is notoriously unreliable, but may include hypertension and decreasing urine output. With severe rejection episodes, fever, leukocytosis, and pain over the graft site may also be seen. Measurement of serum creatinine is the best way to detect an acute change in renal function related to rejection. Instances of acute rejection have been shown to disproportionately affect the long-term graft survival; they are the greatest predictor for the development of chronic rejection, so the focus has shifted from treating acute rejection to preventing it by front loading immunosuppression during the initial vulnerable period. Consequently, patients are most prone to opportunistic infection during this early period.

The differential diagnosis of acute rejection includes cyclosporine or tacrolimus toxicity, acute tubular necrosis, renal artery stenosis, urinary tract obstruction, and urinary tract infection. Patients should undergo renal ultrasonography to rule out obstruction. Cyclosporine and other immunosuppressive drug levels should be drawn to gauge the potential for drug toxicity, and urine should be sent for analysis and culture. The treatment of acute graft rejection initially involves hospitalization for high doses of intravenous steroids. Patients who do not respond to this steroid pulse should be considered for renal biopsy.

Chronic rejection occurs after the initial peak of immunosuppression has been tapered to a maintenance regimen. It is more correctly termed *chronic allograft dysfunction* because the pathophysiologic mechanisms underlying chronic rejection include immunologic causes as well as nonimmunologic factors such as hypertension, hyperlipidemia, and cyclosporine toxicity. This condition manifests clinically by a gradual increase in creatinine over 4 to 6 months accompanied by low-grade proteinuria and progressive hypertension. Immunosuppressive therapy is not considered helpful unless the patient recently dis-

continued or precipitously tapered their medicine. Currently, only non-immunologic interventions such as blood pressure control and hyperlipidemia treatment may be offered to patients with chronic allograft dysfunction.

IMMUNOSUPPRESSIVE AGENTS

Patients generally begin their posttransplant course with an induction regimen of immunosuppression that is then modified to a maintenance regimen after an initial 3- to 6-month period in which the rejection risk is greatest. These regimens are typically combinations of some of the drugs listed below at dosages designed to balance immunosuppression with unwanted side effects. Episodes of acute rejection may be treated with any one of a number of sequential rescue protocols that usually commence with pulse doses of steroids.

Corticosteroids have been a cornerstone of immunosuppressive therapy since the earliest solid-organ transplants. They function by

TABLE 99-2 Important Adverse Effects of Antirejection Medications

MORE COMMON	LESS COMMON
Cyclosporine	
Nephrotoxicity—renal insufficiency	Hyperkalemia
Hypertension	Convulsions—often with hypomagnesemia
Tremor	Hypomagnesemia
Headache	Dizziness
Gingival hyperplasia	Paresthesias
GI disturbance—anorexia, nausea, dyspepsia	Glucose intolerance—hyperglycemia

inhibiting antigen stimulated T-lymphocyte proliferation and lymphokine production. A major drawback of the use of steroids is the nonselectivity of their immunosuppression—they affect both cellular and humoral immunity, resulting in a significantly increased risk of infection. Other deleterious effects of steroids are common (Table 99-2). For these reasons, initial steroid doses are tapered and sometimes discontinued entirely as the risk of acute rejection abates. Patients on maintenance steroid therapy who present to the emergency department with suspicion of infection or other significant physiologic stress should receive intravenous stress doses of steroids.

Cyclosporine is a macrolide antibiotic that blocks the phosphatase action of calcineurin thereby inhibiting the release of interleukin (IL)-2 and the subsequent proliferation of helper and cytotoxic T cells. Since its introduction in 1971, cyclosporine has become a mainstay of immunosuppressive regimens and has contributed to a steady improvement in graft survival percentages. Cyclosporine has significant side effects (see Table 99-2). As a consequence, cyclosporine levels must be strictly maintained in a range that balances graft rejection with adverse effects; trough levels between 150 and 300 ng/mL are associated with improved graft survival. Because cyclosporine is metabolized by the hepatic P450 system, its clearance is affected by many other drugs (Table 99-3).

Tacrolimus is a newer agent that works similarly to cyclosporine, has a comparable side-effect profile, and appears to be more effective in preventing episodes of acute rejection (see Table 99-2).⁸ Additionally, tacrolimus appears to have a steroid-sparing effect that allows up to 60 percent of patients to taper off steroids completely. Tacrolimus has numerous drug interactions (see Table 99-3).

Sirolimus is the newest macrolide antibiotic with immunosuppressive properties. It compares favorably to tacrolimus from the standpoint of graft rejection, but does not induce hypertension, diabetes or neurologic adverse effects. The major side effects are bone marrow suppression and hyperlipidemia.⁹

Azathioprine is a purine analogue that was once a mainstay of transplant immunosuppression, but has been largely supplanted by newer agents. The immunosuppressant action of azathioprine occurs through blocking gene activation of stimulated T lymphocytes. The major adverse effect of azathioprine is bone marrow suppression (see Table 99-2).

Mycophenolate mofetil inhibits de novo purine biosynthesis during cell division and thereby affects both T- and B-lymphocyte cell lines. Side effects include dose-related pancytopenia and diarrhea (see Table 99-2).

Monoclonal antibodies against the IL-2 receptor have emerged as recent promising supplements to traditional immunosuppressive regimens. Although costly, the relative lack of side effects make them especially attractive agents.

INFECTIOUS COMPLICATIONS

Infection is the most common cause of mortality and morbidity for transplant patients in the first year.¹⁰ Between 40 and 80 percent of transplant patients experience at least one infection during the first posttransplant year, although these numbers are decreasing as more transplant recipients undergo preoperative immunizations and take posttransplantation antibiotic prophylaxis.¹¹ Infections most commonly are mucocutaneous (41 percent), urinary tract (17.2 percent), and respiratory tract (13.9 percent).¹¹ The most common infective agents are bacterial (45.9 percent), viral (40.6 percent), fungal (12.5 percent), and protozoan (1 percent). Among the viral illnesses, cytomegalovirus (CMV) (31.5 percent), herpes simplex (23.4 percent), and herpes zoster (23.4 percent) are the most frequent organisms. Death is most commonly caused by infection (32 percent) with pneumonias accounting for about half of the deaths from infection.

The number and type of infection depends largely on time since surgery and the transplant recipient's current state of immunosuppression (Table 99-4).¹² During the first month posttransplant, patients are likely to encounter typical infections associated with any surgical procedure, such as urinary tract infections, pneumonias, intravenous line sepsis, and wound infection. Unexplained fever during this initial postoperative period should draw suspicion to the possibility of perinephric abscess or other local surgical complication. One exception to this is the development of significant herpesvirus disease in the first month, as detailed below.

The second through sixth months after surgery are regarded as the critical period when opportunistic pathogens associated with compromised cellular immunity manifest themselves; CMV, pneumocystis, toxoplasmosis, and various fungal infections. Reactivation of latent mycobacterial disease may also occur. Patients who present during this period—or during bouts of acute rejection for which they are receiving supplemental immunosuppression—should undergo an aggressive diagnostic workup for relatively subtle presentations.

After immunosuppression is curtailed at 6 months posttransplantation, patients with well-functioning grafts on minimal immunosuppression typically have infection profiles comparable to those of the

TABLE 99-3 Cyclosporine and Tacrolimus Drug Interactions

INCREASES LEVELS	DECREASES LEVELS	ENHANCES NEPHROTOXICITY
Cyclosporine		
Calcium channel blockers—diltiazem, verapamil, nifedipine, nicardipine Antibiotics—erythromycin, clarithromycin, doxycycline Antifungals—ketoconazole GI agents—metoclopramide Miscellaneous—amiodarone, allopurinol, grapefruit and grapefruit juice	Antibiotics—nafcillin, rifampin Antiepileptics—phenytoin, phenobarbital, carbamazepine Miscellaneous—St. John's wort, ticlopidine	Antibiotics—gentamicin, tobramycin, vancomycin, trimethoprim-sulfamethoxazole Nonsteroidal anti-inflammatories—all formulations colchicine Antivirals—acyclovir Antifungals—ketoconazole, amphotericin B GI agents—cimetidine, ranitidine Tacrolimus
Tacrolimus		
Calcium channel blockers—diltiazem, verapamil, nifedipine, nicardipine Antibiotics—erythromycin, clarithromycin Antifungals—ketoconazole, fluconazole GI agents—metoclopramide, cimetidine, omeprazole HIV protease inhibitors Miscellaneous—methylprednisolone, grapefruit and grapefruit juice	Antibiotics—rifampin Antiepileptics—phenytoin, phenobarbital, carbamazepine Miscellaneous—St. John's wort	Antibiotics—aminoglycosides Antifungals—amphotericin B Antineoplastics—cisplatin Cyclosporine

TABLE 99-4 Etiology of Infection According to Time from Transplant

7-7s: posttransplant month: infections related to surgery
Urinary tract infections (<i>Escherichia coli</i>) Intravenous lines and wound infections (<i>Staphylococcus aureus</i> , <i>Streptococcus viridans</i>) Pneumonia (<i>Streptococcus pneumoniae</i>)
1-6 Posttransplant months: highest incidence of opportunistic infections
Viremia (cytomegalovirus, Epstein-Barr virus) Pneumonia (<i>Pneumocystis carinii</i>) Meningitis (<i>Listeria monocytogenes</i>) Sepsis (<i>Aspergillus fumigatus</i>)
After 6 posttransplant months: patients divide into three subgroups
Patients with good graft function on minimal immunosuppressants have the same risk of infection as the general population. Patients chronically infected with latent viruses (e.g., cytomegalovirus, Epstein-Barr virus, hepatitis B & C) often have significant and ongoing end-organ damage (e.g., cirrhosis) secondary to these infections. Patients with poorly functioning grafts who have sustained multiple episodes of rejection, now requiring large dosages of immunosuppressants commonly have acute and chronic opportunistic infections (e.g., <i>P. carinii</i> , <i>Candida</i>)

general community, with the exceptions of a higher than normal incidence of CMV retinitis, herpes zoster and cryptococcal disease. Patients who have chronic persistent viral infections with CMV, Epstein-Barr virus (EBV), or hepatitis B or C may demonstrate end-organ damage referable to this chronic infection.

Viral Infections

Viral infections produce significant morbidity and mortality in the renal transplant recipient and present diagnostic challenges because viral cultures are not very sensitive.¹³

The most common viral infections are caused by the herpes group of viruses: CMV, EBV, herpes simplex virus (HSV), and varicella-zoster virus (VZV). Transplant patients are also more susceptible to, and have a worse outcome from, infections with other viruses such as adenovirus, influenza virus, and hepatitis virus.

CMV is the most important viral agent to cause infection in renal transplant recipients, accounting for more than two-thirds of febrile episodes in the first 6 months posttransplant. Transmission of CMV occurs with an organ transplant from a seropositive donor. With primary CMV infection, patients often present with fever spikes and malaise, and sometimes arthralgias, myalgias, and lymphadenopathy. Tissue-invasive disease such as hepatitis, pneumonitis, primary chorioretinitis, or gastrointestinal (GI) tract ulceration may also occur. In addition to causing an infectious syndrome, CMV can cause a leukopenia and depressed cellular-mediated immunity, which increases the incidence of opportunistic infections such as *Pneumocystis carinii*, *Listeria*, and *Aspergillus*. CMV is linked to distinct allograft nephropathy, both acute and chronic, and is associated with decreased long-term patient survival. Diagnosis of CMV infection is best established by DNA capture hybrid assays or quantitative polymerase chain reaction (PCR). Untreated CMV is associated with 10 to 15 percent mortality rates, and patients diagnosed with CMV should generally be treated with ganciclovir or foscarnet despite the potential for adverse side effects. CMV seronegative transplant recipients requiring blood transfusion should receive CMV-seronegative, filtered, or leukocyte-poor blood products.

EBV infection in the renal transplant patient can present as two distinct clinical syndromes, either as the typical uncomplicated mononucleosis syndrome (characterized by fever, mild hepatitis, and leukopenia with atypical lymphocytosis) or as posttransplant lymphoproliferative disease (PTLD). The latter is an EBV-induced activation of B cells with expansion of lymphoid tissue, most frequently occur-

ring in the CNS, renal allograft, or GI tract. PTLD occurs in approximately 1 percent of renal transplant recipients and can range from a mild benign polyclonal disease to a rapidly progressive monoclonal form, which carries a poor prognosis. Other symptoms and signs of EBV are fever of unknown origin, weight loss, hepatotoxicity, pulmonary infiltrates, and gastrointestinal bleeding and perforation. Diagnosis of EBV is generally serologic, although suspicion of PTLD warrants biopsy and histologic examination of affected tissue. Primary EBV infection is treated by reducing immunosuppression and administering intravenous acyclovir. Treatment of PTLD involves excision, radiation, antiviral therapy, and, occasionally, chemotherapy, although there continues to be a substantial mortality rate.

VZV also presents with two distinct clinical syndromes in the renal transplant patient. Most patients will have been exposed to VZV before transplantation, either through primary chickenpox or through pretransplant immunization. These patients are most likely to present with the typical reactivation-type infection limited to skin eruptions. Patients with no prior VZV exposure are at risk of developing primary VZV infection, usually contracted when tissue from a seropositive donor is transplanted to a seronegative host. This primary VZV infection can produce a simple chickenpox syndrome or can progress to virulent disease ranging from hemorrhagic pneumonia to encephalitis, hepatitis, and pancreatitis, with a high mortality rate. Direct immunofluorescence or viral culture is required to make the diagnosis of VZV. Acyclovir, valacyclovir, and famciclovir are indicated for both primary and reactivated VZV, although dosages must be increased as compared to those for HSV infection. Immunization with the attenuated virus is contraindicated after transplant, and seronegative patients who are exposed to VZV should receive varicella immunoglobulin within 96 h as postexposure prophylaxis.

HSV infection is relatively common during the first transplant month, and is largely a reactivation disease presenting with typical mucocutaneous ulcerations. Primary HSV, frequently contracted from the donor organ, may also present during the initial month as a life-threatening hepatitis, pneumonitis, or meningoencephalitis. Classic herpes lesions are the exception rather than the rule in these instances, and diagnosis depends on high index of suspicion, and attention to the timing of symptoms after transplant. Orolabial or anogenital lesions may be more ulcerative than vesicular, and if the diagnosis is unclear, immunofluorescence techniques or PCR may be helpful. Oral acyclovir, valacyclovir, or famciclovir are effective in mucocutaneous disease, whereas treatment with intravenous acyclovir may be indicated in disease that is more widespread.

Hepatitis viruses B and C may be contracted from an infected donor, or may reactivate with immunosuppression following renal transplantation. Immunosuppressive therapy directly stimulates viral replication, and seropositive patients frequently progress to active hepatitis, cirrhosis or hepatocellular carcinoma. In addition, infection with these viruses can suppress the host's immune defenses. Diagnosis is based on serologic and histologic studies. Therapy with interferon and lamivudine has shown limited success.

Respiratory viruses such as influenza and parainfluenza virus do not cause serious disease in transplant patients, although patients should receive routine immunization against influenza and treatment with neuraminidase inhibitors is warranted in symptomatic patients who test positive for influenza during epidemics. Adenovirus has become recognized as an important cause of pneumonia and hemorrhagic cystitis. Respiratory syncytial virus (RSV) has been implicated in pneumonia, and parvovirus in bone marrow suppression.

Bacterial Infections

Urinary tract infections (UTIs) are very common after renal transplantation, occurring in 30 to 40 percent of patients, and are responsible for 60 percent of the gram-negative bacteremias in these patients.¹⁴ Prophylactic treatment during the first 6 months with

trimethoprim-sulfamethoxazole (TMP/SMX) or fluoroquinolone is standard in many transplant centers, and is effective in reducing the incidence of UTIs to between 5 and 10 percent, as well as opportunistic organisms such as *Pneumocystis*, *Listeria*, and *Nocardia*.^{1,2} The organisms responsible for UTIs in transplant patients are similar to those in nontransplant patients: *Escherichia coli*, enterococci, and *Pseudomonas aeruginosa*, although gram-positive organisms may be encountered in the immediate postoperative period because of urinary tract catheterization and instrumentation. UTIs in the first 6 months post-transplant frequently progress to pyelonephritis and urosepsis, and warrant longer courses of treatment (10 to 14 days) with a fluoroquinolone, as well as investigation for the possibility of complicating obstruction and stone formation. Infections in men should be treated for 4 to 6 weeks followed by long-term prophylaxis because of the possibility for prostatic seeding. Infections occurring after the initial 6-month postoperative period can be treated for shorter periods with less-intensive courses.

The gastrointestinal tract is the next most common source of bacterial infection in the renal transplant patient. Acute bacterial gastroenteritis secondary to *Salmonella*, *Campylobacter*, and *Listeria* is common in these patients, and significant diarrhea warrants evaluation with stool cultures. Diverticulitis, often complicated by perforation, is another common gastrointestinal infection encountered in transplant patients. Patients commonly present with findings of vague abdominal pain as the only symptom of this potentially life-threatening disease. A high index of suspicion should be maintained when evaluating transplant recipients with abdominal pain.

Among the common opportunistic bacterial pathogens, *Listeria* and *Nocardia* deserve special mention, although the incidence of these infections has decreased with the advent of prophylactic antibiotics. *Listeria monocytogenes* is a common opportunistic bacterial infection usually acquired by ingesting contaminated foods. Presentation is with diarrhea and abdominal cramps, which can quickly progress to pneumonia, endophthalmitis, and meningitis. Treatment consists of ampicillin and gentamicin, or TMP/SMX. *Nocardia asteroides* in renal transplant patients typically presents with fever, cough, and pulmonary infiltrates, eventually spreading to skin and central nervous system. *Nocardia* may also be effectively treated with TMP/SMX.

Tuberculosis occurs in renal transplant patients both as a primary and as a reactivation disease, and while it occurs in only approximately 5 percent of transplant patients, half of those cases present as disseminated disease.¹⁶ There is no typical presentation for a transplant patient with tuberculosis; instead, a highly variable presentation has been described, including cavitary pulmonary disease, miliary disease, and multiorgan involvement. Diagnosis is rarely aided by tuberculin skin testing. Definitive diagnosis is by organism identification and culture from sputum, pleural effusions, and bronchoalveolar lavage, lung, or bone marrow biopsy. Therapeutic options are complicated because of cyclosporine drug interactions with many antituberculosis medications.

Fungal Infections

Fungal infections affect 2 to 14 percent of renal transplant patients and can occur at every stage of the posttransplant course.¹⁷ Specific tests (fungal cultures) are necessary to make their diagnosis.

Candida albicans infection is the result of immunosuppression (especially from steroid use) causing overgrowth of an endogenous gut flora. Mucocutaneous disease affecting the oropharynx, esophagus, or vagina is the most common presentation. Candidal urinary tract infections, usually associated with indwelling catheters, can run a benign course with just cystitis or spread to pyelonephritis. Disseminated candidiasis often results in endocarditis, aortitis, osteomyelitis, meningitis, and brain abscess. Finding the organism in tissues, blood, or urine makes the diagnosis, but specific fungal cultures must be requested. Treatment of mucocutaneous candidiasis is with nystatin, clotrimazole, or oral fluconazole. Amphotericin is an effective agent for dis-

seminated disease, but intravenous fluconazole may be preferable because of decreased nephrotoxicity.

Cryptococcosis occurs in approximately 3 percent of renal transplant patients. *Cryptococcus neoformans* enters through the lung and can spread to the skin and central nervous system, resulting in meningitis. Diagnosis is made by testing for cryptococcal antigen in serum and/or cerebrospinal fluid. Treatment consists of a combination of amphotericin and fluconazole.

Patients living in endemic areas are at risk for infection with *Coccidioides immitis*, *Histoplasma capsulatum*, and *Blastomyces dermatitidis*. The most common symptoms are nonproductive cough and fever.

Aspergillus fumigatus and *Aspergillus flavus* may cause infections of the lungs, skin, and central nervous system in renal transplant patients, but generally presents with pulmonary symptoms.¹² Risk factors for infection include steroid use, CMV infection, and neutropenia. Diagnosis is by organism identification from sputum culture, bronchoalveolar lavage or lung biopsy. Treatment is with amphotericin and surgical debridement of isolated lung focus if found.

Mucormycosis is caused by infections from fungi of *Rhizopus*, *Abisidia*, and *Mucor* species. Risk factors include diabetes mellitus, steroid use, and deferoxamine therapy. The most feared complication is invasive rhinocerebral disease, which is associated with a high mortality despite aggressive treatment with amphotericin and wide surgical resection.

Parasitic Infections

Pneumocystis carinii pneumonia (PCP) occurred in up to 10 percent of renal transplant patients before the advent of prophylactic therapy, but is less common now. Risk factors for infection include recent increases in immunosuppression and concurrent CMV infections. PCP most often presents during the first 6 months posttransplant with fever, dry cough, dyspnea on exertion, and interstitial pulmonary infiltrates. Diagnosis is based on recovery of the organism on induced sputum or bronchoalveolar lavage, although treatment should begin based on presenting symptoms and clinical suspicion.

OTHER COMPLICATIONS/ SPECIAL CONSIDERATIONS

Cardiovascular Disease

Overall, the risk of coronary artery disease posttransplant is three- to fivefold that for age- and sex-matched control subjects.¹⁸ Risk factors for coronary artery disease include (1) pretransplant coronary artery disease; (2) hyperlipidemia secondary to antirejection medications; (3) hypertension; (4) corticosteroid therapy; (5) insulin-dependent diabetes mellitus; (6) erythrocytosis with increased blood viscosity; (7) smoking; and (8) frequent rejection episodes. Hypertension is found in approximately 50 percent of all transplant patients. Possible causes of hypertension include (1) graft rejection; (2) cyclosporine toxicity; (3) glomerulonephritis (recurrent and de novo); (4) graft renal artery stenosis; (5) essential hypertension from native kidneys; (6) hypercalcemia; and (7) steroids. Calcium channel blockers (CCBs) are particularly efficacious in treating hypertension in renal transplant patients on cyclosporine, although CCBs interfere with cyclosporine metabolism (see Table 99-3).

Chronic Liver Disease

Chronic liver disease is an important cause of morbidity and mortality for renal transplant patients. Causes of hepatic dysfunction include (1) viral hepatitis (CMV is leading cause, followed by hepatitis C and B) and (2) antirejection drugs (both azathioprine and cyclosporine cause cholestatic jaundice).

Malignancy

Transplant patients are at significantly higher risk for cancers than the general population because of (1) chronic immunosuppression; (2) chronic antigenic stimulation; (3) increased susceptibility to oncogenic viral infections; and (4) direct neoplastic action of immunosuppressants. Transplant patients suffer a significant overall two- to five-fold excess risk in both sexes for cancers of the colon, larynx, lung, and bladder, and in men for cancers of the prostate and testis. A ten- to thirtyfold excess risk exists for cancers of the lip, skin (non-melanoma), kidney, endocrine glands, and non-Hodgkin lymphoma, and in women, cancers of the cervix and vulva-vagina.¹⁹

Blood Transfusion

Immunosuppressed patients requiring blood transfusion should receive CMV seronegative blood. If this product is not available, they should be transfused through a leukocyte filter.

PATIENT EVALUATION

History

Because many of the clinical rejection syndromes are correlated with the age of the graft, the date of the transplant surgery should always be obtained (Table 99-5). The donor source is also an important consideration because cadaveric kidneys have higher incidences of ARF and rejection. The patient's immunization status against infectious agents and any information regarding transmissible agents carried by the donor can help target diagnostic and therapeutic interventions. A history of recent and repeated infections gives important clues to the patient's level of immunosuppression. In patients with infections, it is common practice to decrease immunosuppression, which increases the risk of rejection. A complete drug history is very important because many medications affect the levels and toxicity of cyclosporine (see Table 99-3).

The most common reason for a transplant recipient to present to the emergency department is fever, and while fever is the most common symptom of infection, it may be masked by immunosuppressive agents which limit the inflammatory response, and by steroids, uremia, and hyperglycemia, which suppress baseline body temperature. While the absence of fever should not be used to rule out possible infection in a transplant patient, the presence of fever may be caused by factors other than infection, such as hypersensitivity reaction, rejection, or malignancy. That said, fever in a transplant patient should occasion an aggressive workup, even for relatively subtle presentations. This is especially true during the critical period between the first and sixth

TABLE 99-5 Key Historical Elements in Renal Transplant Patients

History of recent temperature elevations?
Date of transplantation surgery?
Graft source: donor living related vs. cadaveric?
Rejection history: Number of rejection episodes? Date of last rejection episode? Note any recent changes in dosages of antirejection medications.
History of immunizations, chronic infections (CMV EBV hepatitis B & C viruses, etc.) and recent exposure to patients with infections (chickenpox, CMV TB, etc.)
A complete list of and compliance with immunosuppressive medications.
Complete list of all medications, including those that are unrelated to renal transplant and all over-the-counter medications. Baseline: blood pressure, body weight, serum creatinine, and cyclosporine or tacrolimus level.

Abbreviations: CMV = cytomegalovirus; EBV = Epstein-Barr virus; TB = Tuberculosis.

postoperative months when immunosuppression is at its highest, or during bouts of acute rejection when immunosuppression has been augmented. A history of recent or repeated rejections may also suggest the presence of increased intensity of immunosuppression because these drugs are commonly increased during periods of rejection. The degree of immunosuppression should direct clinical suspicion toward various opportunistic organisms (see Table 99-4).

Physical Examination

The physical findings of renal failure may be subtle or absent (Table 99-6). Peripheral edema in these patients is often a misleading sign of fluid overload that can occur in hypovolemic patients because of hypoalbuminemia or venous stasis. The vital signs, patient weight, skin turgor, orthostatic pulse, and blood pressure changes may be helpful in identifying hypovolemia. Examination of the renal graft may disclose swelling and tenderness associated with acute rejection, renal vein thrombosis, and obstruction.

A high index of suspicion is required to find infections in unusual sites in an immunocompromised patient. In addition to the common sites of infection (skin, pulmonary tract, and genitourinary tract), the head, neck, rectum, and abdomen should be closely scrutinized for infection. Infections during the first 4 weeks posttransplant are most commonly related to the surgical procedure of engraftment. Special attention should be given to the renal graft looking for signs of wound infection, pyelonephritis, and urine leakage with infection.

TABLE 99-6 Key Physical Examination Elements in Renal Transplant Patients

Mental Status / Neurologic Examination: cyclosporine/tacrolimus neurotoxicity, steroid psychosis, HSV encephalitis, <i>Listeria meningitis</i> /encephalitis, cryptococcal meningitis.
Volume Status: Often invasive hemodynamic monitoring (pulmonary artery catheterization) is the only reliable means of determining volume status in renal transplant patients.
HEENT: Periorbital edema (glomerulonephritis), retina (CMV or toxoplasmic chorioretinitis, <i>Listeria endophthalmitis</i>), sinuses (<i>Staphylococcus aureus</i> , mucormycosis, and invasive fungal disease), mouth (<i>Candida</i> , HSV), neck (meningismus, retropharyngeal abscess), lymphadenopathy (CMV EBV hepatitis)
Skin: Rashes are commonly seen in viral syndromes (hepatitis B and EBV), cellulitis from indwelling catheter sites, nocardial cutaneous lesions.
Lung: Pneumonia is a common source of infections in transplant patients. <i>Streptococcus pneumoniae</i> and other community-acquired agents are still common sources, but opportunistic infections such as PCP, <i>Aspergillus</i> , TB, coccidioidomycosis, and viral pneumonias should be suspected.
Heart: Pericardial friction rubs as a complication of uremia and a wide range of viral infections.
Abdomen: Peritonitis without a defined source is one of the most common sites for infection in transplant patients. RUQ tenderness associated with hepatitis B & C, CMV, and EBV VZV causes pancreatitis. If left in place, peritoneal dialysis catheters can be sources of infection.
Renal Graft: Usually placed in abdominal flap; inspection (look for signs of wound infection), palpation (graft tenderness and swelling are often seen in acute rejection, outflow obstruction, and pyelonephritis), and auscultation (bruits suggest renal artery stenosis and AV malformations).
Rectal: Perirectal abscess is a common, yet often-overlooked, source of infection in transplant patients.
Extremities: Access sites for hemodialysis can be sources of infection. Peripheral edema in renal transplant patient can represent a number of different etiologies: recurrent vs. de novo glomerulonephritis, graft failure, cirrhosis, nephrotic syndrome (from native kidneys), renal vein thrombosis, malnutrition, and heart failure.

Abbreviations: AV = atrioventricular; CMV = cytomegalovirus; EBV = Epstein-Barr virus; HEENT = head, ears, eyes, nose, and throat; HSV = herpes simplex virus; PCP = *Pneumocystis carinii* pneumonia; RUQ = right upper quadrant; TB = tuberculosis; VZV = varicella-zoster virus.

Ancillary Tests

The serum creatinine level is the most valuable prognostic marker of graft function at all times after transplantation, and should be obtained whenever renal failure or infection is suspected (Table 99-7).²⁰ The urinalysis provides important clues to acute changes in graft viability. Red blood cell casts and proteinuria are commonly seen in recurrent or de novo glomerulonephritis. The presence of white blood cells, bacteria, and nitrites is helpful in diagnosing UTIs. Significant proteinuria may signal rejection, drug toxicity, glomerular disease, or other graft nephropathy, although proteinuria from the native kidney should also be considered. Cyclosporine or tacrolimus blood levels should be determined for all patients.

The evaluation of a renal transplant patient with suspected infection should include routine testing as well as additional tests based on the patient's presenting complaint, history, and physical examination (see Table 99-7). Leukocytosis or left shift of the white blood cell count may be blunted by immunosuppressive agents and, conversely, leukopenia with an increase in atypical lymphocytes is commonly seen with viral infections, especially CMV. Liver function tests may show mild transaminase elevations with CMV and EB V infections, and much higher elevations with hepatotropic viruses such as hepatitis B and C viruses. Urine *Legionella* antigen should be ordered prior to treatment of patients with pneumonia or GI complaints. Bacterial cultures and fungal cultures of blood and urine should be obtained on all patients. Because viral cultures are not very sensitive, clinicians should rely on their acumen to order organism-specific antigen assays and antibody titers when contemplating viral or parasitic infections.

Renal ultrasonography is the best test to detect urinary obstruction and color duplex imaging of the renal artery and vein are helpful in assessing renal vascular stenosis or thrombosis. Renal graft ultrasonography should be obtained in patients suspected of having urinary obstruction, pyelonephritis, perinephric abscess, urine leak, wound infection, or an episode of rejection. Renal biopsy is the gold standard for diagnosing rejection.

DISPOSITION

Transplant patients are chronically immunosuppressed, attempting to balance between under-immunosuppression, with the risk of graft rejection, and overimmunosuppression, with the risk of infection. When these patients present to the emergency department with fever, increasing edema, decreased urine output, graft pain or swelling, or increasing fatigue, they should be evaluated for infection and renal graft function. These patients are complex, and it is often difficult to determine on initial assessment the presence of a serious infection or complication. It is recommended that the patient's physician or transplant coordinator be consulted to help the emergency physician in making the disposition decision.

TABLE 99-7 Possible Ancillary Tests for the Evaluation of a Renal Transplant Patient

Serum creatinine
Urinalysis
Chest radiograph (posterior-anterior and lateral)
Complete blood count
Electrolytes
Liver function tests
Cyclosporine or tacrolimus level
Cultures: mouth, sputum, urine, blood, stool, access and wound sites
Serology: cytomegalovirus, Epstein-Barr virus, hepatitis, toxoplasmosis, cryptococcosis
Ultrasonography of the renal graft
Renal biopsy

RENAL IMAGING

Daniel E. Wiener
Emily H. Sheffer

The recent years have seen an explosion in the modalities available to the emergency physician to image the urinary system. This chapter reviews the different methods and discusses their role in the management of patients in the ED.

IMAGING MODALITIES

Plain-Film Radiography

The KUB (kidneys, ureters, and bladder) is a plain full-length film of the abdomen. The kidneys can be visualized because the perinephric fat gives them a lucent outline. Renal calculi can usually be visualized,

but small ureteral calculi may be hidden by bowel shadows. Calculi in the lower ureters may be confused with phleboliths. The KUB by itself rarely adds to patient care in the ED and is most useful in conjunction with ultrasonography or intravenous pyelography (IVP).

Ultrasonography

Ultrasonography is a rapid, painless method to visualize the urinary tract.¹ The patient requires no preparation and is not exposed to the potentially harmful effects of radiation or contrast material. The limitations of this modality include poor visualization of the ureter and difficulty in imaging obese patients. The quality of the study is both operator- and equipment-dependent. Ultrasonography is an anatomic study and provides no data regarding kidney function. Renal ultrasonography can document the presence, location, and size of the kidneys and detect focal parenchymal lesions such as cysts and tumors. Hydronephrosis, and on occasion dilated ureters and calculi, can be demonstrated (Figure 100-1). Fluid collections surrounding the kidney can also be seen. With Doppler flow capability, reduced renal blood flow can be identified.

Ultrasonography is performed using a 3.5-MHz transducer. With the patient in a supine position, the transducer is placed subcostally from the lateral approach. The operator sweeps the ultrasound plane to locate the kidney. Rotation of the probe permits documentation of the longitudinal and transverse renal axes. The liver is usually used as an acoustic window to visualize the right kidney and the spleen to visualize the left. Images on the right are technically superior to those on the left because the liver provides a better acoustic window than does the spleen. An air-filled stomach and dilated loops of bowel can hinder visualization. The kidneys move with respiration, and having patients hold their breath after a maximal inhalation often enhances visualization.

Gerota fascia, the renal cortex, the collecting system, and the renal sinus, as well as proximal and distal calculi, can be visualized. Gerota fascia is associated with perinephric fat and is visualized as a bright area surrounding the kidney. The renal cortex is homogeneous in appearance and more reflective (brighter) than the renal medulla. The renal pelvis is centrally located and appears echogenic. Dilation of the collecting system by fluid (echo-free) is thus readily apparent. The normal ureter is not visualized, but the dilated ureter can sometimes be seen. In the longitudinal plane, the normal kidney is oblong-shaped and measures 9 to 12 cm. In the transverse plane, the normal kidney is C-shaped and measures 4 to 5 cm. The kidneys normally measure within 2 cm of each other in the longitudinal axis.

Intravenous Pyelography

Intravenous pyelography (IVP) provides both anatomic and functional information about the kidney. It is most commonly used in the setting

FIG. 100-1. Sonogram showing hydronephrosis from a right ureterovesicular junction stone. (Photograph courtesy of David Frager, MD.)

of flank pain and hematuria, and has long been considered the "gold standard" for visualizing renal calculi. The disadvantages of the study include the necessity of transporting the patient to the radiology department, the time demand of the study, and the administration of contrast material. Concern regarding potentially poor images in ED patients because of the lack of bowel preparation is unwarranted.²

Before initiation of the IVP, the patient is asked to void and the abdomen is compressed by an inflatable belt to enhance visualization of the calyx and renal pelvis. The standard series of films taken during an IVP include the following:

1. The scout film, a plain radiograph from the level of the kidneys to the bladder prior to the administration of contrast. This allows visualization of stones that may be obscured by contrast material.
2. The nephrogram, a coned view of the kidneys obtained 1 min after injection of contrast material. This film is examined for the absence or delay in visualization, homogeneity, and duration of the nephrogram.
3. The pyelogram, two films taken 5 and 10 min after injection of contrast material. Calyceal dilation or effacement, ureteral dilation, intraluminal filling defects, and the extravasation of contrast material can be seen. The compression device is typically deflated after these images.
4. The bladder film, taken 20 min after injection of contrast material.
5. The postvoid film, used to evaluate postvoid residual bladder volume and to visualize any retained contrast or distal ureteral stone that may have been hidden by the full bladder. Multiple views and tomograms are often used to enhance the quality of the study. When a ureteral obstruction is suspected, two views are required to distinguish a peristaltic contraction from a tumor or a stricture.
6. Delayed views over 1 to 4 h may be necessary in instances of obstruction or nonvisualization.

Computed Tomography

Computed tomography (CT) scanning provides both anatomic and functional information about the kidney. The renal parenchyma, collecting system, extrarenal space, ureters, and bladder can all be visualized. Renal perfusion can be assessed with the administration of contrast material. CT can identify extrarenal pathology or injury not clinically suspected. The disadvantage of CT is the necessity of transporting the patient to the device, the time required to perform the study, and the need to administer contrast if optimal results are to be obtained.

With CT, images of the kidney and urinary system are reconstructed from information collected by focused x-ray beams arranged on a plane that cuts through the patient's body in a transverse or horizontal direction as the patient passes through the CT gantry on a movable table. As these beams pass through the patient, they are absorbed by a ring of detectors on the opposite side of the gantry. The intensity of the x-ray beam that reaches the detector is dependent on the absorption characteristics of the intervening tissue. The radiodensity of a small area of tissue can then be calculated from the absorption pattern of multiple beams crossing the area from different directions.

During helical CT, the x-ray tube is in continuous rotation while the patient is moved smoothly, at a constant speed, through the scanning field. This technique improves the detection of small lesions, as scanning is performed during a single breath-hold, thus reducing the movement of intra-abdominal organs and motion artifact, which occurs when imaging is performed during respiration. Data from multiple scanning planes can be used to produce three-dimensional reconstruction of lesions. In addition, shaded surface displays allow volume surface analysis of parenchymal organs and maximal-intensity projections provide analysis of the vasculature. The selected slice thickness of a scan depends on the clinical presentation. Trauma scans are usually 8- to 10-mm thick and are obtained from the diaphragm down to

the bottom of the pelvis. CT scans for renal colic use 5-mm slices from the top of the kidneys down to the bladder. If there is an area of subtle or equivocal findings, the radiologist may elect to make smaller cuts for clarification.

A CT cystogram is performed by instilling at least 350 mL of diluted contrast material into the bladder via a urinary catheter, the catheter is then clamped and contiguous axial images are obtained from the dome of the diaphragm to the perineum. The clamp is then released and additional images may be obtained after the bladder is emptied.

Intravenous Contrast Enhancement

IVP and CT use intravenous radiocontrast material containing iodinated compounds that absorb x-rays. These agents allow vessels and organs to be more easily differentiated from adjacent nonenhancing structures. A typical imaging protocol involves the administration of 150 mL of intravenous radiocontrast by a power injector into an intravenous catheter of adequate size, typically an 18-gauge catheter in the antecubital vein.

Intravenous radiocontrast media are classified according to two characteristics: ionic versus nonionic and high osmolar versus low osmolar. Nonionic media are approximately 10 times more expensive than ionic media but have only a fourth the incidence of adverse reactions compared to ionic media. High-osmolar contrast media (HOCM) are all ionic, as opposed to low-osmolar contrast media (LOCM), which can be ionic or nonionic. Intravenous contrast media are nephrotoxic; the least nephrotoxic is nonionic LOCM. In patients with normal renal function, there is no measurable impairment of renal function with the use of either HOCM or LOCM.³ However, in patients with preexisting renal insufficiency and diabetes, nonionic LOCM causes less impairment to renal function than does HOCM. Therefore, LOCM should be considered as the first choice of contrast media in patients with the following risk factors: age greater than 50 years, debilitation, known severe cardiovascular disease, asthma, previous reaction to contrast, preexisting renal insufficiency, and/or diabetes.

The following agents have demonstrated some efficacy in reducing the severity of radiocontrast nephrotoxicity: (1) prostaglandin E₁ 20 ng/kg per min infusion started 1 h before contrast administration and continued for 6 h afterwards; (2) acetylcysteine 600 mg PO twice daily started the day before contrast administration and continued for 2 days afterwards; (3) theophylline 200 mg IV 30 min before contrast administration; and (4) fenoldopam mesylate 0.1 µg/kg per min infusion for at least 1 h before contrast administration.^{4,7} To date, studies have been small in size and the effects have been modest. There is no consensus regarding the routine use of these agents in patients at risk for radiocontrast nephrotoxicity.

Oral-Contrast Enhancement

Oral contrast is used with the abdominal CT scan for a patient suspected of having intra-abdominal pathology. This barium- or iodine-based solution markedly increases the density of the gastrointestinal tract, differentiating bowel from other pathology. When there is a suspicion of renal injury, both oral and intravenous contrast is used. **Oral contrast poses no threat to the kidneys** and can be used in patients with depressed renal function.

Dynamic CT Scanning

In dynamic CT scanning, a series of rapid images using helical CT is obtained during peak vessel contrast enhancement. As with IVP, the kidney is visualized in the (1) vascular phase, when major vessels are visualized; (2) nephrogram phase, when contrast reaches the tubules and medullary opacification occurs; and (3) pyelogram phase, when calyceal and pelvic filling is observed. Dynamic CT is useful in

demonstrating impaired of parenchymal perfusion and can also differentiate abscesses and hematomas.

Retrograde Urethrogram

The retrograde urethrogram is used to assess urethral injury (usually from trauma) or strictures, and occasionally used to evaluate urethral foreign bodies. It is an invasive procedure requiring the use of contrast material.

Using sterile procedure, the foreskin is retracted and the penis is stretched perpendicularly across the patient's thigh to prevent urethral folding. Radiocontrast solution is injected into the penis using the catheter tip of a 60-mL syringe or through a nonlubricated 16- or 18-Fr balloon-tipped urinary catheter inserted just inside the urethral meatus. If a catheter is used, the balloon of the catheter is inserted 2 to 3 cm past the meatus and 1 to 2 mL of saline is injected into the balloon to secure the catheter in the fossa navicularis. In the direct syringe technique, slow constant pressure is used to inject 50 to 60 mL of contrast material. With the catheter technique, gravity is used to infuse the contrast medium from the filled syringe with the plunger removed and attached to the catheter, held above the patient's bed. If the medium will not flow, slow, constant pressure can be used, as with the direct syringe approach. The examination is best performed under fluoroscopic visualization, although fixed or portable radiographic equipment can be used with the image taken during the injection of approximately the last 10 mL of contrast.

In instances when a urinary catheter has already been inserted into the bladder and there is a suspected urethral injury, it may be necessary to confirm that the urethra is intact and the catheter is in the bladder. The catheter should not be removed; instead, the urethrogram should be performed around it. Using a lubricated pediatric feeding tube placed alongside the existing catheter, contrast material can slowly be injected to demonstrate the presence or absence of extravasation.

Cystogram

Cystography using radiocontrast solution is the standard examination for bladder pathology. An anteroposterior (AP) pelvic or KUB film should be obtained as a scout film before contrast material is introduced.

Using sterile technique, a 16- or 18-Fr urinary catheter is carefully placed into the bladder. A 60-mL pistonless catheter-tip syringe is attached to the catheter and contrast material is poured into the syringe. Contrast is then allowed to enter the bladder via gravity as the syringe is placed above the level of the patient's bladder. The bladder is allowed to fill until extravasation occurs if done using fluoroscopy or the bladder is filled (400 mL). If bladder contraction occurs during filling, an additional 50 mL is injected by hand. In children younger than age 11 years, estimated bladder capacity is calculated based on the formula (age in years + 2) X 30. Incomplete filling of the bladder can limit the quality of the study. To accurately exclude bladder rupture and extravasation, the bladder must be filled with at least 250 mL of contrast material.

Cystograms should be done using fluoroscopy or plain films in the AP, oblique, and lateral projections. If there is an associated pelvic fracture, the patient should be kept in the supine position to avoid possible disruption of any retropubic hematomas. To detect retrovesical extravasation, an AP film should always be obtained after bladder drainage.

Angiography

Angiography is a test to define vascular injuries of the kidney. It is highly invasive, requiring cannulation of the femoral artery and the use of intravascular radiocontrast material. Indications include the absence

of a functioning kidney on IVP or CT, findings of a large retroperitoneal hematoma, major renal fractures, or segmental areas of renal non-enhancement. In some instances injuries to the parenchyma and arteries can be treated using interventional angiography to stop hemorrhage.

The femoral artery is accessed by the Seldinger technique (flexible catheter advanced over a guidewire). The tip of the catheter is placed in the aorta and a midstream aortogram obtained to evaluate the number and status of the renal arteries. The catheter tip is then placed at the upper level of the proximal artery and films are obtained to capture the arterial, capillary, and venous phases.

Renal Cortical Scintigraphy

Renal cortical scintigraphy (RCS), using dimercaptosuccinic acid (DMSA), is a radionuclear study that evaluates kidney function. RCS is most commonly used in the evaluation of children with suspected pyelonephritis and, occasionally, assessment of a renal transplant.

Two hours after administration of ^{99m}Tc -DMSA, scanning is performed using a gamma camera. DMSA binds to the renal tubules and accumulates in the functioning renal cortex. Intrarenal blood flow and proximal tubular cell membrane transport determine cortical uptake. Focal or diffuse areas of decreased DMSA cortical uptake without any loss of volume indicate the presence of pyelonephritis. Areas of decreased uptake with volume loss indicate old scars. Images are evaluated for the size of the kidneys, their shape and location, and differential renal function as well as the distribution of cortical uptake.

CONDITIONS

Renal Colic

The ideal imaging study in renal colic would (1) determine the size and location of the stone, (2) define the presence and degree of ureteral obstruction, and (3) identify other causes of flank pain and hematuria when renal calculi have been excluded.

Some 90 percent of renal calculi are radiopaque and theoretically visible on plain radiographs. Studies in the 1930s and more recent textbooks report visualization of stones in 85 to 90 percent of cases. These studies did not specify whether the visualized "stone" was related to the patient's symptoms or confirmed by other radiographic studies. Recent comparisons between plain-film radiography and IVP or CT (the "gold standard") found that plain radiography had a sensitivity of about 45 to 60 percent.⁸ Plain radiography alone has low utility and should not be used alone in the evaluation of patients with suspected renal colic; it does, however, play a role as an adjunct to IVP and ultrasonography.

IVP has long been considered the "gold standard" for the evaluation of renal colic. The location of a calculus can be seen by a radiocontrast cutoff in the ureter, the size of the calculus can usually be determined, and ureteral obstruction is suggested by visualization of the entire ureter secondary to a lack of peristaltic contractions. Identifying stones at the ureterovesical (UV) junction or the distal ureter can be difficult but is enhanced by assessment of the postvoid film. Secondary findings of stone disease include delay in the appearance of the

nephrogram, distention of the renal pelvis, calyceal distortion, or radiocontrast extravasation.

Recent studies have compared the efficacy of ultrasonography to IVP or CT in the diagnosis of renal stones in ED patients presenting with renal colic (Table 100-1).^{9,11} These sonographic studies used detection of the stone and/or evidence of hydronephrosis as a positive test result for the diagnosis of renal calculi. Both ultrasonography and IVP are slightly better at identifying obstruction than at localizing a stone. Using either stone identification or detection of obstruction, both modalities have essentially the same range of sensitivity and specificity, although ultrasound has a wider range of sensitivity, reflecting the greater dependence on operator skill and limitations of the modality. Use of Doppler ultrasonography to compare resistive indices of urinary jets entering the bladder has been reported to increase sensitivity. Plain-film radiographs can be used as road maps to focus the ultrasonograph study. Theoretically, ultrasonography has an advantage in imaging radiolucent stones (approximately 10 to 20 percent of urinary calculi), but if there is no dilation of the ureter, it becomes more difficult to place the visualized density correctly. Furthermore, ultrasonography has particular difficulty in visualizing dilations of the upper and mid-ureter. The distal ureter is more accessible, because the bladder acts as an acoustic window. Ultrasonography may also be limited by the delayed appearance of hydronephrosis; in a patients with renal calculi causing ureteral obstruction, the initial sonogram may be negative in up to a fourth but show hydronephrosis when repeated 8 to 12 h later.¹⁰

Published studies indicate that emergency physicians can perform bedside ultrasound examinations in patients with renal colic and detect hydronephrosis with more than 90 percent sensitivity, as compared with an IVP. The availability of ultrasound equipment for use in the ED, and the training of more emergency physicians in the use of this equipment, has the potential to expand the use of this modality and reduce the use of IVP studies for patients with acute renal colic.

Selecting ultrasonography instead of IVP or CT for an individual patient requires some clinical judgment. Certainly, patients with contraindications to radiation should have an ultrasonogram. The clinician will have to further weigh the importance of ascertaining functional information about the kidney, as well as the increased likelihood of identifying the location of the stone using radiocontrast media versus the added time and radiation exposure necessary to complete an IVP or CT. One approach is to obtain an ultrasonogram in all patients presenting with signs and symptoms of renal colic and only proceed to IVP or CT if the patient is deemed to require surgical intervention or if the diagnosis remains unclear.

Helical CT without intravenous contrast material has become the imaging modality of choice in many institutions for patients with acute renal colic.¹¹ The helical CT takes only 5 min to perform and can identify the presence and location of calculi of all compositions except pure indinavir stones, not only providing prompt and accurate diagnosis in most patients with calculi but also identifying extrarenal disorders in patients without calculi. The average dose of radiation at the skin from a helical CT is 3 to 5 cGy, comparable to 1.5 to 3 cGy (0.25 to 0.3 cGy per radiograph) from an IVP. One limitation of the helical CT is that it does not provide functional information about the degree of ureteral obstruction.

TABLE 100-1 Imaging Modalities in Renal Colic: Approximate Sensitivities and Specificities

	Identification of Stone or Hydronephrosis		Identification of Stone		Identification of Hydronephrosis	
	Sensitivity	Specificity	Sensitivity	Specificity	Sensitivity	Specificity
IVP	80-85%	95% 90-	60-80%	95%	90%	95% 85%
Ultrasonography	65-93%	95% 95%	65-93%	95%	95% 85-90%	90-
Helical CT	95-98%		90%	95%	95%	

Abbreviations: CT = computed tomography; IVP = intravenous pyelography.

Studies demonstrate that helical CT has excellent sensitivity and specificity in the diagnosis of renal colic (see Table 100-1).¹¹ It can detect stones as small as 1 mm in diameter. One limitation is distinguishing phleboliths from renal calculi, but secondary signs can be used to help make this distinction. For renal colic, these signs include ureteral dilation (sensitivity 90 percent and specificity 93 percent), perinephric stranding (sensitivity 82 percent and specificity 93 percent), collecting system dilation (sensitivity 83 percent and specificity 94 percent), and renal enlargement (sensitivity 71 percent and specificity 89 percent). The presence of ureteral dilation and perinephric stranding had a positive predictive value of 99 percent, and the absence of both had a negative predictive value of 95 percent. Edema of the ureteral wall surrounding the calculus (rim sign) is up to 100 percent sensitive and 94 percent specific in distinguishing renal stones from phleboliths. Helical CT should be considered positive for calculi when any of the following are seen: (1) a stone, (2) both ureteral dilation and perinephric stranding, or (3) a tissue rim sign. These are of particular importance when indinavir stones are considered. Urologists were able to use helical CT without further imaging in almost 90 percent of patients who underwent lithotripsy or endoscopic stone removal.¹²

Renal Transplant

Renal transplant failure can be secondary to graft rejection or renovascular complications. Modalities available to evaluate the transplanted kidney include angiography, ultrasonography with color-flow Doppler and duplex Doppler, and renal cortical scintigraphy. The choice of modality will depend on the clinician's index of suspicion for graft rejection or vascular compromise.

The most common vascular complication of transplant is renal artery stenosis (RAS), with an incidence of 3 to 15 percent in the first 3 years after transplant. Renal artery and vein thromboses are rare, usually occur in the perioperative period, and are generally catastrophic, resulting in loss of the renal graft. In contrast, identification and treatment of RAS can result in graft salvage. Patients with RAS often present with hypertension and worsening renal function. While posttransplant patients are reported to have a 50 to 60 percent incidence of hypertension unrelated to RAS, a renal transplant patient with hypertension that is progressive or difficult to control with medical therapy should be considered at risk for RAS. The gold standard for diagnosing RAS is angiography. However, angiography is limited by its invasive nature, the use of nephrotoxic contrast agents, the risk of an adverse reaction to contrast media, and complication rates of 0.5 to 2.3 percent (hemorrhage, intimal flaps, and arteriovenous fistulas). Gadolinium-enhanced magnetic resonance angiography (MRA) has several advantages over angiography, including short acquisition time (30 s), no risk of nephrotoxicity secondary to contrast agents, and avoiding hospitalization. MRA has a reported 100 percent sensitivity and 93 to 100 percent specificity for RAS.¹³ However, contrast-enhanced MRA is an anatomic test that provides little information about the functional significance of a stenosis.

The conventional sonogram has limited utility but may detect some anatomic abnormalities suggesting a vascular or nonvascular diagnosis.¹ Duplex and color-flow Doppler have been used to evaluate the renal artery, but are technically difficult and the subject of controversy in the literature about their diagnostic accuracy. Color-flow Doppler has the advantage of sampling long segments of vessels but cannot accurately quantitate flow disturbances. Flow disturbances can be quantified by duplex Doppler. Using peak flow rates, studies have attempted to define a rate of flow that can accurately predict RAS. The threshold flow-rate value that provides the best combination of sensitivity and specificity is controversial. Peak systolic velocity of 190 to 250 cm/s has a sensitivity of 90 to 100 percent for RAS greater than 50 percent luminal narrowing. However, specificity varies from as low as 55 percent to as high as 95 percent. The overall accuracy can be im-

proved by using peak systolic velocity in conjunction with analysis of the waveform (rounded, smaller-amplitude waveform with stenosis) in detecting significant proximal RAS.

Renal scintigraphy is a test of vascular perfusion, parenchymal extraction, and excretion. Abnormal findings from this study include (1) impaired uptake and visualization, which is consistent with vascular obstruction or hyperacute rejection and is a poor prognostic sign; (2) normal uptake and visualization but with parenchymal retention, which is associated with poor urine flow and the retention of the secreted isotope in the tubules; and (3) decreased uptake with normal parenchymal transit time and absent or minimal cortical retention, which is consistent with chronic rejection or renovascular hypertension. Unfortunately, the effects of renal artery stenosis, graft rejection, and cyclosporine toxicity cannot be distinguished by using renal scintigraphy.

Captopril-augmented RCS has been used to distinguish physiologic from nonphysiologic RAS. Patients with normal captopril-augmented RCS are not likely to respond to angioplasty, while patients with abnormal studies will likely have a significant improvement following angioplasty. Captopril-augmented RCS can replace renal vein renin sampling in identifying patients with lesions amenable to intervention.

Urinary Tract Infection

There is considerable controversy regarding the appropriate imaging of children with urinary tract infection (UTI) to identify predisposing functional and anatomic abnormalities.¹⁴ Sometimes, an emergency evaluation is required because of diagnostic confusion based on atypical presentations, a negative urinalysis, or treatment failure based on persistent fever and toxicity 72 h following the initiation of therapy.

RCS using ^{99m}Tc-DMSA is the most sensitive imaging modality for establishing the diagnosis of pyelonephritis with a sensitivity of 90 percent and specificity of 100 percent.^{14,15} Controversy exists concerning the necessity of documenting renal scarring and pyelonephritis in a child with an apparently simple UTI. Because patients with vesicoureteral reflux do not always demonstrate scarring on RCS, the American Academy of Pediatrics currently recommends both ultrasonography and voiding cystourethrogram (VCUG) evaluation for all children ages 2 to 24 months with their first documented UTI.¹⁶ Conversely, a significant proportion of children without reflux demonstrate renal scarring, validating the importance of RCS evaluation despite a negative VCUG.¹⁷ An advantage of RCS is that it can be used in children and neonates with poor renal function. Up to 17 percent of pediatric end-stage renal disease be attributed to chronic VUR and renal scarring.^{16,18} Conversely, there are currently no long-term studies that determine the risk of developing ESRD in infants with VUR and no scarring.

The voiding cystogram is used to demonstrate VUR, the most common abnormality found in the urinary tract of children, which is seen in approximately 35 percent of children with UTI. Children at risk for VUR include those with a family history of reflux and whites. Voiding cystography can be done by radiographic or radionuclide technique. The radionuclide voiding cystogram using technetium pertechnetate no longer has the advantage of less radiation exposure when compared to VCUG using low frequency, pulsed, and grid-based fluoroscopy. Radionuclide technique also has the disadvantage of poor visualization of urethral and bladder abnormalities, including posterior urethral valves, which are commonly seen in boys. Thus, boys should undergo radiographic VCUG. Contrary to previous beliefs, VCUG performed at the time of infection does not result in falsely elevated rates of reflux. Furthermore, performing VCUG early prevents the failure to diagnose VUR secondary to poor compliance and loss to follow up.¹⁹

Ultrasonography is an insensitive method for diagnosing pyelonephritis or VUR but can provide anatomic information unavailable in other modalities. It can visualize renal abscesses, hydronephrosis, strictures, and obstruction at either the ureterovesical or

ureteropelvic junction. Of patients with UTI, 40 to 50 percent of infants, and 30 percent of older children will have an anatomic abnormality. The sensitivity and specificity of ultrasonography for children with posterior urethral valves is 87 and 98 percent, respectively.²⁰ Recently, the practice of prenatal renal ultrasonography has led to earlier diagnosis of urinary tract abnormalities.¹⁵ This may ultimately decrease the associated morbidity of hypertension and ESRD.

MRI may be comparable to RCS for detecting pyelonephritis. Using RCS as the gold standard, MRI has a reported sensitivity of 100 percent and a specificity of 78 percent.²¹ CT signs of pyelonephritis include renal enlargement, poor corticomedullary definition, and patchy areas of decreased definition. Renal and perinephric abscesses are well visualized on CT. CT is not recommended in children because of the proximity of the gonads and their radiosensitivity before puberty. Adults with pyelonephritis only require imaging studies if there is suspicion of complications, including obstruction and perinephric abscess.

GYNECOLOGY AND OBSTETRICS

VAGINAL BLEEDING IN THE NONPREGNANT PATIENT

Laurie J. Morrison

Julie M. Spence

EPIDEMIOLOGY

ED visits for vaginal bleeding by women of reproductive-age are common. An estimated 5 percent of women aged 30 to 49 years will consult a physician for treatment of menorrhagia.

PHYSIOLOGY

Normal Menstrual Cycle

Ten years of age tends to be the lower limit for menarche, and the mean age in North America is 12.5 years. Most children develop secondary breast changes 2 years prior to the onset of menarche. At the time of ovarian stimulation, a white or yellow vaginal discharge, which is both nonodorous and nonirritating, may appear. Early cycles are anovulatory and irregular, but unlike adult anovulatory cycles, bleeding is generally not excessive. The hypothalamic-pituitary axis takes 1 to 5 years to reach full maturity, and the average time to establish ovulatory cycles is 2 years after menarche.

The normal menstrual cycle is 28 days and is divided into four phases: follicular, ovulation, luteal or secretory, and menses. The first 14 days are the follicular phase, during which the ovary matures an oocyte for ovulation, and the granulosa cells, lining the follicle, produce estrogen. This stimulates the endometrium to proliferate and thicken (Figure 101-1). In response to the rising estrogen levels, the pituitary gland secretes follicle-stimulating hormone (FSH) and luteinizing hormone (LH), which stimulate the release of the mature oocyte. The residual follicular capsule forms the corpus luteum. During the luteal phase, the corpus luteum secretes estrogen and progesterone, which maintain the endometrium and make it more receptive to implantation. If fertilization and implantation occur, the developing embryo secretes human chorionic gonadotropin (hCG) into the bloodstream, signaling the corpus luteum to continue the production of progesterone and estrogen necessary to support early pregnancy. In the absence of hCG, the corpus luteum involutes, and estrogen and progesterone levels fall. Hormonal withdrawal causes vasoconstriction in the spiral arterioles of the endometrium. This leads to the final phase, or menses, when the ischemic endometrial lining becomes necrotic and sloughs. The vaginal effluvium contains blood, endometrial tissue, and fluid. The estimated amount of menstrual blood loss ranges from 25 to 60 mL. Judging the amount of bleeding in a menstrual cycle may be difficult. The average tampon or pad absorbs 20 to 30 mL of vaginal effluent, although the number of pads or tampons used is unreliable, as personal habits vary greatly among women. In a normal cycle, fibrinolysis occurs in the uterine cavity and the cervix. In women with heavy bleeding, there may be insufficient time for fibrinolysis, and blood clots may occur. Definitions of terminology commonly used in gynecology have been included in Table 101-1.

Menopause

Menopause on average occurs at age 51 years. During the transition phase, or perimenopausal period, there is lengthening or marked variation in the intermenstrual intervals. By age 45 years, only a few pri-

mordial cells remain, and the production of estrogen decreases. As a result, the pituitary continuously produces large quantities of FSH and LH. There is no midcycle rise in estrogen to trigger a further surge of pituitary hormones for ovulation. Estrogens continue to be produced in lower, subcritical levels for a short time after menopause, until the remaining follicles become atretic, and production falls to almost zero.

DIFFERENTIAL DIAGNOSIS OF ABNORMAL VAGINAL BLEEDING

The gynecologic causes of abnormal vaginal bleeding in nonpregnant, reproductive-age females can be broadly grouped into three categories: ovulatory abnormal bleeding, anovulatory abnormal bleeding, and nonuterine bleeding. Abnormal ovulatory bleeding usually results in menorrhagia and intermenstrual bleeding. Nonovulatory cycles may be irregular and heavy (menometrorrhagia) or frequent and light (polymenorrhea) bleeding. Nongynecologic causes of bleeding should also be considered.

Table 101-2 lists causes of bleeding by approximate frequency and age group.

Ovulatory Bleeding

Ovulatory bleeding is associated with regular menstrual periods that are preceded by breast tenderness, abdominal bloating, and dysmenorrhea. Abnormal bleeding may occur during ovulation as a result of low estrogen levels. Intermenstrual bleeding may also be caused by structural and inflammatory lesions, including cervical polyps, vaginal lacerations, cervicitis, invasive cervical cancer, endometrial cancer, and fibroids. Premenstrual spotting or delayed menses frequently results from an inadequate luteal phase or persistent corpus luteum. Abnormal or heavy menstrual bleeding may be due to pelvic diseases, such as endometriosis, pelvic inflammatory disease (PID), and ovarian neoplasms. Uterine causes include leiomyomas, endometrial polyps, endometrial hyperplasia or malignancy, and adenomyosis. Finally, iatrogenic factors, pregnancy and postpartum complications, and bleeding dyscrasias may result in abnormal bleeding in the woman with ovulatory cycles. Idiopathic heavy menstrual bleeding in the absence of pathology responds to medical therapy at best in 50 percent of cases.

Anovulatory Bleeding

Menorrhagia secondary to anovulation is seen in 10 to 15 percent of all gynecologic patients. It is common in perimenarchal and perimenopausal women, as well as in patients with endocrine disorders, polycystic ovary syndrome, exogenous hormone use, and liver or renal disease.

Anovulatory uterine bleeding in adolescence is secondary to the immature hypothalamic-pituitary-ovarian axis. The amount of bleeding is usually minimal and painless. The findings on pelvic and rectovaginal examination are likely to be normal. Investigations are warranted when bleeding persists after 9 days, recurs at intervals of less than 21 days, or produces anemia. In some cases the blood loss can be considerable, with monthly losses of 100 to 200 mL, resulting in iron deficiency, marrow depletion, and anemia. If bleeding at the onset of menarche is considerable or necessitates blood transfusions, a coagulopathy should be excluded. Acute menorrhagia can generally be controlled with estrogen therapy or the oral contraceptive pill (OCP) (Table 101-3). Dilatation and curettage (D&C) is rarely required.

Anovulatory bleeding in the reproductive-age female may be regular but more often is irregular because of fluctuating estrogen levels

FIG. 101-1. The hormonal, ovarian, endometrial, and basal body temperature changes and relationships throughout the normal menstrual cycle. (Reproduced with permission from Carr BR, Wilson JD: Disorders of the ovary and female reproductive tract, in Isselbacher KJ, Braunwald E, Wilson ID, et al (eds): *Harrison's Principles of Internal Medicine*, 13th ed. New York, McGraw-Hill, 1998, p 2101.)

below the critical level required to maintain endometrial growth. The level of estrogen depends on the age, number, and activity of ovarian follicles. As some follicles degenerate, others resume the production of estrogen and the endometrium continues to proliferate for weeks to months, which may cause glandular hyperplasia ("Swiss cheese" hyperplasia). This estrogen steady state is insufficient to meet the growing needs of the endometrium and produces a relative estrogen insufficiency, and vaginal bleeding ensues. Alternatively, when follicle degeneration and stimulation are not balanced, absolute estrogen levels fall and withdrawal bleeding occurs. Characteristically, anovulatory cycles present as prolonged amenorrhea with periodic menorrhagia. Because of the lack of progesterone-mediated myometrial contractions and arteriolar vasospasm, anovulatory cycles are rarely associated with cramping. This pattern of bleeding increases the risk of endometrial hyperplasia and adenocarcinoma.

OCP use remains the most common cause of midcycle bleeding. Eating disorders, excessive weight loss, stress, and exercise can cause abnormal uterine bleeding. Additionally, medications (e.g., antiseizure medications) that increase the P450 system of the liver may increase

the metabolism of endogenous hormonal glucocorticoids and may cause withdrawal bleeding.

In perimenopausal and menopausal patients, it is important to distinguish true pathology from dysfunctional bleeding. Malignancy should always be considered, since it is the most important, although not the most common, diagnosis.¹ The amount of bleeding does not correlate with the severity of disease. Postmenopausal bleeding warrants prompt referral for evaluation. Older patients may not be able to accurately describe the location of pain or bleeding in the proximity of the bladder, uterus, or rectosigmoid. The vagina and cervix must be adequately visualized on pelvic examination. Bleeding from a vaginal source is uncommon but may be associated with the use of pessaries and douche solutions, which can irritate the mucosa. Cervical polyps may be a source of bleeding. However, an endometrial biopsy is ultimately required to rule out other serious causes of bleeding (Table 101-4).

Although bleeding is frequently caused by an unstable or atrophic endometrium, other causes must be considered. Important conditions in the differential diagnosis include submucosal leiomyomas, endometrial polyps, endometrial hyperplasia, adenomyosis, and tumors. Emergency therapy should be directed at investigating and treating obvious causes of bleeding. Outpatient ultrasound and endometrial biopsy can then be arranged for stable patients.

Nonuterine Bleeding

Nonuterine causes of vaginal bleeding must be included in the differential diagnosis, systematically addressed during the history taking and physical examination, and pursued with relevant investigations and consultations, if indicated. Primary coagulation disorders account for almost 20 percent of acute menorrhagia in adolescents, von Willebrand disease (vWD) is the most common; however, myeloproliferative disorders and immune thrombocytopenia are also possibilities.

Potential sources of nonuterine bleeding include the cervix, vagina, lower urinary tract, and lower gastrointestinal (GI) tract. Cervical causes include carcinoma, polyps, condylomata, eversion of squamocolumnar junction associated with OCP use or pregnancy, trauma, and some infections. Vaginal sources of bleeding include carcinoma, sarcoma, adenosis, lacerations, infections, and retained foreign bodies.

Lower urinary tract lesions, such as urethral caruncles and infected urethral diverticula, may mimic vaginal bleeding. Some patients may not be able to determine the source of bleeding, and lower GI causes may need to be investigated.

CLINICAL FEATURES

History

Adolescent and adult patients presenting to the ED with vaginal bleeding share many common elements of the history and physical examination. Key points that should be routinely addressed when taking the clinical history are age of menarche, menstrual history, date of the last menstrual period (LMP), pattern of abnormal bleeding or discharge, and the presence of dysmenorrhea. Complications related to pregnancy are always possible, and routine inquiries are both appropriate and necessary. Sexually active patients should be asked about contraception, current sexual activity, use of barrier protection, HIV and hepatitis status, and history of PID, sexually transmitted diseases (STDs), or ectopic pregnancy. Signs and symptoms of a coagulopathy, including nosebleeds, petechiae, and ecchymoses, and a family and surgical history should be recorded.

Patients who present with pain should be asked about its quality, timing, location, radiation, and aggravating or alleviating factors. Associated symptoms of the urinary, GI, and musculoskeletal systems, as well as the presence of fever or syncope, should be documented. A his-

TABLE 101-1 Definitions Related to Vaginal Bleeding

Vaginal bleeding	Defined temporally as midcycle (ovulatory), premenstrual, menstrual, and postmenstrual Vaginal bleeding occurring outside the regular cycle
Abnormal vaginal bleeding	
Menorrhagia	Menses >7 days, or menstruation >60 mL, or <21-day recurrence, from any cause Irregular vaginal bleeding outside the normal cycle Excessive irregular vaginal bleeding Abnormal vaginal bleeding due to anovulation
Metrorrhagia	
Menometrorrhagia	
Dysfunctional uterine bleeding	
Postcoital bleeding	Vaginal bleeding after intercourse, suggesting cervical pathology Any bleeding that occurs more than 6 months after cessation of menstruation
Postmenopausal bleeding

BLEEDING			
Adolescent	Reproductive	Perimenopausal	Postmenopausal
Anovulation	Pregnancy	Anovulation	Endometrial lesions, including cancer (30%)
Pregnancy	Anovulation	Uterine leiomyomas	Exogenous hormone use (30%)
Exogenous hormone use	Exogenous hormone use	Cervical and endometrial polyps	Atrophic vaginitis (30%)
Coagulopathy	Uterine leiomyomas	Thyroid dysfunction	Other tumor—vulvar, vaginal, cervical (10%)
	Cervical and endometrial polyps		
	Thyroid dysfunction		

Sources: Modified from Hillard PA: Benign diseases of the female reproductive tract: Symptoms and signs, in Berek JS, Adashi EY, Hillard PA (eds): *Novak's Gynecology*, 12th ed. Baltimore, MD, Williams & Wilkins, 1996, p. 333; and Hacker NF, Moore JG: *Essentials of Obstetrics and Gynecology*. Philadelphia, WBSaunders, 1998, p. 467.

tory of recent illness, psychological stress, weight change, or endocrine problems, including thyroid disease and pituitary tumors, should be obtained.

Taking the history of adolescent girls is challenging. Honest responses to questioning will require assurances of confidentiality by the physician. If the patient requests a female physician, the request should be honored, if at all possible. Always interview the patient without the parent present. Questions regarding STDs and sexual activity can be very disturbing for adolescents. It is important historical information and should be obtained in a nonjudgmental, gentle way that in itself will be educational. It may not be possible to obtain an accurate history about the occurrence of periods early in menarche, as the cycle is usually irregular for the first 1 to 2 years and perhaps as long as 5 years.

Physical Examination

Vital signs should be assessed in all patients. In cases of heavy bleeding, any postural changes in vital signs should be recorded. A complete ex-

amination should include a careful abdominal examination to rule out nongynecologic causes of vaginal bleeding. Femoral and inguinal nodes should be examined for size and tenderness. Signs of other illnesses, including hypothyroidism, galactorrhea, and obesity associated with hirsutism, should be documented.

Male physicians should have a chaperone during gynecologic examinations. Female physicians are equally well advised to have a chaperone. Prior to beginning the examination, a simple explanation should be given and verbal consent obtained. Adolescents should be examined without their parents or guardians. The patient should be allowed to empty her bladder and remove any tampons prior to the examination. Positioning and draping should allow the patient to see the physician during the examination. Occasional eye contact is reassuring.

The examination of nonvirginal patients includes a speculum examination, a vaginobdominal examination (bimanual), and a rectovaginal examination. The vulva and urethral opening should be inspected prior to inserting the warmed and lubricated speculum into the vagina. The site of abnormal bleeding should be determined through careful examination of the perineum, urethra, vulva, and perianal region. The vagina should be inspected for signs of lacerations, fissures, lesions, infection, and foreign bodies. The cervix should be well visualized to rule out polyps, inflammation, infection, ulcers, and evidence of cancer. Cultures are generally taken as part of the examination if a mucopurulent discharge is found. The cervical os should be inspected for blood, tissue, an intrauterine device (IUD), pedunculated leiomyomata or polyps, and signs of infection.

On bimanual vaginobdominal examination, the softness and patency of the cervical os, and pain on movement should be documented. The ovaries and uterus are palpated for size, consistency, pain, and the presence of associated masses. The adnexa and periuterine area should also be carefully examined. The rectovaginal examination is essential and should be done in every patient, especially if the patient cannot tolerate a bimanual examination. The rectovaginal examination enables evaluation of the posterior cul-de-sac for ovarian masses, the posterior wall of the uterus for size and consistency, and the uterosacral ligaments for metastatic nodules or ectopic endometriosis. Stool should be evaluated for the presence of blood.

Virginal patients with menstrual cramps, mittelschmerz, or vaginal discharge do not require a full pelvic examination, because a rectovaginal examination is generally sufficient. In the case of trauma and abnormal vaginal bleeding, a vaginal examination is necessary. Adolescents with intact hymen can generally tolerate a speculum examination if a narrow Pederson-type adolescent or Huffman pediatric speculum is used. Conscious sedation or full anesthesia may be required, depending on psychological response of the patient, the circumstances and the extent of the injury or disease.

Older patients with a history of bleeding should undergo a full gynecologic examination. Degenerative changes to the lumbar spine and hips may make the traditional lithotomy position difficult. Alternatively,

TABLE 101-3 Short-Term Medical Management of Hemodynamically Stable Uterine Bleeding

Estrogen therapy
Oral conjugated estrogen (e.g., Premarin) 10 mg/d (2.5 mg qid) or 25 mg IV every 2 to 4 h for 24 h. Note: the efficacy of oral and intravenous estrogens are similar. When bleeding subsides, add medroxyprogesterone acetate (Provera)
10 mg/d. Continue both the conjugated estrogen and the medroxyprogesterone for 7 to 10 days.
Stop for synchronized withdrawal bleed.
Oral contraceptive pill
Ethinyl estradiol 35 μ g and norethindrone 1 mg—4 tabs for 7 days or Slow taper (ethinyl estradiol 35 μ g and norethindrone 1 mg)
4 tabs for 2 days
3 tabs for 2 days
2 tabs for 2 days
1 tab for 3 days
Progesterone
Medroxyprogesterone acetate (e.g., Provera) 10 mg/d is used for 10 days.
Antifibrinolytic therapy Tranexamic acid: 0.3-1.0 g PO every 8 h for 3 days.

the patient may be examined supine with knees flexed and legs dropped to the side, or lying on her side with the lower arm behind her back and thighs flexed (the Sims position). A small speculum (e.g., a 1- to 1.5-cm Pederson) should be used if the vulva and vagina appear atrophic. Physicians must remember that the vaginal walls may become adherent in individuals who are not sexually active, and a gentle digital examination may be required to ensure that a speculum examination is possible. Vaginal examination is generally well tolerated in women who are on estrogen replacement. Documentation of the size, shape, and mobility of the uterus is especially important when making a diagnosis in this population. The normal ovary should not be palpable 5 years after menopause, and any enlargement should be considered abnormal.

LABORATORY STUDIES AND IMAGING

Pregnancy tests should be ordered routinely in women of childbearing age to rule out pregnancy as a cause of bleeding. A complete blood count is essential in most cases of vaginal bleeding. Coagulation studies are ordered only when indicated by the history and physical examination. In individuals with suspected endocrine disorders, determination of thyroid-stimulating hormone and prolactin levels may be helpful, but the levels are rarely available for ED evaluation.

Ultrasonography is an important imaging modality for gynecologic conditions such as vaginal bleeding, adnexal or uterine masses, or pain. In nonpregnant patients, a formal ultrasonographic evaluation is used to determine uterine size and the characteristics of the endometrium, as well as the presence of leiomyoma, ovarian cysts, hydrosalpinx, pelvic adhesions, tuboovarian abscesses (TOAs), endometriosis, and tumors. Transvaginal (i.e., endovaginal) ultrasonography may be particularly helpful in further delineating ovarian cysts and fluid in the cul-de-sac. Depending on the degree of pain and findings on physical examination, ultrasonography may be done on an emergency basis, or deferred for outpatient evaluation.

Computed tomography is used primarily in the ED for the evaluation of acute abdominal or pelvic pain (see Chap. 102). Magnetic resonance imaging is used primarily for cancer staging.

Referral for follow-up will usually lead to endometrial biopsy in women who are at risk for endometrial cancer and are not pregnant. This procedure is generally indicated for women older than age 35 years with abnormal uterine bleeding or women younger than age 35 years with risk factors for endometrial cancer such as obesity and chronic anovulation. Hysteroscopy is a valuable test that affords a more complete examination of the surface of the endometrium than D&C, which may miss 10 to 25 percent of lesions.²

Hormone replacement therapy (HRT) is commonly used to relieve symptoms associated with menopause and to reduce the risk of cardiovascular disease. Recent trials have called this practice into question, citing no benefit for primary and secondary prevention of cardiovascular disease and excessive risk of endometrial, breast and colorectal cancer and thromboembolism.^{3,4} Perimenopausal women with abnormal uterine bleeding should have an endometrial biopsy prior to the initiation of HRT. Bleeding after 6 months of continuous combined HRT, or unexpected bleeding with cyclic HRT, prompt referral for evaluation. In patients receiving continuous therapy, 40 percent will have abnormal bleeding in the initial 4 to 6 months. There are no acceptable criteria for "abnormal bleeding" on these therapies, and investigations are warranted if bleeding continues beyond 6 months or recurs after amenorrhea is established. Most frequently implicated in patients on HRT are poor compliance, poor GI absorption, drug interactions, failure to synchronize therapy with endogenous ovarian activity, and coagulation disorders.

TREATMENT

General Approach

The main approach to nonpregnant patients with established vaginal bleeding is to determine whether the condition requires general (e.g., resuscitation) or specific ED-based evaluation or intervention. In patients who present primarily with vaginal bleeding, the main issue is to determine whether there has been significant blood loss, and whether a condition exists (such as traumatic injury or bleeding dyscrasia) that places the patient at risk for uncontrolled or significant bleeding. If the

bleeding has not led to hemodynamic compromise (and is unlikely to), then, after pregnancy has been ruled out, the only diagnoses that need to be absolutely established in the ED are trauma (including sexual abuse and assault), bleeding dyscrasia, infection and foreign bodies. Otherwise, patients can be referred for outpatient investigation, with the timing based on the urgency of the presentation.

Short-Term Management

HEMODYNAMICALLY UNSTABLE Patients who are hemodynamically unstable because of bleeding must be resuscitated according to standard protocols. Attempts should be made to localize the source of bleeding. In women with severe, persistent uterine bleeding, immediate D&C is usually indicated. Uterine packing should be avoided, because it increases the risk of infection and may hide ongoing blood loss. Conjugated estrogens may be useful in the ED treatment of life-threatening hemorrhage not caused by pregnancy or tumor or amenable to surgical intervention.

HEMODYNAMICALLY STABLE Medical management should be considered in hemodynamically stable patients provided the diagnosis is clear. Short-term hormonal manipulation allows the endometrium to stabilize, which, in turn, will slow or stop acute bleeding. Estrogen may be used to stimulate growth when ultrasonographic examination has revealed a thin endometrium. With the regimen outlined in Table 101-3, subsequent bleeding may be heavy but should not be prolonged. Oral contraceptives may be used in women who are not pregnant and have no anatomic abnormalities. The progesterone in the OCP decreases the number of available estrogen receptors and, as a result, bleeding may not stop as quickly as when estrogen is used alone. Side effects include nausea and vomiting. Two treatment regimens have been developed using a fixed-dosage pill, with 35 μ g ethinyl estradiol and 1 mg norethindrone (see Table 101-3). In individuals with persistent light bleeding associated with anovulation, progesterone alone can be used to stabilize an immature endometrium. Bleeding occurs 3 to 10 days after discontinuation and may be heavy as a consequence of the large amount of tissue being sloughed. If the diagnosis is unclear, the patient should be referred for further investigation involving formal ultrasonographic evaluation and outpatient management.

Long-Term Management

Many therapies are available for the long-term management of vaginal bleeding. Expectant management is appropriate if episodes of heavy or irregular bleeding are infrequent. The OCP is an excellent choice if contraception is required. Ovulatory menorrhagia is decreased by 50 percent, with a similar reduction in the degree of dysmenorrhea. This therapy may be effective in the treatment of patients with fibroids.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are helpful in the treatment of both ovulatory and anovulatory bleeding and dysmenorrhea. All of these medications have the same basic mechanism of action and inhibit cyclooxygenase in the arachidonic acid cascade. The prostaglandin inhibitors alter the ratio of prostaglandin $F_{2\alpha}$, which causes vasoconstriction, and prostaglandin E_2 , which causes vasodilation. NSAIDs also increase levels of thromboxane A_2 , which causes vasoconstriction and increases platelet aggregation. These medications may reduce blood loss by 20 to 50 percent and reduce dysmenorrhea. They have a mild side-effect profile and are inexpensive. Not all women will respond, although 75 percent of patients report a 30 percent decrease in blood loss.⁵ NSAIDs are less useful in patients with uterine leiomyomas.⁵ Mefenamic acid (500 mg tid) and naproxen (500 mg bid) are the most well studied, and ibuprofen (400 mg q6h) has been shown to reduce menstrual bleeding in IUD users. NSAIDs should be started on the first day of the period and continued until bleeding stops and pain resolves.

Although virtually never initiated in the ED, clomiphene citrate may be used to decrease bleeding as well as to induce ovulation if pregnancy is desired. If there is no contraindication to estrogen usage, oral medroxyprogesterone acetate 10 mg daily for 10 days can be used to produce scheduled bleeding. Intrauterine progesterone release is also available. Danazol may be used to decrease bleeding significantly, although it is expensive. Patient acceptance is similar to that of patients on NSAIDs, and reduction of bleeding may be greater. Side effects include musculoskeletal pain, flushing vertigo, backache, breast atrophy, and hirsutism.⁵ Patients may still ovulate when using this medication. Gonadotropin-releasing hormone agonists may play a role in the induction of amenorrhea, and women on this therapy become menopausal. Other drawbacks include medication expense and bone loss when used for longer than 6 months. Tranexamic acid, a fibrinolytic, reduces objective signs of vaginal bleeding without any increase in side effects and better quality of life when compared to hormone therapy and NSAIDs. Data on thromboembolic events are not available.⁶ Overall there is insufficient evidence to define optimal medical management.^{7,8}

Hysteroscopy is both diagnostic and therapeutic. It can be used to sample the endometrium, as well as to resect polyps and myoma. Endometrial ablation may be performed in patients who do not desire fertility, have no pathologic diagnosis, and for whom medical therapy has failed. This may be performed using laser, electrocautery, or rollerball ablation. Amenorrhea is seen in approximately 50 percent of women treated, and decreased flow is seen in another 35 percent.⁹ Improvement of symptoms of dysmenorrhea is reported in up to 80 percent of patients. Myomectomy may be useful in patients with symptomatic fibroids. Hysterectomy is reserved for selected patient populations. Evidence based on large case series suggests that uterine embolization may be an effective nonsurgical option for the management of bleeding caused by fibroids.

CLINICAL CONDITIONS

Genital Trauma

Vaginal injuries following intercourse are not uncommon. The majority of coital injuries result from vigorous voluntary sexual activity, although violent involuntary sexual activity should be considered. The most common site of injury is the posterior vaginal fornix. Misdiagnosis of coital injuries occurs frequently because either the physician fails to take an adequate history or the patient does not admit to antecedent sexual activity. Most coital injuries are minor, but severe injuries may lead to hemorrhagic shock.

Adenomyosis

In patients with adenomyosis, dysmenorrhea occurs just prior to or at the time of menstruation. In this condition, endometrial glands grow deeply into the underlying myometrium. Menorrhagia is common and is felt to be a result of aberrant tissue impairing the normal uterine contractility. Symptoms gradually increase in the fourth and fifth decades of life. On pelvic examination, there may be a large fibroid-like mass, or adenomyoma, but more commonly it is a diffuse, infiltrative process. Therapy is symptomatic, and simple analgesics are prescribed. Some cases require surgical management.

Leiomyomas

Leiomyomas (fibroids) are benign tumors of muscle cell origin and are the most frequently occurring pelvic tumor. They are found in 25 percent of white women and in 50 percent of African American women, and are usually multiple. The etiology is unclear, and theories include the proliferation from a single muscle cell from a small embryonic

rest or a defined region of tissue with a higher level of estrogen receptors. Leiomyomas decrease in size during menopause, and enlarge early in pregnancy and, in some cases, OCP use. Up to 30 percent of patients with leiomyomas experience pelvic pain and abnormal bleeding. Acute pain is rare, but severe pain may be experienced with torsion or degeneration. Degeneration is a result of rapid growth and loss of blood supply, almost exclusively seen in early pregnancy.

Leiomyomas are diagnosed on examination and by imaging. A mass or multiple masses are palpable. In patients with acute degeneration, tenderness, rebound guarding, a fever, and elevated white blood cell count (WBC) may be seen. Pedunculated subserosal leiomyomas may undergo torsion or cause uterine cramping. Rapid growth at any age or growth after menopause is highly suspicious for malignant transformation. Treatment depends on size and symptoms. Medical management includes administration of NSAIDs, medroxyprogesterone acetate or depomedroxyprogesterone acetate, and gonadotropin-releasing hormone agonists. Pedunculated intracavitary leiomyomas may be removed by hysteroscopy. Surgical removal is associated with a 25 to 30 percent rate of recurrence and significant bleeding complications. A percutaneous interventional technique involving uterine artery embolization shows promise in observational trials. Embolization appears to alleviate symptoms and cause fibroid shrinkage.¹⁰

Blood Dyscrasias

Bleeding disorders may become apparent with an initial presentation of abnormal menstrual bleeding. Uterine hemostasis is not well understood, and any disorder of blood vessels, platelet abnormalities, and coagulation disorders, including vWD, may result in excessive menstrual bleeding. Of historical interest, the first described case of vWD was in a 13-year-old who died as a result of uncontrollable uterine bleeding.¹¹ The prevalence of objectively confirmed abnormal uterine bleeding is increased in patients with vWD, carriers of hemophilia, and factor XI deficiency, at 73, 57, and 59 percent, respectively, when compared with a 9 to 11 percent rate in a population-based sample. Treatment options include use of antifibrinolytics and the OCP. The latter raises factor VIII and vWF levels and is an effective and popular form of therapy. Antifibrinolytics such as tranexamic acid reduce both plasminogen activator activity and plasmin activity to reduce the amount of bleeding. Desmopressin acetate (DDAVP) stimulates endogenous release of factor VIII and vWF and may be used prophylactically for minor procedures or treatment of bleeding episodes and menorrhagia. DDAVP is given intranasally, parenterally, or by subcutaneous injection. It is important that the blood of vWD patients is typed and screened for antibodies prior to instituting DDAVP, because DDAVP may induce thrombocytopenia in certain subgroups. NSAIDs are ineffective and may increase blood loss.

Polycystic Ovary Syndrome

Polycystic ovary syndrome, one of the most common endocrine disorders, is the association of hyperandrogenism and anovulation without underlying disease of the adrenal or pituitary glands. A triad of obesity, hirsutism, and oligomenorrhea is classically described, although obesity is not universally seen. When menses occurs, it is heavy and prolonged.¹² The syndrome is further characterized by acne, androgen-dependent alopecia, elevated serum concentrations of androgens, and hypersecretion of LH with a normal or low FSH level. Typical ovarian morphology, which may be seen by ultrasonography, is not necessary for the diagnosis and may in fact represent a response of the ovary to chronic anovulation. The differential diagnosis includes hyperprolactinemia, acromegaly, congenital adrenal hyperplasia, and androgen-secreting tumors of the ovary or adrenal gland. Management of menorrhagia in women who do not desire fertility includes low-dose oral contraceptives or cyclic progestin administration.

Other Conditions

Periods of physical or psychological stress, illness, malnutrition, rapid weight gain or loss, and intense physical regimens affect the hypothalamus and disrupt the normal pattern of gonadotropin release. This usually causes amenorrhea but may result in irregular, heavy bleeding. In obese women, menorrhagia may be a result of increased circulating levels of estrogen from peripheral conversion of androstenedione to estrone in fatty tissue. Patients with liver and renal disease may also develop irregular bleeding.

SPECIAL CONSIDERATIONS

The Legalities of Treating Adolescents Without Parental Consent

Consent is not required to evaluate and initiate treatment in an emergency. State consent statutes and case law vary; so emergency physicians should know and follow their state law and hospital policy with respect to consent. There should be a mechanism in place to obtain consent from the courts when necessary. Figure 101-2 summarizes the American College of Emergency Physicians policy on consent. All states allow minors to consent to diagnosis and treatment of STDs and drug abuse without parental consent. Many states have similar statutes allowing minors independent direct access to prenatal care, termination of pregnancy, and medical care for crime-related injuries. Special considerations are included in some state legislation for emancipated and mature minors. Common sense and appropriate documentation should prevail above all with respect to issues of consent. An a priori awareness of the statutes and policies and established liaisons with local child protection services and the courts should assist emergency physicians in the ongoing provision of timely emergency care.

HIV-Infected Women

In general, there is no need to change the approach to vaginal bleeding in HIV-positive women. Physicians must look for associated infections and complications of chronic illness. The rate of vaginal and pelvic infections and cervical dysplasia is high in this cohort of patients. In a cross-sectional survey of 386 women younger than age 50

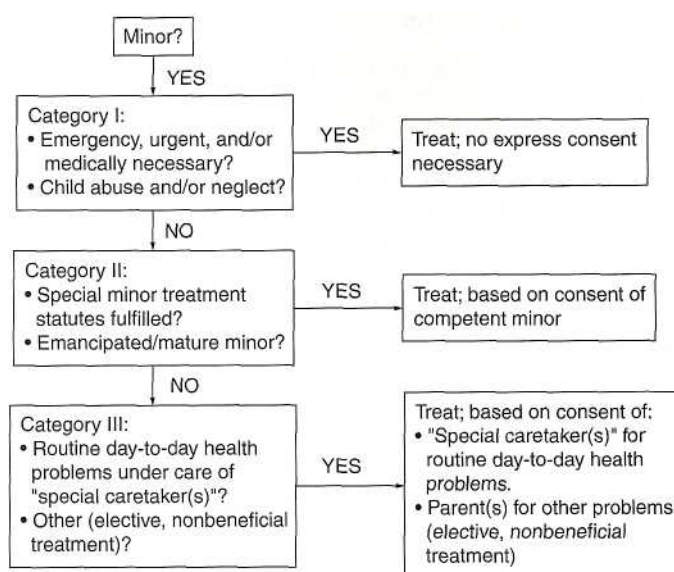

FIG. 101-2. Initial approach to consent for treatment. (Reproduced with permission from Tsai AK, Schafermeyer EW, Kalifon D, et al: Evaluation and treatment of minors: Reference on consent. *Ann Emerg Med* 22:1212, 1993.)

years, with and without HIV, neither infection nor immunosuppression affected menstruation or the rate of abnormal vaginal bleeding.¹³ This was also seen in a study of 85 seropositive women, although the power of the study was low.¹⁴

cramping, poorly localized pain. Pain is typically midline and difficult for the patient to describe. Visceral pain is common in early appendicitis, bowel obstruction, renal colic, and early pelvic inflammatory disease (PID).

Somatic pain fibers are found in the skin, abdominal wall and musculature, and in the parietal peritoneum. Inflammation or irritation in these areas can be from direct injury or bacterial or chemical contact. The resulting pain is typically well localized, sharp, and constant. Tenderness is elicited at the area of peritoneal inflammation. Somatic pain is seen as appendicitis and PID progress. Contamination of the peritoneal cavity by blood, urine, pus, and cystic or gastric fluid also results in somatic pain, which can be diffuse in nature.

Referred pain describes pain that originates in one organ but is described by the patient as located in a distant area. Visceral nerve fibers that innervate the diseased organ enter the spinal cord at the same level as somatic nerve fibers that innervate the areas of referred pain. As somatic pain is better localized than visceral pain, the patient may emphasize the area of referred pain. Typical examples are inner thigh pain seen with appendicitis or PID, or groin and labial pain with renal colic. Table 102-1 lists the nerves that innervate the lower abdominal and pelvic organs.

Females of any age can present with pelvic pain and associated symptoms. The differential diagnosis changes dramatically with the onset of both puberty and sexual activity.

CLINICAL FEATURES

History

A standard history regarding the pain characteristics (location, migration, radiation, quality, onset, severity, and exacerbating and relieving factors) and associated symptoms should be followed by a complete gynecologic, obstetric, and sexual history. The examiner must keep in mind that a negative history for pregnancy is unreliable.¹ In one study, about 7 percent of patients who stated that their last menstrual period was entirely normal and who denied any chance of pregnancy were

TABLE 102-1 Nerves Carrying Pain Impulses from the Pelvic Organs

Organ	Spinal	
	Segments	Nerves
Perineum, vulva, lower vagina	S2-S4	Pudendal, inguinal, genitofemoral, posterofemoral, cutaneous
Upper vagina, cervix, lower uterine segment, posterior urethra, bladder trigone, uterosacral and cardinal ligaments, rectosigmoid, lower ureters	S2-S4	Sacral afferents traveling through the pelvic plexus
Uterine fundus, proximal fallopian tubes, broad ligaments, upper bladder, cecum, appendix, terminal large bowel	T11-T12, LI	Thoracolumbar splanchnic nerves through uterine and hypogastric plexus
Outer two-thirds of fallopian tubes, upper ureter	T9-T10	Thoracolumbar splanchnic nerves through mesenteric plexus
Ovaries	T9-T10	Thoracolumbar splanchnic nerves traveling with ovarian vessels via renal and aortic plexus and celiac and mesenteric ganglia

102 ABDOMINAL AND PELVIC PAIN IN THE NONPREGNANT PATIENT **Reb**

Close

This chapter provides an overview of the approach to a nonpregnant female who presents to the ED with abdominal and/or pelvic pain. Pregnancy-associated abdominal and pelvic complaints are discussed in Chap. 106. The reader is directed to Chap. 72 as well as standard references for more specific discussion on gastrointestinal disorders causing abdominal pain in both men and women. The clinical presentation, ED evaluation, and workup are integral in determining which patients need admission, which require surgery, and which can be safely discharged home.¹

PHYSIOLOGY

Understanding the types and etiology of pain helps the examiner use information obtained through the history and physical examination to narrow the differential diagnosis.

Visceral pain results when obstruction of a hollow organ causes stretch of the smooth muscle wall. Stretch and associated inflammation or ischemia stimulate autonomic nerve fibers resulting in diffuse,

indeed pregnant.² Past medical history [sexually transmitted diseases (STDs), gallstones, kidney stones], surgical history, history of trauma, and history of similar episodes are important and often narrow the differential diagnosis. Specific risk factors for PID (late adolescence, multiple sex partners, frequent douching, recent IUD insertion, prior history, and cigarette smoking) should be ascertained.³ Recent and current medications and allergies should be documented. Family history of breast or ovarian neoplasms should be identified, as patients with such a family history may have unspoken anxieties about these disorders that can bias or confound the evaluation of acute abdominal pain. Screening for domestic violence or sexual assault should also be part of the history taking.

Pain Characteristics

The location of pain coupled with a description of its migration and radiation patterns helps to make a diagnosis. Pain moving from the epigastrium or umbilicus to the right lower quadrant suggests appendicitis. Pain originating in the flank that radiates to the lower abdomen or groin suggests renal colic or pyelonephritis.

Questions about the quality of the pain can be helpful. True colicky pain is of a visceral origin and is associated with stretch of hollow organs. Bowel obstruction, biliary colic, renal colic, and fallopian tube obstruction due to ectopic pregnancy or ovarian torsion are examples. Renal colic represents an atypical presentation of colicky pain in that one wave of pain has typically not resolved before the next wave begins. This pattern of atypical colicky pain may also be seen with obstruction of other hollow organs. Sharp, well-localized pain indicates peritoneal inflammation and can be a late finding seen with appendicitis and PID.

The severity and onset of pain can guide the differential diagnosis. Pain that awakens a patient from sleep is generally associated with acute obstruction, ischemia, inflammation, or perforation of an organ. This can be seen with ovarian torsion or fallopian tube rupture. Severe, sudden-onset pain may be associated with life-threatening pathology, for example with organ rupture, but there are instances in which severe pain may have a typically benign etiology, as seen with nephrolithiasis.

Factors that exacerbate and relieve pain can provide information about the etiology. Pain with movement or pain elicited by tapping the heel suggests peritonitis. Pain that changes with eating, vomiting, or belching suggests gastrointestinal etiology.

Associated gastrointestinal symptoms such as nausea, vomiting, anorexia, diarrhea, or constipation are often nonspecific, as they can coexist with genitourinary and gynecologic disorders as well. Absence of anorexia is unusual in gastrointestinal disorders. Genitourinary symptoms such as dysuria, frequency, urgency, and hematuria suggest urinary tract infection or renal stone. However, dysuria and lower abdominal pain radiating to the groin can also be present with gynecologic disorders and gastrointestinal pathology such as appendicitis. Vaginal discharge, irregular bleeding, and dyspareunia are more common with gynecologic disorders, but can also be seen with other pathology.

Adolescents should always be interviewed without the parent present. This can be accomplished by asking the parent to leave the room for the physical examination. As accuracy of the history is paramount to diagnosis and treatment, it is very important to approach history regarding sexual activity, STDs, and pregnancy in a nonjudgmental manner while reassuring the patient regarding confidentiality.

Physical Examination

Obtaining vital signs and assessment of volume status, including orthostatic signs to detect hypovolemia, is the first step in examination. A patient may have normal vital signs early in the course of very serious disease, and the presence or absence of fever has never been shown to aid in the delineation of medical versus surgical pathology.¹

The patient's general appearance and position of comfort should be noted. A patient with peritoneal irritation tends to lie perfectly still as movement exacerbates the pain. The knees may be drawn toward the abdomen in an attempt to reduce intraabdominal pressure.

Examination of the abdomen and pelvis should concentrate on quality and frequency of bowel sounds, presence of peritoneal findings (involuntary guarding, rebound tenderness), point of maximal pain, and masses. Absence of rebound tenderness should not be used as evidence that the patient is free of a medical or surgical emergency. Early torsion and PID are both diagnoses in which rebound tenderness is unlikely, but in which early surgical or medical treatment is critical to preserve fertility.¹

Rectal Examination

Perirectal abscesses and fistulae are often seen with inflammatory bowel disease. Stool that is grossly bloody, melanotic, or positive for occult blood strongly suggests gastrointestinal pathology. Tenderness in the right lower quadrant elicited by rectal examination can be seen in appendicitis, PID, and ectopic pregnancy, but the overall sensitivity of the rectal examination for diagnosing pathology is low.^{1,4}

Pelvic Examination

All physicians should always have a chaperone present for the gynecologic examination. An assistant also facilitates obtaining specimens. A speculum examination should be performed in nonvirginal patients complaining of pelvic pain, bleeding, or vaginal discharge. The external genitalia, vagina, and cervix should be inspected for discharge, inflammation, lacerations, ulcers, and tumors. A wet mount and cultures for gonorrhea and *Chlamydia* are generally obtained during the speculum examination, especially if there is mucopurulent discharge or other evidence of inflammation.

RELIABILITY AND VALIDITY OF PELVIC EXAMINATION Despite the common performance of the pelvic examination and the historical use of the results for making clinical decisions, few studies have addressed its reliability and validity. Bimanual pelvic examinations performed by experienced emergency physicians in the ED have been found to have poor interobserver agreement for the evaluation of uterine size, uterine tenderness, adnexal tenderness or masses, and cervical motion tenderness.⁵ Padilla and associates found bimanual examinations performed under general anesthesia by medical students, gynecology residents, and attending gynecologists to be inaccurate for detecting adnexal masses that were confirmed surgically. They also found no statistically significant difference in accuracy between the medical students, residents, and attending physicians.⁶ Several studies that have compared bimanual pelvic examination to pelvic ultrasonography and laparoscopy have shown accuracy of pelvic examination to be poor, especially when the results are thought to be "normal."^{7,8} Many texts and articles cite pelvic examination findings that confirm disease states (for example, cervical motion tenderness confirming a diagnosis of PID). Since the reliability of this examination is poor, then its positive or negative findings should not be the sole criterion for diagnosis.⁵ Findings on pelvic examination appear related to examiner experience, patient cooperation, patient body habitus, prior abdominal surgery, and the limitations of the examination itself. Furthermore, criteria have not been standardized for the production of, or scoring of, cervical motion or adnexal tenderness. In addition, infection or inflammation of the peritoneum, urologic, pelvic, or gastrointestinal organs can cause pelvic tenderness.

Therefore, given the current uncertainty about the validity and reliability of the pelvic examination, further diagnostic testing is generally necessary for more precision in diagnosis. There are no validated clinical decision pathways for acute abdominal pain in women, and clinical decisions depend upon results from history and physical ex-

amination, as well as age and risk factors for specific disease processes. Burstin and colleagues published consensus guidelines for the evaluation of abdominal pain, but these are one-step guidelines based on clinical context and have not been validated.⁹

DIAGNOSIS

Abdominal and pelvic pain in women can be of gastrointestinal, genitourinary, or gynecologic etiologies. Gastrointestinal, genitourinary, pregnancy-associated pain, and pain associated with vaginal bleeding are covered in Chaps. 72, 96, 106, and 101, respectively. Table 102-2 lists some common causes of abdominal and pelvic pain. Specific

etiologies are discussed later in this chapter. The differential can be narrowed by aspects of the history and physical examination, and by using some ancillary tests and diagnostic imaging.

Laboratory Evaluation

URINE AND SERUM PREGNANCY TESTS A quantitative urine enzyme-linked immunosorbent assay (ELISA) pregnancy test will detect beta-human chorionic gonadotropin (p-hCG) at levels greater than 20 mIU/mL^{1,10} and will detect urine p-hCG at about day 21 of the menstrual cycle.¹⁰ If point-of-care testing is done in the ED,

TABLE 102-2 Differential Diagnoses of Nontraumatic Pelvic Pain in Nonpregnant Adolescents and Adults

	History	Physical Examination	Ancillary Studies	Special Procedures
Ovarian cysts (rupture, hemorrhage, torsion, infection)*	Sudden-onset unilateral pelvic pain; can be preceded by activity or trauma	Tenderness to palpation; peritoneal signs if rupture	Pregnancy test; hematocrit if suspected rupture with blood loss; urinalysis; pelvic ultrasound	Laparoscopy
Adnexal torsion*	Possible history of adnexal cyst or tumor; sudden-onset unilateral pelvic pain; can be preceded by activity or trauma	Tenderness to palpation; peritoneal signs if rupture	Pregnancy test; hematocrit if suspected rupture with blood loss; urinalysis; ultrasound with Doppler flow	Laparoscopy
Pelvic inflammatory disease*	Lower abdominal or pelvic pain, dull, often bilateral; vaginal bleeding or discharge; urinary symptoms; fever	Fever; tenderness on abdominal and pelvic examinations; cervical motion tenderness; mucopurulent cervical discharge	Pregnancy test; WBC of limited value; cervical cultures for gonorrhea, <i>Chlamydia</i> , wet mount; ultrasound to rule out TOA	
Endometriosis	Dysmenorrhea; chronic pelvic pain; onset typically in third or fourth decades	Normal or may reveal pelvic tenderness or ovarian tenderness or enlargement	Pregnancy test; hematocrit with menometrorrhagia and suspected significant blood loss; urinalysis; ultrasound	Laparoscopy
Adenomyosis	Dysmenorrhea; menorrhagia; onset typically in third or fourth decades	Symmetrically enlarged uterus or fibroid-like mass	Pregnancy test; hematocrit with menometrorrhagia and suspected significant blood loss; ultrasound	Laparoscopy
Leiomyomas	Pelvic pain or pelvic mass	Pelvic or abdominal tenderness; pelvic or abdominal mass	Pregnancy test; ultrasound	
Tuboovarian abscess*	Fever; unilateral lower abdominal or pelvic pain; vaginal bleeding or discharge	Fever; lower abdominal or adnexal tenderness or fullness; possible CMT	Pregnancy test; WBC of limited value; cervical cultures for gonorrhea, <i>Chlamydia</i> , and wet mount; ultrasound	Laparoscopy
Appendicitis*	Periumbilical abdominal pain that migrates to right lower quadrant; fever, anorexia, nausea, vomiting	Right lower quadrant tenderness with possible rebound and guarding; fever; Rovsing sign; psoas and obturator signs	Pregnancy test; CT scan; ultrasound in select patients	Laparoscopy
Diverticulitis*	Left lower quadrant abdominal pain; history of constipation; nausea, vomiting, fever	Tenderness in the left lower quadrant with possible rebound and guarding; peritonitis and sepsis if perforated	CT of the abdomen and pelvis with IV and PO contrast; abdominal series if suspected perforation	
Incarcerated hernia*	Abdominal, pelvic, or inguinal pain; mass; abdominal distention and vomiting; symptoms of bowel obstruction	Distention; palpable mass that is unable to be reduced	X-rays to evaluate obstruction; ultrasound may be used to evaluate the mass; CT of abdomen and pelvis	

*Diagnoses that must be considered as part of ED evaluation.

tPressure applied to left lower quadrant elicits right lower quadrant pain.

Abbreviations: CMT = cervical motion tenderness; TOA = tubo-ovarian abscess; WBC = white blood cell count.

timing must be exact, or false-negative results can occur. A screening urine pregnancy test should be performed on all women of childbearing age with abdominal and pelvic pain, because a positive result will change the differential diagnosis and management options (e.g., medications and radiologic procedures).

COMPLETE BLOOD COUNT An elevated white blood cell (WBC) count is neither sensitive nor specific for the diagnosis of an acute surgical condition. Sellors and colleagues found no difference in WBC count in patients with or without inflammatory disease diagnosed by endometrial biopsy and/or laparoscopy.¹¹ In the patient with vaginal bleeding, the hematocrit may not accurately reflect acute blood loss, although serial determinations of the hematocrit can be of value.

URINALYSIS Positive findings have variable sensitivity and are not specific for urinary pathology. Urinalysis may be falsely positive with hematuria or evidence of infection in patients with appendicitis, likely due to periappendiceal inflammation. Positive urinalysis can similarly be seen with gynecologic infections. The sensitivity of urinalysis for hematuria varies, depending on the pathology and on the definition of positive results [≥ 1 RBC per high-power field (RBC/hpf) vs. ≥ 5 RBC/hpf considered positive]. Sensitivity of hematuria is only about 84 percent in patients suspected of renal colic with CT-proven nephrolithiasis.¹² Also, hematuria (defined as 1 RBC/hpf on microscopic urinalysis) may be present in over 50 percent of patients presenting with flank pain, but without nephrolithiasis as documented on CT.¹³

Depending on the cutoff for diagnosis of urinary tract infection (UTI) (nitrite-positive, leukocyte esterase-positive, and/or positive microscopic evaluation for bacteria and WBC), the sensitivity of urine reagent strip results varies.¹⁴ In a study by Lammers and associates, if urine reagent strip results are defined as positive when leukocyte esterase or nitrite is positive or blood is more than trace, the overtreatment rate was 47 percent and the undertreatment rate was 13 percent, when compared to the results of urine culture. When the results were considered positive, WBCs ≥ 3 per high-power field or RBCs ≥ 5 per high-power field, the overtreatment rate was 44 percent and the undertreatment rate was 11 percent.¹⁴ Also, since infection is a risk factor for nephrolithiasis, both conditions may coexist.¹ Urine culture and sensitivities should therefore be obtained to confirm the diagnosis when there is a moderate to high pretest probability of UTI (see Chap. 94).

TESTING FOR GONORRHEA AND CHLAMYDIA Positive STD test results have public health implications and increase patient risk for future infertility and ectopic pregnancy. Many studies have shown a very high rate of asymptomatic infection in ED patients, especially teenagers and young adults.¹⁵ Newer modalities of testing include first-catch urine (not practical in the ED, as many patients void the first daily urine before entering the ED), random urine, and patient-obtained vaginal swabs. Each of these has been shown to have high accuracy when compared to the gold standard of culture and are better tolerated by the asymptomatic patient, including the young.^{16,20} Individual laboratory capabilities vary by institution.

Radiologic Evaluation

Pelvic ultrasonography with Doppler flow analysis can be utilized in the evaluation of a patient with lower abdominal pain in whom PID, torsion, tuboovarian abscess (TOA), leiomyoma, and ovarian cysts are all possible diagnoses.^{1,21} Whether the study is done in the ED or as an outpatient depends on the patient's clinical status and availability of outpatient procedures. Ultrasonography has been shown to have high sensitivity and specificity for evaluation of surgically confirmed pelvic masses and is routinely the test of choice for evaluating suspected pelvic and gynecologic pathology.^{1,7-22,23} Comparison with CT for accuracy in the evaluation of pelvic organs has not yet been performed. MRI and CT are available for evaluation of abdominal and pelvic complaints, and CT has recently been evaluated for differ-

entiating appendicitis and acute gynecologic conditions, with sensitivity of 100 percent and 87 percent, and specificities of 97 percent and 100 percent for appendicitis and acute gynecologic conditions,

elv²⁴

respectively.

Diagnostic Laparoscopy

Laparoscopy is the gold standard for diagnosing PID and has been shown to aid in the diagnosis and surgical treatment if necessary for ovarian torsion, TOA, and adnexal masses.^{3,25}

TREATMENT

The approach to the nonpregnant patient with pelvic pain is to determine if true emergent conditions exist that require immediate management. Once pregnancy and its associated complications have been excluded, the remaining emergent conditions include infection, torsion, and nongynecologic surgical etiologies. Rarely, a ruptured functional cyst may result in hemodynamic compromise and severe pain. Clinical suspicion, laboratory analysis, ultrasonography, and CT can all be used to determine if a condition requiring emergent management exists.

Pain management is one of the most important cornerstones in patient care. Treating pain is humane, safe, and aids in patient evaluation. Patients with surgical conditions are easier to evaluate when their pain is at least partially controlled, and short-acting parenteral narcotic analgesics can be used to decrease pain and anxiety and to facilitate abdominal examination.^{1,26} Consensus should be reached between emergency services and gynecologic and surgical consultants regarding the necessity of acute pain management.

For patients who are unlikely to have surgical conditions, many other analgesics may be used in the treatment of pain. Nonsteroidal anti-inflammatory drugs (NSAIDs) are typically very helpful with visceral pain and pain associated with inflammation, but should be avoided in the elderly, the diabetic, those with renal dysfunction, and those taking angiotensin-converting enzyme (ACE) inhibitors.

Repeat Evaluation

Very often the etiology of abdominal and pelvic pain will not be clear on initial evaluation. Progression or resolution of pathology can dramatically change the examination findings. Serial examinations over 6 to 12 h can be instrumental in the ultimate diagnosis of abdominal pain.

Disposition

Patients with a diagnosis that requires surgical or medical intervention obviously need admission. Patients with severe pain unable to be controlled with oral medications must be admitted for pain control and further diagnostic evaluation. Patients with persistent volume depletion or vomiting unresponsive to the administration of antiemetics and fluids must also be admitted. With thorough history, physical examination, and laboratory and radiologic evaluation, along with a period of observation, a diagnosis can usually be established for most women with acute pelvic pain. In some, the cause of pain will not be established, and in others the initial diagnosis may be incorrect. For this reason, patients not being admitted to the hospital must have follow-up arranged in 12 to 24 h, and the discharge instructions should include clear signs or symptoms that require immediate return to the emergency department.

SPECIFIC DIAGNOSES IN NONPREGNANT ADOLESCENTS AND ADULTS

Functional Ovarian Cysts

Rupture, hemorrhage, torsion, or infection of an ovarian cyst results in the typical presentation of sudden unilateral pelvic pain. Pain may be preceded by exercise, intercourse, or trauma. Tenderness may be

elicited on the side of the cyst, and peritoneal signs may be present if the cyst has ruptured or is causing peritoneal inflammation. Hemorrhage may be significant. A patient may or may not give a history of past ovarian cysts. Ultrasonography aids in the diagnosis and helps quantitate blood loss in the acutely ill patient. As patients with cyst pain may present very similarly to patients with an ectopic pregnancy, rapid determination of pregnancy status is critical. Ovarian cysts that are less than 8 cm, unilocular, and unilateral are generally observed. The natural history of functional cysts is generally spontaneous resolution within two cycles, with or without hormone administration. Multiloculated, solid, or large cysts (>5 cm) should be considered ovarian endometriomas, dermoid cysts, or potentially neoplastic until proven otherwise.^{22,27} Because of the lack of sensitivity and specificity of the pelvic examination, women with acute abdominal pain and a negative pregnancy test should have ultrasonography to confirm the diagnosis of a functional ovarian cyst. Whether this is accomplished in the ED or during outpatient gynecology follow-up depends upon a number of factors, including the degree of patient discomfort, the physician's comfort with the diagnostic pretest probability of a functional cyst, and the emergency availability of high-quality pelvic ultrasonography.

Adnexal Torsion

Adnexal torsion is a surgical emergency, both for relief of pain and to preserve ovarian function. Ischemia results from twisting of the vascular pedicle. Patients can either present with sudden onset of severe, unilateral pelvic pain or present with dull, aching pain with acute and sharp exacerbations if the torsion is intermittent. Patients with ovarian masses (cysts or tumors) are at increased risk for torsion, as are patients with pelvic adhesions. The onset of pain may occur after trauma, intercourse, or exercise. Tenderness may be elicited on the side of the twisted adnexa with rebound and guarding. Ultrasound with Doppler flow evaluation is used for diagnosis. Early gynecologic consultation and preparation for surgery are important for adnexal salvage. In a 15-year retrospective chart review of ovarian torsion, only 25 percent of patients had a history of an ovarian cyst, pain characteristics were variable, and objective findings on pelvic examination were uncommon.² These features confirm the difficulty in making the diagnosis.

Pelvic Inflammatory Disease

PID is discussed in detail in Chap. 109.

Endometriosis

The true incidence of endometriosis is unknown, but it is estimated that 15 percent of females have some degree of the disease. It is second only to dysmenorrhea as the etiology for cyclic pain in females of reproductive age. Patients typically present in the third decade with pelvic pain related to menses. Endometrial glands and stroma are typically located on the ovaries and pelvic peritoneum, but may be located in sites distant to the pelvis. As the disease progresses and forms pelvic adhesions, a chronic, constant pain syndrome may develop. There are many theories for the development of endometriosis. The most accepted at this point is retrograde menstruation with seeding of endometrial glands to distant sites. Other theories include lymphatic and hematogenous spread.

Primary diagnosis is rarely if ever established during an ED visit. Physical examination may be completely normal or demonstrate pelvic tenderness, ovarian tenderness, or enlargement, but typically does not narrow the differential diagnosis. Ultrasound may reveal endometriomas (endometriosis within the ovarian capsule, also known as chocolate cysts), but is not diagnostic. Diagnosis is confirmed by direct visualization during laparoscopy. Various hormonal therapies may be initiated, with relief of pain for certain patients. Pregnancy can lead to remission and sometimes cure.

Adenomyosis

Adenomyosis occurs when the endometrial glands and stroma extend into the uterine musculature. An adenomyoma occurs when the adenomyosis is confined to one portion of the myometrium. Patients typically present in the third and fourth decades, with secondary dysmenorrhea and menorrhagia. Physical examination may reveal a symmetrically enlarged uterus or a fibroid-like mass. Diagnosis often requires endometrial biopsy to rule out endometrial cancer as an etiology for menorrhagia. No specific ED intervention is required if this diagnosis is established. Initial treatment includes simple analgesics and hormonal therapies, and hysterectomy may be ultimately necessary in refractory cases.

Leiomyomas

Uterine leiomyomas (fibroids) are the most common pelvic tumor and the most common indication for major surgery in women. Fibroids become more common by the age of 40, and there is both an increased incidence and increased rate of growth in black women. The etiology is unclear, but current theories include proliferation of smooth muscle or connective tissue cells. The cells are estrogen-dependent and generally enlarge during pregnancy, potentially causing serious pregnancy-related complications. They are rarely seen before menarche, and typically do not develop or enlarge after menopause unless stimulated by exogenous estrogen. There is an increased frequency of endometrial cancer in patients with leiomyomas.

Leiomyomas may be subserosal, intramural, or submucosal. Both subserosal and submucosal leiomyomas may be pedunculated. Although they appear discrete in outline, there is no cellular capsule. Very few blood vessels are able to traverse the fibrous "pseudocapsule," making degeneration a common etiology of pain associated with leiomyomas, specifically with the rapid growth that occurs during pregnancy. Severe, acute pain may be experienced with degeneration or with torsion of a pedunculated fibroid.

Patients with leiomyomas are typically asymptomatic, but may present with acute pain, insidious onset of pelvic pain, or with an abdominal mass. Physical examination often reveals pelvic or abdominal masses. With acute degeneration, the patient may have severe localized tenderness, rebound tenderness, guarding, and fever. Ultrasound is used to delineate the leiomyomas and helps exclude other etiologies for pain. No specific ED intervention is required if this diagnosis is established. Treatment involves analgesia and occasionally hormonal therapies. Myomectomy and hysterectomy are indicated in those whose symptoms are refractory to conservative management.

2 percent) in 1992, the last year for official reporting in the United States.¹ Reported pregnancies include live births, legally induced abortions, and ectopic pregnancies. An overestimation of the incidence of EP is possible, since the denominator, reported pregnancies, could be biased by lack of reporting of illegally terminated pregnancies or undetected spontaneous abortions. Some possible reasons postulated for the increased incidence of EP include the increased incidence of sexually transmitted tubal infections, unsuccessful tubal sterilizations, assisted reproductive techniques, previous pelvic surgery, and more sensitive and earlier diagnostic techniques.

The case-fatality rate per 10,000 ectopic pregnancies decreased from 35.5 in 1970 to 8.8 in 1980 to 3.8 in 1989. This trend was observed in both white and nonwhite women. However, nonwhite women overall had a 3.4 times greater risk of death than white women. Teenagers were the age group with the highest mortality rate. The observed decreased mortality is attributed largely to improved diagnostics and also a heightened awareness among medical personnel. However, EP remains the leading cause of maternal death in the first trimester of pregnancy and is the second leading cause of maternal mortality overall.¹

PATHOPHYSIOLOGY

Fertilization of the oocyte usually occurs in the ampullary segment of the fallopian tube. In normal pregnancy, after fertilization, the zygote passes along the fallopian tube and implants into the endometrium of the uterus. An EP occurs when the zygote implants in any location other than the uterus. The vast majority of ectopic pregnancies occur in the fallopian tube. Extratubal sites include the abdominal cavity, cervix, and ovary. Abdominal ectopic pregnancies most commonly derive from early rupture or abortion of a tubal pregnancy, with subsequent reimplantation in the peritoneal cavity.

A normal placenta is uncommon in ectopic pregnancies, possibly accounting for the much higher incidence of a blighted ovum in EP. Tubal abortion occurs when the vascular supply to the placenta is disrupted, with bleeding into the fallopian tube and hematoma formation. Intermittent distention of the fallopian tube with blood can occur with leakage of blood from the fimbriated end of the fallopian tube into the peritoneal cavity. The aborting EP and associated hematoma can be completely or partially extruded out of the end of the fallopian tube or through a rupture site in the tubal wall. Tubal rupture is usually spontaneous; however, in anecdotal accounts, precipitating factors include trauma associated with coitus or a bimanual examination.

Meta-analysis of risk factors for ectopic pregnancy indicates that conditions causing damage to the fallopian tube pose the highest risk for subsequent EP.² Major risk factors are shown in Table 103-1. When pregnancy occurs in a patient with prior tubal surgery for sterilization it should be assumed to be an EP until proven otherwise.

CLINICAL FEATURES

History

The classic triad of symptoms in EP is abdominal pain with vaginal bleeding or spotting in a woman with amenorrhea. The positive predictive value of this triad is low, as it is more commonly seen in threatened

ECTOPIC PREGNANCY

Richard S. Krause David
M. Janicke

Ectopic pregnancy (EP) occurs when a conceptus is implanted outside of the uterine cavity. EP is the leading cause of first-trimester pregnancy-related maternal death in the United States. Today, earlier diagnosis and hence decreased morbidity and mortality have been made possible by transvaginal sonography and improved sensitivity of serum pregnancy markers. As a result more patients may be eligible for conservative medical and surgical therapies.

EPIDEMIOLOGY

The incidence of EP increased from 4.5 per 1000 reported pregnancies (0.45 percent) in 1970 to 19.7 per 1000 reported pregnancies (nearly

or spontaneous abortion than in EP, and may occur due to other causes in nonpregnant women. Many other presentations occur, and range from sudden abdominal pain with life-threatening hypovolemic shock to an asymptomatic EP discovered incidentally on ultrasound exam. To achieve the goal of early diagnosis in as many cases as possible, **EP should be considered in all women of childbearing age who present with abdominal or pelvic complaints or with unexplained signs or symptoms of hypovolemia.**

Identified risk factors for EP are often absent (see Table 103-1), and are useful only for raising clinical suspicion.

Abdominal pain or discomfort is the most common symptom of EP, and is reported in 90 percent of EP patients.³ Pain is due to tubal distention or rupture. The classic pain of rupture is lateralized, sudden, sharp, and severe. However, shoulder pain secondary to diaphragmatic irritation from a ruptured EP can also occur. Any lateral or bilateral abdominal discomfort or tenderness in a woman of childbearing age requires consideration of EP.

The menstrual history is often, but not always, abnormal. The classic sign is amenorrhea from 4 to 12 weeks after the last normal period, reported in 70 percent of EP cases.³ No missed menses are reported in 15 percent of EP cases.³ Vaginal bleeding is reported in 50 to 80 percent of EP.³ While bleeding is often scant, heavy bleeding does not exclude an EP. The differential diagnosis of vaginal bleeding in early pregnancy includes EP; threatened, inevitable, missed, or incomplete abortion; implantation bleeding; cervicitis; cervical conditions such as polyp or ectropion; bleeding from the urinary or gastrointestinal tracts; or cervical carcinoma.

Typical early pregnancy symptoms may occur and may not differ from symptoms of previous normal intrauterine pregnancies.³

Physical Examination

The physical examination in EP is highly variable and EP is difficult to diagnose or exclude based upon physical examination. In cases of ruptured EP, patients may present in shock, with peritoneal signs and an adnexal mass and tenderness. Relative bradycardia may occur as a consequence of vagal stimulation. There is poor correlation between the volume of hemoperitoneum and vital signs in ruptured EP.⁴ In cases of rupture without hemodynamically significant bleeding, less prominent peritonitis without significant alteration of vital signs is expected. Fever is rare.

In the more common situation of an unruptured EP, the vital signs are likely to be normal. If an adnexal mass or fullness with tenderness is detected, it may be due to EP or to a corpus luteum cyst. Cervical motion tenderness may be seen and blood is often present in the vaginal vault. The cervix may have a blue coloration, as in a normal pregnancy. Uterine size for estimated gestational age, is most often normal. Pelvic examination may be completely normal in cases of ectopic pregnancy. Patients with unruptured EP compared to those with normal intrauterine pregnancies are expected to have similar clinical characteristics. A study which attempted to develop a clinical prediction model for EP reported that only the rare findings of Doppler fetal heart tones or tissue extruding from the cervical os were reliable signs for excluding EP.⁵

DIAGNOSIS

The differential diagnosis for women of childbearing potential who present with abdominal or pelvic symptoms or abnormal vaginal bleeding is broad (Table 103-2). However, once pregnancy is established, the differential narrows and no combination of signs or symptoms has sufficient negative predictive value to rule out ectopic pregnancy. Pregnancy testing is therefore mandatory. If pregnancy is detected, EP remains in the differential diagnosis until it can be either confirmed or excluded with conviction.

TABLE 103-2 Differential Diagnosis of Ectopic Pregnancy

All Patients (Pregnancy Not Established)	Pregnant Patients
Appendicitis	Normal (intrauterine pregnancy)
Inflammatory bowel disease	Threatened abortion
Ovarian pathology Cyst Torsion	Inevitable abortion
Pelvic inflammatory disease	Molar pregnancy
Endometriosis	Heterotopic pregnancy*
Sexual assault/trauma	Implantation bleeding
Urinary tract infection	Corpus luteum cyst
Ureteral colic	

*Heterotopic pregnancy = combined IUP and EP.

Pregnancy Testing

The diagnosis of pregnancy is central to the diagnosis of possible EP. Pregnancy tests currently in use rely on the detection of the (3 subunit of human chorionic gonadotropin ((3hCG) in the urine or serum. Human chorionic gonadotropin (hCG) is a hormone produced by the trophoblast. Intact hCG consists of the α and (3 subunits. Tests based on detection of the intact molecule or the α subunit can cross-react on immunologic assays with hormones found in the nonpregnant individual and are thus less specific than tests for the phCG subunit.

Human chorionic gonadotropin preparations are currently standardized in relation to the International Reference Preparation (IRP). Other standard preparations are not equivalent. A preparation often referred to in earlier literature is the Second International Standard (Second IS). The IRP is roughly equal to 1.7 times the Second IS. To avoid confusion when interpreting the literature, attention must be paid to the standard used. In this chapter, hCG and (3hCG concentrations are in reference to the IRP unless otherwise noted.

Very early in either an intrauterine pregnancy (IUP) or an EP, detectable amounts of (3hCG are released into the serum and filtered into the urine. The concentration of (3hCG is fairly closely correlated in the urine and serum, with urinary concentration also depending upon urine specific gravity. Qualitative urine and serum tests for pregnancy usually use the enzyme-linked immunosorbent assay (ELISA) methodology. In the laboratory setting, ELISA tests can detect (3hCG at concentrations below 1 mIU/mL.

Qualitative tests in clinical use are typically reported as "positive" when the phCG concentration is ≥ 20 mIU/mL in urine and ≥ 10 mIU/mL in serum. A positive qualitative test therefore implies that PhCG is present in at least this concentration. At this level of detection, the false-negative rate for detection of pregnancy will not be more than 1 percent for urine and 0.5 percent or less for serum. In clinical use, the performance of urine qualitative testing has been found to be from 95 to 100 percent sensitive and specific as compared with serum tests.

Urine tests can be performed rapidly at the bedside, and kits from some manufacturers may be used for either urine or serum. A bedside test for urine is therefore the best first test for pregnancy when EP is suspected. **Dilute urine may cause a false-negative urine pregnancy test**, particularly early in pregnancy when (3hCG levels are low (<50 mIU/mL).

When a bedside urine test is negative and EP is still being considered, a quantitative serum test should be performed. The sensitivity of quantitative serum testing for the diagnosis of pregnancy is virtually 100 percent when an assay capable of detecting ≥ 5 mIU/mL of phCG is used.⁶

Laboratory Tests and Ectopic Pregnancy

The definitive diagnosis of EP is made either by ultrasound (US), direct visualization via the laparoscope, or at surgery. No single diagnostic test or combination of laboratory tests are currently considered to have sufficient negative predictive or positive predictive value to completely exclude EP or to definitively establish the diagnosis.

Differences in the dynamics of phCG production in normal and pathologic pregnancy are useful in the diagnosis of EP. Early in normal pregnancy, phCG levels rise rapidly. phCG levels decline in nonviable pregnancies and in successfully treated EP. Absolute levels of PhCG tend to be lower in pathologic pregnancies than in IUP, but there is much overlap. Owing to the variability in absolute levels and the overlap between normal and pathologic pregnancies, **no single bhCG level can reliably distinguish between a normal and a pathologic pregnancy.** *Doubling time* refers to the time needed for (3hCG concentration in the serum to double. In normal pregnancy, serum levels of [3hCG increase by at least 66 percent every 48 h in 85 percent of patients. Absolute levels of (3hCG are lower and doubling times longer in EP and other abnormal pregnancies. This and many other observations has lead to the widely used rule of thumb stating that the serum concentration of phCG approximately doubles every 2 days early in a normal pregnancy, and that longer doubling times indicate pathologic pregnancy. Varying degrees of sensitivity (36 to 75 percent) and specificity (63 to 93 percent) are obtained using different criteria for evaluating the rate of increase of phCG levels. A serum (JhCG that fails to double in 48 h is thus suggestive but not diagnostic of an EP or an abnormal IUP.

Even in EP, approximately 13 percent of patients will have an increase in serum (3hCG of at least 66 percent in 2 days. In stable patients serial measurements of phCG are therefore used to either heighten or lower the suspicion for EP, but are not diagnostic.⁷ The American College of Emergency Physicians does recommend that a repeat serum (3hCG measurement made at least 2 days after the initial presentation is useful in characterizing the risk of ectopic pregnancy and the probability of a viable IUP (Table 103-3).⁸

Progesterone (P) is a steroid hormone secreted by the ovaries, adrenal glands, and placenta during pregnancy. During the first 8 to 10 weeks of pregnancy, ovarian production of P predominates and serum levels remain relatively constant. After the tenth week of pregnancy, placental production increases and serum levels rise. Absolute levels of P are lower in pathologic pregnancies and fall when a pregnancy fails. This observation has led multiple authors to propose various P levels as a diagnostic aid in differentiating an early normal from a pathologic pregnancy. Most pathologic pregnancies have P levels £10 ng/mL. For P £5 ng/mL, nearly 100 percent of pregnancies will be pathologic; there are no normal pregnancies reported with P <2.5 ng/mL. Progesterone levels >25 ng/mL have 97 percent sensitivity for viable IUP. In a recent study of patients with P £5.0 ng/mL, an empty uterus or nonspecific fluid collection on ultrasound was found to be highly predictive of abnormal IUP or EP. None of 82 patients with an empty uterus and 1 of 29 with nonspecific fluid had a normal IUP.⁹

There is considerable overlap between P levels in normal and pathologic pregnancy. Very low values for serum P thus should increase the clinical suspicion for EP or abnormal IUP, but as with PhCG levels, no value is diagnostic or can completely exclude or definitively diagnose EP. Certain authors strongly advocate protocols using serum P levels instead of or as an adjunct to quantitative phCG levels.

However, P levels may not be routinely available on an urgent basis and, as noted, many patients have intermediate values, thus limiting the usefulness of the test. Consequently, the role of serum progesterone assays is currently unclear and it is undergoing further evolution and evaluation.

Numerous other serum markers for the diagnosis of EP have been investigated. These include secretory endometrial protein, estradiol, the pregnancy-associated proteins A to D, and others, as well as rou-

time laboratory tests such as amylase, creatine kinase, erythrocyte sedimentation rate, and others. None have been accepted as equal or superior to phCG measurements at this time.

Sonography and Ectopic Pregnancy

Sonography plays an essential role in the diagnosis of EP. The primary goal of sonography in suspected EP is to determine if an IUP is present. Sonographic findings may also be useful in planning therapy when an EP is discovered. Noninvasive therapies are often reserved for EPs in which no cardiac activity is seen or those in which the mass is less than a specified size, though this area is undergoing rapid change. In addition, sonography provides information regarding fetal age and viability when an IUP is present.

It has previously been assumed that if an IUP exists, the diagnosis of EP has been excluded. This assumption is based on the historical incidence of heterotopic pregnancy (combined IUP and EP), reported to occur once per 30,000 pregnancies. This is no longer a completely safe assumption, with heterotopic pregnancy now occurring in up to 1 in 3000 pregnancies in the general population. In vitro fertilization and other efforts to enhance fertility with the use of ovulation-inducing drugs have resulted in a higher incidence of heterotopic pregnancy. A recent study of 725 in vitro fertilization pregnancies found 4 percent EP with 2 of 29 heterotopic gestations.¹⁰ Heterotopic pregnancy should be considered even when sonography demonstrates an IUP in the assisted reproduction population. For other patients, demonstrating

an IUP still provides a high degree of confidence in ruling out EP. This confidence should be somewhat tempered when a patient has risk factors for EP.

Advances in sonographic imaging include improved portability, decreased cost, and improved image quality of newer machines. Use of transvaginal (TV) scanning allows earlier detection of an IUP or an EP. These advances have contributed to increasing use of real-time, bedside sonography in the ED performed by emergency physicians. ED sonography has the further advantage of allowing a potentially unstable patient to remain under continuous observation in the ED. Bedside ED sonography in the first trimester of pregnancy has been shown to be accurate and to contribute to earlier diagnosis and treatment of EP. However, sonography remains an operator-dependent procedure and there is limited validation in the community setting of the positive results obtained in academic teaching hospitals. Therefore the limitations of the procedure, equipment, and operator experience must be kept in mind.^{11,12}

The sequencing of transabdominal (TA) versus TV sonography is situation and operator dependent. Usually, TA scanning is performed first. Among other differences, TA scanning is less invasive and offers a wider field of view and easier orientation to the pelvic organs. A full bladder is required for an appropriate acoustic window. When TA sonography is not diagnostic, TV scanning should be performed. A full bladder is not required. The shallower depth of field and higher frequencies made possible by the lack of interposed abdominal fat allows better visualization of small structures such as early pregnancies. Orientation to the pelvic organs is more difficult with TV scanning than with TA. There are reports of negative TV but positive TA sonography in cases of EP, so both studies should be performed if the study performed first is not diagnostic.

When sonography reveals an unequivocal IUP and no other abnormalities, EP is effectively excluded unless the patient is at high risk for heterotopic pregnancy. An embryo with cardiac activity seen within the uterine cavity is referred to as a viable IUP. When an embryo without cardiac activity is visualized within the uterus, the diagnosis of fetal demise can be entertained, provided that the crown-rump length is at least 5 mm. Sonographic findings related to age of gestation are discussed in Chap. 113. Briefly, TV scanning can usually visualize the early sonographic signs of pregnancy, the gestational sac, yolk sac, and fetal pole at 4.5, 5.5, and 6 weeks respectively (see Figures 113-13 through 113-16). Visualization by TA can be done approximately 1 week later.

No further diagnostic testing is needed when sonographic findings confirm or are highly suggestive of EP. An empty uterus with embryonic cardiac activity visualized outside the uterus is diagnostic of EP. This is seen in less than 10 percent of EPs using TA scanning, but in up to 25 percent of cases when the TV approach is used. When a pelvic mass or free pelvic fluid is seen in conjunction with an empty uterus, EP is considered highly likely. The combination of an echogenic adnexal mass with free fluid in the setting of an empty uterus confers a risk of EP near 100 percent, while a large amount of free fluid alone has a 86 percent risk and a mass alone a 70 percent risk (Table 103-4). In addition to a living extrauterine pregnancy, an extrauterine gestational sac is highly predictive of EP. Any adnexal mass (other than a simple cyst) seen with US also has high positive predictive value for the diagnosis of EP.^{13,14} It has also been suggested that increased

thickness of the endometrial stripe is predictive of EP when no other diagnostic findings are noted on sonography. However, the wide overlap between endometrial stripe thickness in normal and EP limits the usefulness of this observation.¹⁵

If sonography fails to reveal a definite IUP or fails to show findings strongly suggestive or diagnostic of an EP, the test should be considered indeterminate and interpreted in light of quantitative serum pHCG levels. The concept of the "discriminatory zone" was developed by Kadar and colleagues to relate pHCG levels and sonography findings in a clinically useful way.¹⁶ The discriminatory zone is the level of pHCG at which findings of an IUP are expected on sonography. If the pHCG level is higher than the discriminatory zone and the uterus is empty, this is interpreted as suggestive of an EP. An empty uterus with a pHCG level below the discriminatory zone or interpreted as indeterminate, neither confirms nor negates the diagnosis of EP. The actual level of (3hCG representing the discriminatory zone is operator and technique dependent. With TV scanning, the discriminatory zone is often considered to be 1500 mIU/mL, or even lower. For TA scanning, an IUP should be detectable when the (3hCG level reaches about 6000 mIU/mL. Clinicians should understand this concept and collaborate closely with imaging specialists in equivocal cases to avoid confusion. **When EP is suspected, sonography should be performed even in patients with low (JhCG levels, as EP can occur even at very low (<500 mIU/mL) |3hCG levels.** Cacciatore and colleagues identified IUP with 100 percent accuracy in patients with pHCG >1000 mIU/mL using TV sonography. Patients with IUP and even lower pHCG levels are often identified.¹⁷

Diagnostic algorithms using the concept of the discriminatory zone have been proposed and validated. A study of 1263 consecutive ED patients with clinically suspected EP by Braffman and associates found 205 cases of EP, of whom 81.5 percent were hemodynamically stable. In stable patients, they correctly diagnosed 49.1 percent of EP and 96 percent of IUP on the initial visit with a combination of (3hCG levels and TV sonography. A level of 1500 mIU/mL was used as the discriminatory zone. If the (JhCG level was >1500 mIU/mL and the uterus was empty, dilation and curettage (D&C) or laparoscopy was used to diagnose EP. (A D&C was performed on patients not wishing to continue the pregnancy.) If chorionic villi were present, IUP was considered confirmed. When the pHCG level was < 1500 mIU/mL and the uterus was empty, serial pHCG measurements were repeated every 2 days. If pHCG failed to increase by at least 66 percent in a 2-day period, an operative procedure was used to diagnose possible EP. TV sonography was repeated if the pHCG level was >1500 mIU/mL. With use of this protocol, 100 percent of EPs were identified without any complications (sensitivity = 100 percent).¹⁸ Other reports using similar protocols confirm these results.

Magnetic resonance imaging (MRI) has also been investigated for the early diagnosis of EP. Small studies have shown high sensitivity and specificity. But cost, availability, and the time to perform the study make this of only theoretical interest at the present time.

Invasive Diagnostic Techniques

Culdocentesis has been largely supplanted by tests for (3hCG in combination with sonography, but it may have use when sonography is unavailable. Laparoscopy may be both diagnostic and therapeutic. D&C may provide a definitive diagnosis of IUP, thus excluding EP except in cases of heterotopic pregnancy.

CULDOCENTESIS Because of the changes in technology, emergency practitioners have either not been trained in culdocentesis or experience has waned during the better part of the last two decades. This procedure is now rarely performed for the diagnosis of EP, even by experienced gynecologist/obstetrician specialists.

Although culdocentesis is less useful than noninvasive tests for the diagnosis of EP, one indication remains. Culdocentesis may be considered

TABLE 103-4 Ancillary Ultrasound Findings Suggestive of Ectopic Pregnancy in High-Risk Patients

Ancillary Findings	Risk of Ectopic Pregnancy
Small amount of free pelvic fluid	52%
Echogenic adnexal mass	70%
Moderate/large amount of free pelvic fluid	86%
Any mass plus echogenic fluid	97%

for both stable and unstable patients when sonography is unavailable. In this setting, a positive test would facilitate an appropriate, rapid surgical intervention.

Possible results include a dry aspiration, which has no diagnostic value. If clear, nonbloody peritoneal fluid is aspirated, the tap is considered negative. Aspiration of nonclotting blood constitutes a positive tap, considered indicative of an EP. However, there is no consensus regarding the criteria for a positive test. Various authors have proposed volumes between 0.3 mL and 10 mL with hematocrit from 3 to 15 percent. The pathophysiologic basis for culdocentesis is that a ruptured EP will bleed into the pelvic peritoneal cavity. Some 85 to 90 percent of patients with a ruptured EP will have a positive culdocentesis. Surprisingly, up to 70 percent of patients with an unruptured EP will also have a positive result. A basic limitation of the technique is that it is less sensitive in the diagnosis of nonruptured than ruptured EP. Another cause of false-negative results is that in cases of rapid bleeding, intraperitoneal blood may clot due to the lack of sufficient dwell time to produce defibrination. False-positive results occur because of technical errors (entering a vein or other vascular structure with the needle) or a ruptured corpus luteum cyst. Aspiration of purulent material may indicate another diagnosis, such as pelvic inflammatory disease.

LAPAROSCOPY Laparoscopy is primarily useful in patients with suspected EP and a nondiagnostic sonogram. It may provide an earlier diagnosis and a possible route for definitive treatment when compared with serial pHCG measurements and sonography. Laparoscopy is an accurate technique for the diagnosis of EP with low false-negative rates. False-positive rates are somewhat greater, but still considered to be rare. As with other invasive techniques, results will vary with the skill of the operator and the quality of the available equipment. If a laparoscopist is available who is skilled in the diagnosis and laparoscopic treatment of EP, laparoscopy is a viable alternative that may be accomplished rapidly and with low morbidity.

DILATATION AND CURETTAGE Uterine curettage (D&C) provides a method for the definitive diagnosis of an IUP when chorionic villi are obtained from the uterine cavity. EP is thus excluded unless a heterotopic pregnancy is present. The procedure can be performed in an outpatient setting with intravenous sedation. D&C terminates an IUP if present and is thus applicable only when termination of pregnancy is desired or when a nonviable pregnancy has been documented. A progesterone level of ≈ 5 ng/mL or stable or falling pHCG levels provide good, though not certain, evidence of nonviability. The specimen obtained at D&C is examined for the presence of chorionic villi. This may be done at the bedside by suspending the specimen in saline. Villi float, and absence of material that floats is presumptive evidence of absent villi and thus suggestive of an EP. However, there are false-negative as well as false-positive observations with this technique, thus formal histologic exam is required.

TREATMENT

The traditional treatment of EP has been laparotomy and salpingectomy. Over the last two decades, more conservative surgical and medical approaches have been developed that allow fallopian tube preservation, outpatient treatment, or shorter hospital admissions, and decreased medical expenditures. The treatment of EP can be divided into surgical, medical, and expectant approaches. Most authors would agree that if laparoscopy is needed for diagnosis, a surgical approach is most appropriate. For unruptured EP, the most frequently used surgical approach is laparoscopic salpingostomy; the most frequently used medical approach is systemic methotrexate treatment. For ruptured EP, laparotomy is the treatment of choice in hemodynamically unstable patients, although laparoscopic approaches have been utilized even in patients with large-volume hemoperitoneum.

Surgical Approach

Laparoscopy, as opposed to laparotomy, has emerged as the preferred surgical approach in the treatment of EP in a hemodynamically stable patient. Laparoscopic salpingostomy is preferred over laparoscopic salpingectomy for the treatment of unruptured tubal EP in patients in whom future fertility is desired. Although salpingostomy may be associated with an increased incidence of persistent and recurrent EP, it permits a higher rate of subsequent IUP by allowing preservation of the fallopian tube. Specific indications for laparoscopic salpingostomy include hemodynamic stability, ectopic size < 5 cm, unruptured or minimally ruptured fallopian tube, appropriate tubal location of the conceptus, and patient desire to preserve reproductive potential.

Laparoscopic salpingostomy is performed by a linear incision over the antimesenteric side of the fallopian tube adjacent to the EP. The products of conception are removed and the tube usually left open to heal by secondary intention.

Currently, laparotomy is reserved for cases that are too difficult for laparoscopic surgery, for hemodynamically unstable patients, and when the operator is inexperienced with operative laparoscopy. A laparotomy for EP may be followed by either salpingectomy or salpingostomy, depending on the clinical circumstances.

To assess for a persistent EP following laparoscopic salpingostomy, a weekly pHCG level is obtained. By the second postoperative week, the pHCG level should be undetectable or less than 20 mIU/mL. Persistent trophoblastic tissue (suspected based on elevated pHCG levels) is most commonly found in the proximal portion of the fallopian tube and may be treated by surgical reoperation, methotrexate treatment, or expectant management.

Medical Treatment

Pharmaceutical agents including methotrexate (MTX), prostaglandins, hyperosmolar glucose, potassium chloride, and mifepristone have been used as systemic agents or for local injection treatment of EP. Expectant management with serial (3hCG levels and ultrasound is also a medical option.

MTX is the only drug currently recommended as a medical alternative to surgical treatment of EP. MTX inhibits cell division in rapidly growing tissues such as those in the trophoblast. Different methotrexate regimens have been used, including both systemic intramuscular injections and direct injection into the ectopic gestational sac. Systemic intramuscular administration of MTX is the most commonly used approach, eliminating the need for laparoscopy or ultrasound guidance for local injection therapy. The largest study of systemic MTX to date revealed a success rate of 91.5 percent.¹⁹

The most common side effects associated with MTX include abdominal pain after treatment (up to 75 percent of patients) followed by flatulence and then stomatitis. Lower abdominal pain lasting up to 12 h is common 3 to 7 days after MTX treatment and is thought to be secondary to MTX-induced tubal abortion or tubal distention due to hematoma formation. The pain is usually self limited and may respond to NSAIDs.

Abdominal pain after MTX treatment can represent a clinical dilemma. It is difficult to differentiate expected pain from therapeutic tubal abortion and pain from rupturing persistent EP. Suggested evaluation of patients presenting with abdominal pain in this time frame following methotrexate administration includes a complete blood count and abdominopelvic US to rule out EP rupture⁷ and significant hemoperitoneum, and consideration of other causes of abdominal pain. Such patients may need admission to the hospital for observation. Hemodynamic instability and/or falling hematocrit require consideration for surgical intervention. Prognostic factors associated with a higher failure rate for MTX treatment include larger tubal diameter, higher initial (3hCG levels, severe abdominal pain, and fetal cardiac activity.¹⁹

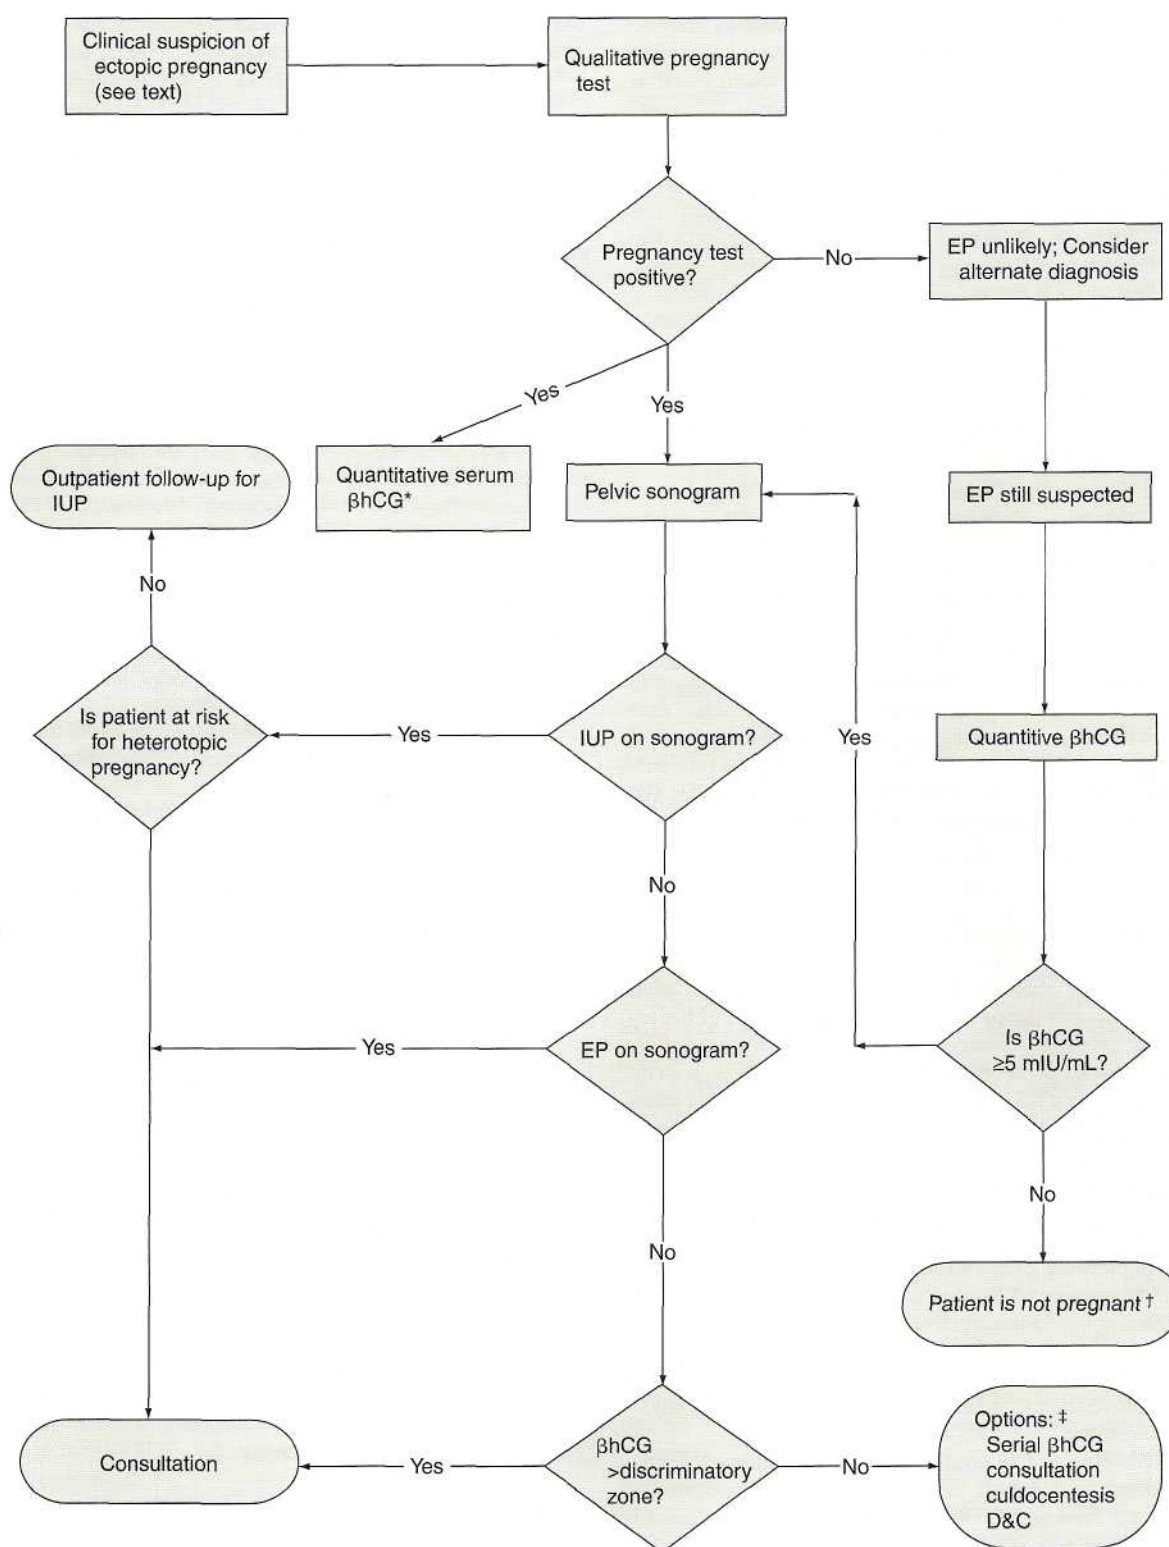

FIG. 103-1. Diagnostic algorithm for suspected ectopic pregnancy (Courtesy of Richard S. Krause, MD).

*Quantitative phCG measurement *prior* to sonography may facilitate rapid patient disposition by saving time.

†There have been extremely rare reports of pregnancy with phCG <5 mIU/mL.

‡Serial outpatient (3hCG measurements are recommended only for stable patients judged to be at low risk for ruptured EP (see text).

MTX administration in properly selected patients with EP may be initiated in the ED, clinic, or OB/GYN office. Treatment initiated in the ED should be in close conjunction with an obstetrician/gynecologist or other physician capable of providing follow-up care. Pelvic examinations after MTX treatment should be kept to a minimum to decrease the risk of tubal rupture. Patient instruction on discharge should include the following points.

1. Treatment failure occurs in up to 36 percent of cases.²⁰
2. Elective or emergency surgical treatment may be necessary if medical therapy fails or tubal rupture occurs (~5 percent of cases).
3. Vaginal bleeding, abdominal pain, weakness, dizziness, or syncope following treatment should be evaluated immediately as possible signs of tubal rupture (see Table 103-3).
4. Patients should refrain from sexual intercourse for 14 to 21 days following treatment (until β hCG levels are undetectable) as it may increase the risk of tubal rupture.

Rh Seroconversion and Indications for Anti-D Immunoglobulin

Rh₀ (D) antigen can be detected as early as 5.5 weeks and certainly by 6 weeks of gestation. Alloimmunization can occur with as little as 0.1 mL of fetal blood admixing with the mother's. There is strong evidence in the literature that alloimmunization can occur as a result of ectopic pregnancy. Circulating blood volume of the fetus is less than 5 mL in the first trimester. Accordingly, both the American College of Emergency Physicians (ACEP) and the American College of Obstetricians and Gynecologists recommend treatment of 50 μ g of anti-Rh₀ (D) immunoglobulin for Rh-negative women with ectopic pregnancy.

DISPOSITION

When a patient with signs or symptoms suggestive of EP is found to be pregnant, further testing to determine if the pregnancy is intrauterine should be undertaken (Figure 103-1). The nature and timing of additional diagnostic measures depends on the clinical condition of the patient. Unstable patients with suspected EP should receive resuscitation, urgent consultation, and operative intervention. Surgery may be both diagnostic and therapeutic if an EP is found, or may reveal another cause for the patient's condition. When bedside ED sonography is available, it may be valuable even in unstable patients, as it should not interfere with resuscitation, consultation, and rapid transfer to the operating room.

Ideally, all pregnant patients with suspected EP should receive immediate sonography. However, issues of availability during off hours may make this impractical. Stable patients who are judged to be at low risk for EP can be considered for discharge and outpatient follow-up. Such patients should have a quantitative β hCG level obtained to facilitate subsequent management. Culdocentesis remains an option where sonography is unavailable, but currently is used rarely due to limitations of the technique and the unfamiliarity of many emergency physicians with the technique.

Stable patients with fShCG levels above the discriminatory zone and an empty uterus on US, with or without other US findings of an EP, are presumed to have an EP. These patients should receive consultation in the ED.

Management options for stable patients with a pHCG level below the discriminatory zone and indeterminate sonography include consultation in the ED or discharge for follow-up in 2 days for reexamination and repeat (3hCG levels. Culdocentesis, D&C, and laparoscopy are also options in this circumstance. Figure 103-1 illustrates a suggested diagnostic approach.

NORMAL PREGNANCY

Christina E. Hantsch
Donna L. Seger

Regardless of the chief complaint, the possibility of pregnancy must be considered in every woman of reproductive age who presents to the ED. In one study pregnancy was documented in over 7 percent of women who stated there was no chance they were pregnant and reported an on-time normal last menstrual period.¹ The use of barrier methods (condoms, diaphragms, etc.), contraceptives, or tubal sterilization does not guarantee pregnancy prevention. The failure rates of barrier methods are variable. Although the failure rate with compliant use of oral contraceptives is less than 1 per 100, nearly 30 percent of women who rely solely on oral contraceptives to prevent pregnancy are not consistently compliant.² During the first 5 years of therapy with levonorgestrel implants, the annual pregnancy rate is 0.8 per 100. The failure rate of implants increases with time.³ Tubal sterilization is

a more reliable means of pregnancy prevention, with the failure rate depending on the surgical technique. Partial salpingectomy achieves pregnancy prevention with a failure rate of only 0.75 percent.⁴

TERMINOLOGY

Gravidity denotes the total number of pregnancies regardless of duration and outcome. *Parity* denotes the number of pregnancies completed to delivery during the viable period. Parity is not increased for a pregnancy resulting in multiple births or decreased for a stillborn fetus. Notation of obstetric history typically lists the gravidity (G) followed by the appropriate number and then the parity (P) followed by the appropriate number. After the gravidity and parity, there may be a listing of the number of term deliveries, preterm deliveries, abortions, and living children. The latter four numbers are separated by hyphens and listed in parentheses. For example, the obstetric history of a woman during her seventh pregnancy who has had four term deliveries, one preterm delivery, and one abortion and has five living children is abbreviated G7 P5 (4-1-1-5).

The duration of pregnancy is approximately 40 weeks. By convention, gestational age (or menstrual age) is calculated from the first day of the last normal menstrual period. Ovulation normally occurs around day 14 of the menstrual cycle. After ovulation, the ovocyte remains capable of being successfully fertilized for up to 12 h. Fertilization usually takes place in the ampulla of the oviduct. The fertilized ovocyte (zygote) transforms into the morula as it travels toward the uterus. By 6 days after fertilization, it enters the uterine cavity and implants in the endometrium. Weeks 2 through 8 (after fertilization) are the embryonic period. Week 9 is the start of the fetal period.

Pregnancy is typically divided into three trimesters of approximately equal length. The first trimester is from conception to 14 weeks, the second trimester is from 14 to 28 weeks, and the third trimester is from 28 to 42 weeks. A term pregnancy requires completion of at least 37 weeks of gestation.

PHYSIOLOGY

Cardiovascular System

Maternal cardiovascular changes during pregnancy include a 40 to 45 percent increase in circulating blood volume, a 43 percent increase in cardiac output, and a 17 percent increase in resting heart rate.⁵ Systemic vascular resistance is 20 percent lower. Blood pressure decreases to a nadir during the second trimester. The diastolic decrement (10-15 mm Hg) is greater than the systolic decrement (5-10 mm Hg). Hemodynamic measurements should be taken with the patient in the left lateral decubitus position because body position has a significant influence on hemodynamic values. The left lateral position increases venous return by relieving the pressure of the uterus on the inferior vena cava. The increase in cardiac output is detectable from the first trimester until after delivery when readings are taken with the patient in this position.⁶

Elevation of the diaphragm displaces the heart superiorly and to the left. This displacement produces a larger cardiac silhouette on chest radiograph and a slight left-axis deviation on the electrocardiogram. A small, benign pericardial effusion also may contribute to the enlarged cardiac silhouette.

Respiratory System

Many women experience dyspnea during pregnancy. Although the respiratory rate is unchanged, this symptom may be the result of a hormone-induced 40 percent increase in tidal volume and the attendant P_{CO_2} decrease (normal value in pregnancy, 30 mm Hg). Functional residual capacity is decreased because of a rise in the level of the diaphragm.⁷

Gastrointestinal System

Pregnancy-induced changes in the gastrointestinal system are due to both progressive displacement of the abdominal viscera and hormone-mediated functional alterations. Gastric reflux commonly occurs as a result of delayed gastric emptying, decreased intestinal motility, and decreased lower esophageal sphincter tone. The size and morphologic characteristics of the liver are not altered by pregnancy, but the presence of placental alkaline phosphatase may increase maternal serum alkaline phosphatase concentration. Bilirubin concentration and aspartate aminotransferase and alanine aminotransferase activities are unaltered. Hepatic enzyme systems are induced during pregnancy. Gallbladder emptying is delayed and less efficient, and pregnancy therefore increases the risk of cholesterol gallstones.

Urinary System

Pregnancy-related renal changes include increases in kidney size, renal blood flow, and glomerular filtration rate (GFR). By the second trimester, the GFR may increase by 50 percent. Consequently, blood urea nitrogen and creatinine levels decrease. Dilatation of ureteral and renal calyces or pelves due to ureteral compression are also seen frequently on imaging studies. These changes are often less pronounced on the left side because the sigmoid colon cushions the left ureter from the pressure of the enlarging uterus.

Hematopoietic System

During pregnancy, circulating blood volume expands by an average of 40 to 45 percent due to an increase in both plasma volume and the number of erythrocytes.⁶ Hemoglobin concentration decreases due to dilutional intravascular volume expansion but should not fall below 11 g/dL. Maternal erythropoiesis combined with fetal erythropoiesis produce the high iron requirements of pregnancy. Reticulocyte count is also slightly increased during the second half of pregnancy, the period of marked erythropoiesis. Leukocyte counts during pregnancy range from 5000 to 12,000 cells/ μ L. Dilutional effects on blood volume also may contribute to the variation in leukocyte counts. Beginning in the second trimester, leukocyte function is usually depressed, and increased susceptibility to infection may occur.⁸ Patients with chronic autoimmune conditions may improve clinically. Circulating coagulation factor concentrations and erythrocyte sedimentation rate increase during pregnancy. Platelet count may decrease slightly due to increased consumption. However, thrombocytopenia should prompt further evaluation for a pathologic cause.

Endocrine System

Pregnancy-related hormonal changes and feedback mechanism adjustments are incompletely understood. Characteristic changes in carbohydrate metabolism lead to hyperinsulinemia and fasting hypoglycemia. The altered response to glucose ingestion produces postprandial hyperglycemia and ensures a sustained glucose supply to the fetus. Mineral (especially iron), protein, and fat metabolism are also changed. Thyroid alterations include increased vascularity and mild hyperplasia, but clinically detectable goiter is not a normal finding in pregnancy. To assess thyroid function during pregnancy, free thyroxine and thyroid-stimulating hormone concentrations should be measured because they are not affected by physiologic changes of normal pregnancy.

Uterus

Uterine weight and intrauterine volume increase during pregnancy from 70 to 1100 g and from 10 to 5000 mL, respectively. These changes occur through marked stretching and hypertrophy of existing

muscle cells rather than formation of new cells. By 12 weeks of gestational age, the uterus exceeds the capacity of the pelvis and expands into the abdominal cavity. There is a progressive increase in uterine blood flow to approximately 450 to 650 mL/min by term.

Breasts

Many women note breast tenderness and tingling from early in the first trimester. The breasts enlarge and become more nodular. Nipple size and pigmentation increase. Striations similar to those often seen on the abdominal wall may develop on the breasts.

HISTORY AND PHYSICAL EXAMINATION

Obstetric and gynecologic history, including menstrual status and contraceptive use, should be obtained on every woman of reproductive age. Cessation of menses, nausea, vomiting, fatigue, and urinary frequency may be suggestive of pregnancy. The date of the last normal menstrual period aids in determination of gestational age (although it may be misleading if, for example, contraceptive use was discontinued recently). Quickening, the first maternal perception of fetal movement, helps establish gestational age. Primigravida women note fetal movement between 18 and 20 weeks' gestation. With subsequent pregnancies, quickening typically occurs about 2 weeks earlier (i.e., between 16 and 18 weeks' gestation). The patient's history of prenatal care and the course of current and past pregnancies, as well as the essential components of any medical history, should be obtained. Physical examination should include routine assessment of maternal well-being as well as an evaluation of fetal status. Fetal heart tones can be heard with a fetal stethoscope by 16 to 19 weeks' gestation. The normal fetal heart rate ranges from 120 to 160 beats/min. Since the fetus easily changes position, the site on the maternal abdomen where the fetal heart tones are best detected varies. Pulsation of the maternal aorta should be distinguished from the fetal heart tones.

A pelvic examination should be performed whenever pregnancy is part of the differential diagnosis. Appearance of the cervix and the presence of discharge or blood in the vaginal vault should be noted. Wet preparation and culture for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* may be indicated. Bimanual examination determines size and tenderness of the uterus and adnexa.

By the end of the first trimester, the size of the uterus also can be assessed by abdominal examination. At 12 weeks' gestation, the fundus should be palpable at the level of the symphysis pubis. At 16 weeks, the fundus should be midway between the symphysis and the umbilicus; at 20 weeks, it should be at the umbilicus. From 20 to 32 weeks, the height (in centimeters) of the fundus above the symphysis approximates the gestational age for a singleton pregnancy. For an accurate measurement, the pregnant patient should have an empty bladder when fundal height is determined. Later in pregnancy, the presenting part of the fetus also should be determined by palpating the maternal abdomen.

DIAGNOSIS

Standard analytical techniques screen blood or urine for human chorionic gonadotropin (HCG), a glycoprotein produced by the trophoblast after implantation. Since implantation occurs about 1 week after conception, these screening tests are particularly helpful in establishing or excluding early pregnancy. At 4 to 5 weeks' gestation and beyond, definitive diagnosis can be made by sonographic visualization of the embryo or fetus (see Chap. 113). Alternatively, in later stages, detection (by fetal stethoscope or sonogram) of fetal heart activity distinct from maternal heart activity or detection of palpable fetal movement may confirm pregnancy.

Analytical Techniques

HCG is composed of α and β (3 subunits). The HCG α subunit is indistinguishable from the α subunit of several other glycoproteins, including luteinizing hormone. The β subunit is unique to HCG. Qualitative enzyme-linked immunosorbent assays (ELISAs) that detect P-HCG in urine can be completed in minutes at the patient's bedside. Available commercial tests can detect P-HCG concentrations as low as 10 to 20 mIU/mL. These tests have a false-negative rate of only 1 percent in detecting pregnancy as early as 1 week after conception. However, to achieve this level of sensitivity, the analysis must be performed on a urine specimen that is not dilute. When urine is dilute, a false-negative result may be obtained for women with early pregnancy (serum HCG <50 IU/mL).⁹ Serum analysis should be performed in clinical situations where pregnancy is a concern but the urine result is questionable. Quantitative serum values are obtained by ELISA technique and can be completed in 1 to 2 h. There are several international standards for serum p-HCG, and the specific reference range should be appropriate for the standard employed.

A positive result on a pregnancy test, whether qualitative or quantitative, does not confirm a normal intrauterine pregnancy. Ectopic pregnancy, recent spontaneous or induced abortion, and HCG-secreting tumors (e.g., molar pregnancy) also may produce a positive result. A single quantitative P-HCG determination in combination with pelvic ultrasonography may differentiate intrauterine pregnancy from these conditions (see Chap. 113). Serial quantitative serum P-HCG determinations may be useful in some outpatient situations because serum p-HCG levels approximately double (66%) every 1.4 to 2.0 days following implantation in early normal pregnancy. Failure of the HCG concentration to double in this time period suggests an ectopic or a nonviable pregnancy.

Pelvic Ultrasonography

More detailed discussions of ultrasonography and its application can be found in Chap. 113. The earliest definitive sonographic finding in pregnancy is a gestational sac. Using transabdominal technique, the gestational sac can be detected at 5.5 to 6 weeks' gestation. With transvaginal technique, the gestational sac can be detected at 4 to 5 weeks' gestation. Other ultrasound markers of pregnancy and the gestational age at which they may be detected by transvaginal ultrasound include the yolk sac at 5 to 5.5 weeks' gestation, the fetal pole at 5.5 to 6 weeks, and cardiac activity at 6 weeks. Correlation of these markers with specific, quantitative serum p-HCG values varies with the capabilities of the ultrasound equipment and the skill of the ultrasonographer.

SPECIFIC ISSUES IN PREGNANCY

Abdominal Discomfort

Many pregnant women experience abdominal discomfort. The differential diagnosis of abdominal pain varies with the stage of gestation and must include all the possibilities in a nonpregnant patient (see Chap. 102) as well as those unique to pregnancy. Ectopic pregnancy and threatened abortion should be considered when abdominal pain occurs during the first trimester. Premature labor, abruption, and uterine rupture should be considered when abdominal pain occurs during late second and third trimesters.

Vascular congestion of pelvic tissue and round ligament tension may cause lower abdominal discomfort early in pregnancy. Round ligament tension produces sharp pain (bilateral or unilateral) that is often precipitated by movement.

Braxton-Hicks contractions are irregular, palpable contractions that may occur particularly during late pregnancy.

Appendicitis, cholecystitis, and other acute abdominal surgical diseases can complicate pregnancy. The incidence of appendicitis is unchanged during pregnancy, but the diagnosis may be more difficult. Symptoms of appendicitis such as nausea, vomiting, and anorexia may be attributed to the pregnancy; location of abdominal pain caused by the inflamed appendix may be altered due to upward and rightward displacement of the appendix, especially in the third trimester. Physiologic gastrointestinal changes result in an increased risk of cholelithiasis throughout pregnancy. Cholelithiasis may be asymptomatic or cause cholecystitis or pancreatitis.

Syncope

Many women experience palpitations, dizziness, near-syncope, or syncope during pregnancy. The differential diagnosis includes anemia, electrolyte imbalance, dehydration, pulmonary embolism, and arrhythmia, but the etiology of these symptoms is often unclear. The incidence of arrhythmias, especially premature atrial and ventricular beats, is increased in pregnancy. In one study, however, only 10 percent of symptomatic episodes of palpitations, dizziness, near-syncope, or syncope were associated with arrhythmias. These may occur in pregnant patients with or without identifiable heart disease.¹⁰

Medication Use

Multiple factors, including gestational age and stage of development, dose and duration of exposure, and individual susceptibility, influence the potential effects of drug exposure during pregnancy. Teratogenesis is defined as the structural or functional dysgenesis of fetal organs. Typical manifestations include restricted growth, fetal death, carcinogenesis, and malformations. The fetus is most vulnerable to teratogenic effects at 4 to 12 weeks' gestation, the period of organogenesis. Administration of drugs early during the period of organogenesis, will affect the organs developing then, such as the heart or neural tube. Closer to the end of the classic teratogenic period, the ear and palate are forming and may thus be affected. Before 4 weeks, exposure to a teratogen produces an all-or-none effect, i.e. either the conceptus survives without anomalies, or does not survive at all. If the organism remains viable, organ-specific anomalies do not develop because repair or replacement permits normal development. A similar insult at a later stage may produce organ-specific defects. Thus, drug exposure early in pregnancy may lead to spontaneous abortion. Drug exposure later in pregnancy may cause teratogenesis by altering placental blood flow and/or directly affecting the fetus. Medication use during pregnancy also may cause neonatal central nervous system (CNS) depression, seizures, respiratory depression, kernicterus, or premature closure of the ductus arteriosus. Manifestations depend on the specific medication. Neonatal withdrawal may occur after maternal use of opiates or benzodiazepines during pregnancy. Finally, the adverse effects of fetal exposure to some medications (e.g., tetracyclines, which produce discoloration of teeth and bone, and diethylstilbestrol, which produces female genital tract abnormalities) may not be evident until later in the life of the child.

Pharmaceutical companies do not test drugs in pregnant women to determine potential fetal effects. Much of the available information on teratogenesis is based on animal studies, inadvertent human exposure during unrecognized pregnancies, and case reports or epidemiologic studies of pregnancy outcome after therapeutic drug administration. Manufacturer labeling and drug reference books often contain ambiguous statements concerning use of drugs in pregnancy. The U.S. Food and Drug Administration (FDA) classifies drugs into five risk categories based on available information (Table 104-1). Because of ambiguity and potential inaccuracy within this system, alternative ways of outlining estimated fetal risk for both physicians and the general population are being investigated. Table 104-2 lists common medications generally considered safe on pregnancy.

TABLE 104-1 Food and Drug Administration Categorization of Drug Risk in Pregnancy*

Drug Category	Risk During Pregnancy
A	Controlled studies have failed to demonstrate a fetal risk in the first trimester (and there is no evidence of risk in later trimesters), and the possibility of fetal harm is remote.
B	Either animal studies have not demonstrated a fetal risk but there are no controlled human studies, or animal studies have demonstrated an adverse effect that was not confirmed in controlled human studies in women in the first trimester (and there is no evidence of risk in later trimesters).
C	Either animal studies have revealed adverse effects on the fetus (teratogenic or embryocidal) and there are no controlled studies in humans, or no human or animal studies are available. Drugs should only be used if the potential benefit justifies the potential fetal risk.
D	Evidence of human fetal risk exists, but the benefits of use in pregnant women may be acceptable despite the risk.
X	Studies in animals or humans have demonstrated fetal risk, or there is evidence of fetal risk based on human experience. The risk of use in pregnancy clearly outweighs any possible benefit. Drugs are contraindicated for use in women who are or may become pregnant.

* Source: [http://www.fda.gov/ohrms/dockets/ac_102/slides/3902\\$1-09-miller/ts/d009.htm](http://www.fda.gov/ohrms/dockets/ac_102/slides/3902$1-09-miller/ts/d009.htm) (accessed May 2003).

ANTIMICROBIAL AGENTS Antimicrobial medications are used frequently during pregnancy. All these agents enter the fetal circulation to some extent. The potential teratogenic effects are unknown for some antimicrobials. Information on the safety of newer extended-spectrum or late-generation agents is limited.¹¹ Table 105-1 includes known pregnancy-related contraindications to some frequently used antibiotics.

Penicillin and cephalosporins generally are regarded as safe for use in any trimester. Neither group has been associated with teratogenesis in either animals or humans. Erythromycin does not cause known adverse fetal effects, but the estolate formulation is contraindicated in pregnancy because it may cause maternal cholestatic hepatitis. Sulfonamides (including the sulfamethoxazole component of trimethoprim-sulfamethoxazole) are not known human teratogens. Maternal use close to term, however, may cause complications in the neonate. Sulfonamides compete with bilirubin for albumin binding. The fetus clears free bilirubin via the placenta, but in the neonate, free bilirubin accumulates and may cause kernicterus. Trimethoprim, the other component of this combination antibiotic, should be avoided in the first trimester because it is a folate antagonist, and decreased folate may cause neural tube abnormalities. If trimethoprim-sulfamethoxazole offers a clear advantage over other antibiotics, it is reasonable to use; however, the period of gestation should be considered in making such a decision. Tetracyclines are contraindicated in pregnancy because they chelate calcium, cause abnormalities in fetal bone development, discolor teeth, and cause maternal hepatic and renal toxicity. Fluoroquinolones have caused fetal cartilage abnormalities in animals and as of this writing remain contraindicated throughout pregnancy.¹²

ANALGESIC AGENTS **Acetaminophen is the agent of choice** for analgesia or antipyresis in pregnancy. Aspirin should be avoided during pregnancy. Although evidence is conflicting, aspirin use in the first trimester has been associated with congenital defects. Use later in pregnancy may cause coagulation abnormalities with hemorrhagic complications in both the neonate and the mother. Premature ductus

Dextromethorphan
Guaifenesin
Anaesthetics
Lidocaine

*Not erythromycin estolate (hepatotoxicity risk), or clarithromycin.

arteriosus closure and cardiovascular complications in the neonate also may be a result of maternal aspirin use late in pregnancy. Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) may prolong gestation and labor through inhibition of cyclooxygenase. Unfortunately, nonaspirin NSAIDs cannot be employed as tocolytic agents because they, like aspirin, cause premature ductus closure and subsequent pulmonary hypertension. Use of NSAIDs (especially indomethacin) also has been associated with oligohydramnios, intestinal perforation, hydrops fetalis, and renal failure.

GASTROINTESTINAL AGENTS Many pregnant women, particularly those in the first trimester, suffer nausea and vomiting. Conservative measures, such as reduced meal size and avoidance of specific foods, frequently ease symptoms. Intravenous fluids and electrolyte replacement may alleviate symptoms, but in some cases medications may be necessary.

The safety of antiemetics has not been studied in prospective human trials, but the benefit of improved metabolic conditions and maternal well-being should be considered in the management decision.¹² Phenothiazines, such as promethazine and prochlorperazine, may be considered. Several other antiemetics, including metoclopramide (5-10 mg PO, IV, IM every 8 h) and ondansetron (8 mg PO every 8 h), are presumed safe based on animal study data.

Physiologic changes in pregnancy often lead to dyspepsia during the third trimester. Most over-the-counter antacid preparations are acceptable. The histamine antagonists cimetidine and ranitidine have no known teratogenic effect in animals. Although they have not been evaluated in humans, their use in general is considered safe.

COLD PREPARATIONS Over-the-counter cold preparations are frequently combination medications containing sympathomimetic agents. All sympathomimetic drugs have vasoconstrictive properties and may lead to vascular-mediated congenital defects. Data on spe-

cific agents and their teratogenic potential are inconclusive. Conservative measures for control of symptoms during upper respiratory infections are preferred. When medication is necessary, each component of a combination preparation should be considered before a choice is made. First-trimester exposure to dextromethorphan or guaifenesin has not been associated with adverse fetal effects.

ANESTHETICS Proper use of most agents for local or regional anesthesia, including subcutaneous infiltration of **lidocaine, has not been associated with detrimental fetal effects.** Combination preparations such as tetracaine, adrenaline-epinephrine, and cocaine (TAC) and lidocaine, adrenaline, and tetracaine (LAT) should not be used due to the potential risks of absorbed cocaine and adrenaline-epinephrine.

CONTRACEPTIVES Pregnancy may occur in women taking oral contraceptive agents due either to a failure of therapy or to noncompliance. While there is no demonstrated risk of fetal malformation due to contraceptive use in early pregnancy, they should be discontinued as soon as pregnancy is recognized.³

Radiation Exposure

Complicating effects of radiation are discussed in Chap. 105.

Immunizations

Live-vims vaccines, including measles, mumps, rubella, poliomyelitis, and varicella, should be avoided in all trimesters of pregnancy as well as for 3 months before conception.¹³ Inactivated (killed-virus) vaccines, including the influenza vaccine, can be administered during pregnancy. In fact, the Advisory Committee on Immunization Practices of the Centers for Disease Control and Prevention recommends vaccination against influenza for women who will be in the second or third trimester during the influenza season¹³ because women at those stages of pregnancy are at increased risk of influenza-related complications. **Tetanus toxoid alone or in combination with diphtheria toxoid can be given during pregnancy.** Immunoglobulins, including tetanus, hepatitis, rabies, and varicella immunoglobulin, can be administered when indicated regardless of the stage of gestation.¹³

PREVENTIVE MEDICINE AND COUNSELING

Nutrition and Nutritional Supplementation

Nutrition is important to pregnancy outcome. Total weight gain as well as the pattern of weight gain affects newborn birth weight. Maternal weight gain begins in the first trimester and is most significant during the first half of pregnancy. Average total gain is 12.5 kg (28 lb). Routine supplementation with a multivitamin is not necessary with a balanced diet. Since folic acid supplementation before and during early pregnancy may prevent neural tube defects, supplementation of 1 mg/d should be started as soon as pregnancy is established.¹⁴ For women with a previous pregnancy affected by neural tube defect, the supplementation should be further increased to 4 mg/d.¹⁴ Appropriate use of vitamin preparations is not harmful, but excess intake of some vitamins (e.g., A, D, C, and B₆) may lead to congenital defects.

Since most women of childbearing age have poor iron stores and normal dietary intake cannot meet the increased demand during pregnancy, iron supplementation is recommended, but other mineral supplementation is not. Zinc deficiency may be associated with neural tube defects. Daily intake of zinc during pregnancy should be 15 mg.¹⁴

Caffeine

Results of human studies on the effects of caffeine use during pregnancy are conflicting. Some evidence suggests an increased risk of

spontaneous abortion in nonsmokers who experience nausea during pregnancy and consume cups of coffee) per 500 mg (equivalent to 5 cups of coffee) per day or more of caffeine.¹⁵

Aspartame

Aspartame (NutraSweet) is metabolized to phenylalanine. Phenylalanine crosses into fetal circulation and at very high concentrations can lead to mental retardation. Except in cases of excessive maternal dietary intake or maternal heterozygous carriers of phenylketonuria, fetal toxicity is unlikely.

Substance Abuse

Illicit substance abuse, as well as alcohol and tobacco use, may affect the fetus and/or the mother and is one of the greatest threats to normal pregnancy. Frequently, multiple substances are involved.

LLICIT SUBSTANCES Use of cocaine, opiates, or amphetamines is associated with multiple complications of pregnancy and congenital abnormalities. Data on other substances, such as hallucinogens and "designer drugs," is inconclusive. Effects of abused substances as well as the general health and well-being of the mother are of concern when treating a pregnant substance abuser. A multidisciplinary approach is important.

NICOTINE Cigarette smoking, a habit to which 25 to 30 percent of reproductive-age women admit, increases the risk of many pregnancy complications. Only 20 percent of smokers quit by the time of the first prenatal evaluation.¹⁶ Although the mechanism by which nicotine produces some of these adverse outcomes is incompletely understood, exposure to nicotine is associated with higher rates of spontaneous abortion, abruptio, preterm labor, and low birth weight. Smoking cessation by 16 weeks' gestation may ameliorate adverse effects. Attempts at cessation should first be made without pharmacologic intervention. Recommendations for the use of nicotine gum (pregnancy category C) and nicotine patches (pregnancy category D) should be individualized. Prior cessation attempts and total number of cigarettes per day should be considered in assessing the potential risks and benefits of such interventions.¹⁶

ALCOHOL Ethanol readily crosses the placenta and enters the CNS of the developing fetus. Fetal exposure to ethanol produces a characteristic clinical condition known as *fetal alcohol syndrome*, which includes CNS dysfunction, growth retardation, and facial abnormalities. CNS abnormalities including microcephaly, mental retardation, and behavioral disorders are typically the most severe. This syndrome may result from ethanol use during any period of gestation; however, the greatest risk is with first-trimester exposure. Furthermore, although evidence supports a dose-related response to ethanol exposure, there is no established safe quantity of alcohol that may be consumed.

Travel

In general, a normal pregnancy does not prevent women from traveling to reasonable destinations. Immunization requirements and the possibility of travel-related diseases or development of complications while in remote areas are issues that should be addressed before travel is begun. High-altitude stays of a few days' duration have not been associated with risk to the fetus, but exposure for longer duration increases the chance of fetal growth retardation, maternal high blood pressure, and premature delivery. Travel in pressurized aircraft has not been associated with adverse outcome in an otherwise uncomplicated pregnancy. Some commercial airlines, however, enforce restrictions limiting travel during the third trimester. Frequent ambulation is important during travel of long duration regardless of the period of ges-

TABLE 104-3 Symptoms and Signs in Pregnancy that Need Prompt Evaluation

Change in fetal movement pattern

Refractory emesis
Visual disturbance
Abdominal pain
Significant headache
Anasarca
Dysuria
Vaginal bleeding and fluid loss
Abnormal vaginal discharge

tation. Protective restraint devices should be used at all times in automobiles and airplanes. Lap belts should have a snug, comfortable fit under the abdomen and across the hipbones.^{17,18}

Exercise

The effects of physical exertion on pregnancy outcome are not known. In general, uncomplicated pregnancy should not limit the ability to engage in moderate physical exercise. The American College of Obstetricians and Gynecologists recommends some modifications in exercise routines in view of the physiologic and morphologic changes of gestation.⁶ Non-weight-bearing activity and activities that minimize the chance of even mild abdominal trauma are preferable. Scuba diving should be avoided due to the increased fetal risk for decompression sickness.¹⁹ Exercise in the supine position should be avoided completely after the first trimester due to potential for decreased cardiac output. Although there does not appear to be a need to alter goal intensity as judged by heart rate, exercise should be stopped at the onset of fatigue rather than continuing to exhaustion. Regular activity is preferable to sporadic exertion. Exercise may be beneficial in the prevention of gestational diabetes. Subjective benefits of exercise both before conception and during early pregnancy have been reported.²⁰ Specific recommendations for exercise during pregnancy need to be individualized and made with the knowledge that there is no conclusive evidence on which to base recommendations.

DISPOSITION

Timely access to prenatal care should be arranged. Recommendations for prenatal care for a normal pregnancy include an initial obstetric evaluation no later than 6 to 8 weeks' gestation. Discharge instructions should include recommendations about symptoms and signs for which the patient should be urgently reevaluated (Table 104-3). Recommendations on activities, lifestyle, and appropriate use of prescription and over-the-counter medications should be given.

Obstetric consultation should be obtained whenever there is uncertainty regarding issues, such as specific travel, immunization, medication, or management options. Gestational age, fetal heart tones (expected if gestational age is greater than 16 to 19 weeks), analytical values, parity, and general maternal information should be provided to the consultant.

COMORBID DISEASES IN PREGNANCY Jessica L.

Bienstock Harold E. Fox

DIABETES

Diabetes mellitus complicates approximately 2 to 3 percent of all pregnancies. Diabetes in pregnancy falls into two categories: Approximately 90 percent of pregnant diabetic patients have gestational diabetes, and 10 percent have diabetes that predates the pregnancy. Those with gestational diabetes are subdivided into classes A₁ and A₂, the former being controlled by diet alone and the latter requiring insulin therapy. Patients with preexisting diabetes, even if they were managed previously with oral hypoglycemic agents, are all treated with insulin therapy during pregnancy. **Oral hypoglycemic agents are not used during pregnancy** because they do not provide an adequate level of glucose control. In addition, some of these agents have been associated with an increased risk of congenital anomalies, hyperbilirubinemia, and irreversible p-cell hyperplasia in exposed infants. Pregnant diabetic patients are at increased risk for fetal death in utero, particularly patients with preexisting vascular disease and preeclampsia, as well as those with poor glycemic control.

The goals of glucose control for all patients with gestational diabetes is a fasting plasma glucose level of less than 90 mg/dL and 1-h postprandial blood glucose levels of less than 140 mg/dL. Patients with gestational diabetes who are managed by diet alone rarely develop acute glycemic complications because their glucose values rarely reach levels consistent with diabetic ketoacidosis.

Among patients with insulin-dependent diabetes, the need for insulin tends to increase throughout the course of pregnancy. In general,

during the first trimester, the initial insulin requirement is 0.7 units/kg per d. By late pregnancy, patients generally require 1 unit/kg per d. Generally, two-thirds of the total insulin dose is given in the morning and one-third in the evening. Usually, two-thirds of the morning dose consists of NPH and one-third of regular insulin. The evening dose consists of half NPH and half regular insulin. Occasionally, this regimen may result in nocturnal hypoglycemia between 1 and 3 A.M. Administering the predinner NPH at bedtime has been suggested as a way of remedying the problem.

Pregnant diabetics are at increased risk for several pregnancy complications, including hypertensive diseases, preterm labor, spontaneous abortion, and pyelonephritis, in addition to hypoglycemia and diabetic ketoacidosis (DKA).

About 10 percent of insulin-dependent diabetics will develop ketoacidosis at some point during pregnancy.¹ Ketoacidosis has been reported to occur more rapidly and at lower glucose levels in pregnant patients as compared with nonpregnant patients. While classically the diagnosis of ketoacidosis requires a plasma glucose level of greater than 300 mg/dL, DKA may develop in pregnancy at lower glucose values. P-sympathomimetic agents used for tocolysis, such as ritodrene and terbutaline, have been associated with an increased risk of diabetic ketoacidosis. Pregnant women in DKA are treated with a constant low-dose insulin infusion. General management guidelines are the same as for nonpregnant patients (see Chap. 211).

With contemporary medical management, fetal loss is less frequent, although the literature reports a high fetal mortality rate in patients treated for DKA. It is not uncommon to find pathologic patterns of fetal heart rate during DKA; these tend, however, to improve as maternal status improves. Steps should be taken to improve uterine blood flow, such as administration of oxygen and left lateral uterine displacement.

Up to 45 percent of insulin-dependent diabetics will require evaluation for severe hypoglycemia at some time during the course of their pregnancy.² Hypoglycemia generally presents as sweating, tremors, blurred or double vision, weakness, hunger, confusion, paraesthesias, anxiety, palpitations, nausea, headache, or stupor. Hypoglycemic episodes generally are well tolerated by the fetus. Mild hypoglycemia—that is, a glucose level of less than 70 mg/dL—in a patient who is able to follow commands can be treated by administration of 1 cup of low-fat milk together with bread or crackers every 15 min. This regimen is preferred over more highly concentrated glucose solutions because it avoids "overshoot" and subsequent hyperglycemia. In patients who are unable to cooperate with oral therapy owing to severe hypoglycemia, parenteral therapy may be begun using one ampule (50 mL) of a D50W solution given via intravenous push. Alternatively, the patient may be treated using glucagon 1 to 2 mg IM or SQ. In addition, intravenous therapy should be instituted with D5W at a rate of 50 to 100 mL/h. Consideration should be given to the avoidance of subsequent hyperglycemia from glycogen mobilization with acute glucose administration. The goal is normoglycemic control without wide swings.

HYPERTHYROIDISM

Hyperthyroidism in pregnancy is associated with an increased risk of preeclampsia and neonatal morbidity, including low birth weight and possibly congenital malformations. Symptoms of hyperthyroidism closely mimic symptoms of normal pregnancy and may consist of nervousness, palpitations, heat intolerance, and inability to gain weight despite a good appetite. Thyrotoxicosis in pregnancy also may present as hyperemesis gravidarum.

Hyperthyroidism in pregnancy is treated with propylthiouracil (PTU). The time to onset of action of PTU is generally 4 to 6 weeks to achieve maximum effect. PTU is started at a dose of 100 to 150 mg three times a day and increased as needed to a maximum dose of up to 200 mg three times a day. The goal of therapy is to maintain a free triiodothyroxine (T₄) level at the upper range of normal. Approximately

2 percent of patients taking PTU will experience a mild purpuric skin rash within the first 4 weeks of therapy. If this occurs, the PTU should be stopped and replaced with methimazole. Agranulocytosis occurs in about 0.3 percent of patients treated with PTU. If agranulocytosis develops, the PTU should be stopped, and methimazole should not be started.

THYROID STORM

Patients with thyroid storm present with fever, volume depletion, cardiac decompensation. Thyroid storm has been associated with a mortality rate of up to 25 percent. Patients are treated with IV fluids, oxygen, antipyretic agents, and PTU 400 mg PO every 8 h and sodium iodide 1 g in 500 mL of IV fluid each day. Long-term use (>10 days) of sodium iodide results in a high incidence of fetal goiter and hypothyroidism. Propranolol 40 mg PO every 6 h is administered unless evidence of cardiac failure is present. Acetaminophen is used for treatment of hyperthermia; a cooling blanket also may be used. Steps should be taken to improve uterine blood flow, such as administration of oxygen as well as maintenance of adequate maternal hydration and left lateral uterine displacement. **Radioactive iodine therapy is not used** because the fetus will concentrate iodine-131 after the tenth to twelfth week of gestation, and congenital hypothyroidism results.

HYPERTENSION

Hypertension in pregnancy can be divided into chronic hypertension and preeclampsia. In addition, patients with chronic hypertension not uncommonly develop superimposed preeclampsia. Preeclampsia is discussed elsewhere (see Chap. 106).

Chronic hypertension complicates 4 to 5 percent of all pregnancies. It is diagnosed by sustained elevation of arterial blood pressure to greater than 140/90 mm Hg before the twentieth week of gestation. Pharmacotherapy for pregnant hypertensive patients generally is started when the systolic blood pressure exceeds 160 mm Hg or the diastolic blood pressure exceeds 100 mm Hg. Commonly used agents for the treatment of chronic hypertension in pregnancy include amethyldopa (Aldomet), labetalol, and nifedipine. Antihypertensive agents that generally are not used in pregnancy include diuretics, because of their association with a reduction of uterine placental blood flow, and angiotensin-converting enzyme (ACE) inhibitors, owing to their teratogenic effects as well as fetal/neonatal hypotension and anuria. Maternal mortality associated with chronic hypertension is usually the result of severe hypertension and associated congestive heart failure or cerebrovascular accident. Fetal perinatal outcome is associated most closely with the development of superimposed preeclampsia or placental abruption. However, antihypertensive therapy has not been shown to alter the incidence of fetal complications.

Management of an acute hypertensive crisis in pregnancy is accomplished most commonly with IV labetalol (10 mg every 5 to 10 min up to a total dose of 300 mg). Hydralazine (5-10 mg every 15 min) given as IV bolus injections is an alternative still used by many obstetricians. The aim of antihypertensive therapy in pregnancy is to maintain the blood pressure between 140 and 150 mm Hg systolic and 90 and 100 mm Hg diastolic. Persistent blood pressure levels below this range may jeopardize placental perfusion. Acute intervention for blood pressure control should include fetal monitoring as well as careful assessment of fetal well-being. In all chronic hypertensives, the possibility of superimposed preeclampsia always must be considered (see Chap. 106).

DYSRHYTHMIAS

Significant cardiac dysrhythmias are rare in pregnancy. However, medications such as lidocaine, digoxin, and procainamide may be used for the usual indications and in the usual therapeutic doses and have

not been shown to be harmful to the fetus. Use of β -blockers for acute tachydysrhythmias has not been associated with adverse neonatal outcomes,³ but maintenance β -blockers are class C drugs that should be prescribed only in consultation with a cardiologist and obstetrician. Verapamil has been shown to be effective in the conversion of supraventricular tachycardia to sinus rhythm without adverse fetal effects. Anticoagulation using unfractionated or low-molecular-weight heparin for the treatment of atrial fibrillation in pregnancy appears safe and may be used if the patient meets the criteria for anticoagulation described for nonpregnant patients. Cardioversion also appears safe for the fetus.⁴ The presence of an artificial pacemaker has not been shown to affect the course of pregnancy.⁵

THROMBOEMBOLISM

The incidence of deep venous thrombosis (DVT) in pregnancy ranges between 0.5 and 0.7 percent.⁶ Factors associated with an increased risk of venous thromboembolism in pregnancy include advanced maternal age, increasing parity, multiple gestation, operative delivery, bed rest, obesity, history of previous thromboembolism, antithrombin III deficiency, protein S or protein C deficiency, and the lupus anticoagulant syndrome. Both DVT and PE occur during the antenatal period more than twice as often as during the post partum period^{6,7} and up to 30 percent may not have any identifiable risk.⁶ Those over 35 years also appear to be at greater risk.^{6,7}

The clinical diagnosis of DVT is similar in pregnant patients to that in nonpregnant patients. Pregnant patients commonly complain of swelling and leg discomfort; duplex Doppler studies should be done to confirm the diagnosis. Impedance plethysmography also may be used safely in pregnancy. **Iodine-125 fibrinogen scanning should not be used** because unbound iodine crosses the placental barrier and enters the fetal circulation, where it may concentrate in the fetal thyroid. Radionuclide venography using particles of technetium-99m is of no risk to the fetus and can be used to obtain studies of the lower extremity as well as to perform perfusion lung scans.

Diagnosis of pulmonary embolism in pregnancy is similar to that in the nonpregnant patient. Ventilation perfusion scans may be performed safely in pregnancy. No adverse fetal effects of xenon-133 or technetium-99m lung scanning have been reported. Pulmonary arteriography also may be performed in pregnant women if scanning is indeterminate. The diagnostic efficiency of spiral computed tomographic (CT) scanning has not been studied in pregnancy. Treatment for both DVT and pulmonary embolism in pregnancy is with intravenous heparin, with the goal of maintaining the partial thromboplastin time (PTT) of 11/2 to 2 times control. Low-molecular-weight heparin also may be used for both the prophylaxis and treatment of thromboembolic disease at a dose of 1 mg/kg enoxaparin SQ twice a day. Warfarin is not used in pregnancy because it crosses the placenta and is associated with embryopathy in the first trimester; in the second and third trimesters it may lead to a variety of central nervous system (CNS) and ophthalmologic abnormalities. Protamine sulfate may be used safely in pregnancy for patients who require rapid reversal of their heparin anticoagulation. Although there is minimal experience with the use of thrombolytic therapy in pregnancy, its use may be entertained in life-threatening situations.

ASTHMA

Asthma complicates between 0.4 and 1.3 percent of all pregnancies. In general, however, there are no differences in the outcome of pregnancies in well-controlled asthmatics versus the general population. Severe asthmatics with poorly controlled disease, however, do have a slight increase in the risk of preterm birth, stillbirth, and low-birth-weight babies. In approximately one-third of patients, asthma worsens in pregnancy; approximately one-third remain stable, and one-third improve.⁸

The presentation of asthma in pregnancy is similar to that of the nonpregnant state, with the usual triad of cough, wheezing, and dyspnea. Unfortunately, pulmonary embolism (PE) also can present with a similar symptom complex, and—as noted, because of the hypercoagulable state of pregnancy—pregnant women are at increased risk for PE. Therapeutic agents that are used safely in pregnancy include inhaled glucocorticoids, such as beclomethasone, and cromolyn sodium by inhaler. These agents are used as preventive therapy. For acute therapy of asthma exacerbations (β_2 -agonists such as salbutamol, metaproterenol, albuterol, and isoproterenol may be given via nebulizer. Intravenous methylprednisolone and oral prednisone can be used in pregnancy because they do not cross the placenta. Any time glucocorticoids are used, maternal hyperglycemia should be expected and considered in acute management (see "Diabetes" above). Epinephrine 0.3 mL (1:1000 dilution) can be given subcutaneously. Oxygen should be administered and titrated to maintain an arterial P_{O_2} of 65 mm Hg or greater. Fetal monitoring should be done after 20 weeks of gestation.

Clinical management of a pregnant asthmatic patient is best guided by the use of the peak expiratory flow rate to assess the severity of the obstruction and monitor the response to therapy. Peak expiratory flow rate is not altered, with mean peak expiratory flow rates in normal pregnant women ranging between 380 and 550 L per min. Peak expiratory flow rates do not change significantly as pregnancy progresses.⁹ Peak expiratory flow rates of less than 100 L per min or that demonstrate less than 10 percent improvement with treatment are a sign of a potentially poor prognosis. Aggressive management is warranted.

Normal values of arterial blood gases are changed during pregnancy. The normal maternal P_{O_2} ranges between 101 and 108 mm Hg early in pregnancy and falls to 90 to 100 mm Hg near term. The normal P_{aCO_2} in pregnancy ranges from 27 to 32 mm Hg, and the normal pH ranges from 7.40 to 7.45. The patient should be placed in a near-sitting position with a leftward tilt because up to 25 percent of normal pregnant women in the third trimester will develop moderate hypoxia in the supine position. There should be a low threshold for obtaining arterial blood gas assessment as part of the evaluation of pregnant women with asthma, particularly patients who present with obvious hypoventilation and cyanosis whose asthma does not improve after initial therapy or who have a peak flow of less than 200 L/min.⁹ Goals of therapy include maintenance of a P_{O_2} at greater than 65 mm Hg or an oxygen saturation of greater than 95 percent on an F_{IO_2} of 35 to 60 percent.

Indications for intubation of the pregnant asthmatic with status asthmaticus include (1) inability to maintain the P_{aO_2} at greater than 65 mm Hg (90 percent hemoglobin saturation) despite supplemental oxygen, (2) inability to maintain a P_{aCO_2} at less than 40 mm Hg, (3) evidence of maternal exhaustion, (4) significant respiratory acidosis (pH <7.20-7.25) refractory to initial management with bronchodilator therapy, and (5) altered mental status.¹⁰ Standard agents for rapid-sequence intubation can be used.

Medications for asthma that may have adverse fetal effects include iodides, which may be associated with neonatal hypothyroidism and goiter, as well as sodium bicarbonate, which, without adequate ventilation, can diminish the transfer of carbon dioxide from the fetus to the mother. Glucocorticoids also may cause alterations in carbohydrate metabolism, although this is a secondary concern in the acute setting. Essentially, acute management should be guided by consideration for the mother. The best outcome for the developing fetus is based on optimal treatment of the mother.

CHRONIC RENAL DISEASE

Maternal risks associated with renal disease are linked to the degree of renal compromise. As renal function diminishes, fertility decreases. Pregnancy rarely occurs in women who have a preconception serum creatine level of greater than 3 mg/dL. Preterm delivery and superim-

posed preeclampsia frequently complicate pregnancies of patients with underlying renal disease. Patients with chronic pyelonephritis may have an increased number of recurrences due to bacteriuria, increased glucosuria, and mechanical compression of the ureter in the third trimester. Those with a history of reflux nephropathy are at increased risk of sudden escalating hypertension and worsening renal function. Urolithiasis is associated with more frequent urinary tract infections. Patients with lupus nephropathy are at greatly increased risk for exacerbations of the disease and superimposed preeclampsia, particularly if their disease was not in remission for at least 6 months prior to conception.

CYSTITIS AND PYELONEPHRITIS

The increased urinary stasis associated with pregnancy makes the urinary tract the most common point of infection during pregnancy. After midpregnancy, mild right-sided hydronephrosis can be found in 75 percent of patients, and mild left-sided hydronephrosis is seen in 33 percent of patients. Asymptomatic bacteriuria is present in between 2 and 10 percent of pregnant women.^{11,12} Acute cystitis occurs in about 1 to 2 percent of pregnant women,¹³ acute pyelonephritis occurs in approximately the same percent of all pregnancies.¹⁴ The presentation of both cystitis and pyelonephritis is similar in pregnant and nonpregnant women. Causative organisms are similar to those in the general population, with *Escherichia coli* being the etiology in approximately 75 percent and *Klebsiella pneumoniae* or *Proteus* being responsible for 10 to 15 percent. It is not uncommon for acute pyelonephritis to precipitate preterm labor. Therefore, prompt therapy is needed. In addition, pregnant women are at increased risk for the development of bacteremia and septic shock as compared with the nonpregnant population.¹⁴

Patients with simple cystitis may be treated with a 3-day course of oral nitrofurantoin, ampicillin, or a cephalosporin. Because of the low prevalence of resistance of urinary pathogens to nitrofurantoin, this agent is generally the preferred method of therapy. Trimethoprim, a folate antagonist, is used by many obstetricians after the first trimester. **Single-dose antibiotic therapy is not used for the treatment of cystitis in pregnant patients** owing to the high rate of treatment failure.

Treatment of pregnant patients with pyelonephritis is much more intense than that of nonpregnant patients. Approximately 10 to 15 percent of pregnant patients with pyelonephritis become bacteremic,¹⁵ and 2 to 8 percent will develop respiratory insufficiency from acute lung injury.¹⁶ Due to the high rate of complications, patients are generally hospitalized, aggressively hydrated, and treated with intravenous antibiotics. The intravenous antibiotics of choice are generally a second or third generation cephalosporin. Intravenous antibiotics are continued until the patient is afebrile for at least 48 h, and costovertebral angle tenderness has resolved. Patients are then discharged home on oral antibiotics to complete a 10-day course of therapy. Many providers choose to continue women with a history of pyelonephritis during the course of their pregnancy on antibiotic suppression for the remainder of their pregnancy. This generally is accomplished using nitrofurantoin at a dose of 50 to 100 mg per d.

INFLAMMATORY BOWEL DISEASE

Pregnant patients with inflammatory bowel disease are at increased risk for nutritional and metabolic abnormalities that may put the fetus at increased risk for intrauterine growth restriction. Pregnancy itself, however, seems to have little effect on inflammatory bowel disease. When an exacerbation does occur during pregnancy, it happens most frequently in either the first trimester or the postpartum period. It is hypothesized that this is due to a correlation with levels of circulating corticosteroids during pregnancy.

In general, treatment of the pregnant patient with inflammatory bowel disease is the same as that of the nonpregnant patient. Antidiar-

rheal drugs including codeine, opium, paregoric, and Lomotil also may be used safely in pregnancy. While sulfasalazine and corticosteroids may be used safely in pregnancy, the possibility of the development of gestational diabetes must be considered in all patients on steroid therapy. Sulfa drugs are theoretically contraindicated in the third trimester due to concerns about neonatal hyperbilirubinemia, but they are used fairly commonly by obstetricians without adverse effect. It is important to supplement women who are taking sulfasalazine with folic acid because sulfasalazine is known to inhibit the absorption and metabolism of folate. The use of suppressive therapy with azathioprine or 6-mercaptopurine has been reported to be safe during pregnancy, but experience with these agents is very limited. Total parental nutrition is a potentially useful adjunct to therapy in some patients who have severe nutritional deficiencies, and it may be used safely in pregnancy. Metronidazole for the treatment of perianal fistulas in patients with Crohn disease is generally not recommended until after completion of the first trimester.

SICKLE CELL DISEASE

Women with sickle cell disease are at increased risk for miscarriage, preterm labor, and other complications due to impaired oxygen supply and sickling infarcts in the placental circulation. Pregnant women are at increased risk for vascular occlusive events, particularly during the third trimester and the postpartum period. Painful crises present similarly in the pregnant and the nonpregnant state. Treatment of painful crises in pregnancy is similar to that for nonpregnant patients. Cornerstones of management include aggressive hydration and analgesic therapy. Both oral and intravenous narcotics can be used. Caution should be exercised when using nonsteroidal anti-inflammatory agents, particularly after 32 weeks of gestation, because of oligohydramnios and a significant risk of premature closure of the fetal ductus arteriosus. Hydroxyurea should not be used in pregnancy because of its teratogenic effects. Sickle cell crisis that does not respond to conservative management is commonly managed using partial exchange transfusion via automated erythrocytapheresis. Simple transfusion alone can be helpful when the hemoglobin level is less than 6 g/dL.¹⁷ The incidence of fetal death in utero can be minimized during sickle cell crisis by using information from continuous electronic fetal monitoring in a woman with a potentially viable fetus. While fetal heart rate patterns frequently are nonreassuring during the acute episode of vasoocclusive crisis, fetal heart rate patterns tend to normalize as the crisis improves. In utero resuscitation (oxygen, intravenous hydration, left lateral uterine displacement) should be initiated prior to consideration of emergency delivery.

While the majority of sickle cell crises in pregnancy are vasoocclusive crises, aplastic crises present a unique problem because they usually are caused by parvovirus B19 infection, which has been associated with hydrops fetalis. This disease thus presents a risk to both the pregnant woman and her fetus. Careful sonographic fetal assessment should be performed to evaluate the fetus for evidence of parvovirus infection. Once patients with sickle cell disease has been exposed to parvovirus B19, they are unlikely to acquire the infection a second time due to acquired immunity.¹⁸ Thus, the pregnant patient with a past history of aplastic crisis is unlikely to experience it again.

MIGRAINE

Pregnancy usually improves classic migraines. However, when migraines do occur, they are difficult to treat because ergot alkaloids should not be used and there has been little experience with the use of sumatriptan in pregnancy. Treatment therefore rests on the use of analgesics and antiemetic agents. Acetaminophen, codeine, and meperidine all have been shown to be safe for use in pregnancy.

Prophylactic therapy using (3-blockers such as propranol (40-160 mg per d) or atenolol (50-100 mg per d) also effective.

SEIZURE DISORDERS

Seizure disorders occur in 0.15 to 1.0 percent of all women of child-bearing age. Seizure frequency tends to increase slightly in pregnancy because of the increased volume of distribution, an increase in plasma clearance, and poor medication compliance. Management of a pregnant patient with a known seizure does not differ from that of a nonpregnant woman. Consideration of potential adverse effects of anti-seizure medication mandates the use of single-drug therapy when possible. About half of patients will experience an increase in seizure frequency during pregnancy. Medication doses may need to be increased in pregnancy; however, the serum therapeutic levels do not change. The use of valproic acid generally is avoided in early pregnancy because of its association with 1 to 3 percent risk of neural tube defects.

A single maternal grand mal seizure may be followed by fetal bradycardia lasting for up to 20 min. While transient maternal hypoxia and acidosis are potential threats to the fetus, there is usually no apparent harm caused by isolated seizures. Steps should be taken to optimize the intrauterine environment, including administration of oxygen and left lateral uterine displacement. In contrast, status epilepticus poses a real threat to both mother and the fetus, with 50 percent of fetuses and 33 percent of mothers not surviving the event. Aggressive management with intubation and ventilation should be considered early in the management of pregnant women with status epilepticus.

HUMAN IMMUNODEFICIENCY VIRUS (HIV) INFECTION

All pregnant HIV-infected patients beyond 14 weeks' gestation should be on zidovudine therapy in an effort to decrease the risk of vertical transmission. Randomized clinical trials of zidovudine have documented a reduction in the vertical transmission rate from 25 to 8 percent.¹⁹ Pregnancy does not appear to alter the natural course of HIV disease,¹⁹ nor do uninfected babies born to HIV-positive women appear to be at increased risk for neonatal complications when compared with appropriate control patients. Patients with CD4⁺ T-cell counts of less than 200/pX should be maintained on prophylaxis for *Pneumocystis carinii* pneumonia using trimethoprim-sulfamethoxazole (TMP-SMX; Bactrim DS). The risks and benefits of TMP-SMX therapy should be weighed if needed during the first trimester. Folate supplementation may be appropriate if benefit appears to outweigh risk. Alternatively, aerosolized pentamidine also may be used in pregnant patients. Treatment of overt opportunistic infections in HIV-infected pregnant women should be addressed just as in those who are not pregnant. Patients may present with respiratory insufficiency. The prompt initiation of artificial ventilation in such patients may improve the intrauterine environment and therefore the outcome for the fetus.

SUBSTANCE ABUSE

All pregnant women identified in the ED as substance abusers should be referred to a high-risk obstetrics clinic and be offered substance-abuse counseling.^{20,21} The incidence of a positive urine toxicology test for cocaine ranges from 4 to 76 percent in urban and suburban hospitals. However, when hair analysis is employed, cocaine exposure can be identified by up to four times more.^{22,23} Cocaine use has been associated with an increased risk of placental abruption and fetal death in utero as well as an increased risk of intrauterine growth restriction, preterm labor, premature rupture of membranes, spontaneous abortion, and cerebral infarcts in the fetus. Maternal complications of cocaine use include myocardial infarction, hypertension (which can

result in aortic dissection), pulmonary edema, and cardiac dysrhythmias. Subarachnoid hemorrhage, ruptured aneurysms, and strokes all have been reported in cocaine users and are most likely related to transient hypertension. Treatment of acute cocaine intoxication is handled in the usual manner.

Pregnant women in opiate withdrawal are currently treated with methadone or clonidine. There is currently insufficient evidence regarding the use of buprenorphine in pregnancy. Pregnant women should not have methadone discontinued during pregnancy because it may increase the risk of fetal death in utero and tends to decrease compliance with prenatal care. Patients in withdrawal may be treated with clonidine 0.1 to 0.2 mg sublingually every hour up to 0.8 mg until signs of withdrawal resolve. The maintenance dose is then 0.8 to 1.2 mg per d in divided doses for the first 7 days and tapering for the following 3 days.

The incidence of alcohol abuse during pregnancy is difficult to determine because most studies have been limited to single hospitals or urban settings, but it probably ranges between 1 and 2 percent. In the largest study, almost 7 percent of women had detectable alcohol in urine samples taken at the time of delivery.²⁴ It is felt that two or more drinks a day may contribute to increased rates of spontaneous abortion, low-birth-weight infants, preterm deliveries, and perinatal mortality. Alcohol use in pregnancy can result in fetal alcohol syndrome. The incidence of fetal alcohol syndrome is difficult to characterize due to significant differences in patient populations studied and methods used. However, it is likely in the range of 0.1 to 0.3 percent of live births. Patients who present in coma due to acute alcohol intoxication or in alcohol withdrawal are managed similarly to nonpregnant patients. Short-acting barbiturates such as pentobarbital can be used for withdrawal, although benzodiazepines should be avoided in early pregnancy if at all possible because of possible teratogenicity. Disulfiram (Antabuse) is a potential teratogen and should be avoided in pregnancy.

DOMESTIC VIOLENCE

Between 14 and 17 percent of pregnant women experience domestic violence during the course of their pregnancy.^{25,26} It is a particularly vulnerable time during which "intimate violence" may escalate. Late entry into prenatal care, unintended pregnancy, drug and alcohol use, depression, and housing problems have all been associated with an increased risk of domestic violence. Pregnant women who are the victims of domestic violence are at an increased risk for placental abruption, fetal fractures, uterine rupture, and preterm labor. It is imperative to keep a high index of suspicion and be prepared to initiate appropriate referrals to social service and law enforcement agencies. In addition, for Rh-negative women who have experienced blunt abdominal trauma, consideration should be given to the administration of Rhogam to prevent isoimmunization (see Chap. 106 for a detailed discussion).

MEDICATIONS FOR CONCURRENT ILLNESS DURING PREGNANCY AND LACTATION

The classic teratogenic period is from day 31 after the first day of the last menstrual period (LMP) in a 28-day cycle to 71 days from the LMP. During this critical time, organs are forming, and teratogens may cause overt malformation. Administration of drugs early in the period of organogenesis will affect the organs developing then, such as the heart or neural tube. Closer to the end of the classic teratogenic period, the ear and palate are forming and may be affected by a teratogen.

Before day 31, exposure to a teratogen produces an all-or-none effect. With exposure around conception, the conceptus usually either does not survive or survives without anomalies. If the organism remains viable, organ-specific anomalies do not develop because repair or replacement permits normal development. A similar insult at a later stage may produce organ-specific defects; after the first trimester, chronic exposure may produce growth restriction.

The Food and Drug Administration (FDA) lists five categories of labeling for drug use in pregnancy (see Table 104-1 in Chap. 104).

Table 105-1 lists medications for acute or chronic illness to be avoided in pregnancy. Table 104-2 briefly summarizes medications that are generally considered safe during pregnancy. Table 105-2 lists medications to be avoided during lactation, as well as those generally considered safe during breastfeeding.

COMPLICATING EFFECTS OF RADIATION

The major factor determining the degree of risk to the fetus in an imaging technique is the amount of ionizing radiation involved in the test. Exposure to ionizing radiation occurs with plain x-ray films, angiography, fluoroscopy, nuclear medicine, and computed tomography (CT). Nonionizing studies include magnetic resonance imaging (MRI) and ultrasound.

The risks of radiation exposure vary with gestational age. The predominant deterministic effect due to exposure during the first 2 weeks of pregnancy is resorption of the embryo. The second to eighth week postconception is the period of organogenesis. Significant x-ray exposure during this period may result in teratogenesis (birth defects). Examples include gross malformation and growth restriction, the latter of which can occur both at term and later at adulthood. Neuropathology and small head size also may occur as a result of significant exposures during weeks 2 to 8.

The embryo has developed into a fetus at about the seventh to eighth week, and neurologic development occurs during the next 7 weeks. Significant x-ray exposure at this time (between weeks 8 and

TABLE 105-1 Therapeutic Agents Commonly Used in Emergency Settings with Known Adverse Effects in Human Pregnancy

Drug	Effect
ACE inhibitors	Renal failure, oligohydramnios
Aminoglycosides	Ototoxicity
Androgenic steroids	Masculinize female fetus
Antibiotics	
Erythromycin estolate	Maternal hepatotoxicity
Fluoroquinolones	Fetal cartilage abnormality
Kanamycin	Fetal cranial nerve VIII damage
Metronidazole	Fetal midline facial defects (1st trimester)
Streptomycin	Fetal cranial nerve VIII damage
Sulfonamides	Fetal hemolysis, neonatal kernicterus (near term)
Tetracyclines	Fetal teeth and bone abnormalities
Triniethoprim	Folate antagonist (1st trimester)
Anticonvulsants	Dysmorphic syndrome, anomalies
Antithyroid agents	Fetal goiter
Aspirin	Bleeding, antepartum and postpartum
Cytotoxic agents, i.e., methotrexate	Multiple anomalies
Isotretinoin	Hydrocephalus, deafness, anomalies
Lithium	Congenital heart disease (Ebstein anomaly)
Methotrexate	Anomalies
Nonsteroidal anti-inflammatory drugs (prolonged use after 32 weeks)	Oligohydramnios, constriction of fetal ductus arteriosus
Thalidomide	Phocomelia
Warfarin	Embryopathy—nasal hypoplasia, optic atrophy

15) may result in mental restriction, small head size, and decreased IQ. Other possible but less likely effects due to significant exposure during this period include growth restriction as an adult and sterility. Even less likely but still possible are cataracts, neuropathology, and growth restriction at term.

Most of the deterministic effects just mentioned are either not observed or observed much less frequently when the fetus receives a significant radiation dose beyond 15 weeks after conception. Mental retardation has been observed as a result of significant exposure during the eighth to twenty-fifth weeks but not beyond. Other effects that have been observed because of exposure after week 15 include sterility and growth restriction as an adult. Less likely effects that have been demonstrated are cataracts, neuropathology, and growth retardation at term.

The most recent evidence suggests that 10 rad is a threshold for human teratogenesis, and the fetus appears to be most vulnerable at 8 to 15 weeks' gestation.²⁷ However, cumulative doses from multiple procedures may enter the harmful range. The radiation doses involved in commonly used diagnostic tests are given in Table 105-3.

A common nuclear medicine imaging study used by the ED physician is the ventilation-perfusion scan. Total fetal exposure to xenon-133 and technetium-99m is about 0.5 rad, and they can be used safely in pregnancy. Fetal exposure from other studies using technetium-99 range from 0.03 to 0.06 rad/mCi and is safe in pregnancy. Because the excretion of these radionuclide particles is often via the maternal bladder, which is close to the fetus, hydration and frequent voiding need to be encouraged.

The two nonionizing imaging studies used frequently are ultrasound and MRI. Ultrasound has been extensively studied over the past 25 years and has no known teratogenic effect. There is much less experience with MRI, but thus far there are no known harmful effects.

TABLE 105-3 Radiation Exposure to the Uterus/Fetus

Dosage, rad	Procedure
0.00005	Chest radiography (two views) with shielding of the maternal abdomen.

EMERGENCIES DURING PREGNANCY AND THE POSTPARTUM PERIOD

Gloria J. Kuhn

While the majority of pregnancies in the United States result in the delivery of a healthy infant from a healthy mother, there are conditions that can complicate the natural course of pregnancy. The birth rate in 2000 was 14.8 births per 1000 population, an increase of 2 percent from 1999.¹ This translates to a large population of patients who may require emergency care. This chapter discusses diseases that have the potential of complicating pregnancy and increasing morbidity and mortality rates for either the mother or the fetus.

MORTALITY AND MORBIDITY RATES

One of the national health objectives for the year 2000 was to reduce the overall *maternal mortality ratio* (MMR), defined as the number of maternal deaths per 100,000 live-born infants, to no more than 3.3. However, during 1982-1996, the MMR remained at approximately 7.5.² An increase was seen among women of all races. A higher risk of pregnancy-related death is associated with increasing maternal age, increasing live-birth order, absent prenatal care, unmarried status, and minority race.²

Direct maternal death includes the death of the mother due to obstetric complications of pregnancy, labor, or the puerperium. Indirect maternal death includes death not directly due to obstetric causes but resulting from previously existing disease or a disease that developed during the gravid period or was exacerbated by the pregnancy.

The black-white mortality rate differential is greatest for diseases seen in the first trimester: ectopic pregnancy, spontaneous abortion,

induced abortion, and gestational trophoblastic disease (GTD). Maternal mortality rates remain stable despite evidence that many maternal deaths are preventable.⁴ The leading causes of pregnancy-related deaths are hemorrhage, pulmonary embolism (mostly thromboembolic), and hypertensive disorders of pregnancy (leading to cerebrovascular accident).³

EMERGENCIES DURING THE FIRST HALF OF PREGNANCY

While pregnancy is usually considered in terms of trimesters, when discussing patterns of emergencies, dividing pregnancy into halves is advantageous. Emergencies during the first half include ectopic pregnancy, vaginal bleeding, GTD, urinary tract infection (UTI), and hyperemesis gravidarum.

Vaginal Bleeding

The differential diagnosis of vaginal bleeding during the first trimester is shown in Table 106-1. Any woman of childbearing age who presents with a chief complaint of abdominal pain or vaginal bleeding and has not had a hysterectomy should be tested for pregnancy. If a serum or urine pregnancy test result is positive, further evaluation, particularly for ectopic pregnancy or spontaneous abortion, is indicated. Ectopic pregnancy is discussed in Chap. 103. Women of childbearing age with syncope, hypotension, or mental status changes should have pregnancy testing and ectopic pregnancy considered within the differential diagnosis.

Abortion

The World Health Organization (WHO) defines spontaneous abortion as loss of pregnancy before 20 weeks or loss of a fetus weighing less than 500 g. Estimates of pregnancies that abort spontaneously range from 20 to 40 percent. About 75 percent of spontaneous abortions occur before 8 weeks of gestation. *Threatened abortion* is defined as pregnancy-related bloody vaginal discharge or frank bleeding during the first half of pregnancy without cervical dilatation. *Inevitable abortion* will occur in the face of vaginal bleeding and dilatation of the cervix. *Incomplete abortion* is defined as passage of only parts of the products of conception and is more likely to occur between 6 and 14 weeks of pregnancy. *Complete abortion* is passage of all fetal tissue, including trophoblast and all products of conception, before 20 weeks of conception. *Missed abortion* is a fetal death at less than 20 weeks without passage of any fetal tissue for 4 weeks after fetal death. *Septic abortion* is evidence of infection during any stage of abortion.

The most common cause of fetal wastage is chromosomal abnormalities, accounting for 50 to 60 percent of all losses. Related and other risk factors include advanced maternal age, prior poor obstetric history, concurrent medical disorders, previous abortion, certain infections (including syphilis and HIV), and some anatomic abnormalities of the upper genital tract. Exposure to some agents, such as certain anesthetic agents, certain heavy metals, and tobacco, is also thought to contribute to the incidence of abortion.

A pelvic examination is mandatory as part of the history and physical examination in order to define the type of abortion, determine the

*Very common.

amount and site of bleeding, whether the cervix has dilated, and whether any tissue has been passed. The amount of bleeding as pads used per hour, last menstrual period, and past medical and obstetric history should be part of the history obtained.

A complete blood count (CBC), blood type, Rh factor and antibody screen, urinalysis (UTI has been associated with increased fetal wastage), and quantitative serum beta human chorionic gonadotropin ((3-hCG) level should be obtained. Vaginal ultrasound studies should be performed to rule out ectopic pregnancy, as a prognostic tool for fetal viability, and to diagnose retained products of conception.

If the patient is bleeding heavily, a Yankauer suction tip is useful to suction blood from the vaginal vault. All material in the vaginal vault should be examined to determine whether it is blood clot or products of conception. Products of conception should be sent for pathologic examination. If tissue is protruding from the cervical os, its careful removal with ring forceps may allow the os to close and decrease bleeding. However, care must be taken to ensure that the tissue is not the rare cervical ectopic pregnancy. If profuse bleeding continues in the face of inevitable abortion, 20 units of oxytocin can be added to 1 L of NS solution and infused at 150 to 200 mL per h to obtain hemostasis until dilatation and curettage (D&C) can be arranged. If hemodynamic instability is present, fluid resuscitation should be started immediately.

The quantitative (3-hCG analysis may be very helpful. The beta-subunit of hCG is first detectable as early as 9 to 11 days following ovulation (usually 24 days after the last menstrual period) and reaches 200 IU/mL at the expected time of menses.⁵ An abnormally high P-hCG level suggests advanced pregnancy, multiple gestation, GTD, or rarely, an ovarian tumor.

Ultrasound studies combined with determinations of (3-hCG levels can be both diagnostic and prognostic. If the 3-hCG level is greater than 1,500 IU/mL, an intrauterine gestation should be visible using transvaginal technique. (Note: The 1500 IU/mL is somewhat arbitrary and the value is set at each institution. In some institutions, the value is set at 1000 IU/mL or even lower.) A yolk sac is seen at 36 days, and a heartbeat is noted 41 to 47 days after the last menstrual period. Gestational sacs with a mean diameter greater than 25 mm without an embryo or greater than 20 mm without a yolk sac are definitely abnormal, and loss of pregnancy will result.⁵

Patients with a diagnosis of threatened abortion can be discharged safely if close follow-up is ensured. While low level of activity and even bed rest are sometimes advised, there is no proven effectiveness of this practice. Generally speaking, a miscarriage cannot be avoided. Intercourse and tampons are to be avoided to minimize likelihood of infection. The patient with an incomplete abortion should have the uterus evacuated. The patient with a complete abortion, as shown by ultrasound and/or complete passage of products of conception, can be discharged safely after follow-up is ensured to ascertain that the bleeding has stopped. If there is any doubt, obstetrics consultation for possible D&C should be initiated. The patient with a nonviable fetus can be either admitted or discharged to be followed up within a week by her physician, depending on the comfort level of the patient and physician with this decision. Warnings should be given to return immediately if there is heavy bleeding (more than one pad per hour for 6 h), pain, or fever.

If unsensitized, all pregnant patients with vaginal bleeding who are Rh-negative should be treated with Rh₀ (D) immune globulin (Rhogam). Because the total fetal blood volume at 12 weeks is less than 4.2 mL, the volume of fetal blood for admixture during the first trimester is small. Some authorities suggest using only 150 μ g Rhogam, and others recommend a dose as small as 50 μ g. There is no uniform agreement, and many continue to recommend the full dose. This is discussed in detail in Chap. 254. Ideally, Rhogam should be administered prior to discharge, but it also can be administered within 72 h by the primary care physician or obstetrician when the woman presents several days or weeks after vaginal bleeding has begun.

Gestational Trophoblastic Disease

GTD consists of a broad spectrum of conditions ranging from an uncomplicated partial hydatidiform molar pregnancy to stage IV choriocarcinoma with cerebral metastases. It is a neoplasm that arises in the trophoblastic cells of the placenta. It complicates 1 in 1700 pregnancies in North America and is more common in Asian women. The non-invasive form of the disease is the hydatidiform mole, which is either complete or partial. Complete moles are more common, and in this form there is no actual fetus, whereas in the partial mole a deformed, nonviable fetus is present. Both moles and invasive forms of GTD are composed of trophoblasts that produce P-hCG. Patients with a history of hydatidiform molar pregnancy are at increased risk of future molar pregnancies, with a risk of 1 percent in subsequent gestations after one molar pregnancy and a risk as high as 23 percent after two molar gestations.

Symptoms include vaginal bleeding in the first or second trimester (75 to 95 percent of cases) and hyperemesis (26 percent). GTDs, or molar pregnancies, that persist into the second trimester are associated with preeclampsia. When pregnancy-induced hypertension is seen prior to 24 weeks of gestation, the possibility of a molar pregnancy should be considered. The uterus is excessive in size for gestational age and shows a placenta with many lucent areas interspersed with brighter areas on ultrasound study. Since not all molar pregnancies are found on ultrasonography, all tissue extracted from the uterus on suction curettage or during pelvic examination should be sent for histologic examination.⁶ If GTD is suspected because of abnormally high 3-hCG levels, a uterine size either larger or smaller than expected, and ultrasound findings suggestive of the diagnosis, obstetric consultation should be obtained. Treatment is by suction curettage in the hospital setting because of risk of hemorrhage. [3-hCG levels that fail to decrease after evaluation are evidence of persistent or invasive disease necessitating chemotherapy. Metastasis to lung, liver, and brain may occur, but the prognosis for most patients is very good. Trophoblastic embolization, although extremely rare, may occur, with resulting rapid onset of respiratory distress resembling amniotic fluid embolus.

Nausea, Vomiting, and Hyperemesis Gravidarum

Nausea and vomiting of pregnancy (NVP) generally are seen in the first 12 weeks and affect 60 and 80 percent, respectively. Most cases are usually mild. The etiology is unknown, but NVP is thought to be associated with a protective function because some studies have shown a lower rate of miscarriages in women with NVP.⁷ Severe NVP is known as *hyperemesis gravidarum* and is defined as intractable vomiting with weight loss, volume depletion, and laboratory values showing hypokalemia or ketonemia. It occurs in up to 2 percent of all pregnancies. Patients with GTD also may present with intractable vomiting. The cause is not known. Women who lose more than 5 percent of prepregnancy body weight have an increased risk of intrauterine growth restriction and low-birth-weight infants.

The presence of abdominal pain in NVP or hyperemesis gravidarum is highly unusual and should suggest another diagnosis. Ruptured ectopic pregnancies occasionally present with nausea and vomiting as well as diarrhea and abdominal pain. After the first trimester, the volume of the gallbladder increases during fasting and after contraction after a meal. Also, biliary sludge seems to increase in pregnancy in 30 percent, predisposing to stone formation. Cholelithiasis and cholecystitis are more common in pregnant women than in women of comparable age and health status who are not pregnant. Differential diagnosis of vomiting or vomiting with abdominal pain should include cholecystitis, cholelithiasis, gastroenteritis, pancreatitis, hepatitis, peptic ulcer, pyelonephritis, ectopic pregnancy, and fatty liver of pregnancy, and HELLP syndrome (see below).

Findings on physical examination in NVP are usually normal except for signs of volume depletion. Laboratory tests to consider include

CBC, determination of serum electrolytes, BUN, creatinine, and urinalysis. The finding of ketonuria is important because it is an early sign of starvation. However, there is no evidence in the literature that ketosis per se is harmful to the fetus. Serial measurements of urinary ketones can be used to determine success of therapy.

Treatment consists of intravenous fluids containing 5% glucose in either LR or NS to replete volume and reverse ketonuria. A number of antiemetic drugs can be used (Table 106-2) for patients who remain nauseated or continue to vomit. Initially, the patient should be given nothing by mouth. Oral fluids should be started after the nausea and vomiting are controlled but prior to discharge.

The patient may be discharged after reversal of ketonuria, correction of electrolyte imbalance, and a successful trial of oral fluids. Discharge with antiemetic medication is usually necessary. There is no clear drug of choice.

Phenothiazines have the disadvantage of causing drowsiness or dystonic reactions in some patients. Ondansetron (Zofran) (8 mg IV or 4 mg PO three times daily) can cause headache, constipation, diarrhea, or light-headedness. It does not cause dystonia. Its chief disadvantage is cost. It is apparently no more effective than promethazine.⁸ Bendectin (doxylamine and pyridoxine), a mainstay of therapy in the past, was discontinued due to fears of teratogenicity, but recent information suggests it does not represent an increase in fetal risk.⁹

Admission guidelines include uncertain diagnosis, intractable vomiting, persistent ketone or electrolyte abnormalities after volume repletion, and weight loss of over 10 percent of prepregnancy weight.

EMERGENCIES DURING THE SECOND HALF OF PREGNANCY

Hypertension, Preeclampsia, Eclampsia, and HELLP Syndrome

Hypertensive disorders of pregnancy remain the second most common cause of maternal death in the United States (after thromboembolic disease), accounting for 15 percent of maternal deaths. Hypertension is also implicated in abruptio placentae and in the birth of preterm and low-birth-weight infants. Hypertension during pregnancy is defined as

a blood pressure of 140/90 mm Hg or greater or a 20-mm Hg rise in the systolic or 10-mm Hg rise in the diastolic blood pressure. Thus **a normal-appearing blood pressure may in fact be in the preeclampsia range for a given patient.** Hypertension during pregnancy may be classified as (1) chronic hypertension, (2) preeclampsia superimposed on chronic hypertension, (3) transient hypertension, and (4) preeclampsia or eclampsia. Transient hypertension develops after the midtrimester, is mild, does not compromise the pregnancy, and regresses postpartum but may return in subsequent gestations.

Preeclampsia is the combination of hypertension and proteinuria with or without pathologic edema that occurs in the second half of pregnancy. The cause of preeclampsia is not known, but recent research suggests that there are fewer placental cytotrophoblasts in women who will develop preeclampsia. These do not invade as deeply, remaining in an early stage and failing to take on the characteristics of blood vessel cells.¹⁰ Whatever the placental abnormality, the end result is widespread vasospasm and endothelial injury. There is no test to detect women at risk for the disease, nor is there effective therapy to prevent preeclampsia. The disease complicates 5 to 10 percent of pregnancies. There are multiple risk factors (Table 106-3). It is a clinical diagnosis that includes persistent elevation of blood pressure to 140/90 mm Hg or higher after 20 weeks' gestation, proteinuria (urine protein concentration of 0.1 g/L or more in at least two random urine specimens collected 6 h or more apart or 0.3 g per d in a 24-h collection), and usually edema (Table 106-4). From the ED perspective, even a single blood pressure reading of 140/90 mm Hg or higher is sufficient to indicate further ED evaluation of preeclampsia (see below). Presenting complaints may include headache, visual disturbances, edema, or abdominal pain. It always occurs after 20 weeks of gestation unless GTD is present. **The treatment for preeclampsia is delivery of the fetus.** In mild preeclampsia (asymptomatic, trace protein only) the decision regarding delivery is more complicated. When the woman is less than 37 weeks' gestation, the question of whether the fetus is mature enough for delivery without significant morbidity arises. The decision is further complicated by the fact that uteroplacental blood flow is already reduced by about 50 percent by the time the patient develops clinical signs of preeclampsia. There are currently few data that have shown the value of antihypertensive medication to improve either maternal or fetal outcome in mild preeclampsia.

TABLE 106-2 Antiemetics

Antiemetic	Brand Name	FDA Category	Oral	Rectal	Intravenous
ACUTE INTERVENTION FOR BOTH N/V AND HG					
Promethazine	Phenergan	C	25 mg q4h	25 mg q4h	25-50 mg IV push 50 mg in 500 mL NS over 2 h
Prochlorperazine	Compazine		10mgq6-8h	25 mg q12h	10 mg over 2 rain Maximum of 40 mg q24h
Chlorpromazine	Thorazine	C	10-25 mg q4-6h	100mgq6-8h	25 mg in 500 mL NS at 250 mL/h
MAINTENANCE THERAPY FOR N/V					
Doxylamine with pyridoxine	Unisom		25 mg every evening		
	Vitamin B ₆		25 mg q8h

TABLE 106-3 Risk Factors for Development of Hypertension during Pregnancy

Nulliparity
Age >40 years
Prepregnancy hypertension
Chronic renal disease
African-American heritage
Diabetes mellitus
Multiple gestation
Gestational trophoblastic disease
Obesity
Previous history of preeclampsia

Severe preeclampsia is a systolic blood pressure of 160 mm Hg or greater systolic or 110 mm Hg or greater diastolic, proteinuria of at least 5 g/24 h, microangiopathic hemolysis, thrombocytopenia, elevated serum transaminase levels, uterine growth restriction, or symptoms of end-organ involvement such as headache, visual disturbances, or abdominal pain.

Eclampsia is the superimposition of seizures on preeclampsia or aggravated hypertension. Seizures are defined as eclamptic if they occur from the twentieth week of gestation to 7 days after delivery but have been reported as late as 1 month after delivery. All chronic hypertensive disorders, regardless of their cause, predispose to the development of preeclampsia or eclampsia. Blood pressure alone is not always a dependable indicator of severity of disease and must be evaluated in the context of other signs and symptoms." It should be remembered that during normal pregnancy, blood pressure decreases gradually to a nadir between 14 and 24 weeks and then increases to prepregnancy values in the third trimester.

The *HELLP syndrome* (an acronym for Hemolysis, elevated liver enzymes, and low platelets) is an important clinical variant of preeclampsia that has a predilection for the multigravid patient (in contrast with the primigravida, in whom preeclampsia is more common). In the HELLP syndrome, the blood pressure is variable and may not be elevated initially. This fact, combined with the usual complaint of epigastric or right upper quadrant pain, makes it easy to mistake the HELLP syndrome for other causes of abdominal pain, such as gastroenteritis, hepatitis, pancreatitis, or pyelonephritis. The HELLP syndrome should be considered in any pregnant or postpartum patient who presents to the ED with a chief complaint of abdominal pain. The diagnosis can be made based on clinical findings coupled with laboratory results (Table 106-5).

All patients with a sustained blood pressure of 140/90 mm Hg or greater and any symptoms that may be secondary to hypertension need emergency obstetric consultation and consideration for hospitalization. A patient with severe hypertension whose blood pressure is greater than 140/90 mm Hg and who has epigastric or liver tenderness, visual disturbance, or severe headache is managed in the same way as a patient with eclampsia, i.e., with administration of magnesium sulfate, antihypertensive drugs as needed, and delivery of the fetus. The dose of IV magnesium sulfate is 4 to 6 g over 15 min, followed by IV infusion of 1 to 2 g per h. Reflexes and serum magnesium

TABLE 106-4 Criteria for Hypertension, Preeclampsia, and Eclampsia

Hypertension	BP > 140/90 measured twice at least 6 h apart
Transient hypertension	BP > 140/90 without other signs of preeclampsia or eclampsia
Preeclampsia	BP > 140/90, or >20 mm Hg rise in systolic, or > 10 mm Hg rise in diastolic BP Proteinuria (300 mg/24 h or 1 g/mL) Generalized or pedal edema or weight gain of at least 5 lb over 1 week
Eclampsia	Above findings plus generalized seizure

TABLE 106-5 Laboratory Evaluation for Suspected Preeclampsia or HELLP Syndrome

Test	Findings in HELLP Syndrome
CBC and peripheral smear	Schistocytes
Platelet count	<100,000 but suspicious if <150,000
Liver function tests (AST, ALT)	Elevated but below levels usually seen in viral hepatitis (<500 IU/L)
Renal function tests	Normal or elevated BUN and creatinine levels
Coagulation profile	Abnormal

Abbreviations: ALT = alanine aminotransferase; AST = aspartate aminotransferase; BUN = blood urea nitrogen.

levels should be followed to avoid neuromuscular depression. Angiotensin-converting enzyme (ACE) inhibitors never should be used because of fetal side effects.

Complications of severe preeclampsia, HELLP syndrome, and eclampsia include spontaneous hepatic and splenic hemorrhage, end-organ failure, abruptio placentae, intracranial bleeding, and death of the fetus. Emergency obstetric consultation should be obtained, or transfer to a tertiary care hospital should be arranged as soon as the patient is stabilized.

Methyldopa is the drug used most often to treat pregnant patients with chronic hypertension because use of this drug does not adversely affect the fetus.¹¹ Dosage can be started at 250 mg every 6 h and titrated for control of blood pressure. Sedation may occur during initiation of therapy or when dosage is increased but usually is transient. Obstetric consultation should be obtained before beginning therapy because there is controversy over the efficacy of treatment of hypertension in the prevention of complications to mother and fetus.

Vaginal Bleeding During the Second Half of Pregnancy

The differential diagnosis of vaginal bleeding during the second half of pregnancy includes abruptio placentae, placenta previa, preterm labor, and bleeding from various lesions of the cervix and lower genital tract. One-third of fetuses die when vaginal bleeding occurs after 20 weeks of gestation.¹²

ABRUPTIO PLACENTAE *Abruptio placentae*, premature separation of the normally implanted placenta from the uterine wall, occurs in 1 percent of all pregnancies. It is one of the most dangerous complications for mother and fetus. It should be suspected when a gravid patient presents with the triad of sudden onset of antepartum vaginal bleeding, a tender uterus with increased resting tone, and hypertonic or hyperactive uterine contractions. However, patients may complain of nausea and vomiting or dizziness. Some patients have only mild abdominal cramping. This complication can occur either spontaneously or as the result of trauma to the abdomen. The spontaneous form is far more common, with hypertension the most common risk factor. Other risk factors include maternal trauma, increased maternal age, multiparity, smoking, cocaine use, and previous abruptions. Abruptio can be complete, partial, or concealed. If the abruptio is concealed (blood does not reach the cervical os), there may be only mild or no vaginal bleeding. Clinical signs and symptoms depend on the size of the abruptio, the amount of blood loss, and whether bleeding is evident. Fetal distress, hypotension, and disseminated intravascular coagulation can develop. Abruptio placentae frequently is misdiagnosed as preterm labor. Complications include fetal death, maternal death from hemorrhage or disseminated intravascular coagulation (DIC), fetomaternal transfusion, and amniotic fluid embolism. Separation of 50 percent or more of the total effective placental area usually results in fetal demise. Ultrasonography will allow the exclusion of placenta

previa as an etiology of vaginal bleeding but may not be diagnostic of abruption. Therefore, a high index of suspicion must be maintained in women with shock, an abnormally tender uterus, or hypertonic contractions. Laboratory tests that should be ordered include a CBC, type and crossmatch, coagulation profile, and renal function studies. Approximately 50 percent of patients will have laboratory evidence of a coagulopathy, as shown by thrombocytopenia, prolonged prothrombin time, hypofibrinogenemia, and elevated fibrin split products. A fibrinogen level of less than 200 mg/dL is abnormal, and bleeding may appear when the level is less than 100 mg/dL. DIC should be expected when the fibrinogen level is 150 mg/dL. Crystalloids should be given to maintain maternal volume status and fresh frozen plasma should be given for coagulopathy. Emergency obstetric consultation is necessary whenever abruption is suspected. Cardiotocodynamometry and ultrasound studies are used to monitor fetal well-being, and emergency delivery may be necessary. Tocolytics should not be given by the emergency physician in the presence of suspected abruption.

PLACENTA PREVIA Placenta previa, implantation of the placenta over the cervical os, accounts for 20 percent of bleeding episodes in the second half of pregnancy. Incidence is increased with multiparity and prior cesarean section. The patient presents with painless bright-red bleeding. This complication should be distinguished from the "bloody show" that is passage of a very small amount of bright-red blood mixed with mucus at the onset of labor. Disruption of the placenta by digital or speculum examination can lead to catastrophic bleeding. **Whenever placenta previa is considered within the differential diagnosis digital and speculum examination should be avoided.** The safest course is to perform an emergency abdominal ultrasound study first because ultrasound is between 93 and 98 percent accurate for diagnosis.¹³

PREMATURE LABOR AND PREMATURE RUPTURE OF MEMBRANES (PROM) *Preterm (premature) labor* is defined as labor prior to 37 weeks' gestation,¹⁴ whereas *premature rupture of membranes (PROM)* is rupture of membranes prior to onset of labor. Preterm labor occurs in 10 percent of deliveries and is the leading cause of perinatal death and disease, accounting for approximately 85 percent of neonatal deaths not due to lethal genetic or congenital abnormalities.

With advances in prenatal neonatal care, previable PROM includes those with membrane rupture before 23 to 24 weeks. Three major factors contribute to spontaneous or induced delivery before 34 weeks: (1) PROM, (2) spontaneous preterm labor without PROM, and (3) complications that jeopardize fetal or maternal health, mandating early delivery.

Many known factors are associated with preterm labor. More common ones include PROM, abruptio placentae, illicit drug use (particularly of cocaine and amphetamines), multiple gestations, polyhydramnios, cervical incompetence, and infection. Sexually transmitted diseases, including syphilis, gonorrhea, *Chlamydia*, and bacterial vaginosis, are two to three times more likely to be associated with preterm labor. The presence of low-grade infection is felt to be one of the most important causes of PROM because bacterial colonization can reduce the tensile strength of membranes. Of importance is the association of digital pelvic examinations and increased frequency of PROM. As a result of this finding, **cervical examinations should not be performed from 37 weeks' gestation unless the results of the examination clearly will influence clinical management.** All digital examinations during the latter portion of pregnancy performed for emergency reasons should be done using sterile gloves.

Labor is defined as regular uterine contractions resulting in progressive cervical effacement and dilatation. When a woman presents to the ED with the suspected onset of labor, the date of the last menstrual period should be ascertained and the estimated date of delivery calculated. The gestational age is the number of weeks from the first

day of the LMP. If that date is not known, gestational age can be estimated clinically (see Chap. 104). The patient should be asked about the frequency and duration of contractions, about passage of blood-stained mucus ("bloody show"), and whether there has been rupture of membranes, usually signaled by a gush of fluid or constant leakage of fluid.

In addition to the routine physical examination, the fundal height should be measured, fetal heart tones auscultated, and a sterile speculum examination performed. A pooling of fluid in the vaginal vault or leakage of clear fluid from the cervix in the absence of labor is evidence of PROM. If there is no fluid, the woman should be asked to press on the fundus or perform a Valsalva maneuver to determine whether there is leakage of fluid. Any fluid should be tested with nitrazine paper (pH > 6.5 indicates amniotic fluid) and swabbed on a glass slide to be examined for ferning, indicating amniotic fluid. The presence of blood or semen may interfere with both these tests. On visual examination, if the cervix is posterior in the vagina, thick, and closed, it is not yet ripe for labor. In this case, it may be better not to perform a digital examination, but if one must be done, use sterile technique. If, in contrast, it is midposition to anterior within the vagina, moderately effaced, and approximately 2 cm dilated, the uterus is undergoing changes preparatory to delivery. Tests for *Chlamydia*, gonorrhea, and group B streptococcus should be performed and secretions examined for bacterial vaginosis. If PROM is suspected or confirmed, digital examination should be deferred if possible or, if performed, should be done using sterile gloves.

A number of critical questions must be considered. Has PROM occurred? Is the woman in premature labor? What is the best estimate of gestational age? Is there fetal distress? Is the woman a candidate for tocolytic therapy? All women suspected of premature labor or PROM require obstetric consultation.

Viability of the fetus is possible before 23 weeks of gestation, but mortality and morbidity rates are extremely high. A number of drugs have been used to inhibit labor, but none are completely effective. Some are contraindicated, and there is potential for serious side effects (Table 106-6). Tocolysis was the third most common cause of adult respiratory distress syndrome and death in pregnant women in Jackson, Mississippi, over a 14-year period.¹⁵ Since tocolytic drugs can delay delivery by only a few days, the purpose of tocolytic therapy is to allow time for administration of glucocorticoids to speed fetal lung maturity.¹⁶ A typical agent and dose is betamethasone 12 mg IM q24h for 2 doses or dexamethasone 6 mg IM q6h for 4 doses and weekly thereafter. If a patient presents to an ED in preterm labor and the fetus is not mature enough to do well (prior to 34 weeks' gestation), the patient should be transported to a tertiary care facility that has a high-risk intensive care unit for mother and child.

Candidates for tocolysis are women in preterm labor between 24 and 34 to 36 weeks of gestation. Prior to 23 weeks, chances of survival of the fetus are remote and the probability of permanent disability high, but fetal viability at earlier gestational age is increasing, so the decision to begin tocolytic therapy is complicated. At about 25 weeks, even a 2-day increase in the length of gestation can add 10 percent to the likelihood of neonatal survival. Beyond 34 to 36 weeks, the infant should be mature enough to do well without specific treatment, and the possible side effects of tocolysis are to be avoided.

There is no clear protocol for management that results in a favorable outcome.^{17,18} The decision to institute tocolysis and the drugs used should be made by the obstetrician who can explain the risks and benefits to the patient (see Table 106-6). Tocolytics (Table 106-7) should not be given if abruption is suspected. The American College of Gynecology has issued a practice bulletin for the management of preterm labor.¹⁹

The value of antibiotics has not been elucidated clearly. Infection has been shown to be associated with both preterm labor and PROM, as well as fetal morbidity, but whether use of antibiotics can prevent these complications is not clear.^{18,20} Therefore, administration of an-

TABLE 106-6 Contraindications and Potential Complications to Tocolytics

Contraindications	Maternal Effects	Fetal and Neonatal Effects
(3-ADRENERGICS) Cardiac arrhythmias Poorly controlled thyroid disease Poorly controlled diabetes mellitus	Arrhythmias, ACS, CHF, hyperglycemia, hypokalemia, antidiuresis, altered thyroid function Physiologic tremor, nervousness, nausea and vomiting, fever, hallucinations	Fetal tachycardia, hyperglycemia, cardiac hypertrophy, cardiac ischemia Neonatal tachycardia, hypocalcemia, hyperbilirubinemia, hypotension, intraventricular hemorrhage
MAGNESIUM SULFATE Myasthenia gravis	Flushing, lethargy, headache, muscle weakness, diplopia, dry mouth, CHF, cardiac arrest	Lethargy, hypotonia, respiratory depression, demineralization*
CALCIUM CHANNEL BLOCKERS Cardiac disease Caution with renal disease, avoid with magnesium	Flushing, headache, dizziness, nausea, transient hypotension	None known
PROSTAGLANDIN SYNTHETASE INHIBITORS Major renal or hepatic impairment Active PUD Coagulation disorders, thrombocytopenia NSAID-sensitivity	Nausea, dyspepsia	Constriction of DA, pulmonary impaired renal function (reversible) with oligohydramnios, intraventricular hemorrhage, hyperbilirubinemia, necrotizing enterocolitis

*With prolonged use.

tibiotics prior transfer should be a shared decision between the transferring and receiving physicians.

EMERGENCIES DURING THE POSTPARTUM PERIOD

Pulmonary embolus (PE) as a complication of deep venous thrombosis (DVT) is one of the most common causes of maternal death either during pregnancy or in the postpartum period. Postpartum hemorrhage and infection continue to be the most common emergencies seen during the postpartum period, but amniotic fluid embolism, while rare, is associated with high morbidity and mortality rates for both mother and fetus. **Eclampsia may persist and even present occasionally during the postpartum period.** Among those who developed eclampsia in a large cohort of over 100,000 pregnant patients, almost one third occurred more than 48 h postpartum, with some occurring up to 3 weeks post delivery.²¹ Peripartum cardiomyopathy (PPC) is seen during the last month of pregnancy or within 5 months of delivery.

Thromboembolic Disease

The likelihood of venous thromboembolism in normal pregnancy and the puerperium is increased by a factor of 5 when compared with the nonpregnant woman of similar age. Normal consequences of stasis from impeded blood flow and increased clotting predispose toward the formation of thrombosis and the complication of PE. Estimates of DVT during the first postpartum month may be as high as 20 times the estimates in nonpregnant women. The increased risk of PE is greatest in the first few weeks after delivery. Added risk factors include obesity, bed rest, advanced age, prior DVT and varicose veins, trauma, and multiparity. Symptoms of DVT are similar to those in nonpregnant patients. The left leg is involved more commonly. Diagnostic testing by ultrasound is most sensitive for detecting thromboses in the thigh veins. The iliac veins must be imaged by computed tomography (CT) or magnetic resonance imaging (MRI).²² Half of PEs arise from the iliac veins. The amount of radiation from a CT scan is within acceptable radiation limits for fetal exposure,²³ and MRI may be used after the first trimester. Treatment of DVT of the

TABLE 106-7 Tocolytic Therapy Protocols

Agent	initial Dose	Maintenance	Comment
Terbutaline	0.25 mg SC	0.25 mg SC q20min up to 3 h or until contractions stop	Hold for pulse > 120 beats per min
Ritodrine	50-100 i-gIVpermin	Increase 50 xg per min q10min (max 350 xg per min) until contractions cease	Cease if side effects develop (see Table 106-7)
Magnesium sulfate	4–6 g IV bolus over 20 min	2-3 g per h	Monitor for side effects
Nifedipine	30MGPOor 10 mg SL q20min X 3	10-20 mg PO or SL q4-6h	Monitor for side effects
Indomethacin	50 mg PR, or 50-100 mg PO	25-50 mg PO q6h X 48 h	
Kotorolac	60 mg IM	30 mg IM q6h X 48 h	
Sulindac	200 mg PO	200 mg PO q12h 48 h	

Abbreviations: SL = sublingual; PR = per rectum.

Source: Adapted from Hearne AE, Nagey DA: *Clin Obstet Gynecol* 43(4):787, 2000.

thigh is anticoagulation with heparin or low-molecular-weight heparin (LMWH) in standard doses.

PE should be in the differential diagnosis of any pregnant woman complaining of shortness of breath, syncope, chest pain, or shock. The threshold for ordering a CT or ventilation-perfusion scan to diagnose PE should be low. Either of these studies can be performed safely in the pregnant patient. Treatment is similar to that in nonpregnant patients, except for use of warfarin. Thrombolytics can be used.

Postpartum Hemorrhage

Postpartum hemorrhage is implicated in approximately 28 percent of pregnancy-related deaths. Since most postpartum hemorrhages occur in the first 24 h after delivery, unless the delivery takes place at home or in a free-standing birthing center, such patients are unlikely to present to the ED. However, delayed hemorrhage may be seen days to weeks postpartum.

The differential diagnosis of hemorrhage in the period immediately following delivery includes uterine atony, uterine rupture, laceration of the lower genital tract, retained placental tissue, uterine inversion, and coagulopathy. After 24 h, retained products may cause bleeding. Other causes include uterine polyps or a coagulopathy, most commonly von Willebrand disease.

Physiologic bleeding that takes place in the postpartum period may be of variable duration, not uncommonly extending for periods of up to 5 weeks after delivery. The patient should be questioned about difficulty delivering the placenta. Manual delivery of the placenta increases the risk of postpartum hemorrhage.

A careful history and physical examination should elicit the diagnosis in most cases (Table 106-8). The most common cause of bleeding within the first 24 h is uterine atony. Normally, after delivery, the uterus is firm, globular in shape, and palpable at or below the umbilicus. When uterine atony occurs, the uterine fundus is "doughy" in consistency and possibly palpable above the umbilicus. If the tone of the uterus is good but blood is seen to be coming from the cervical os, the possibility of retained products of conception or uterine rupture must be considered. Uterine rupture is more common after prior cesarean section as a result of separation of the scar. Prior uterine surgery and multiparity also can predispose to this complication. Very rarely, rupture occurs in the face of no prior risk factors. Diagnosis of the cause will allow proper treatment.

The management of postpartum hemorrhage depends on stabilization of the patient and diagnosis of the cause of bleeding (see Table 106-9). If bleeding is massive, two large-bore intravenous lines should be started, a CBC and clotting studies should be performed, and the patient should be typed and crossmatched for blood. A red-top tube should be kept by the bedside, and if a clot has not formed by 7 min, a coagulopathy, either causing the bleeding or resulting from the blood loss, may be present.

Good lighting and suction should be maintained. A speculum examination should be performed to inspect for trauma to the vaginal, vulvar, or cervical tissues. Any lacerations should be repaired after local anesthesia is provided. If a laceration is extensive, the patient should be taken immediately to the operating room.

If a mass is seen in the vaginal vault and the uterus cannot be palpated on the abdominal examination, the possibility of uterine inversion is strong. Emergency obstetric consultation is required.

If blood is seen to be coming from the cervix, the possibility of atony or retained products of conception is high. If atony is present and the uterus is large and doughy, the patient should be treated with oxytocin. It is administered by diluting 20 to 30 units in 1 L of NS or LR solution and infusing the fluid at 200 mL per h. Methylergonovine maleate, an alternative agent, can be given at a dose of 0.2 mg IM, has an onset of action of 7 min, and lasts for 2 h. This agent should not be used if hypertension or preeclampsia is present. Once bleeding is controlled, the patient can be discharged on an oral maintenance dose of 0.2 mg methylergonovine every 6 h.

If the uterus has good tone, the possibility of retained products of conception is high. An ultrasound study confirms the diagnosis.

Postpartum Infections

Pelvic infection is the most common serious complication of the puerperium. Any persistent fever over 38.0°C (100.4°F) is caused by genital tract infection until proven otherwise. Extragenital causes of fever include respiratory tract infection (more common after cesarean section), pyelonephritis, mastitis, and thrombophlebitis.

The route of delivery is the single most significant risk factor for uterine infection, with the vast majority of endometritides occurring secondary to cesarean section. Other risk factors include lower socioeconomic level, multiple gestations, younger maternal age, longer duration of labor and membrane rupture, and internal fetal monitoring. Women with these risk factors who were not given antibiotics prophylactically have been found to have a 90 percent rate of pelvic infection. Digital examination after 37 weeks' gestation also is thought to predispose to infection.

The most common pathogens are those which normally reside in the bowel and also colonize the perineum, vagina, and cervix. Both gram-positive and gram-negative aerobes, anaerobes, *Mycoplasma hominis*, and *Chlamydia trachomatis* are seen. *Gardnerella vaginalis* is isolated more often in younger women. Many infections are polymicrobial.

Signs and symptoms of postpartum endometritis are foul-smelling, profuse, bloody discharge and abdominal pain. Only scant discharge may be present, especially in patients with group A *p-hemolytic streptococci*. Shaking chills suggest bacteremia. Uterine and adnexal tenderness is found on bimanual examination.

Infection may be localized to the decidua and adjacent myometrium and, if this is the case, responds readily to antibiotic therapy. Complications include parametrial phlegmons; surgical, incisional, and pelvic abscesses; infected hematomas; septic pelvic thrombophlebitis; necrotizing fasciitis; and peritonitis. Necrotizing fasciitis is a feared complication with high mortality and morbidity rates. Risk factors for this complication are obesity, diabetes mellitus, and hypertension.

The mainstay of treatment is antibiotic therapy (see below), drainage of any collections of purulent material, and debridement of necrotic tissue. Routine vaginal cultures are of little clinical utility be-

TABLE 106-8 Physical Findings, Cause, and Treatment of Postpartum Hemorrhage

Finding	Cause	Treatment
Enlarged, doughy uterus	Uterine atony	Oxytocin 20-30 U/L at 200 mL per h or methylergonovine maleate 0.2 mg IM and 0.2 mg PO q6h
Globular, firm uterus	Retained products of conception	Dilatation and curettage
Inability to palpate uterus	Uterine inversion	Manual reduction
Blood in vagina but not coming from uterus	Laceration of lower genital tract	Repair in emergency department or operating room
History of cesarean section	Possible uterine rupture	Surgery
Blood does not clot in red-top tube	Coagulopathy	Fresh-frozen plasma

cause of contamination with local flora. Blood culture results are positive in a minority of patients.

Oral antibiotics can be used on an outpatient basis for mild illness, i.e., the disease is confined to the decidua and myometrium. Any patient who appears toxic or moderately ill, has had a cesarean section, or has underlying comorbid conditions should be hospitalized for parenteral therapy. There are many regimens of therapy. The combination of ampicillin and gentamicin is sufficient for 90 percent of patients. The p-lactam antimicrobials have the advantages of being safe and requiring administration of only one drug, thus being cost-effective. Cephalosporins that can be used include cefoxitin (2 g IV every 6 h), cefotetan (2 g IV every 12 h), and cefotaxime (2 g IV every 6 h). Other regimens include clindamycin (500 mg IV every 6 h) and gentamicin (4.2 mg/kg IV daily) or metronidazole (500 mg IV every 8 h) plus ampicillin and an aminoglycoside.

AMNIOTIC FLUID EMBOLUS Mortality rates between 60 and 80 percent have been reported for amniotic fluid embolism. Neurologic morbidity rates are even higher, and few patients are without sequelae. In a national registry of patients with amniotic fluid embolus, if the amniotic fluid had meconium staining, no mother survived without a neurologic deficit.²⁴ If the infant is still in utero at the time of the embolus, both mortality and neurologic morbidity rates are high. The only significant relationship found thus far is fetal male sex.

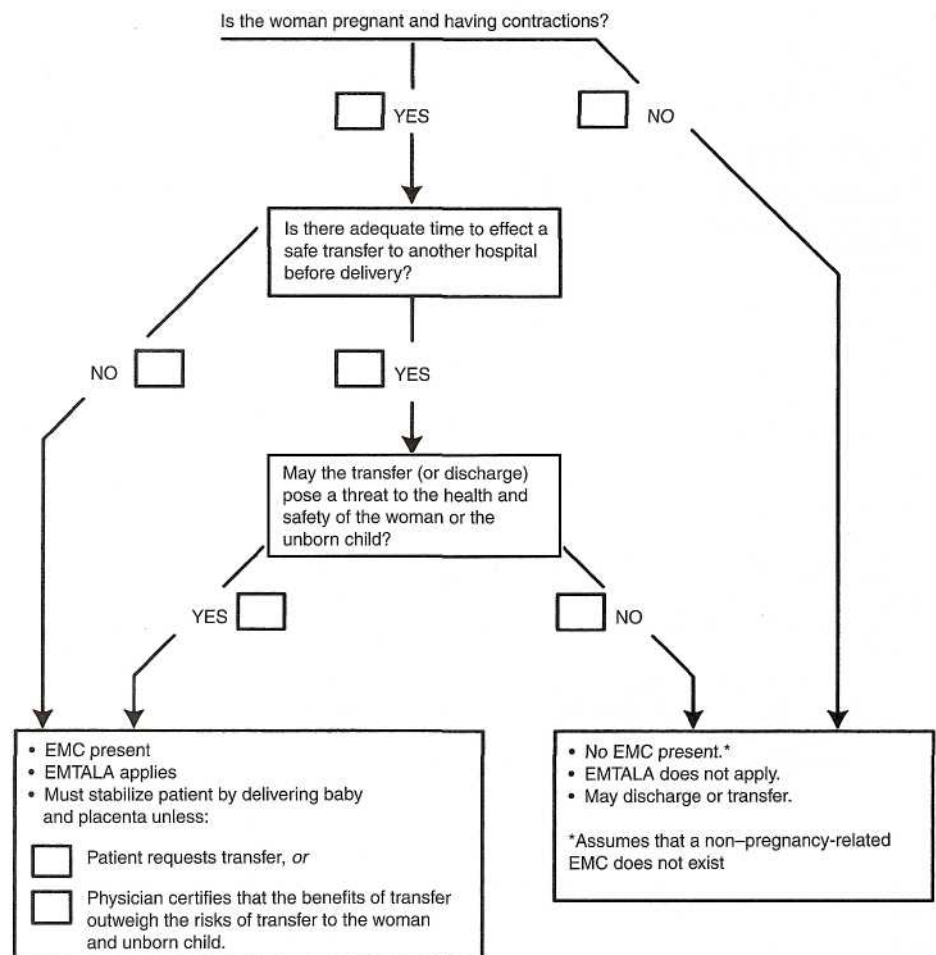

Onset is sudden, with the mother displaying cardiovascular collapse. Seizure or seizure-like activity at the time of collapse is common. Patients display profound cardiovascular instability, severe hypoxemia, and if survival is long enough, DIC. Death is rapid, with many patients dying within 1 h of onset of symptoms.

Care is supportive, with use of high concentrations of oxygen and standard treatment of DIC (see Chap. 219) if the patient survives long enough. Delivery of the infant should be immediate, but infant mortality and morbidity rates remain high even with immediate delivery.²⁴

PERIPARTUM CARDIOMYOPATHY Peripartum cardiomyopathy (PPC) is the development of heart failure during or shortly after labor with no apparent cause. Most women have an underlying cause found during workup for PPC.²⁵ Causes include chronic hypertension, mitral stenosis, obesity, viral myocarditis, and preeclampsia. Terbutaline administration for tocolysis has been found to have an association with congestive heart failure in patients with no underlying heart disease. In a small group, no cause can be found. PPC appears to be similar to the idiopathic cardiomyopathy seen in young nonpregnant women. Biopsy shows evidence of myocarditis in up to 30 percent.

Patients present with signs and symptoms of congestive heart failure. Dyspnea, orthopnea, cough, palpitations, and chest and abdominal pain are common complaints. Massive dilated cardiac chambers are seen on chest radiograph and echocardiograph. Treatment is with

diuretics and fluid restriction. Digitalis should be used with caution because 60 percent of patients have complex ventricular arrhythmias. Afterload reduction has been used, but ACE inhibitors should be avoided if the patient is undelivered. Because of the high association of PE with PPC, anticoagulation with heparin is often recommended. If no underlying cause can be found, the prognosis is very poor, with mortality of almost 50 percent at 1 year. Many survivors demonstrate diminished contractile reserve when studied with dobutamine challenge in periods remote from pregnancy.²⁵

TRANSFER OF THE PREGNANT PATIENT

There are times when a pregnant patient will require transfer to another hospital. If the emergency physician works in a hospital that does not provide obstetric services, it is highly recommended that he or she be familiar with the protocols in place for transfer and inpatient care of these patients. The Emergency Medical Treatment and Active Labor Act (EMTALA) specifically addresses the issue of the pregnant patient. All rules and regulations of EMTALA mandating care before and during transfer apply. Additionally, if a woman is having contractions, she is considered to have an emergency medical condition if there is insufficient time for transfer before delivery or the transfer may pose a threat to the health or safety of the child. In this situation, the patient may not be transferred prior to delivery unless the patient requests transfer.²⁶ If contractions are not present, an emergency medical condition is not automatically present, and the regular rules of providing medical care and determining the need for transfer of patients applies (Figure 106-1).

EMERGENCY DELIVERY

Michael J. VanRooyen Kimberly B. Fortner

The anxiety experienced by emergency physicians caring for a woman in active labor is not simply due to the lack of familiarity with normal deliveries but also is due to the awareness of the potential for serious and rarely fatal complications of labor. In addition, the initial management of third-trimester emergencies such as preeclampsia, eclampsia, and hemorrhage has major consequences for maternal and infant survival.

PREHOSPITAL MANAGEMENT

Precipitous delivery in the ED setting is a relatively uncommon phenomenon. With advances in prenatal care and nearly ubiquitous availability of obstetrical units in the United States, the incidence of out-of-hospital delivery has fallen to less than 1 percent of deliveries.¹ However, the desire for planned home deliveries is on the rise and sometimes results in rapid transport to the hospital for difficult deliveries. One study in Washington State found that of 7000 planned home births, 500 women were transferred emergently to the hospital for delivery.² Other reasons for out-of-hospital delivery may include poorly educated patients, those with no prenatal care, inadequate preparations by family members, lack of transportation options, remote locations, and premature delivery. A relatively recent and controversial practice is intentional precipitous labor, in which a woman desiring to avoid hospital charges delays care until the final stages of labor.

Emergency medical system (EMS) personnel must be trained to recognize active labor and manage the precipitous delivery appropriately. Pregnancy-related complications that may occur in the prehospital setting include preeclampsia, eclampsia, maternal hemorrhage, and complications of labor such as cord prolapse, shoulder dystocia, and fetal distress. This requires an integrated approach to management of the patient in labor, including knowledge by prehospital personnel of available obstetric and neonatal units in the system's catchment area for appropriate transport.

Transport of Pregnant Patients

The need to recognize maternal and neonatal complications in the prehospital setting has become more important with the availability of transport systems for high-risk obstetrical patients to specialty centers. The development of specialty centers has led to a significant decline

in neonatal mortality, particularly for infants weighing less than 1500 g at birth. High-risk maternal units have proliferated as well, and as a consequence, transport of pregnant patients for reasons of maternal bleeding, eclampsia or preeclampsia, fetal distress, multiple gestations, fetal anomalies, and other maternal health problems including traumatic injuries has increased markedly. The most common reason for transport of obstetric patients to a tertiary care center is the premature rupture of membranes.

Prehospital units transporting the actively laboring patient should be prepared by carrying sterile delivery packs and medical supplies and medications for maternal and neonatal emergencies (Table 107-1). The transport team should be trained to assist in the precipitous delivery of an infant and educated in the use of basic obstetrical supplies. Prehospital protocols should be reviewed often so that EMS personnel remain prepared for the rare and potentially catastrophic pregnancy-related event.

Emergency Department Preparedness

Whether patients deliver in the prehospital setting or immediately on arriving to the ED, every ED should be prepared for emergency delivery by preparing a basic delivery kit, along with resources for the initial care and potential resuscitation of the newborn. (Tables 107-1 and 107-2). These include an infant warmer/isolette and supplies for neonatal resuscitation (see Chap. 13). Because of the relative infrequency of ED delivery, extra care should be taken to educate physician and nursing staff through educational programs, annual in-services, and equipment orientation sessions.

EVALUATION OF THE PREGNANT PATIENT

Any pregnant woman beyond 20 weeks' gestation who arrives in the ED with signs of active labor should be evaluated carefully to determine the condition of the mother and the fetus. An important component of this is the medical and obstetrical history of the patient, including parity and estimated date of confinement (EDC). If the last menstrual period (LMP) is known and a pregnancy wheel is not available, the EDC can be calculated by adding 9 months and 7 days to the LMP (Naegle rule). Although useful for providing a rough estimate, ultrasound examination late in the third trimester is not an accurate predictor of gestational age because estimates of EDC can vary by ± 3 weeks. Fundal height also provides a rapid estimate of gestational age in the patient who does not recall LMP or EDC. Fundal height is measured in centimeters (cm = weeks of gestation ± 2 weeks) from the pubic symphysis to the top of the fundus as palpated by the examiner, although this measurement can be greatly overestimated in obese patients. In addition to the obstetrical history of the patient, it is important to obtain pertinent medical information such as allergies, medications, drug and alcohol use, and prenatal care and to elicit any past history of complications with prior deliveries or precipitous labor.

TABLE 107-1 Equipment and Supplies for Emergency Delivery

Surgical scissors
Placenta basin
Rubber suction bulb
Neonatal airways
Towels
Hemostats
Cord clamps
Sterile gloves
Sterile towels and drapes
Gauze sponge (4 X 4)
Syringes (10 mL)
Needles (23 gauge)

Note: List excludes standard adult and neonatal resuscitation equipment.

TABLE 107-2 Medications for Emergency Delivery and Indications for Use

Medication	Dose	Indication
Oxytocin 10 units/mL	Infuse 2 L of 20 units/L NS solution	Give routinely for uterine contraction and hemostasis immediately post partum
Methyl ergonovine	0.2 mg IM	Control of postpartum hemorrhage
Hydralazine 20 mg/mL	5-10 mg IVP q3-5 min to treat diastolic BP > 110 mmHg	Control of hypertensive crisis (to diastolic BP 80-90 mm Hg)
Magnesium sulfate (50% solution: 5 g/10 mL)	Bolus 4-6 g IV over several minutes	First-line control of eclamptic seizures
Calcium gluconate 10% solution	10 mL IV over several minutes	Magnesium toxicity
Fosphenytoin	10 mg/kg PE loading, followed by second loading dose of 5 mg/kg 2 h later	Second-line drug for eclamptic seizures
Terbutaline sulfate 1 mg/mL	0.25 mg SC q3h	Tocolysis
Fentanyl 50 μ g/mL	50 μ g (1 mL) q1h	Short-acting opiate analgesic
Lidocaine 1% solution	1-10 mL locally	Local anesthetic
Prochlorperazine 10 mg/2 mL	5-10 mg IV	Nausea and vomiting
Naloxone 0.4 mg/mL	0.8-2 mg IV	Narcotic overdose

Abbreviations: IVP = intravenous push; PE = phenytoin equivalent.

Every patient presenting with signs of active labor should have immediate monitoring of maternal vital signs (particularly blood pressure) and fetal heart rate. Doppler heart tones are helpful to confirm normal fetal heart rate (120-160 beats/min). A persistently slow fetal heart rate (<120 beats/min) is an indicator of fetal distress, and emergent obstetrical consultation is necessary.

Distinguishing True versus False Labor

The confirmation of true labor as opposed to false labor is an important initial step in the management of the term or near-term pregnant patient. *False labor* is defined as uterine contractions that do not lead to cervical changes, and false labor is characterized by irregular, brief contractions usually confined to the lower abdomen. These contractions, commonly called *Braxton-Hicks contractions*, are irregular in both intensity and duration. False labor may be persistent for several days. It is treated most commonly with hydration and rest but uncommonly may require admission with supportive care.

True labor is characterized by painful, repetitive uterine contractions that increase steadily in intensity and duration and lead to progressive effacement and dilatation of the cervix. True labor pains typically begin in the fundal region and upper abdomen and radiate into the pelvis and to the lower back. True labor also leads to progressive descent of the fetus into the pelvis in preparation for delivery and cervical dilatation and effacement.

There are three stages of labor.³ The first stage begins with the onset of regular uterine contractions and ends with full cervical dilatation. The first stage can then be divided into two phases, latent and active. The la-

tent phase is characterized by uterine contractions that are infrequent, irregular, but moderately uncomfortable and result in gradual cervical changes. This is a preparatory phase in which the uterus is orienting to contractions and the cervix is undergoing effacement and softening. The active phase typically is accepted as starting once the cervix has dilated to 3 to 5 cm and leads to cervical dilatation at an average rate of 1.2 cm/h in nulliparas and 1.5 cm/h in parous women. The second stage of labor, from full dilatation to delivery of the infant, is usually brief and lasts an average of 20 min for parous women and 50 min for nulliparous women. The third stage of labor is from delivery of the infant to delivery of the placenta.

Physical Examination

Patients without vaginal bleeding should be evaluated with a sterile speculum examination and a bimanual examination. Patients presenting with vaginal bleeding should be evaluated with ultrasound prior to any speculum or bimanual examination to rule out placenta previa (see below). The typical method for pelvic examination is in the lithotomy position. Stirrups are not necessary, although they are helpful. Alternatively, an inverted bedpan may be employed to elevate the patient's buttocks enough to allow speculum examination. Lubricant should be avoided unless rupture of membranes has been confirmed because lubricant may produce a false-positive nitrazine test.

If spontaneous rupture of membranes (SROM) is suspected, sterile speculum examination should be performed and digital examination avoided because studies have shown an increased risk of infection after a single digital examination.⁴ It is particularly important to avoid digital examinations in the preterm patient in whom prolongation of gestation is desired. Sterile speculum examination allows confirmation of SROM by three tests: verification of pooling of amniotic fluid in the vaginal vault, a positive nitrazine test, and evidence of ferning on a microscope slide. The speculum examination also provides for visualization of the cervix with estimation of dilatation with collection of cervical cultures, in particular, group B *Streptococcus*, *Neisseria gonorrhoeae*, and *Chlamydia* cultures.

The abdomen should be inspected and palpated to determine fundal height and evaluated for fundal tenderness. The cervix is examined to determine effacement, dilatation, and station. *Effacement* of the cervix refers to the process of thinning that occurs during labor. Effacement conventionally has been described in terms of a percentage of normal cervical length. This method often has been confusing and poorly reproduced between examiners. More recently, the preferred method is to describe the degree of effacement in terms of actual length of remaining cervix in centimeters. Cervical *dilatation* describes the diameter of the internal cervical os and is an indicator of the progression of labor. The index and middle fingers of the examining hand are used to determine the diameter; expressed in centimeters (fingertip to 10 cm). Ten centimeters indicates full dilatation. The *station* indicates the level that the fetus occupies in the pelvis, with the reference point being the maternal ischial spines, palpable on either side of the vaginal canal at about 4 and 8 o'clock. If the presenting fetal part remains above the ischial spines, the station is described as negative. Once the presenting fetal part has reached the level of the ischial spines, the station is zero, with further descent into the pelvis described as +1 or +2. A +3 station corresponds to visible scalp at the introitus, indicating a fetal position consistent with impending delivery.

Leopold maneuvers (see below) and digital examination provide information about the presentation of the child and can indicate a potential breech presentation or cord prolapse. The frequency of malpresentation at 32 weeks is up to 15 percent, whereas nonvertex presentation at term is from 4 to 7 percent. Leopold maneuvers are the palpation of the fetus through the maternal abdomen to determine fetus position and presentation. This can be used for screening for malpresentation as well as fetal weight. Sensitivity in identification of fetal malpresentation among experienced clinicians ranges from 28 to 88 percent, but specificity is usually high (94 percent).^{5,6} Nahum found that estimation of fetal weight is within 15 percent of actual with these maneuvers.⁷ Conversely, Leopold maneuvers are relatively unreliable in inexperienced hands.

On digital examination, vertex presentation is best confirmed with palpation of the cranial sutures. Palpation of small parts, such as feet or hands, is often indicative of malpresentation. If very thick meconium is present on the examining finger after palpation of fingertip to 1-cm dilatation, breech presentation should be ruled out immediately. If available, sonographic verification of presentation is preferred.

Care should be taken to ensure that the pregnant woman does not remain flat on her back for a prolonged period of time because compression of venous return by the gravid uterus can lead to hypotension in the mother and decreased blood supply to the fetus. After examination, the patient should be placed in the left lateral position.

Rupture of Membranes

Determining if membranes have ruptured is an important predictor of the likelihood of imminent labor, as well the potential for complications such as infection or cord prolapse.⁸ SROM occurs during the course of active labor in most patients, although it may occur prior to the onset of labor in 10 percent of third-trimester patients.

The history of SROM typically involves a reported gush of clear or blood-tinged fluid; occasionally, patients recount continued leaking or dampening of their underwear on standing or with the Valsalva maneuver. At this time, screening for symptoms of infection, such as fevers, chills, flushing, and palpitations, should occur. Rupture of membranes can be confirmed by using nitrazine paper to test residual fluid in the fornix or vaginal vault while performing a sterile speculum examination. Amniotic fluid has a pH of 7.0 to 7.4 and will turn nitrazine paper a dark blue. Vaginal fluid typically has a pH of 4.5 to 5.5, and the nitrazine strip will remain yellow. False-positive tests may occur with blood, lubricant, and the presence of *Trichomonas*, semen, or cervical mucus. Another test used to confirm rupture of membranes (ROM) is ferning, or observing sodium chloride crystals on a slide as amniotic fluid dries. At the time of this pelvic examination, it is prudent to also evaluate for signs of chorioamnionitis, such as maternal fever, maternal tachycardia, fetal tachycardia, and fundal tenderness.

If membranes are intact, an amniotomy should not be performed in the ED setting because this may lead to precipitous labor and the potential for cord prolapse. It is also important to note the presence of meconium after the ROM, indicated by the presence of thick, greenish brown fluid.

Premature Rupture of Membranes

Rupture of the amnion and chorion that occur more than 1 h prior to the onset of labor is called *premature rupture of membranes* (PROM).⁹ If rupture occurs prior to 37 weeks of gestation, this is termed preterm premature rupture of membranes (PPROM). Prolonged ROM occurs if delivery does not occur within 18 h of ROM. Given that this is a major cause of maternal transports, it is important to review a few details about PROM and PPRM. Possible causative factors include infection, history of PPRM, history of trauma, multiple gestations, fetal anomalies, placental abruption, and placenta previa. Conservative management of PPRM usually is employed in gestations of less than 34 weeks; obstetricians will wait for signs of chorioamnionitis or non-reassuring fetal testing before intervening. Use of tocolytics is reserved for cases where maternal transport is necessary or if a delay of delivery is needed to initiate steroids for fetal lung maturity. Mercer and colleagues showed that latency of noninfected PPRM patients can be prolonged with ampicillin and erythromycin for 7 days.⁸

Fetal Distress

Fetal distress may occur during active labor, and care must be taken to evaluate the fetal status as often as possible. Indicators of fetal distress include decelerations in fetal heart rate, defined as a persistent drop in fetal heart rate during contractions lasting greater than 30 s after a contraction. While most EDs do not have fetal monitoring devices,

Doppler heart tones should be measured after each contraction to detect the presence of decelerations. Episodic bradycardia lasting for more than 5 min is an indication for immediate cesarean section. Interventions for decelerations attempt to increase maternal blood flow or increase maternal serum oxygenation. For decelerations, maternal repositioning to the left lateral, the right lateral, and then the knee-chest position should be attempted until return of fetal heart rate to baseline is achieved. Fetal scalp stimulation also should be initiated with sterile bimanual examination. In addition, maternal oxygen by face mask can be initiated to increase oxygen supply to the fetus for late decelerations. Lastly, an injection of terbutaline can halt uterine contractions and increase blood flow to the fetus.

EMERGENCY DELIVERY

The initial step in the management of a woman in active labor is to obtain vital signs and initiate supportive therapy, including obtaining venous access and monitoring the mother and fetus if fetal monitoring is available. If the pelvic examination reveals complete cervical effacement and fetal presentation at the introitus, then delivery is imminent. It is important to realize that patients, particularly multiparous patients, can progress very rapidly. The stage of labor and the parity of the patient should be taken into account when considering transport of a laboring patient to another facility, and also when determining if the patient can be safely transported from the ED to the labor and delivery suite. For patients who are crowning, or who are fully dilated and effaced, it is generally best to have the obstetrician come to the ED, rather than risk precipitous delivery during transport.

As the cervix becomes fully dilated and effacement becomes complete, the fetus continues to descend, and the patient will experience the urge to push. Patients delivering in the emergency setting may have difficulty controlling these expulsive efforts, and they are in even greater need of assistance, reassurance, and instruction. Preoccupation with the delivery should not exclude the needs of the mother nor minimize the importance of maternal cooperation to accomplish a controlled delivery.

Determination of fetal position is best accomplished in the emergency setting by evaluation of the presenting portion of the infant. Pelvic examination should reveal evidence of the infant's position, including palpable skull sutures and fontanelles or, in the case of breech delivery, the infant's buttock or extremity. Confirmation may be accomplished by personnel familiar with Leopold maneuvers.

The typical delivery position is the dorsal lithotomy position, which allows maximum visualization and control of the delivery. However, a patient laboring naturally often may prefer delivery in the knee-chest position. If this is the case, all maneuvers for delivery must be in the opposite direction, or the patient must be rotated to the dorsal lithotomy position. As time allows, the perineum may then be prepared by washing with mild soap and water and swabbing with povidone-iodine. Drapes should be placed over the patient, and gowns, masks, and gloves should be donned by medical personnel attending the patient. Obstetrical support should be notified as indicated.

The process of fetal descent during labor and delivery is described by six cardinal movements: (1) engagement, (2) flexion, (3) descent, (4) internal rotation, (5) extension, and (6) external rotation (see Figure 107-1). The following discussion describes delivery in the cephalic, occiput anterior (OA) position. As the fetus descends through the birth canal and reaches the introitus, the perineum bulges to accommodate the fetal head. Delivery can be aided by gentle digital stretching of the inferior portion of the perineum. The perineum will undergo gradual thinning and stretching to enable passage of the newborn. The use of routine episiotomy for a normal spontaneous vaginal delivery has been discouraged in recent years and has been demonstrated to increase the incidence of third- and fourth-degree lacerations occurring at the time of delivery.^{10,11} If an episiotomy is necessary, it may be performed as follows: 5 to 10 mL of 1% lidocaine solution is injected with a small-gauge needle into the posterior

fourchette and perineum. While protecting the infant's head, a 2- to 3-cm midline cut is made with scissors to extend the vaginal opening. The incision must be supported with manual pressure from below, taking care not to allow the incision to extend into the rectum.

Control of the delivery of the neonate is the major challenge. As the infant's head emerges from the introitus, the perineum should be supported by placing a sterile towel along the inferior portion of the perineum with one hand and supporting the fetal head with the other hand. Mild counterpressure is exerted to prevent rapid expulsion of the fetal head, which may lead to third- or fourth-degree perineal tears. Control of the head away from the anterior structures also will reduce anterior tears near the urethra and clitoris.

As the infant's head presents, the left hand may be used to control the fetal chin while the right remains on the crown of the head, supporting the delivery. This controlled extension of the fetal head will aid in the atraumatic delivery. The mother is then asked to breathe through contractions rather than bearing down and attempting to push the baby out rapidly. Immediately after delivery of the infant's head, the infant's nose and mouth should be suctioned. This is particularly important in infants presenting with meconium in order to prevent aspiration. A simple suction bulb will assist in routine clearing of the infant's nose and mouth. After suctioning, the neck should be palpated for the presence of a nuchal cord. Nuchal cord is a common condition, found in 25 percent of all cephalad-presenting deliveries.¹² If the cord is loose, it should be reduced over the infant's head, and the delivery may proceed as usual. If the cord is wound tightly, it may need to be clamped in the most accessible area by two close clamps and transected to allow delivery of the infant.

After clearing the airway, delivery of the body is allowed to progress. After delivery of the head, the head will restitute, or turn to one side or the other. As the head rotates, the physician's hands are placed on either side of the head, providing gentle downward traction to deliver the anterior shoulder. Care should be taken to provide only gentle traction because jerky or forceful movements may cause a brachial plexus injury. Once the anterior shoulder is visible, the physician's hand then gently guides the fetus upward, delivering the posterior shoulder and allowing the remainder of the infant to be delivered. At this point, it is very important to control the delivery of the body to prevent perineal lacerations.

A point of practical concern is the need to maintain control of the newly born infant such that inadvertent dropping does not and cannot occur. The combination of amniotic fluid, blood, and vernix results in a very slippery infant. It is useful to prepare for the delivery by placing the posterior (left) hand underneath the axilla of the infant prior to delivering the rest of the body. The anterior hand may then be used to grasp the ankles of the infant and ensure a firm grip. In obstetrical training, students often are instructed to hold the infant close to their chest "like a football." In order to promote the clearing of secretions in the neonate, it is best to hold the infant so that the head is below the heart, tilting downward with the infant's head secured in the palm of the hand.

The infant is then loosely wrapped in a towel and stimulated as it is dried. In the setting of an uncomplicated delivery, the mother may hold the child immediately while the cord is being cut, providing the child has responded well to initial stimulation and has a clear airway and good respiratory effort. The umbilical cord is double clamped 3 cm distal to its insertion at the umbilicus and transected with sterile scissors. The infant is further dried and warmed under an incubator, where postnatal care may be provided and Apgar scores calculated at 1 and 5 min after delivery. Scoring includes general color, tone, heart rate, respiratory effort, and reflexes (Table 107-3).

In the case of suspected meconium aspiration, the infant is delivered, the cord is double clamped and cut immediately, and the infant is placed in an incubator for airway assessment and possible intubation prior to stimulating the child to breathe spontaneously. Intubation allows for the trachea to be suctioned adequately prior to spontaneous breathing, thus reducing the risk of meconium aspiration. If a cyanotic

FIG. 107-1. Movements of normal delivery. Mechanism of labor and delivery for vertex presentations. A. Engagement, flexion, and descent. B. Internal rotation. C. Extension and delivery of the head. After delivery of the head the infant's nose and mouth should be suctioned and the neck checked for encirclement of the umbilical cord. D. External rotation bringing the thorax into the anteroposterior diameter of the pelvis. E. Delivery of the anterior shoulder. F. Delivery of the posterior shoulder. Note that after delivery, the head is supported and used to gently guide delivery of the shoulder. Traction should be minimized.

or apneic child is delivered and does not respond immediately to stimulation, neonatal resuscitation is instituted (see Chap. 13).

Delivery of the Placenta

After the infant is delivered and the umbilical cord is clamped, the placenta delivers in 15 to 30 min. The placenta should be allowed to separate spontaneously, assisted with gentle traction. Aggressive traction

on the cord risks uterine inversion, tearing of the cord, or disruption of the placenta, which can result in severe vaginal bleeding. After removal of the placenta, the uterus should be massaged gently to promote contraction. Oxytocin (10 to 20 IV units in 1 L NS at 250 mL/h or 10 units intramuscularly) is administered to maintain uterine contraction.

Uterine atony may follow a precipitous delivery and may lead to excessive vaginal bleeding. Additional oxytocin may be administered, as well as methylergonovine 0.2 mg IM, or carboprost tromethamine, .25 mg IM. With significant postpartum hemorrhage, vigorous bimanual massage should be continued while administering contractile agents. Episiotomy or laceration repair may be delayed until an experienced obstetrician is able to close the laceration and inspect the patient for fourth-degree (rectovaginal) tears.

TABLE 107-3 PGAR Scoring for Newborns

Sign	0 Points	1 Point	2 Points
A Activity (muscle tone)	Absent	Arms and legs flexed	Active movement
P Pulse	Absent	Below 100 beats/min	Above 100 beats/min
G Grimace (reflex irritability)	No response	Grimace	Sneeze, cough, pulls away
A Appearance (skin color)	Blue-gray, pale all over	Normal, except for extremities	Normal over entire body
R Respiration	Absent	Slow, irregular	Good, crying

COMPLICATIONS OF DELIVERY

Cord Prolapse

In the event that the bimanual examination reveals palpable, pulsating cord, the examiner's hand should not be removed but rather should be used to elevate the presenting fetal part to reduce compression on the cord.¹² Immediate obstetrical assistance is necessary because a ce-

FIG. 107-2. Management of the vaginal frank breech delivery. A. The Pinard maneuver. The operator's hand is placed behind the fetal thigh, putting gentle pressure at the knee and allowing delivery of the leg. B. A similar maneuver of the opposite leg. C. The feet are grasped with the thumb and third finger over the lateral malleolus and the second finger is placed between the two ankles. D. With maternal expulsive efforts, the breech is delivered to the level of the umbilicus. The sacrum should be kept anterior. E. Again, with maternal expulsive efforts, the infant is delivered to the level of the clavicles, keeping the sacrum an-

terior. F. The fetus is rotated 90° allowing visualization of the now anterior right arm. G. The arm is well visualized and a single digit is used to deliver it. Delivery of the opposite arm is accomplished by rotating the fetus 180° in a clockwise direction and repeating the maneuver. H. Delivery of the fetal vertex is accomplished by placing the operator's fingers over the maxillary processes of the fetus, keeping the body parallel to the floor. The body should never be lifted above parallel to prevent hyperextension of the neck. An assistant applies suprapubic pressure, aiding flexion of the fetal head and accomplishing delivery.

sarean section is indicated. The examiner's hand should remain in the vagina while the patient is transported and prepared for surgery in order to prevent further compression of the cord by the fetal head. No attempt should ever be made to reduce a prolapsed cord.

Shoulder Dystocia

Shoulder dystocia is the impaction of fetal shoulders at the pelvic outlet after delivery of the head. Typically, the anterior shoulder is trapped behind the pubic symphysis, leading to delay of delivery of the rest of the infant. It usually occurs in the delivery of larger infants with disproportionately large shoulders compared with the fetal head. Although rare, shoulder dystocia is a serious concern because of the risk of fetal morbidity and mortality if it is not managed promptly and appropriately. Complications of shoulder dystocia include brachial plexus injury from overaggressive traction and fetal hypoxia from impaired respirations and compression of the umbilical cord and compromised fetal circulation.

Shoulder dystocia is first recognized after delivery of the fetal head, when routine downward traction is insufficient to deliver the anterior shoulder. After delivering the infant's head, it retracts tightly against the perineum (the turtle sign).¹³ If a shoulder dystocia is recognized, the physician should use the momentum from delivery of the head to deliver the anterior shoulder. After delivery of the anterior shoulder, the infant's nose and mouth can then be suctioned. If the shoulder is still impacted, call for assistance and have an assistant note the time. It is then important to position the mother in the extreme lithotomy position, with legs sharply flexed up to the abdomen (the McRobert maneuver) with the legs held by the mother or an assistant. The bladder should be drained if this has not been done already. A generous episiotomy also may facilitate delivery. Next, **an assistant should apply suprapubic pressure to disimpact the anterior shoulder from the pubic symphysis. It is important to remember never to apply fundal pressure because this will further impact the shoulder on the pelvic rim.** Pressure also can be applied to the infant's sternum to decrease shoulder diameter.

To deliver the impacted anterior shoulder, a corkscrew maneuver (Woods' maneuver) is the first manipulation attempted. The physician grasps the posterior scapula of the infant with two fingers and rotates the shoulder girdle 180 degrees in the pelvic outlet in an attempt to rotate the posterior shoulder into the anterior position and in the process deliver the shoulder. Gentle traction may then be applied as the mother pushes, and the infant is delivered through an oblique pelvic diameter. If the corkscrew maneuver fails to reduce the dystocia, the physician may then attempt to deliver the posterior shoulder. The examiner's hand is passed posteriorly in the vagina, and the infant's posterior arm is felt. The elbow is grasped and flexed, and the arm is delivered with the posterior shoulder, and the anterior shoulder usually follows.

Breech Presentation

Breech presentations occur in 3 to 4 percent of term pregnancies and are associated with a morbidity rate three to four times greater than that of cephalad presentations.¹⁴ Breech presentations occur most frequently in premature infants, since final rotation in the pelvis may not have occurred (25 percent of pregnancies at less than 28 weeks and 7 percent of pregnancies at 32 weeks of gestation). The major concern in breech deliveries is head entrapment. In a normal cephalic delivery, the larger head dilates the cervical canal, thus ensuring that the rest of the infant follows. With breech deliveries, however, the head emerges last and may become trapped by an incompletely dilated cervix.

Breech presentation is associated with a greater incidence of fetal distress and umbilical cord prolapse. Breech presentations may be classified as frank, complete, incomplete, or footling. Frank and complete breech presentations serve as a dilating wedge nearly as well as the fetal head, and delivery may proceed in an uncomplicated fashion.

The main point for the emergency physician to remember in a breech presentation is to keep hands away and let the delivery happen spontaneously. This allows the presenting portion of the fetus to maximally dilate the introitus prior to presentation of the fetal head. It is recommended that the examiner literally refrain from touching the fetus until the umbilicus appears. At that point, the physician should place fingers medial to each thigh, pressing out laterally to deliver the legs (Figure 107-2). The fetus should then be rotated to the sacrum anterior position, and the trunk and lower half should be wrapped in a towel. When the scapulae appear, gently rotate until the right humerus can be followed down, rotated across the chest, and swept out. The fetus should then be turned in a counterclockwise position to allow delivery of the other arm. Then, keeping the infant's head flexed, the physician should place the index and middle fingers over the infant's maxillary bones (not in the infant's mouth) to help keep the head flexed. This should allow the mother to expel the fetus. It is important not to pull on the fetus because this may impact the head in the pelvis or entrap the extended fetal arm. Footling and incomplete breech positions are not considered safe for vaginal delivery because of the possibility of cord prolapse or incomplete dilatation of the cervix. In any breech delivery, obstetrical consultation should be obtained immediately.

Preterm Delivery

Preterm delivery is a major cause of precipitous childbirth and is often the cause of emergency delivery. Preterm infants also present more often in the breech position and have a greater incidence of morbidity and mortality. Carefully control the delivery to reduce the likelihood of trauma to the fragile preterm infant. Deliver the infant slowly and immediately dry and warm the infant while performing the initial assessment because the premature infant is much more likely to require resuscitation. The decision whether to initiate resuscitative efforts in the ED is often difficult because patients may deliver an extremely premature fetus of unknown gestational age. In general, even very premature deliveries (18-22 weeks) should receive initial resuscitative efforts until determination of viability is made (see Chap. 13).

VULVOVAGINITIS Gloria

J. Kuhn

Vulvovaginitis is inflammation of the vulva and vaginal tissues. It is usually characterized by a vaginal discharge and/or vulvar itching and irritation. A vaginal odor may be present. It accounts for 10 million visits to physicians per year in the United States, and is the most common gynecologic complaint in prepubertal girls.¹

The most common causes of acute vulvovaginitis include:

1. Infections,
2. Irritant or allergic contact,
3. Local response to a vaginal foreign body, and
4. Atrophic vaginitis.

The three most frequent infectious causes are bacterial vaginosis (BV) caused by replacement of normal flora by overgrowth of anaerobes and *Gardnerella vaginalis*, candidiasis (usually caused by *Candida albicans*) and, trichomoniasis (caused by *Trichomonas vaginalis*).² BV is the most common cause of vaginal discharge or malodor. Polymicrobial infection in women with vaginitis is not uncommon. Vulvovaginal candidiasis, contact vaginitis, and atrophic vaginitis may occur in virgins and after menopause, but other forms of infectious vulvovaginitis are generally found only in sexually active women.

GENERAL APPROACH TO VULVOVAGINITIS

A detailed gynecologic history should be obtained and a pelvic examination performed. Microscopic evaluation of fresh vaginal secretions using both normal saline solution (demonstrating clue cells for BV and motile *Trichomonas vaginalis* for trichomoniasis) and 10 percent potassium hydroxide (KOH) slide preparation (demonstrating yeast or pseudohyphae for candidiasis) and fishy odor in BV (whiff test) will, in most instances, provide a diagnosis (Table 108-1). Checking the pH and microscopic examination of secretions is mandatory because symptoms are nonspecific, signs on physical examination may vary, and patients may have more than one etiology causing vulvovaginitis. Culture for *T. vaginalis* is more sensitive than microscopic examination but is very infrequently performed. One of the most helpful diagnostic tools is measurement of the pH of the vaginal secretions using Nitrazine paper. A pH greater than 4.5 is typical of BV or trichomoniasis, while a pH below 4.5 represents physiologic discharge or a fungal infection.²

TABLE 108-1 Diagnosis of Vaginitis Based on Vaginal Secretions

Test	Finding	Diagnosis
pH	4.0-4.5	Normal
	4.0-4.5	Candidiasis
	>4.5	Bacterial vaginosis
	>4.5	Trichomoniasis
Normal saline solution	Clue cells	Bacterial vaginosis
	Motile trichomonads	Trichomoniasis
	Pseudohyphae and/or buds	Candidiasis
KOH preparation	Fishy odor (whiff test)	Bacterial vaginosis
	Pseudohyphae and/or buds	Candidiasis

Signs of vulval inflammation and minimal discharge in the absence of vaginal pathogens suggest the possibility of mechanical, chemical, allergic, or other noninfectious causes of vulvovaginitis.

All treatment recommendations are taken from the 2002 guidelines for the treatment of sexually transmitted diseases from the Centers for Disease Control and Prevention (CDC).²

NORMAL VULVOVAGINAL ENVIRONMENT

In females of childbearing age, estrogen causes the development of a thick vaginal epithelium with a large number of superficial cells serving a protective function and containing large stores of glycogen. Glycogen is used by the normal flora, consisting of lactobacilli and acidogenic corynebacteria, to form lactic and acetic acids. The resulting acidic environment favors the normal flora and discourages the growth of pathogenic bacteria. Lack of estrogen or a dominance of progesterone results in an atrophic condition, with loss of the protective superficial cells and their contained glycogen. This results in loss of the acidic environment. Normal vaginal secretions may vary in consistency from a thin, watery material to one that is thick, white, and opaque. The quantity may also vary from scant to a rather copious amount. This material is odorless and produces no symptoms. The normal vaginal pH varies between 4.0 and 4.5. Alkaline secretions from the cervix before and during menstruation and semen (which is alkaline) reduce acidity, predisposing to infection. Before menarche and after menopause, the vaginal pH varies between 6 and 7. Because of scant nerve endings in the vagina, the patient usually does not have symptoms until both the vagina and vulva are involved in an inflammatory or irritant process.

Factors thought to contribute to vaginitis in prepubertal females include less-protective covering of the introitus by the labia majora, low estrogen concentration, exposure to irritants such as bubble bath, poor hygiene, and specific pathogens. The role of poor hygiene and infection is disputed.¹ Infectious etiologies may be more common in adolescents.³

BACTERIAL VAGINOSIS

BV is a clinical syndrome that occurs when the normal H_2O_2 -producing *Lactobacillus* species in the vagina are replaced by high

FIG. 108-1. Stippled clue cell of *G. vaginalis* vaginitis.

concentrations of anaerobic bacteria, *G. vaginalis*, and *Mycoplasma hominis*. BV is the most common cause of a malodorous discharge, but more than half of the women who meet the clinical criteria for diagnosis are asymptomatic. The cause of this microbial alteration in the normal vaginal flora is not understood. While BV is rarely seen in women who have never been sexually active, it is not clear whether the disease is the result of a sexually transmitted pathogen. However, BV is associated with having multiple sex partners.²

Bacterial vaginosis can be diagnosed by the use of clinical and microscopic criteria. The CDC states that for the disease to be diagnosed, three of the following signs or symptoms must be present:

1. A homogeneous, white, noninflammatory discharge that smoothly coats the vaginal walls;
2. Presence of clue cells on microscopic examination (epithelial cells coated by bacteria) (Figure 108-1);
3. pH greater than 4.5; and
4. A fishy odor to the discharge after addition of KOH (whiff test).²

Gram staining, which demonstrates a concentration of bacterial morphotypes characteristic of BV is an acceptable laboratory method of diagnosing BV. Culture of *G. vaginalis* is not recommended.²

Research demonstrates an association between BV and adverse pregnancy outcomes because of preterm labor and premature rupture of membranes (PROM), leading to recommendations that high-risk patients (i.e., those who previously delivered a premature infant) be screened for BV during the second trimester of pregnancy.⁴ BV is also associated with pelvic inflammatory disease, endometritis, and vaginal cuff cellulitis after surgical procedures.

All symptomatic patients, unless allergic to the drug, should be treated with metronidazole regardless of pregnancy status.² Several drug regimens are available (Table 108-2). There is no proof of teratogenicity from metronidazole in humans and this drug is recommended for pregnant patients.²

Treatment is not recommended for asymptomatic nonpregnant patients who are not undergoing surgery. Because of the association of BV with postsurgical infection, strong consideration should be given to prophylactic treatment of infected women prior to surgical abortion. More data are needed before recommendation for treatment of all asymptomatic infected women undergoing other surgical procedures

TABLE 108-2 Treatment Regimens for Bacterial Vaginosis

Agent	Dose
RECOMMENDED REGIMENS	
Metronidazole*	500 mg PO bid for 7 d
Clindamycin cream 2%	One full applicator intravaginally qhs for 7 d
Metronidazole gel 0.75%	One full applicator intravaginally bid for 5 d
ALTERNATIVE REGIMENS†	
Metronidazole	2 g PO in a single dose
Clindamycin	300 mg PO bid for 7 d
REGIMENS FOR PREGNANT WOMEN	
High-risk patients	
Metronidazole	250 mg PO tid for 7 d
Alternative regimens†	
Metronidazole	2 g PO in a single dose
Clindamycin	300 mg PO bid for 7 d
Low-risk symptomatic patients	
Metronidazole	250 mg PO tid for 7 d
Alternative regimens†	
Metronidazole	2 g PO in a single dose
Metronidazole gel 0.75%	One full applicator intravaginally bid for 5 d
Clindamycin	300 mg PO bid for 7 d

*Avoid alcohol during and 24 h after treatment.

†Lower efficacy.

is made. However, consideration of treatment of these patients prior to surgery seems reasonable.² **AH pregnant women should be treated because of the negative impact this infection has on pregnancy.**²

Overall cure rates 4 weeks after treatment do not differ significantly between a 7-day regimen of either oral metronidazole, metronidazole vaginal gel, or clindamycin vaginal cream. Metronidazole vaginal gel has the benefit of fewer side effects (i.e., gastrointestinal disturbance and unpleasant taste) but should not be used in women who are allergic to the oral preparation. All patients on oral metronidazole should avoid alcohol during use and for 24 h after, and in some cases longer, after treatment because of the disulfiram-like reaction that can occur. The vaginal clindamycin cream appears less efficacious than the metronidazole regimens. Based on frequency of cure rates, alternative treatments to metronidazole are not as efficacious.

The use of clindamycin vaginal cream during pregnancy is not recommended because of the possibility of preterm deliveries among pregnant women treated with this medication (Table 108-2). Recurrence of symptoms is seen within 3 months in 30 percent of treated patients who initially respond. The reasons for this are unclear. Prolonged therapy for 10 to 14 days may be tried.⁵

CANDIDA VAGINITIS

Candida species are a common cause of vaginitis. There are no reliable prevalence data of vulvovaginal candidiasis (VVC) because the disease is not reportable, many women self-medicate with over-the-counter preparations, and as many as half the women given this diagnosis have other conditions. Although the actual prevalence is unknown for the above reasons, it is estimated that 75 percent of women will experience at least one infection during their childbearing years (with the highest attack rate during the third trimester of pregnancy), making it the second commonest vaginal infection. A small subpopulation of women, less than 5 percent, have repeated episodes of disease with no clinically proven factors being responsible for recurrent infection.

The organism can be isolated from up to 20 percent of asymptomatic, healthy women of childbearing age, some of whom are celibate. Therefore, this infection is not considered a sexually transmitted disease (STD), although it can be transmitted that way. At least one study, although small, has shown frequent intercourse to be a risk factor for infection.⁶ Factors that favor increased rates of asymptomatic vaginal colonization include pregnancy, oral contraceptives, uncontrolled diabetes mellitus, and frequent visits to STD clinics (perhaps as a result of antimicrobial therapy). It is rare in premenarcheal girls but does occur.³ It has a decreased incidence after menopause unless replacement estrogen is being used, emphasizing the hormonal dependence of VVC. Immunity to *Candida* infections is primarily cell mediated.

C. albicans strains account for 85 to 92 percent of those strains isolated from the vagina. *C. glabrata* and *C. tropicalis* are the commonest non-*albicans* strains and are often more resistant to conventional therapy. Candidal organisms gain access to the vaginal lumen and secretions predominantly from the adjacent perianal area. Candidal organisms must first adhere to the vaginal epithelial cells for colonization to take place, and *C. albicans* adheres in greater numbers than do other strains.

Factors that enhance the germination of *Candida* (e.g., pregnancy and estrogen therapy) tend to precipitate symptomatic vaginitis, while conditions that inhibit germination (normal flora and local mucosal cell-mediated immunity) prevent acute vaginitis in carriers of yeast. The growth of *Candida* is held in check by the normal vaginal flora, and symptoms of vaginitis usually occur only when the normal balance is upset. Conditions that inhibit growth of normal vaginal flora, particularly *Lactobacillus* species (e.g., systemic antibiotics, especially broad-spectrum agents), diminish the glycogen stores in vaginal epithelial cells (e.g., diabetes mellitus, pregnancy, oral contraceptives, and hormonal replacement therapy), or increase the pH of vaginal secretions (e.g., menstrual blood or semen), may cause increased colonization by *Candida*, which is an opportunistic organism, and cause subsequent symptomatic infection. Tight-fitting, particularly syn-

FIG. 108-2. Hyphal elements of *C. albicans* seen on high-power magnification during saline microscopy. The patient had florid candidal vaginitis.

thetic, undergarments may also contribute to the problem because of increased temperature, moisture, and local irritation.

Clinical symptoms include leukorrhea, severe vaginal pruritus (commonest symptom), external dysuria, and dyspareunia. Symptoms vary in severity, but exacerbation is frequently seen in the week prior to menses or with coitus. Odor is unusual.

Gynecologic examination may reveal vulvar erythema and edema, vaginal erythema, and, occasionally, thick "cottage-cheese" discharge, seen most often in pregnant patients. The discharge may vary from none to watery to homogeneously thick.

The diagnosis is made by finding a normal vaginal pH (4 to 4.5) and positive results on microscopic exam. Exam of a wet mount or normal saline sample of vaginal secretions will reveal yeast buds and pseudohyphae (Figure 108-2; sensitivity 40 to 60 percent). Two drops of 10 percent KOH added to the vaginal secretions dissolves the vaginal epithelial cells, leaving yeast buds and pseudohyphae intact, increasing the sensitivity (80 percent) of microscopic examination and yielding almost 100 percent specificity. Culture is almost never initiated from the ED. It is suggested for symptomatic patients with negative findings on microscopic examination. However, even this can lead to a false diagnosis as 10 to 20 percent of women usually harbor *Candida* spp. and other yeasts in the vagina.² Therefore, treatment of culture-positive patients is limited to those with compatible symptoms.

Most treatment regimens (see Table 108-3) are effective in relieving in excess of 80 percent of infected women.⁷ The topically applied azole drugs are more effective than nystatin, with relief of symptoms in 80 to 90 percent of patients who complete treatment. Creams, lotions, sprays, vaginal tablets, suppositories, and coated tampons are all equally efficacious, and the choice of vehicle should depend on the patient's preference. The azole drugs are all available over-the-counter with treatment for 1, 3, or 7 days. Uncomplicated WC (i.e., mild to moderate symptoms, sporadic, nonrecurrent disease in a normal host with normally susceptible

TABLE 108-3 Treatment Regimens for Vulvovaginal Candidiasis*

Agent	Formulation	Dosage Regimen
Uncomplicated VVC		
Butoconazole (Femstat)	2% Cream 100 mg vaginal	5 g/d X 3 days
Clotrimazole (Lotrimin, Mycelex-G)	tablet 200 mg vaginal	2 tablets/d X 3 days
(Monistat)	suppository	1 suppository/d X 3 days
Nystatin (Mycostatin)	100,000-unit vaginal tablet	1 tablet/d X 14 days
Tioconazole (Vagistat)	6.5% ointment	5 g intravaginally X one dose 1 tablet X
Fluconazole (Diflucan)	150 mg oral tablet	
Complicated WC		
Fluconazole (Diflucan) ^f *	150 mg oral tablet	1 tablet on days 1 and 3
Clotrimazole (Lotrimin, Mycelex-G)	500 mg vaginal suppository or tablet	1 suppository/tablet weekly
Pregnant patients^f Topical azole therapy only		Apply for 7 days

*Not all possible regimens listed.

^fOral therapy not recommended for pregnant patients.

C. albicans) responds to all azoles, including single-dose therapy. Complicated WC (i.e., severe symptoms, recurrent disease, abnormal host, or resistant organism such as *C. glabrata*) requires therapy lasting from 10 to 14 days with topical or oral azoles.^{2,7} Other than initial burning and irritation, side effects of local agents are unusual. Oral agents occasionally cause nausea, abdominal pain, and headaches.

One-day treatment with oral fluconazole is as effective as use of topical preparations but cannot be used in pregnancy and can cause gastrointestinal intolerance, headache, and rash.⁸ Ketoconazole can cause liver toxicity as well as adverse drug interactions with a variety of other medications. Oral agents are not recommended to treat candidiasis in pregnant patients. Partners should not be treated unless the woman has frequent recurrences.

Self-medication should only be advised in women with previously diagnosed VVC and recurrence of similar symptoms. If symptoms persist or recur within 2 months, the patient should be seen so that vaginal and microscopic examinations can be performed. Recurrent WC is defined as four or more episodes per year and occurs in less than 5 percent of healthy women.⁹ All possible precipitating factors, such as high blood-glucose levels, should be controlled. However, the majority of women with recurrences do not have obvious precipitating causes.

Management of women with frequent recurrences is aimed at control, rather than cure, with a long-term suppressive prophylactic regimen. Why a minority of women, many of whom have no underlying pathology, have frequent recurrences of infection with resulting morbidity is not fully understood. Current views suggest that local vaginal immune mechanisms may be responsible for frequent relapses. Diagnosis should be certain, oral contraceptives stopped, and blood glucose level checked in diabetics.

TRICHOMONAS VAGINALIS

The causative organism of trichomoniasis is a flagellated protozoan, *T. vaginalis*, that may live quiescently in paraurethral Skene's glands and from this nidus of infestation cause overt infection in the susceptible vagina. Trichomonads are frequently found in the urethra and may be recovered from urine. It is estimated that 2 to 3 million American women contract the disease annually. **Trichomonas is almost always a STD**, and its prevalence correlates with the overall level of sexual activity of the population studied. Recent epidemiologic surveys indicate a possible decline in prevalence. Vaginal trichomoniasis may be associated with adverse pregnancy outcomes, particularly PROM

and preterm delivery.¹⁰ Seventy percent of men having intercourse with infected women demonstrated the organism within 48 h, while 85 percent of women whose male partners were infected developed *Trichomonas* infection. There is a high prevalence of gonorrhea in women with trichomoniasis. Oral contraceptives, spermicidal agents, and barrier contraceptives are all thought to reduce transmission.

Infection ranges from asymptomatic carrier state to severe, acute inflammatory disease. A vaginal discharge is reported by 50 to 75 percent of patients. It may vary in character from the classic picture of a yellow-green frothy discharge, seen in 20 to 30 percent of patients, to a gray discharge to scant or no discharge. Other symptoms include vulvovaginal soreness and irritation (25 to 50 percent), pruritus, which may be severe (25 to 50 percent), dysuria (25 percent), and malodorous discharge (25 percent). A sense of vulvovaginal fullness may be intense or mild. As many as half of symptomatic women complain of some degree of dyspareunia. Symptoms may be more severe before, during, or after menstruation when the vaginal pH is more alkaline. Lower abdominal pain is rare and should alert the physician to the possibility of other diseases.

Just as symptoms vary in severity, so do the findings on examination. Gynecologic examination reveals the classic "strawberry cervix" secondary to diffuse punctate hemorrhages in only 2 percent of patients. Diffuse erythema is seen in 10 to 33 percent of patients.

The diagnosis is made through use of the "hanging-drop" slide test, which has a sensitivity of 80 to 90 percent in symptomatic patients. A cotton swab is used to obtain a specimen of secretions from the vaginal vault (not the endocervix) and is placed within a drop of normal saline solution on a glass slide. Microscopic examination reveals many polymorphonuclear leukocytes (PMNs) and motile, pear-shaped, flagellated

trichomonads, which are slightly larger than the leukocytes (Figure 108-3). As a screening test in asymptomatic individuals, the microscopic test may only be 50 to 70 percent sensitive, but has virtually 100 percent specificity. Cultures are approximately 95 percent sensitive and should be considered in symptomatic patients with elevated pH, PMN excess, and absence of motile trichomonads and clue cells.

T. vaginalis may survive up to 24 h in tap water, in hot tubs, in urine, on toilet seats, and in swimming pools, but the usual sequence of events begins with a large deposit of inoculum of organisms contained in the alkaline semen at time of intercourse. Because up to 25 percent of women and 90 percent of men harboring the organisms are asymptomatic, it is difficult to control spread of disease. The cornerstone of therapy remains metronidazole (Table 108-4).² Recurrence of disease is frequent and may necessitate more than one course of treatment. There is a 90 percent cure rate with either the single- or multiple-dose regimen. Cure rates increase to more than 90 percent when sexual partners are treated simultaneously. The single-dose treatment is preferable because of lower cost, fewer side effects, and greater patient compliance. Patients not responding may require a 7-day course of therapy. Patients who are allergic may be desensitized but there is no alternative treatment that is efficacious (CDC recommendation).

GENITAL HERPES

Genital herpes is a sexually transmitted infection caused by a deoxyribonucleic acid (DNA)-containing virus specific to human beings. Approximately 25 million individuals are infected with genital herpes in the United States. Sexual transmission can occur during asymptomatic periods. Usually, genital herpes is the most frequently encountered of the diseases causing genital ulcers in the United States,² and it may be one of the most frequent sexually transmitted diseases. There are two antigenic groups: herpes simplex virus 1 (HSV-1) and herpes simplex virus 2 (HSV-2). Initially, HSV-1 caused oral lesions and HSV-2 genital lesions, but this is no longer the case. Overall, 85 to 90 percent of genital herpes infections are caused by HSV-2, but some studies have found up to 30 percent are caused by HSV-1. Most cases of recurrent genital herpes are caused by HSV-2. Neonatal infection with high mortality and morbidity rates after passage through an infected birth canal has been seen. It is estimated that at least 50 million persons in the United States are infected.² It remains a recurrent disease with no cure at this time.

Initial presentation occurs 1 to 45 days (mean 5.8 days) after exposure. Usually, initial infection is more severe and lasts longer than do subsequent recurrences. There may be both local and systemic manifestations. The lesions begin as painful, fluid-filled vesicles or papules, which progress to well-circumscribed, occasionally coalescent, shallow-based ulcers. They then heal by reepithelialization of mucous membranes or by crusting by the epidermal surface. Symptoms peak in 8 to 10 days and decrease over the next week. Ulcers last 4 to 15 days, with total healing in 21 days. Lymphadenopathy is usually present, and when the deep inguinal nodes are involved, severe pelvic pain may result. Urethritis is usually present, causing severe dysuria, which may cause urethral spasm and urinary retention. Initial disease involves the cervix in more than 80 percent of cases. Pharyngitis and secondary spread of lesions to other body sites, usually below the waist, have been reported in up to two-thirds of patients. Systemic symptoms, such as

FIG. 108-3. Trichomoniasis: high-power microscopic view of secretions showing multiple trichomonads.

TABLE 108-4 Treatment Regimens for Trichomoniasis

Agent		Dose	
Metronidazole	RECOMMENDED REGIMEN	2 g PO in a sin; »le dose	
	ALTERNATIVE REGIMEN	500 mg PO bid	for 7 d

Note: Avoid alcohol during and for at least 24 h after treatment. Metronidazole can be used in pregnant women, but is not approved for use by the US FDA until the second trimester; and only if other treatment fails.

fever, malaise, headache, and myalgias, are common. Hepatitis, aseptic meningitis, and autonomic nervous system dysfunction can occur. Aseptic meningitis has been seen more frequently with HSV-2 than with HSV-1 infection and has been reported in approximately 30 percent of patients. Sacral autonomic nervous dysfunction is rare but can result in decreased cutaneous sensation and bladder and bowel dysfunction. After the attack is over, the inactive virus resides in the sacral dorsal root ganglia. Under various stimuli, both exogenous and endogenous, the virus travels down the sensory nerve root to the lower genital area, where it replicates and becomes symptomatic.

Recurrent episodes are usually milder than the initial disease, and the patient usually does not have systemic symptoms. A recurrence may be heralded by genital tingling. Recurrent genital lesions are fewer, smaller, and more often unilateral. Lesions may be ulcerative or resemble a fissure or excoriations. Recurrences tend to occur in the same location and have the same appearance from episode to episode. Symptoms last 4 to 8 days, and the lesions have usually disappeared by 10 days. Frequency of attacks and intervals between attacks are highly variable. The average number of symptomatic recurrences is 5 to 8 per year. Asymptomatic infections, defined as culture-positive viral shedding in the absence of symptoms or lesions, have been documented.

Approximately 25 percent of initial presentations occur in women with preexisting antibody to herpes simplex virus. The initial episodes tend to be less severe. They may, in fact, represent recurrent infections in patients who had previous asymptomatic infections. Clinically, it is impossible to distinguish between HSV-1 and HSV-2 infections, but HSV-1 usually causes milder initial disease, results in recurrence less frequently, and results in milder recurrent episodes.

Diagnosis is suspected by clinical presentation and confirmed by either culture, which is the preferred virologic test according to 2002 CDC guidelines (may become positive within 2 to 3 days of inoculation), or polymerase chain reaction (PCR). Although PCR is extremely sensitive in detecting low concentrations of viral DNA, the CDC has not yet recommended it as the test of choice. The virus can be isolated from vesicle fluid and the base of a wet ulcer. Intact vesicles, if present, should be unroofed and the fluid cultured directly. Scrapings of an ulcer may be taken for a Papanicolaou (Pap) smear or Tzanck preparation. A Tzanck smear stained with either Wright or Giemsa stain is positive if multinucleated giant cells are present, which may be seen in up to 50 percent of cases, but may be falsely positive. Serologic analysis is useful in classifying the initial herpetic episode as primary or nonprimary but is usually not indicated.

Treatment is not curative. Multiple antiviral agents and regimens are available (Table 108-5). Systemic antiviral agents provide partial control of the signs and symptoms and accelerate healing of the lesions, but do not affect the frequency or severity of recurrences. Topical therapy is ineffective.² Patients with severe disease may need hospitalization and intravenous therapy. In recurrent episodes, treatment should be started during the prodrome or within 1 day of onset of lesions if treatment is to be beneficial. For patients with frequent recurrences (six or more episodes per year) daily suppressive therapy can be used but should be discontinued after 1 year to allow assessment of the patient's recurrent episodes. Daily suppressive therapy reduces the frequency of recurrences by at least 75 percent. Suppressive therapy does not lessen the rate of viral shedding, and therefore patients should be advised of their continued risk of infecting sexual partners.

The safety of acyclovir and valacyclovir during pregnancy has not been established, however there has been no increased risk for major birth defects in pregnant women treated with these agents as compared to the general population. In pregnant patients with life-threatening disease, such as encephalitis, pneumonitis, or hepatitis, intravenous acyclovir should be used. It should not be used for recurrent episodes or as suppressive therapy. Pregnant women treated with the drug should be reported to the Glaxo-Wellcome registry, which is kept in cooperation with the CDC (1-800-722-9292, extension 38465). Current registry findings do not indicate an increased risk for major birth defects after acyclovir treatment.²

Systemic analgesics may be needed. Some patients have severe dysuria when the urine comes in contact with vaginal and vulvar tis-

TABLE 108-5 Treatment of Genital Herpes

Agent (Oral Tablets or Caplets)	Dose
INITIAL EPISODE	
Acyclovir	400 mg tid for 7-10 d

PREGNANCY	
Acyclovir	If severe or IV required 5-10 mg/kg qid for 5-7 d

Note: All agents categorized class B may be used for pregnant patients.

sues. Pouring warm water over these tissues during urination may provide symptomatic relief. HSV infection is a major source of morbidity and mortality for newborns. When active lesions are present at time of delivery, cesarean section may be necessary. Every effort should be made to prevent infection during pregnancy and to treat active disease.

CONTACT VULVOVAGINITIS

Contact dermatitis results from the exposure of vulvar epithelium and vaginal mucosa to a primary chemical irritant or an allergen. In either case, characteristic local erythema and edema occur. Severe reactions may progress to ulceration and secondary infection. Common irritants and/or allergens include chemically scented douches; soaps; bubble baths; deodorants; perfumes, dyes, and scents in toilet paper, tampons, and pads; feminine hygiene products; topical vaginal antibiotics; and tight slacks, pantyhose, and synthetic underwear.

Clinically, patients report local swelling and itching or a burning sensation. The gynecologic examination reveals an erythematous and edematous vulvovaginal area. Local vesiculation and ulceration are seen more commonly with allergens or when primary irritants are used in strong concentrations. Vaginal pH changes may promote colonization and infection with *C. albicans*, thus obscuring the primary cause.

Diagnosis of contact vulvovaginitis is made by ruling out an infectious cause and by identifying the offending agent. Most cases of mild vulvovaginal contact dermatitis resolve spontaneously when the causative agent is withdrawn. For patients with severe, painful reactions, cool sitz baths and wet compresses of dilute boric acid or Burow's solution may afford relief. Topical corticosteroids, such as hydrocortisone acetate (0.5 to 2.5 percent), fluocinolone acetonide (0.01 to 0.2 percent), or triamcinolone acetonide (.025 percent), relieve symptoms over a few applications and promote healing. Creams can be applied two or three times a day. Oral histamines may be helpful if a true allergic reaction is present. Superinfection with *C. albicans*, should it occur, should be treated as previously described. In these cases Mycolog (nystatin/triamcinolone) can be used.

Vulvovaginitis in the HIV-1-Positive Woman

Presence of vulvovaginitis may predispose women to infection by the human immunodeficiency virus (HIV) virus. Women who are HIV-1-positive may have an increased incidence of vulvovaginitis and may be

more likely to infect others during this period. There is evidence that disturbance of the normal vaginal flora and presence of BV may be a risk factor for acquisition of HIV infection.² Among HIV-1-seropositive women, the prevalence of *Candida* vulvovaginitis is reported to be as high as 62 percent.¹ Rates of colonization are similar in nonimmunocompromised HIV-positive women and HIV-negative women. When CD4⁺ T-cell counts are below 200/ μ L rates of colonization are increased as is symptomatic vaginitis. Recurrence of disease is also more frequent in immunocompromised HIV-positive women, as compared to HIV-positive women with CD4⁺ T-cell counts >200/ μ L and HIV-negative women.¹² Treatment of WC infection resulted in decreased viral shedding and thus infectivity in women who have *Candida* vaginitis.¹³ The optimal treatment of HIV-positive patients remains undefined; therefore, these patients should be treated with the same regimen as HIV-negative women.⁷ Treatment of patients with trichomoniasis has resulted in decrease of cell-free HIV-1 in vaginal secretions which may lead to decreased infectivity.¹⁴ Herpes genitalis is thought to be associated with an increased risk for HIV infection.²

VAGINAL FOREIGN BODIES

Children and adolescents may insert objects intravaginally during periods of genital exploration or sexual stimulation. In young girls, the most commonly inserted foreign bodies are rolled-up pieces of toilet paper, toys, and small household objects. In adolescents and adult women, it is often a forgotten tampon or sponge contraceptive. Foreign objects left in place for more than 48 h can cause severe localized infections due to *Escherichia coli*, anaerobes, or overgrowth of other vaginal flora. Patients present with a foul-smelling and/or bloody vaginal discharge. The only treatment necessary for vaginitis secondary to the presence of a foreign body is removal of the object.¹ In most cases, the vaginal discharge and odor will disappear without further therapy within several days.

PINWORMS

Pinworms (*Enterobius vermicularis*) may migrate from the anus to the vagina in children and cause intense pruritus that is often most intense during the night, when gravid female worms pass out from the intestinal tract to lay eggs on the perineal skin. Cellophane tape can be used to obtain material for a slide, which can be examined microscopically for the presence of ova, which are large and double-walled in appearance. The child and all family members need treatment with an antiparasitic agent, either mebendazole 100 mg PO X 1 and repeated in 2 weeks; albendazole, 400 mg PO X 1 and repeated in 2 weeks; or pyrantel pamoate 11 mg/kg PO X 1 dose with a repeat dose q 2 weeks X 2 (maximum single dose 1g). Repeat treatment 2 weeks later should be administered because mature worms seem more vulnerable to treatment than do young worms. Albendazole is contraindicated in pregnancy; mebendazole can be used with caution. Pyrantel pamoate is available without prescription.

ATROPHIC VAGINITIS

During menarche, pregnancy, and lactation, and after menopause, the vaginal epithelium lacks the stimulation of estrogen. The maturation of the vaginal and urethra mucosa depends on the presence of estrogen and can be altered by the absence of estrogen or the presence of anti-estrogenic factors, such as hormones, drugs, or diseases. Menopause results in a vaginal mucosa that is attenuated, pale, and almost transparent as a result of decreased vascularity. The vagina loses its normal rugae. The squamous epithelium atrophies, the glycogen content of the cells decreases, and the vaginal pH ranges from 5.5 to 7.0. The mucosa is only three or four cells thick and is less resistant to minor trauma and infection. Marked atrophic changes can cause atrophic vaginitis. It is important to distinguish between symptomatic atrophic vaginitis,

which is rare, and an atrophic vagina that is a result of physiologic changes of menopause. When symptomatic vaginitis occurs, the vaginal epithelium is thin, inflamed, and even ulcerated. Symptoms include vaginal soreness, dyspareunia, and occasional spotting or discharge, which may be a thin, scant, yellowish or pink material. The cervix atrophies and retracts and may become flush with the apex of the vault. The upper one-third of the vagina constricts, and the entire vagina becomes shorter in length and loses its elasticity. The increased vaginal pH may permit the growth of nonacidophilic coliform organisms, bacteria not normally found in the vagina, and the disappearance of *Lactobacillus* species. This can lead to the development of a clinical vaginal infection with copious purulent discharge. Unless estrogen replacement therapy is used, *Candida* and *Trichomonas* infections are rare. The changes seen vary widely from one patient to another.

A Papanicolaou (Pap) smear of the cervix and vagina is mandatory in the face of bleeding to rule out carcinoma. A wet preparation will show erythrocytes and increased PMNs associated with small, round epithelial cells, which are immature squamous cells that have not been exposed to sufficient estrogen.

The treatment of atrophic vaginitis consists primarily of topical vaginal estrogen. Nightly use of vaginal tablets is effective. Estradiol absorption from vaginal tablets has been found to be negligible when low dose formulations (10 to 25 μ g) are used.¹⁵ Estrogen should not be prescribed for any patient with a past history of cancer of any of the reproductive organs. Atrophic vaginitis is usually not seen in patients who are already on systemic estrogen replacement therapy. Patients should be referred for follow-up to monitor therapy and for the results of the Pap smear.

PELVIC INFLAMMATORY DISEASE

Amy J. Behrman William H. Shoff
Suzanne M. Shepherd

Pelvic inflammatory disease (PID) comprises a spectrum of infections of the female upper reproductive tract. It is a common and serious disease initiated by ascending infection from the cervix and vagina. PID may include salpingitis, endometritis, and tubo-ovarian abscess and may extend to produce pelvic peritonitis and perihepatitis. The annual rate of PID in industrialized countries has been reported to be as high as 10 to 20 per 1000 women of reproductive age, with as many as 1.5 million cases estimated to occur per year in the United States.¹ These numbers likely underestimate the true incidence because of widely variable symptoms and the relatively poor reliability of the clinical diagnosis. Long-term sequelae, including tubal factor infertility (TFI), ectopic pregnancy, and chronic pain, may occur in as many as 25 percent of patients. The annual direct costs of the acute disease and its sequelae were estimated to be \$1.88 billion in 1998.¹

Patients with PID frequently present to the ED with nonspecific complaints and findings. Early diagnosis and aggressive treatment may provide rapid clinical and microbiologic improvement, identify coexisting disease, decrease transmission, and minimize the likelihood of serious sequelae.

ETIOLOGY

Neisseria gonorrhoeae and *Chlamydia trachomatis* can be isolated in many, if not most, cases of PID, and therapy traditionally has been directed primarily against these organisms. However, newer, more sensitive, and more specific culture techniques have improved our understanding of PID significantly. Polymicrobial infection, including anaerobic and aerobic vaginal flora, clearly has been demonstrated in studies relying on cultural material from the upper reproductive tract. Earlier culdocentesis studies suggested that 80 percent of PID was polymicrobial, but there is evidence that this may represent a degree of contamination of the cul-de-sac by the procedure. Laparoscopy cultures more conservatively point to mixed infection in 30 to 40 percent of cases. Pathogenic organisms may include anaerobes, *Gardnerella vaginalis*, enteric gram-negative rods, *Haemophilus influenzae*, *Streptococcus agalactiae*, *Mycoplasma hominis*, and *Ureaplasma urealyticum*. *N. gonorrhoeae* and *C. trachomatis* often may be instrumental in the initial infection of the upper genital tract, whereas anaerobes, facultative anaerobes, and other bacteria are isolated increasingly as inflammation increases and abscesses form. Bacterial vaginosis also may play a role in the initiation of ascending infection, particularly after abortion or gynecologic surgery.^{2,3} HIV-1 infection is associated with an increased incidence of *C. trachomatis* infection and an increased risk of progression to PID.⁴ PID also may result from *M. tuberculosis* in endemic areas.⁵ The microbiology of PID also reflects the predominant sexually transmitted diseases prevalent within a given population.

Pathology and Risk Factors

Most cases of PID are presumed to originate with sexually transmitted diseases (STDs) of the lower genital tract, followed by ascending infection of the upper tract. The original STD may be asymptomatic. It is estimated that 10 to 20 percent of untreated gonococcal or chlamydial cervicitis may progress to PID. The precise mechanisms by which infection and inflammation in the upper genital tract are initiated and propagated remain under investigation. Although the cervical mucus serves as a functional barrier to ascending infection much of the time, its efficacy may be decreased by hormonal changes during ovulation and by retrograde menstruation. Bacteria also may be carried by or along with sperm into the uterus and tubes. Uterine infection usually

is limited to the endometrium but may be more invasive in a gravid or postpartum uterus. Tubal infection initially affects only the mucosa, but acute, complement-mediated transmural inflammation may develop rapidly and increase in intensity with repeated infection. Inflammation may extend to uninfected parametrial structures, including the bowel. If purulent material from the tubes spills into the abdomen, pelvic peritonitis may result. Infection may extend by direct or lymphatic spread beyond the pelvis to involve the hepatic capsule with acute perihepatitis and focal peritonitis (FitzHugh-Curtis syndrome).

Risk factors for PID within a sexually active population include multiple sexual partners, history of other STDs, history of sexual abuse, and frequent vaginal douching.^{6,9} Younger age is associated with increased risk, possibly because of a larger zone of cervical ectopy in young women, increased cervical mucosal permeability, lower prevalence of protective chlamydial antibodies, risk-taking behavior, or a combination of these factors. Consistent barrier contraception is associated with lower risk of PID. Intrauterine device (IUD) use has been associated with a two- to ninefold increased risk for PID, but recent data indicate that the risk with current IUDs may be much less.¹⁰ Oral contraceptive pills (OCPs) have been thought to increase the risk of endocervical infection (probably by increasing the zone of cervical ectopy) but to decrease the risk of symptomatic PID, possibly by increasing the viscosity of cervical mucus, decreasing menstrual blood flow (and hence decreasing retrograde menstruation), or modifying local immune responses. Recent data, however, suggest that OCPs may have no effect on PID incidence.¹¹ Bilateral tubal ligation (BTL) does not provide protection against PID, but patients with BTL may have delayed and/or milder forms of the disease.¹² Pregnancy decreases the risk of PID because the cervical os is protected by a mucous plug. However, PID can occur during the first trimester and may cause fetal loss.

In addition to host factors, genetic polymorphisms of PID pathogens may affect the likelihood that a lower tract infection will progress to frank PID. P9-Opa(b) protein expression in *N. gonorrhoeae*¹³ and CHSP60 antigen expression in *C. trachomatis*¹⁴ are recent examples of specific bacterial genes implicated in PID pathogenesis.

Complications

PID is associated with a number of serious clinical sequelae. Tubo-ovarian abscess is reported in up to one-third of women hospitalized for PID. Infection and inflammation can lead to scarring and adhesions within tubal lumens. The rate of potentially fatal ectopic pregnancy is 12 to 15 percent higher in women who have had PID. TFI is increased 12 to 50 percent in women with a past diagnosis of PID, and the incidence of TFI increases with the number and severity of past PID episodes. Asymptomatic or silent PID appears to be associated with TFI as well; 50 percent of women with TFI have no history of PID but do have scarring of the fallopian tubes and exhibit antibodies to *N. gonorrhoeae* and/or *C. trachomatis*. Chronic pelvic pain and/or dyspareunia has been reported in 18 percent of women with past histories of PID.

DIAGNOSIS

Clinical Findings

HISTORY Lower abdominal pain is the most frequent presenting complaint in PID. Other symptoms may include abnormal vaginal discharge, vaginal bleeding, postcoital bleeding, dyspareunia, irritative voiding symptoms, fever, malaise, nausea, and vomiting. PID may be minimally symptomatic or asymptomatic.¹⁵ The differential diagnosis of these nonspecific presentations includes cervicitis, ectopic pregnancy, endometriosis, ovarian cyst, ovarian torsion, spontaneous abortion, septic abortion, cholecystitis, gastroenteritis, appendicitis, diverticulitis, pyelonephritis, and renal colic.

PHYSICAL EXAMINATION The physical examination is usually notable for lower abdominal tenderness, cervical motion tenderness, and uterine and/or adnexal tenderness. The positive predictive value (PPV) of these findings will vary depending on the prevalence of PID in a given clinical population. However, one large multicenter trial found adnexal tenderness to be the most sensitive finding on physical examination (95 percent sensitive; $p < 0.001$).¹⁶ Mucopurulent cervicitis is common and has a significant negative predictive value when absent.¹⁵ Disproportionate unilateral adnexal tenderness and/or adnexal mass or fullness may indicate an ovarian abscess. Abdominal guarding and rebound tenderness will develop with peritonitis. Right upper quadrant tenderness, particularly with jaundice, may indicate FitzHugh-Curtis syndrome. Signs of other STDs should be noted and evaluated.

Laboratory Evaluation

Laboratory evaluation in the ED always should include a pregnancy test. The possibility of ectopic pregnancy or septic abortion must be considered, and concurrent pregnancy will influence PID therapy. Saline- and potassium hydroxide-treated wet preparations of vaginal secretions should be examined for leukorrhea (more than one polymorphonuclear leukocyte per epithelial cell), trichomoniasis, and clue cells. The absence of leukorrhea in saline preparations is a negative predictor for PID.¹⁵ Endocervical swabs should be sent for culture and can be Gram stained for gonococci. DNA probes for gonorrhea and *Chlamydia* are useful and increasingly available. Quantitative culture for *Chlamydia*, the most common causal agent for PID, identifies rapidly replicating bacteria that appear to be associated with active disease,¹⁷ but these results will not be available to the emergency physician at the time of evaluation.

Elevated white blood cell counts, sedimentation rates, and/or C-reactive protein support the diagnosis of PID. The rapid plasma reagin test for syphilis should be performed. Patients should be counseled and tested for hepatitis and HIV. HIV-infected women with PID may present more often with tubo-ovarian abscess and coinfection with *Candida* and human papillomavirus.¹⁵ Blood cultures do not aid in the diagnosis or management of PID.¹⁸

Procedures

A number of procedures can be performed to improve the accuracy of PID diagnosis. These procedures are not necessary, nor are they indicated, in every case of presumptive PID. However, since PID is difficult to diagnose definitively on clinical grounds and may mimic surgical emergencies,¹⁹ the clinician should be familiar with these modalities.

Transvaginalpelvic ultrasound may demonstrate thickened (>5 mm), fluid-filled fallopian tubes or free pelvic fluid in acute, severe PID. These findings alone are not specific enough to make a definitive diagnosis. However, pelvic abscesses may be seen as complex adnexal masses with multiple internal echoes. In the individual who appears toxic or has asymmetric pelvic findings, ED pelvic ultrasound is an important diagnostic tool for the identification of a tubo-ovarian abscess. Pelvic ultrasound also will be useful in evaluating the possibility of ectopic pregnancy in those patients in whom the differential diagnosis includes both entities. Power Doppler transvaginal sonography is reported to be extremely accurate in diagnosing PID and assessing the severity of the disease.²⁰

Endometrial biopsy can be used for the histopathologic diagnosis of endometritis. Endometritis is uniformly associated with salpingitis. Specimens for culture also may be obtained but frequently will be contaminated with vaginal flora. The procedure is performed with an endometrial suction pipette/curette and is well tolerated. Endometrial biopsy is approximately 90 percent specific with similar sensitivity. However, diagnostic utility in the ED is limited because results are not immediately available.

Culdocentesis can be performed rapidly in the ED. However, its utility is also limited. The potential positive findings of leukocytes and bacteria are nonspecific and may be a product of other inflammatory processes, such as appendicitis or diverticulitis, or due to contamination with vaginal contents.

Laparoscopy is the "gold standard" for the diagnosis of PID. It is significantly more sensitive and specific than clinical criteria alone. The minimum criteria to diagnose PID laparoscopically include visible hyperemia of the tubal surface, tubal wall edema, and the presence of exudate on the tubal surface and fimbriae. Pelvic masses consistent with tubo-ovarian abscess or ectopic pregnancy also can be visualized directly. Hepatic capsule exudate and/or adhesions may be demonstrated. Material may be obtained for definitive culture without the risk of vaginal contamination. However, the procedure is invasive and expensive, requiring an operating room and anesthesia. Findings on laparoscopy do not necessarily correlate with the severity of illness because the laparoscopist can see only the surfaces of structures. Laparoscopy may fail to define up to 20 percent of cases.²¹

Diagnostic Guidelines

To expedite treatment and maximize compliance, the diagnosis of PID in ED and clinics is usually based on clinical criteria with or without laboratory evidence. The Centers for Disease Control and Prevention (CDC) regularly reviews STD research and epidemiology in order to update guidelines for diagnosis and treatment. Current guidelines¹⁵ for PID stratify diagnostic criteria into the three groups shown in Table 109-1.

THERAPY

Treatment

Treatment of PID is aimed at relieving acute symptoms, eradicating current infection, and minimizing the risk of long-term sequelae. There is no clear role for anti-inflammatory drugs at this time, but effective analgesia should be administered. Therapy initiated in the ED must include empirical broad-spectrum antibiotics to cover the full range of likely organisms. All regimens should be effective against anaerobes, gram-negative facultative organisms, and streptococci, as well as *N. gonorrhoeae* and *C. trachomatis*. Long-term outcomes are improved if antibiotics are begun immediately.¹⁵

No published studies have effectively compared parenteral and oral antibiotic regimens or inpatient versus outpatient regimens with regard to documented elimination of endometrial and tubal infection. Many studies have demonstrated the effectiveness a variety of parenteral and

TABLE 109-1 Treatment Guidelines for PID Based on Diagnostic Criteria

<i>Group 1: Minimum criteria.</i> Empirical treatment indicated if no other etiology to explain findings
Uterine or adnexal tenderness
Cervical motion tenderness
<i>Group 2: Additional criteria</i>
<i>improving diagnostic specificity</i>
Oral temperature $>101^{\circ}\text{F}$ (38.3°C)
Abnormal cervical or vaginal mucopurulent secretions
Elevated erythrocyte sedimentation rate
Elevated C-reactive protein
Laboratory evidence of cervical infection with <i>N. gonorrhoeae</i> or <i>C. trachomatis</i> (i.e., culture or DNA probe techniques)
<i>Group 3: Specific criteria for PID based on procedures that may be appropriate for some patients</i>
Laparoscopic confirmation
Transvaginal ultrasound (or MRI) showing thickened, fluid-filled tubes with/without free pelvic fluid or tubo-ovarian complex
Endometrial biopsy showing endometritis.

TABLE 109-2 Parenteral Treatment Regimens for PID

1. Cefotetan 2 g IV q12h or cefoxitin 2 g IV q6h and doxycycline 100 mg PO or IV q12h
2. Clindamycin 900 mg IV q8h and gentamicin 2 mg/kg IV loading dose followed by 1.5 mg/kg q8h
3. Ofloxacin 400 mg IV q12h or levofloxacin 500 mg IV q24h (prefer > 18 years of age due to concerns regarding adverse effects on cartilage)²² with or without metronidazole 500 mg IV q8h or ampicillin-sulbactam 3 g IV q6h and doxycycline 100 mg PO or IV q12h

Note: PO doxycycline has the same bioavailability as IV and avoids painful infusion. Gentamicin dosing may be every 24 h. Source: Adapted from the CDC.¹⁵

oral regimens in the elimination of acute symptoms and the achievement of microbiologic cures. Currently accepted treatment regimens are summarized in Tables 109-2 and 109-3. Physicians should be familiar with current patterns of drug resistance in their patient populations.

If an IUD is present, it should be removed after antibiotics have been started.

Twenty-four hours after clinical improvement, patients with PID who require initial intravenous antibiotics can be switched to oral antibiotics, which should be continued for a total of 14 days. Oral therapy is usually doxycycline (100 mg PO bid). In the setting of tubo-ovarian abscess, oral therapy should be continued with clindamycin (450 mg PO qid) or metronidazole with doxycycline for better anaerobic coverage.

All patients should be reevaluated in 72 h for evidence of substantial clinical improvement (defervescence, decreased abdominal tenderness, decreased uterine, adnexal, and cervical motion tenderness) and compliance with their regimen.

Surgical Intervention

Patients who do not improve within 72 h should be reevaluated for possible laparoscopic or surgical intervention, i.e., drainage of pus loculations or tubo-ovarian abscess, or to reconsider other possible diagnoses.

The majority of tubo-ovarian abscesses (60-80 percent) will resolve with antibiotic administration alone. If patients do not respond clinically to antibiotics, laparoscopy may be useful to identify pus loculations requiring drainage, or alternative pathologies. An enlarging pelvic mass may indicate bleeding secondary to vessel erosion or a ruptured abscess. Unresolved abscesses may be drained percutaneously, laparoscopically, or surgically.

DISPOSITION

Guidelines for the admission (Table 109-4) and inpatient treatment of PID patients have evolved over the past decade (see Table 109-2). Parenteral therapy no longer requires admission in many settings, and there are no data to demonstrate that inpatient treatment is more effective than outpatient treatment in optimizing long-term clinical outcomes. Admission of adolescents and those with coexisting HIV infection should be reviewed on an individual basis.²² Admission

TABLE 109-3 Oral/Outpatient Treatment Regimens for PID

1. Ofloxacin 400 mg PO bid for 14 days or levofloxacin 500 mg PO qd for 14 days (prefer >18 years of age due to concern regarding adverse effects on cartilage)²¹ with or without Metronidazole 500 mg PO bid for 14 days
2. Ceftriaxone 250 mg IM once or cefoxitin 2 g IM once and probenecid 1 g PO once and doxycycline 100 mg PO bid for 14 days with or without metronidazole 500 mg PO bid for 14 days

Note: Other parenteral third-generation cephalosporins can be substituted for ceftriaxone or cefoxitin.

TABLE 109-4 Admission Considerations

- Surgical emergency cannot be excluded from the differential
- Pregnancy
- Failure to respond to outpatient treatment
- Inability to tolerate or comply with outpatient treatment
- Severe toxicity, nausea, vomiting
- Tubo-ovarian abscess

Source: Adapted from the CDC.¹⁵

decisions in the ED are based on severity of illness, likelihood of compliance with outpatient medications, likelihood of major anaerobic infection (IUD, suspected pelvic or tubo-ovarian abscess, or history of recent uterine instrumentation), certainty of diagnosis, coexisting illness and immunosuppression, pregnancy, patient age, and other major fertility issues. A gynecologist must be consulted on all patients considered for admission, including those with coexisting pregnancy, IUD, or tubo-ovarian abscess. A surgeon should be consulted if appendicitis cannot be excluded. Abdominal computed tomographic examination with oral and intravenous contrast material is the best modality to use in this instance to clarify the situation.

PREVENTION

Uncomplicated endocervical infections with *N. gonorrhoeae* and *C. trachomatis* are often underdiagnosed and undertreated. One study found a 10.4 percent prevalence of unrecognized genital gonorrhea and *Chlamydia* infection in a general urban ED population.²³ Improving education, diagnosis, and empirical treatment rates for these infections, as well as for minimally symptomatic PID, should result in a lower incidence and prevalence of PID and should decrease the incidence of major long-term sequelae, such as infertility and ectopic pregnancy. In addition, routine screening for *N. gonorrhoeae* and *C. trachomatis* in women at risk for PID using DNA probes of cervical specimens or urine^{15,24} could theoretically reduce the incidence of PID and its sequelae.

Patients discharged with PID may be noncompliant with medications, may not understand their diagnoses, and frequently do not obtain partner treatment. Patients should be educated about these issues, as well as the advisability of testing and treatment for other STDs, including syphilis and HIV. Patients should understand the use of barrier contraceptives and other "safe sex" techniques to lessen their risk of reinfection.

Finally, and perhaps most important, partner treatment is crucial to preventing repeated episodes of PID. Partners of PID patients should be treated empirically for *N. gonorrhoeae* and *C. trachomatis* if they have had sexual contact with the patient in the 60 days preceding the onset of her symptoms. Sexual contact should be avoided until one full course of treatment is completed for each partner.¹⁴

plaint relating to their breasts.¹ In 2001, incidence of all breast cancers exceeded 192,000 new cases, with an estimated 40,200 deaths attributable to breast cancer.² Therefore, while the acuity of the problem may be low, the prevalence of presenting breast disorders may be quite high.

ANATOMY AND PHYSIOLOGY

Adult Anatomy

Normal breast tissue is a circular mass of glandular tissue located on the anterior chest wall and extending from the sternocostal junction medially to the midaxillary line laterally and from the second to the sixth ribs in the midclavicular line. Sensory innervation is from a dermatomal distribution, whereas the arterial supply to the breast arises from the internal mammary, lateral thoracic, thoracodorsal, and subscapular arteries. The lymphatic drainage of the breast is primarily to the axilla, with a small portion going to internal mammary lymph nodes. Lymph flow is not regionally distributed; lymphatic drainage to either the axilla or the internal mammary chain can originate in any quadrant of the breast.

Breast Physiology

Stromal and lobular tissues continue to develop until approximately 25 years of age. The adult breast is composed of approximately 20 percent ductal tissue, whereas the remaining breast volume consists of fat and connective tissue that give the breast its characteristic texture and shape.

Cyclic variances in estrogens, progesterone, follicle-stimulating hormone (FSH), and luteinizing hormone (LH) signal stromal and glandular changes in breast physiology. Due to the effects of rising circulating progesterone and a small peak in estrogen levels, the resulting interlobular edema causes the breast swelling, engorgement, and tenderness associated with the premenstrual phase. Breast tissue volume and tenderness are at a minimum 5 to 7 days after menstruation due to the relative lack of progesterone, allowing for a more sensitive and comfortable breast examination. At the onset of menstruation, the rapid decline in estrogen and progesterone levels leads to ductal involution. In contrast, menopausal breast changes involve actual loss of glandular tissue secondary to the gradual loss of estrogen and progesterone synthesis. The resulting postmenopausal breast consists predominantly of prepectoral fat, connective tissue, mammary ducts, and minimal lobular elements.

HISTORY AND PHYSICAL EXAMINATION

A routine breast examination can be a significant source of anxiety for the patient. The history and examination should be as private, comfortable, and reassuring as possible and should be followed by a discussion in which the diagnosis and treatment strategy are both understandable and acceptable to the patient.

Patient History

The patient should be questioned about onset of any mass or pain, location of the affected area, and duration of the symptoms. Complaints that vary with menses suggest a benign cause, whereas cancers are often asymptomatic. Radiation of the pain to any other body site is particularly important when a malignancy is suspected. The presence of symptoms in the contralateral breast parenchyma is also more reassuring for a benign diagnosis. The color and consistency of a nipple discharge, if present, should be evaluated, although the color of the discharge does not differentiate a benign from a malignant process. Changes that the patient notes on breast self-examination may be significant and should be correlated with the menstrual cycle. Family his-

BREAST DISORDERS

Janet Simmons Young

The most common breast problems in the ED usually involve breast pain, breast mass, nipple discharge, breast infection, or postoperative complications. Rarely is the problem emergent, but a patient's perception for the potential for cancer may contribute to increased anxiety over the presenting problem.

EPIDEMIOLOGY

Few data are available regarding the incidence of emergency presentations for general breast disorders. Approximately one in every three to four women in the United States sees a physician with a chief com-

tory specifically inquiring about the presence of first-degree relatives with breast cancer and other risk factors (delayed childbearing after age 30, biopsy confirmation of atypical hyperplasia, or history of chest irradiation) should be obtained. However, it also must be remembered that most women who develop breast cancer have no obvious risk factors beyond the two strongest factors, namely, female gender and age. More than 50 percent of breast cancers are diagnosed in women 65 years of age or older, and women under age 30 are diagnosed with less than 1 percent of all breast cancers.³

Physical Examination

The breast tissue examination (Figure 110-1) is best performed with the patient supine with the ipsilateral forearm behind the head. Palpation in a rotatory clockwise or counterclockwise motion ensures evaluation of the entire breast mound. The upper outer quadrant of each breast should be examined with extra care because approximately half of breast carcinomas originate in that area, with a higher propensity for left-sided involvement.^{4,6} Asymmetry in glandular consistency and nodules or thickenings should be described by their quadrant of location (upper and lower, inner and outer) and distance from the nipple-areola complex. Examination of the nipple-areola complex occurs by gentle manipulation to detect subareolar masses and latent nipple discharge. The breasts then should be compared with the patient in an upright or sitting position, with any breast asymmetry or skin dimpling noted. Subtle abnormalities in the lower quadrants may be accentuated by having the patient raise her arms above her head. The axillae should be examined to note the presence, consistency, and mobility of any palpable lymph nodes. The anterior and posterior neck as well as the supraclavicular area should be examined for lymphadenopathy.

PHYSIOLOGY AND DISORDERS OF THE LACTATING BREAST

During pregnancy, marked glandular growth occurs under the influence of estrogen, progesterone, placental lactogen, prolactin, and chorionic gonadotropin, as well as maternal cortisol and thyroid hormones. Proliferative and secretory glandular changes, which begin early in the first trimester, prepare the breast alveolar cells for milk production at parturition. However, inhibition of lactation during pregnancy is mediated by a central nervous system (CNS) dopaminergic pathway. The abrupt fall of progesterone, human placental lactogen, and estrogen that occurs at parturition leads to the glandular secretion of colostrum and the cessation of milk production inhibition. Within 3 to 4 days, milk rich in lipid, protein, carbohydrate, and immunoglobulin is produced. The nursing infant's tactile stimulation of the nipple-areola complex provides a neurogenic signal to maintain milk production that can lead to discharge for years if stimulation is maintained after weaning.

ABNORMAL LACTATION

Any inappropriate secretion of milky discharge from the breast is referred to as *galactorrhea*. Galactorrhea often results from abnormally elevated levels of prolactin, although some women will have normal prolactin levels on testing. Physiologic causes of elevated serum prolactin levels are sleep, stress, exercise, volume depletion, intercourse or orgasm, pregnancy, and breast stimulation. Abnormal stimulation of the chest wall, such as from surgery, trauma, or herpetic infection, can increase prolactin secretion. Elevated levels of prolactin can occur from inadequate inhibition of secretion or from increased production of prolactin. Any exogenous damage or disruption of the pituitary

FIG. 110-1. Positioning for the examination of the breasts. [From August, DA and Sondak, VK: Breast disease, in Greenfield LJ (ed): *Surgery: Scientific Principles and Practice*. Philadelphia, Lippincott, 1996, pp 1357-1415.]

stalk or endogenous hypothalamo-pituitary signaling may result in increased prolactin secretion. Prolactinomas, benign anterior pituitary neoplasms, are distinguished by symptoms of galactorrhea, amenorrhea, hirsutism, facial acne, visual field deficits, and headaches. Other neoplastic disorders implicated in hyperprolactinemia are renal cell carcinoma, lymphoma, craniopharyngioma, bronchogenic carcinoma, and hydatidiform mole.

Multiple medications are known to interfere with dopamine-mediated inhibition of prolactin. Specifically, antidepressants such as monoamine oxidase inhibitors (MAOIs), selective serotonin reuptake inhibitors (SSRIs), and tricyclic antidepressants (TCAs) target dopamine to exert their clinical effects. The antihypertensives atenolol, methyldopa, reserpine, and verapamil, as well as the antipsychotic phenothiazines and antihistamines, are known to cause galactorrhea. Several herbs, often contained in dietary supplements, are associated with galactorrhea: anise, fennel, nettle, clover, and thistle. Fenugreek seed has even been used to induce lactation. Many illegal drugs such as amphetamines, cocaine, opioids, and marijuana can cause galactorrhea.

Consideration of systemic diseases should be given in the evaluation of galactorrhea. Chronic renal failure results in a diminished capacity to clear circulating prolactin. Hypothyroidism causes increased thyrotropin-releasing hormone (TRH), which results in increased pituitary secretion of prolactin. Hypercortisolism (Cushing disease) and acromegaly due to abnormal growth hormone secretion are both associated with galactorrhea.

Evaluation of the patient with galactorrhea should focus on a history of associated menstrual abnormalities and the presence of acne, hirsutism, infertility, or libido changes. Symptoms of increased intracranial pressure and hypothyroidism also should be investigated. All medications and dietary supplements should be reviewed with the patient.

The physical examination should include evaluations of the visual fields, breasts, skin, and thyroid gland. ED studies include a urine or serum pregnancy test, neuroimaging (computed tomography or magnetic resonance imaging), and neurosurgical consultation if there is concern for an intracranial mass. Treatment, other than the discontinuation of a suspected medication, may be deferred to the primary care physician or the follow-up specialist.

COMPLICATIONS OF LACTATION

Breast engorgement usually presents on the third to fifth postpartum day, with symptoms of painful, hard, and enlarged bilateral breasts. The pain may be accompanied by a low-grade fever. The presence of carbohydrate-rich milk during lactation facilitates bacterial overgrowth and colonization by *Candida* species in the lactiferous ducts should obstruction to flow from any of the major ducts occur. Pumping the breasts usually alleviates the pain and allows for decompression of the nipple-areola complex, facilitating effective breast-feeding. Topical antifungals, in conjunction with breast pumping, usually are effective at eradicating the fissuring and scaly rash of the nipple and areola due to *Candida albicans*.

Puerperal mastitis occurs most often after bacterial colonization secondary to areolar inflammation and glandular obstruction, creating an increased susceptibility to suppurative mastitis during nursing. Puerperal mastitis, or endemic mastitis, often occurs during the first few weeks to months postpartum, when the skin of the nipples is damaged most easily, and much later when the infant may inflict dental trauma. The patient may report fever, chills, myalgias, or flu-like symptoms, and examination of the breast reveals an erythematous, localized area of pain. Puerperal mastitis is most commonly caused by *Staphylococcus aureus*, although *Escherichia coli* and *Streptococcus* spp. are also known pathogens. Treatment requires breast emptying, skin cleansing, analgesia, and antistaphylococcal penicillins or cephalosporins.⁷ There is no need to interrupt breast-feeding with puerperal mastitis. However, if the infection fails to respond rapidly to antibiotics, an abscess should be suspected.

Differentiation between mastitis, usually associated with cellulitis of the overlying skin, and breast abscess, usually accompanied by palpable fluctuance, can be difficult. An abscess may present with the signs and symptoms of mastitis or may demonstrate only minimal focal induration. Ultrasound examination of the erythematous area may be helpful in diagnosis of a subcutaneous purulent collection. Interruption of breast-feeding to prevent neonatal infection and cephalosporins or clindamycin for anaerobic coverage may be required. Immediate referral for surgical drainage is necessary, although an excisional biopsy of tissue also may be performed by the surgeon to rule out an inflammatory carcinoma.⁸

INFLAMMATORY BREAST CONDITIONS

Breast Infections

The differential diagnosis of an inflammatory breast complaint includes infectious mastitis, breast abscess, periductal mastitis, ruptured breast cysts, inflammatory carcinomas, lymphosarcomas, carcinoma erysipeloides (inflammatory skin metastases from thyroid carcinoma), syphilis, tuberculosis, and Paget dermatitis.⁹ ED presentations of each entity can mimic other, more benign conditions. While the classic *peau d'orange* appearance is highly suggestive for cancer, other signs such as the clarity of erythematous demarcation, the amount of tissue involved, or the presence of ulceration are not pathognomonic for any specific diagnosis. A failure to improve with antibiotics indicates the need for immediate surgical consultation and possible biopsy to exclude the presence of an inflammatory neoplasm.¹⁰

Acute Mastitis and Breast Abscess

Acute infections of the breast generally present with erythema, edema, tenderness, malaise, and often fever. Mastitis, or superficial cellulitis of the breast, usually is treated conservatively with antistaphylococcal antibiotics and frequent reassessment. Puerperal mastitis, which was discussed in the preceding section, is also treated with antibiotics and frequent breast emptying. Breast cellulitis, if recognized early, responds to antibiotic treatment with an antistaphylococcal penicillin (e.g., dicloxacillin 250 mg PO qid for 7 days) or first-generation cephalosporin (such as cephalexin 500 mg PO qid for 7 days). In contrast, a breast abscess presents with inflammatory skin changes, mastalgia, but may or may not exhibit induration. Abscesses require surgical drainage. Oral versus parenteral antibiotic administration is based on the extent of breast involvement and the degree of systemic illness. Periareolar abscesses often simply may be incised and drained, whereas **general anesthesia may be required for larger peri- or retroareolar abscesses**. Breast ultrasound or needle aspiration may be helpful for diagnosis. A large-bore needle, usually 16-gauge or larger, may be necessary to aspirate purulent material under local anesthesia. Aspiration permits bacterial culture and sensitivity testing and may be adequate management for very small fluid collections with limited breast involvement. While aspiration of the fluctuant mass does in fact cause microscopic tissue displacement, there is little evidence to suggest, in contrast to lung neoplasms, that breast aspiration will spread an indolent cancer significantly.¹¹ In either case, infections should respond rapidly to antibiotics, demonstrating at least partial resolution within 48 h. Repeat clinical evaluation is recommended at 48 to 72 h. Duration of therapy should occur for at least 2 weeks. However, management for breast abscess should include a referral for surgical evaluation for open drainage.

Occasionally, either mastitis or abscess may result in systemic toxicity. General indications for admission and immediate surgical consultation are patients with obvious sepsis or hemodynamic compromise, immunosuppressed or immunocompromised hosts (e.g., diabetics), rapidly progressive infection, or failure of outpatient antibiotic therapy. Parenteral antibiotics recommended are cefazolin 1 g IV every 8 h or nafcillin 1 g IV every 6 h.

cillin 2 g IV every 4 h. In penicillin-allergic patients, fluoroquinolones, rifampin, or vancomycin should be considered, although multiple-drug-resistant *Staphylococcus* spp. have been reported.

Periductal Mastitis (Mammary Duct Ectasia)

Periductal mastitis, also called *plasma cell mastitis* or *mammary duct ectasia*, is an uncommon benign disorder characterized by dilated or ectatic ducts with retained secretions surrounded with significant inflammation. Women over 40 years of age generally present with constant mastalgia associated with nipple retraction or discharge. In severe cases, subareolar abscesses form and can burrow through the skin at the areolar border to form mammary duct fistulas. Younger women tend to present with cellulitis or recurrent subareolar abscesses, whereas perimenopausal and postmenopausal women are more likely to present with nipple discharge and retraction, or sterile subareolar masses.

Infection should be treated, and the patient should be referred to a specialist for definitive diagnosis and treatment.

Hidradenitis Suppurativa

Hidradenitis suppurativa frequently presents with recurrent multiple cutaneous abscesses, sinus tracts, and scarring of the breast folds, axillae, and groin and perineum. It is a chronic inflammatory disease involving the obstruction of sweat glands associated with polymicrobial colonization, with *Staphylococcus* and *Streptococcus* spp. implicated in the pathogenesis of infection.¹² Frequently, patients present with painful sebaceous abscesses along the inferior, pendulous surface of the breast and request incisional drainage for pain relief. Incision and drainage usually are adequate therapy for a limited area of abscess formation. Antibiotics are rarely used for outpatient management of simple abscesses in immunocompetent patients, although antibiotic suppression therapy may be used by the specialist to decrease the frequency and severity of the disease. There is no cure for the disease except extensive surgical excision of the apocrine tissue, which often results in higher recurrence rates at the excisional sites.

Inflammatory Breast Cancer

Of all the potential presentations of a breast malignancy, *inflammatory breast cancer* (IBC) is the entity associated with the greatest mortality and longest delay from initial presentation to definitive diagnosis. IBC accounts for 1 to 3 percent of all breast cancers. The clinical presentation is composed of symptoms of mastalgia and breast inflammation due to tumor infiltration of dermal lymphatics that results in an inflammatory response of the breast stroma. The combination of erythema and edema results in the classic orange-peel (*peau d'orange*) appearance of the overlying skin and ultimately nipple retraction as the edema progresses. Initially, the patient presents with a clinical syndrome of breast enlargement, breast warmth, tenderness, edema, erythema, and sometimes discoloration of the overlying skin. The absence of a palpable underlying mass or axillary lymphadenopathy does not rule out the diagnosis. The signs of inflammatory breast cancer are often indistinguishable clinically from infection. Prompt mammography and biopsy of the skin and any palpable or radiographic breast lesions are required by the follow-up physician. Similarly, the diagnosis of IBC must be considered promptly if there is not an initial good response to antibiotics or if a breast cellulitis or abscess fails to completely resolve.

Axillary Lymphadenopathy and Pain

In women with axillary adenopathy, the possibility of breast cancer metastatic to axillary nodes must be considered. This is true even if careful physical examination does not reveal a palpable breast abnormality. Referral to a breast specialist for bilateral mammograms is in-

dicated. Unless there is excellent evidence that the adenopathy may be attributed to an infectious or other benign etiology, palpable axillary nodes should prompt a referral to a breast specialist.

NONINFLAMMATORY PAINFUL BREAST DISORDERS

Mastodynia

One of the most common urgent presentations is for breast pain, also termed *mastodynia* or *mastalgia*. The discomfort usually is cyclic, waxing or waning with the menstrual cycle. Cyclic mastodynia is usually most severe in the immediate premenstrual phase and decreases or resolves completely following menstruation. The pain is bilateral and usually is most severe in the upper outer quadrants of the breast. It may be referred to the axilla, underarm, or scapula. Diagnosis relies on the history and physical examination to confirm that the pain actually originates from the breast. At times, the examination reveals tender, nodular breasts, suggesting a diagnosis of fibrocystic changes, although breast cancer must remain in the differential diagnosis. For most patients, occasional use of nonsteroidal anti-inflammatory drugs is the only therapy required. Patients with breast pain should be referred to their primary care physicians for follow-up treatment and imaging, if necessary.

Nipple Discharge

Table 110-1 lists some common causes of nipple discharge. Most discharges, even bloody, are not usually due to malignancy. In general, milky, green, gray, or black discharges that are either unilateral or bilateral and can be expressed from several ducts are not suggestive of cancer.¹³ However, follow-up to the patient's primary care physician for mammography and possible fluid analysis of the discharge is always needed.

Intraductal papillomas usually present with a unilateral bloody nipple discharge in women from 20 to 40 years of age. Bleeding is secondary to increased tissue vascularity. A mass may not be palpable on examination. Other etiologies of bloody nipple discharge include mammary duct ectasia and breast cancer. Again, outpatient follow-up is required for mammogram and eventual biopsy.

Bilateral spontaneous milky nipple discharge can be indicative of an elevated serum prolactin level. Discussion of this entity can be found earlier in this chapter. Any postmenopausal nipple discharges are significant and should be referred immediately to a breast specialist.

SKIN AND NIPPLE ABNORMALITIES

Mondor Disease

Thrombophlebitis of the superficial thoracoepigastric vein, or *Mondor disease*, results in a cordlike mass in the breast, sometimes associated with skin changes such as dimpling. Without an identifiable etiology in most cases, localized trauma or an inflammatory process has been associated with Mondor disease. Breast pain is the usual presenting complaint, with examination findings of a characteristic cordlike mass in the superficial subcutaneous tissue of the breast, most commonly in the lower quadrants. Mondor disease, which can be mistaken for an inflammatory cancer, is benign and self-limited. Treatment is usually a nonsteroidal anti-inflammatory medication for symptomatic relief.

Nipple Irritation

Nipple irritation may be caused by repeated friction from clothing or sunburn. The nipples are easily protected from chronic abrasion by application of a small dab of petroleum jelly or use of protective pads

TABLE 110-1 Relationship Between Nipple Discharge and Possible Etiologies

inserted into the cups of a support bra. Nipple irritation, however, also may be indicative of atopic dermatitis, erosive adenomatosis, or Paget disease. Erosive adenomatosis is a benign proliferation of the lactiferous ducts presenting with eczema or an erosion of the nipple. Treatment is surgical excision, and referral to a breast specialist is needed. Paget disease, which is heralded by the appearance of a weeping, eczematoid lesion of the nipple, occurs in less than 2 percent of all breast cancers. However, Paget disease is almost always associated with an underlying breast carcinoma and usually is diagnosed in postmenopausal women. Paget disease may present with an associated palpable breast mass, often correlating with the presence of an intraductal carcinoma. Because skin edema and inflammatory changes may respond transiently to incorrectly prescribed topical treatments, there is usually a delay of 6 to 12 months in diagnosis. Urgent referral for bilateral mammography and follow-up with a breast specialist are mandatory.

FIBROCYSTIC DISEASE AND THE EVALUATION OF BREAST MASS

The most common cause for benign breast disease in premenopausal women is fibrocystic breast disease, which is a constellation of breast symptoms linked by the common pathognomonic finding of breast cysts. The nodularity and tenderness, which occur as a result of breast tissue responses to hormonal cycling, is called *fibrocystic breast disease* or *fibrocystic changes of the breast*. Fibrocystic changes do not include skin thickening, edema, discoloration, nipple retraction, or discharge. If the history and physical examination in the ED are normal, then outpatient mammography and specialist follow-up should occur if the patient is over age 40. If the patient is under age 30 and presents with a breast mass, then fibrocystic changes or a fibroadenoma are more likely, and the patient will require outpatient ultrasonography, possible needle aspiration, and referral to a breast specialist. Women with recurrent or severe symptoms, skin changes, solid masses, nipple abnormalities, or severe anxiety about the possibility of cancer should be referred to a breast specialist.

Breast cancer is rare in patients younger than 20 years of age and uncommon in women younger than 30 years of age. Risk factors for young women include inheritance of the *BRCA1* or *BRCA2* gene, a history of childhood malignancy, or a history of chest irradiation. A family history of a first-degree relative with breast cancer, increased exposure to endogenous estrogens (nulliparity or delayed childbearing until after age 30), or biopsy-confirmed breast atypical hyperplasia increases the risk for women aged 30 years and older. However, most patients diagnosed with breast cancer have only two risk factors: age greater than 50 years and female gender.²

Physical signs that should prompt immediate surgical referral include a palpable mass with or without the following: lymphadenopathy, skin ulceration, fixation to the chest wall, fixed axillary nodes, or the presence of ipsilateral arm edema.

Characteristics associated with a delayed diagnosis of breast cancer are nonwhite race, lower socioeconomic status, normal/false-negative mammogram, presentation with nipple lesions or axillary mass, or inadequate biopsy technique.^{14,15}

BREAST TRAUMA

Blunt trauma to the breast is usually seen in association with multiple thoracic injuries and often accompanied by extensive chest wall ecchymoses, commonly referred to as a "seat belt sign." Traumatic breast injuries rarely necessitate specific therapy unless there is significant avulsion of breast tissue or an expanding hematoma, which should prompt immediate surgical intervention. The presence of a significant isolated breast injury should raise the possibility of abuse or cancer. Long-term sequelae of breast trauma include inflammatory and architectural distortions of the breast, as well as persistent microcalcification observed on mammography. Fat necrosis is the most common type of inflammatory response to breast injury, but few patients actually remember a discrete breast injury. Fat necrosis can be confused easily with carcinoma because it may present with a palpable mass and even skin dimpling and retraction. While no specific treatment is required for fat necrosis, the presence of cancer must be excluded. Any persistent mass after trauma must raise the question of underlying pathology or malignancy, and referral to a breast specialist for evaluation is required.

PERIOPERATIVE AND POSTOPERATIVE COMPLICATIONS

Hematoma

Immediate postoperative hemorrhage or expanding hematoma formation is best evaluated and treated by the operating surgeon. Emergent evaluation requires determination if the hematoma is expanding, tensely distended, or stable. Expanding hematomas, especially those occurring within the first few postoperative days, may signify the presence of continued bleeding and usually require surgical evaluation for evacuation of the hematoma or ligation of bleeding vessels. Later presentations of breast hematoma are usually managed conservatively, with analgesics, a compressive bra, and the correction of any coagulopathy. Aspiration of the hematoma generally is not effective in the ED. The presence of an infected hematoma requires inpatient management, percutaneous drainage, or open drainage and packing, and parenteral antibiotics generally are indicated.

Infection

Postoperative wound infections may be treated with an oral first-generation cephalosporin on an outpatient basis if there is no evidence of abscess, systemic signs of toxicity, or immunocompromise. Worsening signs of cellulitis or systemic response to infection, development of purulent drainage, or failure to improve after 48 h require inpatient management. Postoperative drain infections generally require drain removal and antibiotic therapy. Any fluid collections that develop subsequently usually require drainage either by repeated aspiration or by incision. The operating surgeon should be consulted for any of these complications.

UROGYNECOLOGIC DISORDERS AND GYNECOLOGIC ONCOLOGY Michael

Londner Daniela Meshkat

INCONTINENCE

The six main anatomic structures contributing to continence are:

The *detrusor muscle*, a meshwork of fibers surrounding the bladder.

The *urethra*, a 3- to 4-cm tube surrounded mainly by smooth muscle.

The *urethral sphincter*, which provides the secondary defense against urinary incontinence and about 50 percent of total urethral resistance.

Two posterior *pubourethral ligaments*, which suspend the urethra, holding it close to the pubic bone.

The *autonomic nervous system*, the parasympathetic and sympathetic nerves that supply the lower genitourinary tract. Parasympathetic fibers S₂ to S₄ cause detrusor contraction (cholinergic drugs do the same). Sympathetic fibers T₁₀ to L₂ have α- and (3-adrenergic components. Alpha fibers stimulate the bladder neck and urethral contraction while relaxing the detrusor muscle. Beta fibers relax the urethra and contract the detrusor muscle.

Pudendal nerves provide voluntary urethral contraction.

Continence is maintained because intraurethral pressure exceeds intravesical pressure. The levator ani and surrounding fascia and ligaments help to maintain urethral anatomy in times of abrupt changes associated in intra-abdominal pressure.

The four most common classifications of continence are:

Urinary stress incontinence

Urge incontinence Total

incontinence Overflow

incontinence

Stress urinary incontinence occurs when urine is lost involuntarily as a result of increased intra-abdominal pressure, i.e., when the intra-urethral pressure is less than the intra-abdominal pressure. It is associated with multiparity, vaginal delivery, pregnancy, menopause, chronic cough (i.e., chronic obstructive pulmonary disease), or other forms of

pelvic relaxation. Symptoms include leaking of urine during cough, straining, laughing, sneezing, running, or other causes of increased intra-abdominal pressure. Stress incontinence per se is not a diagnosis that is important to establish in the ED. Of importance is the differential diagnosis, which includes infection, neurologic disease, medications, or other systemic illness as possible causes of stress urinary incontinence. A thorough history and physical examination are required, along with a comprehensive neurologic examination. Further, a full vaginal examination with inspection of all the vaginal walls is necessary. If important etiologies in the differential diagnosis are excluded, the patient can be referred safely to a consulting gynecologist. Outpatient workup includes stress testing and, if necessary, urodynamic testing. Nonoperative options include Kegel exercises, estrogen, α-adrenergic stimulants, intravaginal weights, biofeedback, transcutaneous electrical nerve stimulation (TENS), and urethral plugs. Operative management to correct the defect and restore the anatomy of the urethra is the approach used most commonly. Surgery may be laparoscopic, vaginal, abdominal, or a combination of these. The list of procedures and variations is very long, but the most common include the Marshall-Marchetti-Krantz, Burch, Pereyra, Stamey, and Raz procedures, collagen injections, and sling suspensions.

Urge incontinence occurs in the setting of detrusor muscle instability. The incidence of this entity is around 15 to 20 percent of all women with incontinence, but it increases markedly with increasing age. It is often seen in conjunction with stress urinary incontinence, when it is known as *mixed incontinence*. The precise etiology of urge incontinence is unknown, but it is seen in the presence of foreign bodies (suture inadvertently placed in the bladder), intravesical stones, menopause (hypoestrogen states), and/or infection. Symptoms include urinary urgency, frequency, nocturia, and incontinence. Observing involuntary detrusor contractions during cystometric or urodynamic studies is diagnostic. Treatment includes pharmacologic agents (e.g., anticholinergics, p-sympathomimetics, musculotrophics, tricyclic antidepressants, or dopamine agonists), bladder training, biofeedback, and functional electrical stimulation.

Total incontinence is most commonly the result of a urinary fistula. Fistulas usually occur as a result of pelvic surgery, radiation, and obstetric injuries (in underdeveloped countries). Patients present with constant, painless leaking of urine and/or recurrent infections. Placing a tampon into the vagina and instilling methylene blue or sterile milk into the bladder helps to make the diagnosis. In the event that a vesicovaginal fistula is present, the tampon will stain blue. If there is no staining, then indigo carmine is injected intravenously. If the tampon then stains blue, a ureterovaginal fistula is present. An intravenous pyelogram (IVP) should be obtained in either situation to help define the anatomy and rule out other multiple fistulas. Treatment is initiated with insertion of a diverting Foley catheter and may lead to spontaneous healing if the injury is recent. Usually, however, operative repair is required.

Overflow incontinence is a result of urinary retention from a hypotonic detrusor muscle. This is seen in the setting of neuropathy secondary to diabetes, spinal cord injuries, outflow obstruction, postoperatively, or lower motor neuron diseases (i.e., multiple sclerosis). Symptoms include postvoid bladder fullness (the "feeling" of never having an empty bladder), small quantities on micturition, and leaking. Diagnosis is made through complete history and physical examination with emphasis on the neurologic examination and determination of postvoid residual volume. Therapy is directed at treating the underlying cause and teaching intermittent self-catheterization.

PROLAPSE

The female pelvic organs, i.e., vagina, uterus, bladder, and rectum, are held in proper alignment by supporting ligaments, fascia, and the pelvic floor muscles. When any or all of these structures fail, the pelvic organs may prolapse within and occasionally protrude through

the vagina. This prolapse or displacement may occur singly or more commonly in combination. Prolapse can be divided into two broad categories, uterine and vaginal.

Uterine prolapse is graded as first through third degrees:

First degree: The cervix remains within the vagina. *Second degree:* The cervix protrudes beyond the introitus. *Third degree:* This implies descent of the entire uterus outside the vulva, also known as *procidentia*.

This classification system is slowly being replaced with staging of all pelvic prolapses through one pelvic organ prolapse quantification (POPQ) profile, now standardized terminology.

A prolapsed, elongated, inflamed, edematous cervix may be mistaken for uterine prolapse if careful evaluation is not undertaken. Procidentia represents complete failure of all supporting structures. The vagina can prolapse without accompanying uterine prolapse, but the uterus cannot prolapse without bringing the upper vagina with it.

Vaginal prolapse is best subdivided into four basic quadrants:

Upper anterior vaginal wall: cystocele (represents weakness of the pubocervical fascia)

Lower anterior vaginal wall: urethral displacement Upper posterior vaginal wall: enterocele (usually associated with herniation into the pouch of Douglas)

Lower posterior vaginal wall: rectocele

In addition, inversion of the vagina is known as *vault prolapse*. Most commonly, prolapse results from attenuation of pelvic fascia, ligaments, and muscles following extensive stretching during vaginal delivery. However, prolapse can occur after easy labor or in the nulliparous woman, in which case it is considered a congenital or developmental weakness of pelvic connective tissue. Virtually any cause of repeated increased intra-abdominal pressure may lead to prolapse, including chronic cough, ascites, heavy lifting, or habitual straining on defecation. These mechanisms should raise concern to search for occult malignancy, e.g., lung cancer in a person with chronic cough or colon cancer in someone straining to defecate. Atrophy of the supporting tissue plays a significant role in initiating or worsening this condition.

The degree of symptomatology is quite variable. The most common complaint is a "feeling of heaviness or fullness in the pelvis." Others may describe "something falling out." More diffuse complaints include backache, pelvic discomfort, and discomfort or straining with defecation or urination. Cystocele may present with frequency, urgency, incontinence, or ultimately, retention (especially if displacement causes kinking of the ureter), whereas rectocele may present with difficulty evacuating the rectal vault.¹ A characteristic not to be overlooked is the worsening of symptoms with prolonged standing followed by alleviation when lying down. Women may become extremely tolerant of prolapse symptoms and present with advanced complications such as infection of the prolapsed segment, decubitus ulceration, bleeding, and carcinoma of the cervix.

Diagnosis revolves around a thorough history and physical examination, including vaginal examination. Use of a Sim's speculum or separating the two halves of the standard Grave's speculum and using the posterior blade allows for adequate vaginal inspection. Depress the posterior vaginal wall, and ask the patient to bear down. This will demonstrate descent of the anterior vaginal wall in the setting of cystocele and/or urethral displacement. Reversing the speculum to elevate the anterior vaginal wall allows visualization of the intruding posterior wall during straining, demonstrative of enterocele or rectocele. A rectal examination often will help to distinguish rectocele from enterocele.

Treatment modalities are grouped into nonoperative and operative.² The patient's age, future fertility, degree of sexual activity, and degree of prolapse must be considered in defining a management plan. Nonoperative treatments generally are tried first if future childbearing

is desired, the degree of pathology is mild, or the patient is a poor surgical candidate. These options include Kegel (pelvic floor strengthening) exercises, pessaries, estrogen, and electrical muscle stimulation. Operative management options are used in patients failing nonoperative treatments, those with severe prolapse, and those who are symptomatic. The overall goal of surgery is to return the pelvic anatomy to as close to normal as possible. Procedures include anterior/posterior colporrhaphy, enterocele repair, hysterectomy, obliteration of the vaginal vault, urethropexies (colpocleisis), urethral sling procedures, and/or suspension of the vaginal vault.

URETHRAL SYNDROME

Urethral syndrome describes a complex of symptoms involving the lower urinary tract and including urinary frequency, urgency, dysuria, suprapubic discomfort, postvoid fullness, incontinence, and/or dyspareunia with no objective findings of urologic pathology. Grandmultiparity, delivery without episiotomy, two or more abortuses, and pelvic relaxations appear to predispose.³ The true incidence of urethral syndrome in the United States among adult women is unknown, as is the cause. The most widely accepted etiology of this enigmatic syndrome is an inflammatory process. Other etiologies include psychogenic factors, *Chlamydia* or *Mycoplasma* infection, atrophic urethritis in the perimenopausal/postmenopausal patient, fastidious organism bacterial infection, urethral stenosis and/or spasm, allergy, neurogenic, and trauma during intercourse. The diagnosis is one of exclusion founded on a thorough history and physical examination, followed by urine microscopic examination and culture. Referral is often obtained then for dynamic cystourethroscopy and urodynamic studies. Treatment encompasses many modalities because the etiology is uncertain.⁴ The first approach is often pharmacologic, with antibiotics (doxycycline) or anticholinergics, followed by instillation of dimethyl sulfoxide, periurethral injection of triamcinolone, serial urethral dilation with or without massage, cryosurgery (internal urethrotomy and urethrolisis), bladder neck reconstruction, biofeedback, and psychotherapy. Recent research has led to the use of urethral suppositories with multiple medications, including lidocaine, hydrocortisone, and topical estrogens. Lastly, supportive therapy is helpful in all patients.

GYNECOLOGIC MALIGNANCIES

The female reproductive tract cancers account for 13 percent of all cancers in women, following breast, lung, and colon cancer. Symptoms occurring as a result of natural progression of malignancy include bleeding, nausea and vomiting, obstructive uropathy, failure to thrive, and/or paraneoplastic syndromes. Treatment with surgery, chemotherapy, and radiation can cause complications. Surgical complications include bowel and urogenital tract injury, thromboembolism, and bleeding. Chemotherapy-related complications include anemia, febrile neutropenia, thrombocytopenia, neuropathy, uropathy, nausea and vomiting, extravasation injury, and stomatitis. Radiation-related complications focus mainly on injury to the gastrointestinal and genitourinary tracts.

Ovarian Cancer

Cancers of the ovary and fallopian tube are discussed together because of the rarity of fallopian tube cancer and similarity in gross and microscopic appearance, pattern of spread, and disease process. Over 25,000 women are diagnosed with ovarian cancer yearly in the United States, with about half dying from the disease. A woman with no family history has a 1 to 2 percent chance of developing ovarian cancer in her lifetime. Peak incidence occurs between the ages of 55 and 65 years, although some types occur earlier. The following risk factors have been identified: infertility, low parity, high-fat diet, lactose intolerance, history of breast or colon cancer, and a family history of site-

specific ovarian cancer or its associated syndromes. Oral contraceptives seem to be protective against ovarian cancer.

Cancers of the ovary and fallopian tube come in three main histologic types: epithelial (85 percent), germ cell tumors (10 percent), and sex cord stromal tumors (5 percent). Patients often present after the disease has spread beyond the ovary, with symptoms such as abdominal pain, bloating, ascites, early satiety, weight loss, and/or respiratory distress secondary to effusion. Sertoli-Leydig tumors produce androgens, often resulting in masculinization and often occurring at age 25 years. **It is most important to recognize that a woman presenting to the ED with ascites has a gynecologic malignancy until proven otherwise.** As a first diagnostic step after pelvic examination, computed tomographic (CT) scanning can be done in the ED. Aspiration of ascitic fluid should not be done.

The single most important factor in the large death rate is the advanced stage at diagnosis. Diagnosis and staging of ovarian cancer are based on surgical evaluation. The International Federation of Gynecology and Obstetrics (FIGO) devised an extensive and universal staging classification. In summary (a simplification):

Stage I: Growth limited to one or both ovaries *Stage II:* One or both ovaries with pelvic extension *Stage III:* One or both ovaries with growth outside the pelvis *Stage IV:* One or both ovaries with distant metastasis

Treatment of ovarian cancer may involve surgery, chemotherapy, and/or radiation therapy.

Uterine Cancer

Uterine cancer is the most common gynecologic malignancy. In 1997, 32,800 cases were diagnosed. The average age at occurrence is 58 years. Adenocarcinoma of the endometrium is the most common histologic type. Other histologic types of endometrial cancer that occur less frequently are papillary serous, clear cell, adenosquamous, and adenocanthoma. Sarcomas are malignancies of the uterine muscle. They behave very aggressively and have a worse prognosis than endometrial cancer.

Multiple risk factors have been associated with endometrioid adenocarcinoma of the uterus, such as early menses, late menopause, nulliparity, obesity, diabetes, hypertension, and unopposed estrogen use. The use of progestins has dramatically reduced the risk of endometrial cancer. Tamoxifen, an antiestrogen that competes with estrogen at its receptor site, has been shown to increase the risk of adenocarcinoma of the uterus.

The most common symptom of endometrial cancer is postmenopausal bleeding. Sarcomas, however, may present with bleeding but also with abdominal pain or prolapse of friable tissue through the cervical os.

The diagnosis of uterine cancer is made by sampling the endometrium. This may be achieved through office endometrial biopsy, a dilatation and curettage specimen, or hysteroscopy. A pathologic specimen must be obtained for proper diagnosis and further treatment planning. A sonogram that measures the endometrial stripe as greater than 5 mm in a postmenopausal woman must be evaluated.

Staging for uterine cancer is as follows (summary of staging):

Stage I: Confined to the uterine corpus
Stage II: Involvement of the cervix
Stage III: Extends to the uterine serosa, ovary, vagina, and para-aortic/pelvic lymph nodes
Stage IV: Involvement of the bladder/bowel, inguinal/intra-abdominal lymph nodes

Staging is surgical. Treatment involves surgery and also may include radiation and chemotherapy.

The vaginal cuff, vagina, and pelvis are common sites for recurrence. Patients with recurrence often present with vaginal bleeding,

vaginal or pelvic masses, or uremia secondary to ureter obstruction. Pulmonary metastases are less common in recurrent uterine cancer but still need to be considered in a woman presenting with respiratory symptoms and a history of uterine cancer.

Cervical Cancer

Currently, 15,800 new cases of cervical cancer are diagnosed each year. The average age at the time of diagnosis is 54 years. Risk factors include early coitus, multiple sexual partners, high-risk male partners, smoking, human papillomavirus, and HIV infection (or other immunosuppressive states). The diagnosis of cervical cancer in an HIV-positive patient is now considered an AIDS-identifying illness. Smoking increases the risk of cervical cancer in women by 3.5 times, and even passive smoke increases the risk 3-fold. Approximately 90 percent of cervical cancers are of squamous histologic type, but adenocarcinoma, which comprises 5 to 10 percent of cervical cancers, is increasing and has a worse prognosis.

The presenting signs and symptoms of cervical cancer, in decreasing order, are postmenopausal bleeding, abnormal vaginal bleeding, postcoital bleeding, vaginal discharge, pain, or leg swelling. Diagnosis must be made by cervical biopsy (not only Papanicolaou smear). Often, on speculum examination, a mass or ulcerative lesion is seen on the cervix. The gynecologic consultant should be called to perform a biopsy, cone biopsy, or loop electrosurgical excision procedure (LEEP).

Staging of cervical cancer is performed clinically. Once a diagnosis is made by biopsy, a thorough physical examination must be performed, including an examination under anesthesia (cystoscopy and proctoscopy) of the parametrium, pelvic sidewalls, bladder, and rectum, and a chest x-ray. These results are combined to clinically stage the individual. The tumor tends to spread by direct extension, causing parametrial thickening, and by lymphatic spread to obturator nodes and then to pelvic and para-aortic nodes.

The staging of cervical cancer is complex, but the following is a brief overview:

Stage I: Confined strictly to the cervix
Stage II: Beyond the cervix but not to the pelvic sidewall
Stage IIA: No parametrial involvement
Stage IIB: Parametrial involvement
Stage III: Extends to the pelvic sidewall
Stage IV: Beyond the true pelvis, bladder or rectum involvement

Treatment of cervical cancer requires a team of gynecologic oncologists and radiation oncologists. In stage I to IIA cervical cancer, radical hysterectomy or radiation therapy has demonstrated similar excellent 5-year survival rates. Any persons with stage IIB or greater must be treated with radiation.

Recurrent or persistent cancer causes devastating problems for patients, their families, and clinicians. Patients have a markedly diminished 5-year survival rate when recurrence occurs. Recurrent cervical cancer can be treated palliatively or with some hope of a cure. Curable lesions are those which are easily resected, i.e., single lesions located at the vaginal apex or in the lung or lesions located centrally in the pelvis without lymph node involvement. Pelvic exenterative surgery is very extensive surgery removing the bladder, rectum, uterus (if not already done), and vagina. A colostomy is required, and a neovagina and urinary diversion are created. Patients with recurrent cervical cancers often present to the ED with vaginal bleeding, uremia secondary to ureter obstruction or invasion, deep venous thrombosis, leg swelling, or pain.

Vaginal Cancer

Vaginal cancer accounts for only 1 to 2 percent of all gynecologic malignancies. The true definition of primary vaginal cancer is that it must

arise from the vagina and not be an extension or metastasis from the cervix or vulva. The main histologic type is squamous cell carcinoma. Squamous lesions usually occur in postmenopausal woman, whereas other histologic types (rhabdosarcoma, endodermal sinus tumor, adenocarcinoma, and clear cell adenocarcinoma from diethylstilbestrol) usually occur in younger women. The last diethylstilbestrol (DES) administration was around 1971, which would place these women in their forties. The mean age of occurrence for vaginal cancer is 60 to 65 years of age. Epidemiologic factors contributing to the occurrence of vaginal cancer are immunosuppression, chronic irritation (long-term pessary use or prolapse of female organs), decreased socioeconomic status, radiation for cervical cancer, hysterectomy for dysplasia, multiple sexual partners, and DES exposure. The tumor usually presents in the posterior upper third of the vagina. Abnormal vaginal bleeding is the presenting symptom most of the time. Some complain of abnormal discharge or postcoital bleeding.

Staging for vaginal cancer is summarized as follows:

Stage I: Vaginal wall involvement *Stage II:* Parametrial involvement *Stage III:* Pelvic wall involvement *Stage IV:* Bladder/rectum or beyond pelvic involvement

Most vaginal cancers are best treated with radiation therapy.

Embryonal rhabdomyosarcomas (sarcoma botryoides) occur in children younger than 5 years of age and present with vaginal bleeding, discharge, or grapelike masses protruding from the vagina. These cancers respond very well to the chemotherapeutic regimen of vincristine, dactinomycin, and cyclophosphamide with either surgery or radiation. Complications associated with vaginal cancers are bleeding, infections, fistulas, or complications from chemotherapy, radiation, or surgery.

Vulvar Cancer

Vulvar cancer is responsible for only 1 to 4 percent of all gynecologic malignancies and less than 1 percent of all cancers. Most women diagnosed with vulvar cancer are older than 55 years of age. The most common histologic type is squamous cell carcinoma, followed by melanoma, basal cell carcinoma, adenocarcinoma, sarcoma, Bartholin gland tumors, and metastasis. Luckily, the prognosis is generally good because recognizable symptoms allow for early diagnosis. The most common presenting symptoms include a mass, pruritus, pain, or ulceration (in decreasing order of frequency). The cause for vulvar cancer is still unknown, but there have been associations of vulvar cancers with other cancers of the anogenital tract. Human papillomavirus (HPV) types 16, 18, 31, 35, and 39 all have been suggested as causative factors.

It seems that the etiology is multifactorial, and HPV alone is not the culprit. Other possibilities include immunodeficiency, vulvar dysplasia, smoking, and exposure to aniline dyes such as benzene. Multicentric lesions are seen more commonly in younger women, whereas unifocal lesions are seen most often in older women. On physical examination, the lesions may appear white, pigmented, raised, thickened, nodular, or ulcerative. A vulvar biopsy should be performed liberally in women with any suspicious lesions. Treatment depends on the stage at the time of diagnosis. More recent years have welcomed the advent of more conservative treatment modalities. The treatment of choice is surgery with adjuvant radiotherapy in more advanced stages.

Staging is summarized as follows:

Stage I: Confined to the vulva or perineum and less than 2 cm *Stage II:* Confined to vulva or perineum and greater than 2 cm *Stage III:* Any size lesion spread to lower urethra, vagina, or anus with unilateral positive nodes *Stage IV:* Involvement of the upper urethra, bladder, rectum, or pelvic bone with positive bilateral nodes

Partial vulvectomy is the treatment of choice for patients with lesions smaller than 2 cm. The use of postoperative radiation may decrease the incidence of recurrence and improve survival in women with lesions larger than 2 cm and positive lymph nodes. The morbidity from surgery is groin wound breakdown and lymphedema from lymph node dissections. Recurrent vulvar cancer may be local or distant or involve lymph nodes. Patients often present with bleeding, lymphedema, deep venous thrombosis, or metastasis (usually to bone or lung).

Gestational Trophoblastic Disease

Gestational trophoblastic disease (GTD) is a disease of trophoblastic placental tissue. There are four forms of GTD: (1) hydatidiform mole, (2) invasive mole, (3) choriocarcinoma, (4) placental site tumors.⁵

The incidence of molar pregnancy is about 1 in 2000 pregnancies, but the incidence is much higher in Asian women. The risk of developing a second molar pregnancy is higher. Molar pregnancy is seen with a bimodal distribution. Persons younger than age 20 and older than age 40 are at greatest risk. GTD may be benign or malignant and, when malignant, can be divided into metastatic and nonmetastatic.

The benign form of this disease is hydatidiform mole, either partial or complete. Table 111-1 lists some of the major differences between partial and complete moles.

Treatment of hydatidiform mole is suction curettage or hysterectomy. Hyperthyroidism or hypertension must be stabilized prior to surgery. Follow-up is essential because dilatation and curettage alone is curative in only 80 percent of patients, leaving 20 percent at risk for persistent trophoblastic disease.

Gestational trophoblastic neoplasm (GTN) includes invasive mole and choriocarcinoma. These tumors can progress to malignancy and ultimately death if left untreated. Luckily, they are highly responsive to chemotherapy.

Invasive mole is the myometrial invasion of the hydatidiform mole. Common sites for metastasis of this cancer are the lungs and vagina. Invasive moles occur in 1 of 15,000 pregnancies, and 15 percent of hydatidiform moles result in invasive moles. Diagnosis is confirmed by consistently elevated or rising beta human chorionic gonadotropin (3-hCG) levels after a molar evacuation.

Choriocarcinoma is characterized by atypical trophoblastic hyperplasia with direct and vascular invasion into the myometrium and distant sites, most commonly the lungs, brain, liver, pelvis, or vagina. The incidence of choriocarcinoma is approximately 1 in 40,000 pregnancies. Twenty-five percent follow abortion or ectopic pregnancies, 25 percent are seen with term gestations, and the remaining 50 percent result from hydatidiform moles. Fortunately, only 2 to 3 percent of hydatidiform moles result in choriocarcinoma.

TABLE 111-1 Some Major Differences between Partial and Complete Moles

	Complete Mole	Partial Mole
Symptoms	Vaginal bleeding Uterine size > estimated gestational age Hyperemesis gravidarum Pre-eclampsia at <20 weeks gestation Hyperthyroidism Trophoblastic embolization Absent fetal heart tones	Incomplete or missed abortion Vaginal bleeding
Diagnosis	Ultrasonography reveals "snowstorm" appearance coupled with a high (3-hCG) level	Usually on histologic examination from tissue obtained from a missed or incomplete abortion

Symptoms of GTN are continued bleeding after dilatation and curettage for hydatidiform mole or bleeding after a pregnancy event (e.g., vaginal delivery, cesarean section, ectopic pregnancy, miscarriage, or abortion). Patients with metastasis may present with dyspnea, cough, chest pain, central nervous system abnormalities, or vaginal mass. The most common site for metastasis is the vagina, followed by the lung.

Treatment depends on the presence of metastasis. Patients with no metastatic disease who wish to preserve their fertility are treated with single-agent chemotherapy, methotrexate, or dactinomycin; otherwise, hysterectomy is the treatment of choice. This initial therapy leads to cure in 85 to 90 percent of patients. When metastatic disease is present, combination chemotherapy is given.

COMPLICATIONS OF GYNECOLOGIC MALIGNANCIES

The complications of gynecologic malignancies are related to the natural progression of disease, surgery, chemotherapy, or radiation. Any combination of these complications can occur depending on the type and stage of neoplasm and treatment modality.

The complications related to the natural progression of disease often represent the symptoms that help to diagnose the disease. These include, but are not limited to, genital tract bleeding, gastrointestinal obstruction, masses or ascites, fistulae (both genitourinary and gastrointestinal), obstructive uropathy, metastasis, lymphedema, and hypercoagulable states leading to deep venous thrombosis or pulmonary embolism.

By far the most common oncologic complication (most frequently seen with cervical or uterine cancer) **is bleeding**. It may be acute or chronic, massive or minimal, external or internal. Sources include friable tissue, tumor erosion into iliac or femoral vessels, adnexal mass rupture, or coagulopathies that develop secondary to chemotherapy or radiation. Assessment and management begin with the principles of emergency care. Then a thorough history and physical examination, including prior diagnoses and treatment, should be undertaken to find the likely source and cause of bleeding. Where externally accessible sites of bleeding occur, apply direct pressure. If this fails to control the bleeding, next use topical silver nitrate or MonsePs solution. If bleeding persists, topical absorbable hemostat material can be applied such as Gelfoam, Instal, or Surgicel. Where the vagina is the source of bleeding, vaginal packing may become necessary. Use a long strip of continuous gauze, and place a Foley catheter to prevent urinary retention. Regardless of the causes of bleeding, after stabilization, the gynecology service should be consulted.

Patients occasionally present with abdominal distention and discomfort. This often is concomitant with other complications of cancer and therefore may be accompanied by early satiety, nausea, vomiting, anorexia, weight loss, constipation or diarrhea, urinary frequency, urgency, incontinence, dyspnea, or orthopnea. As always, the first step is complete history and physical examination, including both pelvic and rectal examinations. Diagnostic testing may reveal worsening of known disease, recurrence of cancer, new cancer, torsion of a large ovary, bowel perforation, or intra-abdominal hemorrhage. Consultation with a gynecologist, gynecologic oncologist, or surgeon is indicated.

Gastrointestinal complications include obstructions and fistulae. Obstruction is common as a progressive symptom of malignancy, especially with ovarian and uterine tumors that are associated with enlarging masses or ascites. The resulting obstruction may be mechanical or due to tumor ileus from encasement of the nerve plexus leading to dysfunction of a segment of bowel. Patients often present with nausea, vomiting, early satiety, abdominal pain, distention, constipation, and/or obstipation. The normal management scheme for obstruction applies (as discussed in Chap. 79 in more depth). Surgical palliation may give temporary symptomatic relief, but recurrence rates are extremely high. Consultation with a gynecologist, gynecologic oncolo-

gist, or surgeon is indicated to discuss and provide permanent proximal decompression and supplemental nutrition.

Fistula formation occurs secondary to bowel encasement or obstruction. The fistula may drain to the abdominal wall, peritoneal cavity, vagina, uterus, or bladder. Instillation of colored medium (e.g., charcoal, food dye in tube feeds), upper gastrointestinal series, barium enema, or a fistulogram often aids diagnosis. Consultation with a gynecologist, gynecologic oncologist, or surgeon is indicated to determine the best treatment.

Urinary tract complications also include obstruction and fistula. Ureteral obstruction classically is seen in cervical cancer but also occurs with progression or recurrence of other pelvic malignancies. Radiation also may cause permanent scarring of the lumen leading to obstruction. Patients may develop acute renal failure and require percutaneous or cystoscopic emergent decompression. A vesicovaginal or ureterovaginal fistula may develop at the site of untreated cancer or recurrent cancer or after radiation therapy.

Chronic mild lymphedema of the lower extremities often follows inguinal node resection. Pedal lymphedema is seen after pelvic radiation therapy. Aside from the associated discomfort, the greatest concern is deep venous thrombosis, especially if lymphedema is unilateral. Duplex ultrasound is necessary. Lymphedema is treated supportively with elevation and support stockings.

Thromboembolic disease has long been associated with gynecologic malignancies and is discussed in Chap. 59.

Most of the side effects of chemotherapeutic agents are predictable and can be lessened with adjuvant medications. Risk factors for poor tolerance of chemotherapy are advanced age, advanced disease, poor nutritional status, or severe systemic involvement. Chemotherapeutic agents may have debilitating effects on many organ systems (Table 111-2).

The complications related to radiation are temporally divided into acute and chronic. The chronic manifestations may be further broken into gastrointestinal, genitourinary, and pulmonary. Acute findings include nausea, vomiting, diarrhea, cystitis, nephritis, pneumonitis, and myelosuppression. Gastrointestinal symptoms are often self-limiting and are controlled with supportive therapy, including antiemetics, antidiarrheals, and avoidance of high-fiber diets. Newer studies point to glutamine-rich diets, and the use of sucralfate may further reduce diarrhea. The genitourinary symptoms range from infection to hemorrhagic cystitis with extreme pain. Treatment of these symptoms includes adequate hydration, surveillance for infection, and bladder irrigation with analgesia or steroids. Resolution of myelosuppression is often spontaneous and begins after radiation has been completed.

Chronic findings are divided into gastrointestinal, genitourinary, and pulmonary. The most common complication is radiation enteritis, which presents with chronic diarrhea, malabsorption, or digestive difficulty. Other chronic gastrointestinal complications include strictures, fistulas, perforations, obstructions, and hematochezia. These findings often occur within 2 years of treatment. Management should be a collaborative effort between the oncologist, surgeon, and gastroenterologist. Emergency management includes adequate hydration and symptomatic relief. Genitourinary complications include incontinence, fistula formation, stricture formation, and hemorrhagic cystitis. Incontinence and fistulas were discussed earlier. The most severe complication of stricture formation is obstructive uropathy. This always should be considered as recurrence of disease until proven otherwise and as a result of radiation by diagnosis of exclusion. Both hemorrhagic cystitis and stricture require cystoscopy for evaluation. An oncologist and urologist should institute appropriate treatment.

Lastly, secondary malignancies may arise from radiation therapy. This results from the local nonmalignant tissue being exposed to ionizing radiation. The resulting damage to genetic material leads to mutation that is the presumed mechanism for carcinogenesis. The secondary malignancy is often observed years after the initial radiation therapy, and accuracy in predicting its occurrence is difficult at best.

TABLE 111-2 Chemotherapeutic Agents and Their Toxicities

Agent	Toxicity	Type of Cancer Treated
ALKYLATING AGENTS		
Cyclophosphamide	Myelosuppression, cystitis, hepatitis, alopecia	Ovarian, breast, sarcoma
Ifosfamide Chlorambucil	Myelosuppression, CNS abnormalities, bladder and renal toxicity	Ovarian, cervical
Nitrogen mustard Cisplatin	Myelosuppression, dermatitis, hepatitis, gastrointestinal dysfunction	Ovarian
(alkylating like)	Nausea, vomiting, myelosuppression	Ovarian, malignant effusions
	Nephrotoxicity, tinnitus, hearing loss, myelosuppression, peripheral neuropathy,	Ovarian, cervical, germ cell
Carboplatin (alkylating like)	nausea, vomiting Neuropathy, ototoxicity, myelosuppression, nephrotoxicity	Ovarian, germ cell
ANTIMETABOLITES		
Methotrexate	Myelosuppression, hepatitis, pneumonitis, stomatitis	Breast, ovarian, choriocarcinoma
5-Fluorouracil	Myelosuppression, alopecia, nausea, vomiting	Breast, ovarian
Hydroxyurea	Nausea, vomiting, anorexia, myelosuppression	Cervical
PLANT ALKALOIDS		
Vinblastine	Myelosuppression, alopecia, nausea, vomiting, neurotoxicity	Germ cell, choriocarcinoma
Vincristine	Myelosuppression, alopecia, nausea, vomiting, neurotoxicity	Germ cell, cervical, sarcoma
Paclitaxel (Taxol)	Myelosuppression, alopecia, arrhythmias, hypersensitivity	Ovarian, breast Germ cell,
Etoposide (VP-16)	Myelosuppression, alopecia, hypotension	choriocarcinoma
ANTITUMOR ANTIBIOTICS		
Bleomycin	Fever, anaphylaxis, pulmonary fibrosis, dermatitis	Cervical, germ cell, malignant effusions
Doxorubicin (Adriamycin)	Myelosuppression, alopecia, cardiotoxicity, nausea, vomiting	Ovarian, breast, uterine Breast,
Mitomycin-C	Nephrotoxicity, stomatitis, nausea, vomiting, myelosuppression	ovarian, cervical Germ cell,
Actinomycin-D (Dactinomycin)	Nausea, vomiting, dermatitis, myelosuppression, stomatitis	choriocarcinoma

COMPLICATIONS OF GYNECOLOGIC PROCEDURES

Michael A. Silverman
Karen M. Hardart

Because of convenience, cost effectiveness, and apparent safety, the number of ambulatory surgeries continues to increase. The indications appropriate for ambulatory surgery also continue to increase. These trends are accompanied by a decrease in the length of hospitalization following major gynecologic surgery. Unanticipated hospital admission after ambulatory surgery occurs in approximately 1 percent of cases and is an important measure of outcome.¹ Gynecologic outpatient surgery has been associated with an unscheduled admission rate of more than 5 percent, with postoperative emesis being the most common reason for admission.²

HISTORY AND PHYSICAL EXAMINATION

The most common reasons for ED visits during the postoperative period following gynecologic procedures are pain, fever, and vaginal bleeding. A focused but thorough evaluation should be performed. The history should include the surgical procedure performed (abdominal

versus vaginal), the reason for it, time of symptom onset and its proximity to the surgery, complications already experienced, the patient's postsurgical history, and medications prescribed. The interval between the surgery and the onset of symptoms is very important in determining their cause. For example, most cases of early postoperative fevers (less than 24 h) are not infectious, and causes may include pulmonary atelectasis, hypersensitivity reactions to antibiotics, pyogenic reactions to tissue trauma, or hematoma formation.

Relevant examination of all appropriate systems should then be performed. It should not be assumed that the etiology of the complaint is gynecologic. Other potential explanations of the symptoms should be investigated. Postoperative pain and tenderness can be difficult to assess. Some tenderness is normal, but rebound tenderness is not. After laparoscopy, patients may have pain radiating to their shoulder for several days because of remaining CO₂ bubbles. Postoperative pain and tenderness is more concerning if associated with nausea and vomiting and a change in bowel sounds. The surgical wound should be examined, and a pelvic examination should be performed, including both a sterile speculum and a bimanual examination. The pelvic examination should be performed with caution, or even deferred in infertility patients, due to the possibility of rupturing enlarged ovarian follicles. The sterile speculum examination should visualize the cervix, or if it is absent, the vaginal cuff, and any evidence of bleeding, discharge, erythema, or cuff or labial cellulitis should be noted. Cervical cultures should be considered. Bimanual examination after a vaginal or abdominal hysterectomy should evaluate for tenderness, masses, and an intact cuff. Following hysteroscopy or dilation and curettage, cervical motion, uterine, and adnexal tenderness should be evaluated. A rectal examination should always be performed to evaluate tenderness or masses.

Laboratory studies should be directed towards the patient's complaints. A complete blood count with a manual differential count is almost always indicated. A serum P-human chorionic gonadotropin level should be obtained for all women with childbearing potential. A catheterized urine specimen, along with urine, blood, wound, and cervical (if present) cultures, should be obtained if the patient is febrile. A chemistry panel may be necessary to evaluate hepatic and renal function.

Imaging procedures are often necessary. A chest radiograph can confirm pneumonia or inappropriate air under the diaphragm. Air or insufflated CO₂ should be completely absorbed by the third postoperative day. Supine and erect abdominal series help confirm bowel obstruction. Pelvic sonogram remains the gold standard for visualizing the pelvic structures. However, a computed tomography (CT) scan may be necessary, especially if an abscess is suspected.

COMPLICATIONS OF ENDOSCOPIC PROCEDURES

Laparoscopy

Both diagnostic and therapeutic gynecologic laparoscopy are accomplished by passing a rigid endoscope through a trocar that is inserted bluntly through a small infraumbilical incision into the abdominal cavity after a Veress needle has been used to insufflate the abdomen with carbon dioxide. The pneumoperitoneum must be sufficient to displace the bowel and is maintained throughout the surgery. Additional trocars can be placed so that other accessories can be used during the surgery. Laparoscopy is almost always an ambulatory surgical procedure and is performed under general anesthesia with endotracheal intubation.

There are numerous indications for gynecologic laparoscopy, ranging from diagnosing gynecologic disorders (e.g., endometriosis or ectopic pregnancy) to performing complex gynecologic surgery. The most common surgical procedure in the United States is female sterilization. More than 60 percent of these procedures are performed laparoscopically and have a complication rate of 1.6 per 100 procedures.³ Infertility is one of the most common indications for diagnostic laparoscopy. Laparoscopy is also used for lysis of adhesions, CO₂ laser ablation of endometriosis, uterine surgery (including myomectomy), tubal surgeries (including salpingectomy), ovarian surgery (including oophorectomy and oophorocystectomy), paraovarian cyst excision, laparoscopic vaginal hysterectomy, and retropubic urethropexy.

All of these procedures entail the same potential complications, but more complex surgeries carry considerably more risk. The incidence of major complications in the United States for laparoscopy may be as low as 0.22 percent.⁴ In the last decade, the most comprehensive survey on this topic reported complications for 45,042 procedures as follows: hemorrhage 1 percent, unintended laparotomy 1 percent, blood transfusion for hemorrhage 0.45 percent, and bowel or urinary tract injury 0.41 percent. Further studies have supported these data.^{5,6,7} Approximately half of all complications may be related to the installation of laparoscopy, though some studies show that open laparoscopy may be safer.^{7,8} In 1996, the overall incidence of complications in major operative laparoscopy was reported as 10.4 percent.⁹ This rate is still significantly less than the 25 to 50 percent overall complication rate of abdominal surgery, such as hysterectomy or oophorectomy through abdominal incisions, although data related to the two approaches are not directly comparable because of other factors that may mandate a traditional surgical procedure.

The major complications associated with laparoscopy are thermal injury of the bowel, perforation of a viscus, bleeding or other vascular injury, ureteral or bladder injuries, and incisional hernia or wound dehiscence.

Thermal injury is the most serious potential complication. While many significant complications of laparoscopy are recognized in the operating room under direct visualization, patients with thermal injury may not develop symptoms for several days and up to several weeks postoperatively. Various series have reported the incidence of electrothermal injuries to be in the range of 0.5 to 3.2 per 1000 cases. Patient presentations may include bilateral lower quadrant pain and tenderness, fever, elevated white blood cell count, or peritonitis. Plain radiographs may show an ileus or free air under the diaphragm. Patients with greater-than-expected pain after laparoscopy should be considered to have a bowel injury until proven otherwise. Early gynecologic consult is critical if a thermal injury is suspected.

Traumatic injury to the bowel is usually less serious than thermal injury. The small diameter Veress needle is usually the cause of a bowel perforation, which is recognized on withdrawal of the needle. A sharp trocar may cause more damage, though most surgeries are now performed with a blunt trocar. Gastric perforation may result, usually due to stomach distention from aerophagia or as a result of a difficult intubation. The large or small bowel may also be perforated. These injuries are usually noted during the operation. On rare occasions, perforation may occur through a single loop of bowel adherent to the anterior abdominal wall. Complications include peritonitis, abscess, enterocutaneous fistula, and septic shock.

Vascular injury occurs at a rate of 0.1 to 6.4 per 1000 cases. While such injuries may be immediately life-threatening, they are almost universally recognized during the operation. Patients may present with a postoperative hematoma. Local compression, if feasible, is the initial treatment. If the mass enlarges or signs of hypovolemia occur, the wound must be explored by the gynecologist.

Bladder and ureteral injuries may occur from mechanical or thermal trauma. Trocar or dissection injuries to the bladder are typically recognized intraoperatively. Thermal injuries, however, may not be initially apparent and may present with peritonitis or fistula. The diagnosis of a ureteral injury is usually delayed. Thermal injury may present up to 14 days postoperatively with abdominal or flank pain, fever, and peritonitis. There may be an elevated white blood cell count, and an intravenous pyelogram (IVP) shows extravasation of urine or a urinoma. Mechanical obstruction of the ureter from sutures or staples may be recognized intraoperatively by direct visualization, but may present up to 1 week postoperatively with fever and flank pain. An IVP or a CT scan of the abdomen and pelvis helps define the site and degree of obstruction.

Incisional hernias and dehiscence are rare complications after laparoscopy. Incisional hernias are more common when defects larger than 10 mm are made and may develop within the first postoperative week. Patients may be asymptomatic or may present with pain, mass, evisceration, or signs and symptoms of a mechanical bowel obstruction. Fever may occur if the bowel is incarcerated, and peritonitis may develop following bowel perforation. Dehiscence usually involves protrusion of the omentum, and, in rare cases, the small bowel passes through the opening. Immediate incisional repair by a gynecologist is usually sufficient; however, a laparotomy may be necessary if the bowel is incarcerated or perforation is a risk.

Wound infection after laparoscopy is uncommon and often not a serious complication. Most are minor skin infections that can be managed expectantly with oral antibiotics or with drainage. The risk of infection after laparoscopy is much lower than that after abdominal or vaginal surgery. Excluding minor skin infections, pelvic infection is reported in fewer than 1 in 1000 cases. Pelvic cellulitis and abscess can occur, and severe necrotizing fasciitis, while rare, has been reported. Most infections are probably secondary to a subacute coexisting infection present prior to the procedure or secondary to skin contamination. Broad-spectrum antibiotics typically provide a rapid response.

Hysteroscopy

Hysteroscopy is the direct visualization of the uterine cavity using a rigid or flexible fiberoptic instrument. Hysteroscopy can be done as an office procedure under intravenous sedation or in an operating room under general anesthesia, spinal or epidural anesthesia, or intravenous sedation. Hysteroscopy is done for both diagnostic and therapeutic purposes. The most common indication for hysteroscopy is abnormal vaginal bleeding. Other indications include uterine leiomyomata, intrauterine adhesions, proximal tubal obstruction, removal of intrauterine devices, müllerian anomalies, and infertility evaluation. Therapeutic applications include directed biopsies, removal of small myomata or polyps, and endometrial ablation for menorrhagia. Complications of hysteroscopy occur in less than 1 percent of cases and include fluid

overload, uterine perforation with possible damage to intraabdominal organs, infection, toxic shock syndrome, anesthesia reaction, postoperative bleeding, and embolism.¹⁰

Fluid overload is rare but can occur from absorption of electrolyte and nonelectrolyte solutions during lengthy procedures. The entry of dextran into the circulation can lead to pulmonary edema and disseminated intravascular coagulation. For this reason, no more than 500 mL of dextran should be used during a procedure. A lack of recovery of distention medium in excess of 1000 mL also places the patient at risk for fluid overload. If fluid overload is suspected, hyponatremia is likely. Therapy to decrease the serum sodium level may prevent generalized cerebral edema, seizures, and death (see Chap. 27).

Uterine perforation is a relatively common complication. A midline uterine perforation generally does not have significant sequelae. A lateral perforation may lacerate uterine vessels and cause substantial bleeding. Most often, the perforation is noted at the time of surgery, and a laparoscopy is done to investigate for bleeding and/or damage to bowel or bladder. If the complication is not noted at the time of surgery, the patient may present with peritoneal signs if the bowel has been injured or pain and/or bleeding if the vessels were lacerated.

Infection is very rare and most commonly occurs in patients with concurrent genital tract infections. Endometritis or even toxic shock can result.

Postoperative bleeding may be uterine or cervical in origin. Cervical lacerations may be caused by forceful dilation or tears from the tenaculum. Uterine bleeding can result from resection procedures. After hemodynamic stabilization of the patient, the gynecologist can place a Foley or balloon catheter into the uterine cavity and fill it with approximately 10 to 15 mL of water or saline solution. One technique is to remove one-half the fluid from the balloon after 1 h and the other half after 2 h. If bleeding remains stopped, the patient can usually be discharged. If bleeding persists, the patient should be admitted. The catheter is reinflated and left overnight, and occasionally reexploration is required.

Embolism is the most feared complication of using CO₂ gas as a distention medium. The risks of such an occurrence are low when the principles of low flow and low pressure are followed.

COMPLICATIONS RELATED TO MAJOR ABDOMINAL SURGERY

Complications from major abdominal procedures that lead to ED visits usually occur at least 3 days postoperatively. Expected complications include, but are not confined to, wound infection and related morbidity, phlebitis (both superficial and deep), urinary tract infection, bladder and ureteral injury, ileus and bowel obstruction, pneumonia, and atelectasis.

Hysterectomy remains one of the most common major surgical procedures in the United States, with abdominal hysterectomy being performed more frequently than laparoscopic hysterectomy and vaginal hysterectomy.¹¹ It also carries significant morbidity, with postoperative infection rates reported between 3.9 and 50 percent for abdominal hysterectomies and 1.7 to 64 percent for laparoscopic vaginal hysterectomies. There are numerous risk factors for postoperative infections. Lower socioeconomic status is a risk factor for infection in gynecologic surgery, which may be related to inadequate nutrition or poor hygiene. Obesity also carries an increased risk of infection, possibly due to poor hygiene, altered nutrition, or increased operative time. Additional risk factors include altered immunocompetence, diabetes, lack of prophylactic antibiotics when indicated, or excessive operative blood loss.

Wound Infection

CLINICAL FEATURES Wound infections may occur early postoperatively or up to several months after the surgery. Greater than 90 percent occur within the first 2 postoperative weeks. Early infections

range from mild cellulitis to those associated with fever, tachycardia, increased wound tenderness, and severe local cellulitis. As the infection progresses, the wound may be fluctuant or indurated. Wound breakdown and dehiscence can occur if treatment is not initiated rapidly. The infected incision is swollen, erythematous, edematous, and tender. There may be spontaneous purulent drainage from the wound. Initial management consists of opening the incision, probing with a sterile cotton swab to confirm an intact fascia, vigorous cleaning with saline solution, and packing with saline-soaked wet-to-dry dressings. If staples have been placed, they should be removed. Aerobic and anaerobic cultures should be obtained. The operating gynecologist should always be informed about the patient. Late-onset infections are characterized by persistent low-grade fevers and purulent drainage from the incision. Local wound care as described above is appropriate.

DISPOSITION Parenteral therapy with a penicillin-based antibiotic and aggressive local wound care are typically used for early postoperative infections, particularly when there is underlying cellulitis. Consultation with the gynecologic surgeon would be appropriate. Most patients are readmitted.

Infected Vaginal Cuff Hematoma, Cellulitis, or Abscess

CLINICAL FEATURES A vaginal cuff is formed during a hysterectomy and is composed of the contiguous retroperitoneal space immediately above the vaginal apex and the surrounding soft tissue. This cuff may become infected, leading to cellulitis, hematoma, or abscess.

Vaginal cuff cellulitis is a common complication following both abdominal and vaginal hysterectomy. Symptoms and signs usually present between postoperative days 3 and 5, and may begin in the hospital or just after discharge. Patients often complain of lower abdominal pain, pelvic pain, back pain, fever, and abnormal vaginal discharge. Induration, tenderness of the vaginal cuff, and possibly a purulent discharge or labial edema or erythema are prominent during the pelvic examination. The white blood cell count is usually elevated.

A vaginal cuff abscess usually presents early in the postoperative course. Patients complain of fever, chills, pelvic pain, and rectal pressure. On examination, lower abdominal and vaginal cuff tenderness is present. A tender fluctuant mass near the cuff may be palpable, and purulent drainage from the cuff may be seen.

Infected cuff hematomas may present later in the postoperative course, and if large, are associated with a decrease in the patient's hemoglobin and hematocrit levels. The hematoma may not be palpable on examination.

DISPOSITION Patients should be readmitted for intravenous antibiotics and possible drainage. Broad-spectrum antibiotics should be started early, with coverage for gram-negative, gram-positive, and anaerobic organisms. Most pelvic infections require similar treatment. Triple antibiotic therapy with ampicillin (2 g IV q6h), gentamycin (1.5 mg/kg load IV then 1.0 mg/kg IV q8h) and clindamycin (900 mg IV q6h) are still appropriate. Aztreonam (1 to 2 g IV q8h) can be substituted if the patient is at risk for nephrotoxicity. Other options that are more expensive but have a more favorable profile when renal compromise is an issue include ticarcillin-clavulanate (3.1 g IV q6h) or ampicillin-sulbactam (3 g IV q4 to 6h). Abscess, septic pelvic thrombophlebitis, or drug fever should be considered in patients who do not respond. A CT scan may be necessary for diagnosis or to better define an abscess or hematoma.

Postoperative Ovarian Abscess

CLINICAL FEATURES Patients with fever and abdominal and pelvic pain shortly after discharge from the hospital may have a pelvic abscess. Such abscesses are usually ovarian in nature. A sudden increase in pain may be a signal that the abscess has ruptured. This is a surgical emergency and requires a laparotomy. If time permits or the diag-

nosis is in question, a CT scan can aid in identifying the size and location of the abscess.

DISPOSITION Patients with a pelvic abscess need to be admitted. Some abscesses respond to broad-spectrum antibiotics, and others may require drainage either by an interventional radiologist or by colpotomy.

Dehiscence and Evisceration

CLINICAL FEATURES Wound disruption is a failure of normal healing and includes the breakdown of any layers of a surgical incision. Dehiscence is disruption of all layers, including fascia and peritoneum. Evisceration occurs when there is complete breakdown of the healing processes through all levels of the abdominal wall and the omentum or bowel presents through the incision. The classic sign of impending dehiscence is the sudden outpouring of serosanguineous blood from the abdominal incision. Most often this occurs between postoperative days 5 and 8. The patient may describe a "pop" or tearing sensation. About one-third of cases of wound dehiscence are associated with evisceration. While gynecologic surgery has a lower wound disruption rate than the 1 to 3 percent reported following major abdominal surgery, the mortality rate is high, up to 35 percent or greater.¹²

DISPOSITION When evisceration has occurred, the abdomen should be covered with moist sterile towels and supported with tape to prevent further extrusion of the gut.

The patient should be taken directly to the operating room for closure. In cases in which there is a sudden appearance of blood but no bowel, it is best to follow the same procedure because evisceration usually is imminent.

Ureteral Injury

CLINICAL FEATURES Operative injury to the ureter results from one of three types of trauma: crushing, transection, or ligation. Each type of injury may be either partial or complete. This complication occurs more often during the performance of abdominal hysterectomy than during any other pelvic surgery. In patients who develop flank pain shortly after surgery, ureteral injury should be suspected. Patients may have fever and costovertebral angle tenderness. A urinalysis should be performed, and if obstruction is suspected, an abdominal and pelvis CT with intravenous contrast or an IVP should be obtained. If obstruction is noted, it is usually near the ureterovesical junction.

DISPOSITION Patients should be admitted for attempted ureteral catheterization under cystoscopic guidance and possibly exploratory laparotomy. Percutaneous nephrostomy with delayed repair may also be considered.

OTHER COMPLICATIONS OF GYNECOLOGIC SURGERY

Urinary Retention

Urinary retention in a healthy female after gynecologic surgery is uncommon. However, many women experience either an inability to void or incomplete emptying of the bladder during the postoperative period. Urinary retention is usually a temporary result of pain or bladder atony resulting from anesthesia.

CLINICAL FEATURES Inability to void is more frequent after operations such as radical hysterectomy or those that involve the urethra and bladder neck (i.e., anterior repair or any modification of the retropubic urethropepy). Most problems with voiding following any of these procedures resolve with time and without medication.

DISPOSITION Retention can be initially relieved with insertion of a Foley catheter for 12 to 24 h. Most patients are able to void after this period. An alternative method is intermittent straight catheterization. Patients are instructed to attempt to void on a timed schedule at intervals of less than 3 h. Patients should be taught to perform self-catheterization if they are unable to void. Self-catheterization can be taught in the ED, and the patient should be reassured that voiding function will return in time. If a patient still has trouble voiding after temporary placement of a Foley catheter, the problem may be ureteral spasm, which can be treated with phenazopyridine (200 mg, tid) or oxybutynin (5 mg bid/tid).

Vesicovaginal Fistula

CLINICAL FEATURES Vesicovaginal fistulas may occur after total abdominal hysterectomy. Patients present 10 to 14 days after surgery with a watery vaginal discharge. The diagnosis can be confirmed by inserting a cotton tampon into the vagina and then instilling methylene blue or indigo carmine dye via a transurethral catheter. If the tampon stains blue, a vesicovaginal fistula is present. If no staining occurs, a ureterovaginal fistula must be ruled out by injecting 5 mL of indigo carmine dye IV. If a ureterovaginal fistula is present, the tampon should stain blue within 20 min.

DISPOSITION Gynecologic consultation is necessary. A Foley catheter should be inserted for prolonged drainage if a vesicovaginal fistula is present. With continuous drainage, up to 15 percent close spontaneously within 4 to 6 weeks. The remainder ultimately require surgical repair.

Osteomyelitis Pubis

CLINICAL FEATURES Osteomyelitis pubis is a rare complication of pelvic surgery that presents 6 to 8 weeks after surgery with pain and tenderness along the symphysis pubis, especially with ambulation. Osteomyelitis pubis results from direct or contiguous seeding of the periosteum from pelvic surgery. It has been seen following certain types of bladder neck suspension. Patients have a low-grade fever, elevated sedimentation rate, and leukocytosis. Blood should be drawn for culture, since the results are sometimes positive.

DISPOSITION Patients should be admitted for parenteral antibiotics and possibly surgical debridement.

Wound Hematoma

CLINICAL FEATURES Hematomas are a common complication of wound closure and are more frequent in transverse than in vertical incisions. The wound itself may swell and be painful.

DISPOSITION In general, smaller hematomas can and should be managed expectantly. If there are any signs of infection, the wound should be opened and drained. An ultrasound examination of the incision may be helpful if hematoma is suspected. The patient should be instructed to return if signs of infection develop.

Wound Seroma

CLINICAL FEATURES Wound seromas are relatively common in gynecologic incisions. A wound seroma is a collection of serous fluid and may drain spontaneously. In general, it is the presence of drainage, not fever or pain, that prompts patients to seek emergency care.

DISPOSITION If the wound remains intact after gentle probing, the seroma can be watched and usually disappears. If the seroma has reached

a large size, drainage can be performed by aspiration and light pressure over the lymphocyst. Wound infection precautions should be given.

Postconization Bleeding

CLINICAL FEATURES High-grade squamous intraepithelial lesions of the cervix may be treated by loop electrocautery or cold-knife conization. The most common complication of these procedures is bleeding. If delayed hemorrhage occurs, it usually occurs 7 days postoperatively. Bleeding following this procedure can be rapid and severe.

DISPOSITION Visualization of the cervix is the key to controlling such bleeding. Application of Monsel solution (a commercially available ferrous subsulfate solution) is a reasonable first step if it is readily available. Monsel solution should be available from the hospital pharmacy. Direct pressure for 5 min with a large cotton-tipped swab may be effective. Alternatively, cauterization with silver nitrate may be attempted. If these maneuvers are not successful, a gynecologist should be consulted for suturing or cauterization of the bleeding arteriole. The vagina can be packed with gauze if the bleeding is severe until more definitive therapy is available. Often the patient must be taken to the operating room for repair because adequate visualization is difficult in the ED.

Septic Pelvic Thrombophlebitis

CLINICAL FEATURES Septic pelvic thrombophlebitis (SPT) is a diagnosis of exclusion complicating 0.1 to 0.5 percent of gynecologic procedures. The diagnosis is made when a patient with a postoperative fever does not respond to appropriate antibiotics in the absence of an undrained abscess or infected hematoma. Patients with SPT rarely present to the ED, since the complication typically presents in the hospital and delays discharge.

There are two forms of SPT. The classic form occurs 2 to 4 days after abdominal surgery and is characterized by fever, tachycardia, gastrointestinal distress, and unilateral abdominal pain. A palpable abdominal cord develops in 50 to 67 percent of cases. The enigmatic form complicates vaginal delivery and pelvic surgery. Patients have spiking fevers despite clinical improvement on antibiotics. Findings upon pelvic examination may be normal in patients with either form.

DISPOSITION Heparin and antibiotics for 7 to 10 days is the mainstay of treatment. Long-term anticoagulation is not needed unless septic pulmonary emboli have occurred. Antibiotics against heparinase-producing *Bacterioides* species (e.g., clindamycin 600 to 900 mg IV q8h) should be given to all patients.

Induced Abortion

There are three major methods for termination of a pregnancy: instrumental evacuation by the vaginal route, stimulation of uterine contraction, and major surgical procedures. Abortions performed surgically have complication rates of 18 to 29 percent^{13,14} and can be immediate, delayed, or late. Immediate complications, less than 24 h after the abortion, include bleeding and pain. Most immediate complications are arrested at surgery, but many present within 24 h to the ED. Retained products of conception, uterine perforation, and cervical lacerations are the most common causes of immediate bleeding and pain. Delayed complications occur between 24 h and 4 weeks postabortion and include excessive bleeding, primarily due to retained products of conception, and postabortive endometritis. Late complications include postabortal amenorrhea, psychological problems including depression, and Rh isoimmunization.

If a cervical laceration is noted, treatment includes pressure followed by application of Monsel solution or use of silver nitrate sticks.

Suturing may be necessary if there is no resolution of bleeding. Uterine perforation occurs in approximately 1 to 3 per 1000 abortion procedures. Most perforations are noted at the time of surgery and are asymptomatic. However, those that go unnoticed can present with pain and/or bleeding and possibly signs of shock. The incidence of retained products of conception is 0.5 to 1.0 percent. On physical examination, the cervical os is generally open. The uterus is usually boggy, enlarged, and tender. A pelvic sonogram should be obtained to evaluate the uterine cavity for retained products. Repeat dilatation and curettage is necessary. If coexistent endometritis is present, treatment with antibiotics (as previously noted) is required for 10 to 14 days. Usual therapy includes broad-spectrum antibiotics until the patient is afebrile for 24 to 48 h.

Postabortal endometritis not associated with retained products of conception presents with a firm yet tender uterus and closed cervical os. Uncomplicated endometritis requires antibiotics, as previously discussed, and possible reaspiration based on sonographic findings. Rh₀(D) immune globulin (300 jig IM) should be given to Rh-negative women after a spontaneous or induced abortion. If it is not prescribed within 72 h, the overall risk of sensitization in the second pregnancy is approximately 3 percent.

Brachytherapy

Brachytherapy is the treatment of malignant tumors by radioactive sources that are implanted, typically under general anesthesia, close to (intercavitary) or within (interstitial) the tumor. It may be used as adjuvant therapy following surgery or as primary therapy if the malignancy is advanced. Currently, radiation therapy is geared mainly toward cervical and uterine cancers and remains limited in ovarian cancer.

The normal tissues of the cervix and uterus can tolerate very high doses of radiation. In contrast, the sigmoid, rectosigmoid, and rectum do not, and are therefore more susceptible to radiation injury. Usually the small bowel is spared because it is in motion. Acute radiation cystitis can occur in the immediate postoperative period. Symptoms of cystitis are present but cultures are negative. Treatment is to increase oral intake and take a urinary analgesic. Chronic radiation cystitis with hematuria requires continuous bladder irrigation.

Radiation-induced soft tissue necrosis can also be a significant complication. It is thought to be due to a progressive endarteritis leading to decreased blood flow and eventually hypoxia. Often this leads to inflammation, infection, tissue breakdown, and fistula formation. The use of hyperbaric oxygen has been shown to enhance healing.

Postoperative Fatigue

Postoperative fatigue following major gynecologic surgery is quite common and often underappreciated by both the patient and physician. Sixty to ninety percent of posthysterectomy patients report postoperative fatigue to the point of interference with daily activities. Pain, sleep disturbances, and psychological factors all play a role in postoperative fatigue; however, the majority of patients have fatigue persist past resolution of postoperative pain. An average of 10 weeks is required before patients can resume normal activities. Anemia can contribute to fatigue and oral iron supplementation should be considered. In some cases, postoperative fatigue can persist for 6 to 12 months. In these chronic cases, depression and anxiety disorders should be ruled out.

Assisted Reproductive Technology

Transvaginal ultrasonographically guided aspiration of oocytes is used universally during in vitro fertilization. Previously, laparoscopic oocyte collection was used, which carried the occasional complications of laparoscopic surgery, including those related to general anes-

thesia. Complications related to ultrasound-guided retrieval and preparation for retrieval of oocytes are rare and include ovarian hyperstimulation syndrome, pelvic infections, intraperitoneal bleeding, and adnexal torsions.¹⁵ However, the acute abdomen has developed hours to weeks after the procedure and has required prompt surgical intervention.

Ovarian hyperstimulation syndrome can be a life-threatening complication of induction of ovulation.¹⁶ The incidence of the moderate-to-severe form is 1 to 2 percent. Symptoms include abdominal distention, ovarian enlargement, and weight gain in the mildest form. In the most severe form, patients have massive third-spacing of fluids into the abdominal cavity, which can lead to ascites, electrolyte imbalances, pleural effusions, and hypovolemia. Clinically, one sees increased coagulability and decreased renal perfusion. The decreased renal perfusion leads to increased salt and water reabsorption in the proximal tubule, leading to oliguria. **Abdominal and pelvic examinations are contraindicated due to extremely fragile ovaries that are at high risk of rupture or hemorrhage.** Defer examination until after discussion with the gynecologist. Patients are also at high risk for ovarian torsion because of the size of their ovaries. Electrolyte studies, renal function tests, a complete blood count, coagulation studies, and blood for type and cross-match should be obtained. An electrocardiogram to evaluate hyperkalemia should also be obtained. The gynecologist should be consulted for admission. Treatment is volume repletion.

Postembolization Syndrome

Since the mid 1990s, uterine artery embolization has become a more common approach for treating symptomatic uterine fibroids.¹⁷ This nonsurgical approach is safe and effective and helps patients avoid myomectomy and hysterectomy. Performed by invasive radiologists, typically in collaboration with the patient's gynecologist, this procedure may be performed on an outpatient basis under conscious sedation, though many patients spend one night in the hospital for pain control. All patients who undergo the procedure experience some form of postembolization syndrome: pelvic pain and fever lasting 2 to 10 days as a result of transient myometrial and persistent fibroid ischemia. Patients may present to the ED with pain ranging from mild to severe. The emergency physician must work to control the pain as well as consider other etiologies that may cause the patient's symptoms, particularly an infectious etiology such as endometritis. Evaluation may include a complete blood count and a CT scan. Between 1 and 9 percent of patients may have symptoms of menopause after this procedure, with temporary or permanent loss of menses. While up to 10 percent of patients ultimately undergo hysterectomy, approximately 1 percent of patients undergo hysterectomy due to infection. Vaginal discharge and fibroid expulsion are other complications. Some patients may require admission for pain control and/or intravenous antibiotics.

PELVIC ULTRASONOGRAPHY

Robert F. Reardon Dietrich V. K. Jehle

Ultrasonography is a standard diagnostic tool used in the evaluation of pregnancy and female pelvic pathology.¹ Bedside pelvic ultrasound is used commonly in the ED in order to guide the evaluation of women with pelvic pain, pregnancy-related problems, and maternal trauma. The use of early pelvic ultrasound is essential for the timely diagnosis of ectopic pregnancy and placenta previa. Recent studies have demonstrated that bedside transabdominal and transvaginal ultrasound performed by emergency physicians improves early detection and decreases morbidity of patients with ectopic pregnancy.²⁻⁵ The availability of bedside pelvic sonography decreases the ED length of stay for women with early pregnancy.⁶

This chapter describes many other indications for ED bedside pelvic sonography. Since training and experience with pelvic sonography are highly variable among emergency physicians, a cautious approach to "ruling out" serious conditions should be employed initially. For example, ordering a "formal" ultrasound to be performed in the radiology or obstetrics and gynecology department is reasonable when no intrauterine pregnancy is identified in a symptomatic pregnant patient.

IMAGING TECHNIQUES

Transabdominal imaging and transvaginal imaging are complementary studies in evaluating the female pelvis. Transabdominal sonography (TAS) gives a good overview of the pelvis but requires a full urinary bladder. The bladder acts as an acoustic window to the pelvis for transabdominal scanning. If it is empty, retrograde filling of the bladder with 300 to 500 mL of saline, with careful avoidance of introducing air, may be necessary to obtain adequate visualization. By contrast, transvaginal sonography (TVS) is best performed with an empty bladder. Transabdominal scanning of the pelvis usually is performed with lower-frequency transducers (3-5 MHz) that provide a larger field of view and deeper penetration but have poorer resolution. TVS uses a higher-frequency probe (5-8 MHz) and provides better resolution with

a smaller field of view because the transducer is placed closer to the area of interest. The standard transabdominal views are sagittal, with the marker dot cephalad, and transverse, with the marker dot toward the patient's right (Figures 113-1 through 113-4). The standard transvaginal views are sagittal, with the marker dot toward the ceiling, and coronal, with the marker dot toward the patient's right (Figures 113-5 through 113-8). Orientation of pelvic anatomy using the transvaginal probe is difficult initially, but identifying the uterus before searching for other pelvic structures is a good way to simplify transvaginal imaging. Keeping the marker dot of the transvaginal probe in one of only two positions, toward the ceiling or toward the patient's right, also will help to simplify transvaginal imaging. Finally, palpation of the lower abdomen during transvaginal imaging will push mobile loops of bowel out of the pelvis and allow identification of relatively fixed structures such as ovaries and adnexal masses.

SONOGRAPHIC PELVIC ANATOMY

Transabdominal versus Transvaginal Imaging

Transabdominal midline images of the pelvis in the longitudinal plane show the long axis of the uterus posterior to the distended bladder. The cervix is immediately posterior to the deepest point of the bladder. The posterior cul-de-sac (pouch of Douglas) is a potential space posterior to the uterus where free intraperitoneal fluid may be seen (Figure 113-9). When a normal (anteverted) uterus is seen, the uterus meets the vagina at an angle of 90 degrees or greater, depending on the amount of bladder distention. Retroversion of the uterus is a normal variant and can make transabdominal visualization of the uterus difficult. The position of the uterus is less important when the transvaginal probe is used.

Uterus

Normal uterine size for a nulliparous menstruating female is up to 8 cm in length and 3 to 5 cm in transverse and anteroposterior (AP) diameter. Maximal uterine size for multiparous women may be 1 to 2 cm greater in each plane. The empty uterus is a thick-walled, muscular organ with moderate echogenicity. It contains a hyperechoic midline stripe formed by the opposed surfaces of the endometrial cavity. In the nonpregnant patient, the appearance of the endometrium is variable depending on the phase of the menstrual cycle. Early in the cycle, the proliferative endometrium is thin, measuring 2 to 8 mm in width (see Figure 113-8). Late in the cycle, during the secretory phase, the endometrium generally measures 7 to 14 mm and displays increased

FIG. 113-1. Technique for TAS showing how to obtain the standard midline sagittal view. The probe is placed just above the pubic bone with the marker dot cephalad.

FIG. 113-2. Normal pelvic anatomy in the standard midline sagittal view with TAS. The uterus and vagina are posterior to the bladder. The cervix is immediately posterior to the angle (deepest part) of the bladder.

echogenicity (see Figure 113-6). The echogenicity and size of the menstrual endometrium are variable and depend on the amount of blood and clot present within the uterus. The endometrium of the postmenopausal patient without hormone-replacement therapy is generally less than 9 mm in width. Postmenopausal women with vaginal bleeding and/or increased endometrial width need evaluation for endometrial carcinoma. A markedly thickened postpartum endometrium suggests the presence of retained products of conception (Figure 113-10).

Ovaries

The ovaries usually can be found lateral to the body of the uterus, anterior to the internal iliac vessels, and anteromedial to the external iliac vessels (Figure 113-11). There is significant variability in the position of the ovaries in women with a past history of pregnancy, and they may be found posterior or cephalad to the uterus (Figure 113-12). Also, a distended bladder may displace the ovaries cephalad. A normal ovary is about 2 by 2 by 3 cm in size and contains several small hy-

FIG. 113-3. Technique for TAS showing how to obtain the standard transverse view. The probe is placed just above the pubic bone with the marker dot toward the patient's right.

FIG. 113-4. Normal pelvic anatomy in the standard transverse view with TAS. The uterus is posterior to the middle of the bladder. The right ovary is seen on the left of the image, and the left ovary is difficult to identify.

poechoic structures, which are the maturing follicles (see Figure 113-11). The sonographic appearance of the ovary changes throughout the menstrual cycle as several follicles are recruited and then a dominant follicle emerges, followed by the development of a corpus luteum.

NORMAL EARLY PREGNANCY

Ultrasound Findings

The first sonographic finding in early pregnancy is the gestational sac (Table 113-1). This is a discrete hypoechoic structure that is slightly eccentric in its location within the uterine cavity (Figure 113-13). The decidua capsularis and decidua vera are seen as two distinct hyperechoic layers surrounding the early gestational sac; this is known as the *double decidual sac sign* (Figure 113-14). The yolk sac is the next embryonic structure to be visualized. It appears as a small hyperechoic ring within the gestational sac (Figure 113-15). Finally, the embryo (fetal pole) can be seen adjacent to the yolk sac⁷ (Figure 113-16). Cardiac activity usually can be observed whenever a fetal pole is present.

FIG. 113-5. Technique for TVS showing how to obtain the standard midline sagittal view. The marker dot is toward the ceiling, and the probe handle is moved from side to side to scan the entire pelvis.

FIG. 113-6. Normal uterus in the standard midline sagittal view with TVS. The endometrium is in the secretory phase, so the midline stripe is thick and prominent, and there are three Nabothian cysts in the myometrium near the cervix.

The normal fetal heart rate seen in early pregnancy is 112 to 136 beats per minute, slower than heart rates observed in the second and third trimesters. If the ovaries are imaged early in pregnancy, a corpus luteum cyst may be seen (see Figure 113-16). These cysts are benign and usually measure about 2 to 4 cm in diameter. Corpus luteum cysts are generally anechoic but sometimes bleed into themselves causing internal echoes.

Pregnancy Testing

The biochemical diagnosis of pregnancy may be made very early with the use of qualitative serum beta human chorionic gonadotropin (B-hCG) tests of blood and urine. Modern tests can detect serum B-hCG levels of 20 mIU/mL or lower in urine and can diagnose pregnancy within 7 to 10 days after conception, at 3 weeks of gestational age (measured from the first day of the last menstrual period). Quantitative serum p levels correlate approximately with the gestational age of the normal pregnancy. At any given gestational age, serum B-hCG titers are markedly higher when twins (or multiple gestations) are

FIG. 113-7. Technique for TVS showing how to obtain the standard coronal view. This drawing is a cross section from the patient's right. The marker dot is toward the patient's right, and the handle is moved up and down to scan the entire pelvis.

FIG. 113-8. Normal uterus in the standard coronal view with TVS. The endometrium is in the proliferative phase, so the midline stripe is thin.

present. Table 113-1 indicates the approximate gestational age at which different sonographic and serum markers appear in early pregnancy. The standards shown in the table are those of the International Reference Preparation (IRP). Some institutions may use an older standard called the Second International Standard, with values approximately one-half the IRP values.

Determining Gestational Age

When sonographic evidence of an early pregnancy is definitive, the gestational age of the pregnancy can be estimated by measurements of the gestational sac, crown-rump length, or biparietal diameter. Measurement of sonographic structures very early in pregnancy allows a better estimate of gestational age than later measurements because the growth of the embryo during the first trimester is consistent among individuals and not dependent on genetic or nutritional factors. Measurement of the mean gestational sac diameter or the crown-rump length provides the best estimate of gestational age during the first trimester. Mean sac diameter (MSD) is the average of three gestational sac measurements:

$$\frac{\text{length} + \text{width} + \text{depth}}{3}$$

Gestational age measured in days is:

$$\text{Gestational age (days)} = \text{MSD (mm)} + 30$$

FIG. 113-9. Free pelvic fluid (FF). TAS in the midline sagittal view showing anechoic free fluid (left lower) in the posterior cul-de-sac behind the uterus (center). The hypoechoic bladder is in the right upper portion of the image (ex = cervix).

FIG. 113-10. Retained products of conception. TAS in the midline sagittal view showing a very thick midline stripe due to an incomplete abortion. (Courtesy of Mateer, M. B. Phelan, and the Department of Emergency Medicine, Medical College of Wisconsin.)

If an embryo is identified, crown-rump length (CRL) can be measured easily. It is important to obtain the maximal embryo length, excluding the extremities and yoke sac.

$$\text{Gestational age (wks)} = \text{CRL (cm)} + 6.5$$

Both MSD and CRL give very accurate estimates of gestational age. A significant discrepancy between CRL and MSD dates suggests a failing pregnancy. After the first trimester, gestational age should be estimated by measuring the biparietal diameter (BPD) of the fetal skull. The BPD is a transverse measurement of skull diameter at the level of the thalamus. The markers are positioned at the leading edge (outside) of the near side of the skull and the leading edge (inside) of the far side of the skull. Modern ultrasound equipment is capable of calculating the gestational age automatically when any of the preceding measurements are marked on the display (Figure 113-17).

FIG. 113-11. Normal ovary. TVS showing the appearance of a normal premenopausal ovary with multiple small anechoic follicles. It is in the usual location adjacent to an iliac vessel on the right.

FIG. 113-12. Ovary in an unusual location. TVS in the standard mid-line sagittal view showing a normal-size ovary in the posterior cul-de-sac behind the uterus. The cervix is well visualized on the right.

ECTOPIC PREGNANCY

Diagnosing ectopic pregnancy (EP) in a timely manner is a challenge for emergency physicians. Significant morbidity and mortality may result from a missed or delayed diagnosis. Early diagnosis of an EP may allow nonsurgical therapy with methotrexate. (See Chap. 103 for a detailed discussion of EP.) About half of all EPs are missed on first presentation to the ED.⁴ Liberal use of transvaginal pelvic ultrasound decreases the rate of missed ectopic pregnancy.^{3,4,7,8}

Ectopic Location

EP occurs when the fertilized ovum implants anywhere except in the endometrium of the intrauterine cavity. Approximately 95 percent of EPs occur in the fallopian tube, with the ampulla being the most common location of implantation. Other sites of implantation include the interstitial region (proximal tube), the cervix, and the abdomen. Interstitial EPs are located in the fallopian tube as it traverses the uterine wall and may appear to be inside the uterus.⁹

Initial Evaluation of Patients at Risk for EP

A detailed approach to the woman at risk for EP is discussed in Chap. 103. A protocol that includes bedside TVS allows emergency physicians to evaluate high-risk patients more quickly and effectively.^{4,6} If no intrauterine pregnancy (IUP) is present, both TAS and TVS should be performed.

TABLE 113-1 Estimated Sonographic and Serum (3hCG Landmarks

Gestational Age	Transabdominal Landmarks	Transvaginal Landmarks	Serum (3hCG Level, IRP
4–5 weeks	± Gestational sac	Gestational sac	1000 mIU/mL
5 weeks	Gestational sac ± yolk sac	Gestational sac with yolk sac, ± fetal pole	1000-7000 mIU/mL
6 weeks	Yolk sac and fetal pole	Yolk sac and fetal pole with cardiac activity	10,000-23,000 mIU/mL

FIG. 113-13. Gestational sac. TVS showing a small anechoic gestational sac within the uterus slightly eccentric to the midline stripe (ES = endometrial stripe).

Ultrasound Evaluation

Patients who are at risk for an EP usually should have both a TAS and a TVS. TAS can identify an IUP after about 6 weeks of gestational age. TAS sometimes can detect masses that are too high in the pelvis to be seen by TVS (Figure 113-18). In addition, TAS can be used to estimate the amount of free intraperitoneal blood in patients with a ruptured EP. Therefore, it is prudent to scan both the pelvis and the right upper quadrant in all patients at risk for EP. Patients who have free fluid in both the pelvis and Morison pouch require an urgent obstetrics consultation and aggressive resuscitation. TVS is more sensitive and specific for evaluating early pregnancy. TVS can identify an IUP at about 5 weeks and can detect more subtle signs of EP such as tubal rings, adnexal masses, and small amounts of pelvic free fluid. ED TVS has 69 percent sensitivity and 99 percent specificity for diagnosing EP.⁸ TVS can differentiate between an IUP and an EP in 75 percent of pregnant women who present with pain or bleeding. Finding a definitive IUP rules out the diagnosis of EP as long as there is just a single gestation. Patients taking fertility drugs have a significant chance of both an IUP and an EP. The presence of a yolk sac, fetal pole, or cardiac activity within an intrauterine gestational sac confirms the presence of an IUP. Visualization of a gestational sac alone is not definitive evidence of an IUP unless a double decidual sign is seen clearly. In patients with an EP, about 15 percent can be identified immediately by

FIG. 113-14. Gestational sac and double decidual sign. TAS showing an anechoic gestational sac surrounded by two clear hyperechoic rings formed by the decidia capsularis and the decidia vera.

FIG. 113-15. Yolk sac. TVS showing a small discrete hyperechoic ring inside of a hypoechoic gestational sac. There is a thick hyperechoic decidual reaction surrounding the gestational sac.

transvaginal ultrasound. Signs of an obvious EP include an extrauterine gestational sac with a yolk sac and/or fetal pole and/or cardiac activity (Figure 113-19). Finding a tubal ring in the adnexa is not definitive evidence of an EP, but it is highly suggestive (Figure 113-20). Also, an EP is strongly suspected when pelvic free fluid or a complex adnexal mass is seen^{10,12} (Figures 113-21 and 113-22). TVS is very sensitive for detecting pelvic free fluid. When free pelvic fluid is seen in combination with a tubal ring or a complex adnexal mass, the diagnosis of EP is almost certain (see Figure 122-20). Identification of pelvic free fluid is easy using TVS, even for inexperienced sonographers (see Figures 113-9 and 113-21). However, identifying a tubal ring or complex mass can be more difficult because a more complete sonographic survey of the pelvis is required. Therefore, request for a "formal" pelvic ultrasound should be considered when no obvious IUP or EP is identified, especially when pelvic free fluid is seen or the risk of EP is high.

Quantitative Serum (3-hCG and Discriminatory Zone

Although a quantitative P-hCG level used to be the pivotal test in rule out EP protocols, the utility of a single quantitative P-hCG level is questionable. **Transvaginal pelvic ultrasound is clearly the best ini-**

FIG. 113-16. Yolk sac and embryo. TVS showing an intrauterine pregnancy at 7 weeks' gestational age. A discrete embryo (fetal pole) is seen adjacent to the yolk sac, and a large hypoechoic ovarian cyst (corpus luteum cyst) is seen on the left.

tial test and indicated to rule out an EP, regardless of the p-hCG level.¹³¹⁴

Implications and use of the "discriminatory zone" in the evaluation of EP is discussed in Chap. 103.

Potential Errors Related to Sonography in the Diagnosis of EP

Several errors related to sonography should be avoided in evaluating a patient with a potential EP. Overreliance on the serum (3-hCG level was discussed earlier. It is prudent to perform a complete sonographic survey of the pelvis if the uterus is empty, regardless of the (3-hCG level. Assumption that the uterus is empty due to a very early IUP or spontaneous abortion may prove erroneous.

Misinterpretation of pelvic sonography can lead to a delayed diagnosis of EP, with disastrous results. An anechoic fluid collection without a clear double decidual reaction (pseudo-gestational sac) may be misinterpreted as an IUP. A pseudo-gestational sac is present in about 10 to 20 percent of patients who have an EP.¹⁵ A pseudo-gestational sac is the result of endometrium that is stimulated by trophoblastic hormones and intrauterine bleeding (see Figures 113-18 and 113-23).

FIG. 113-18. Complex mass high in the pelvis. TAS in the standard midline sagittal view showing a complex mass/ectopic pregnancy (*left*) cephalad to the uterus and a pseudo-gestational sac within the uterus (*center*) (ex = cervix; cm = complex mass).

FIG. 113-19. Obvious ectopic pregnancy. TVS showing a clear embryo inside of a large gestational sac (*right*) adjacent to an empty uterus (*left*). Cardiac activity was seen inside the embryo.

The double decidual sac sign can be used to differentiate a true gestational sac from a pseudo-gestational sac. Failure to appreciate the presence of free pelvic fluid or the implications may be disastrous. About two-thirds of patients with an EP will have pelvic free fluid. Also, pelvic free fluid is the only abnormal sonographic finding in about 15 percent. The greater the volume of free intraperitoneal fluid, the greater is the likelihood of EP. In fact, pregnant patients with free fluid in Morison pouch have a large hemoperitoneum and almost a 100 percent chance of having an EP.⁵ Not performing sonography of the right upper quadrant is a mistake because identifying free fluid in Morison pouch is very easy, even for inexperienced sonographers.

Missing a subtle adnexal mass or tubal ring is a mistake that may be difficult to avoid. Identifying such abnormalities usually requires a complete sonographic survey of the pelvis, which requires increased training and experience.

Misjudging the intrauterine or extrauterine location of a pregnancy is a serious mistake. The location of the uterus should be identified clearly before a gestational sac, yolk sac, and/or fetal pole is called an IUP or EP. A normal pregnancy should be located in the fundus of the uterus.

Interstitial pregnancies can be difficult to differentiate from an IUP and should be considered when a patient presents in shock with an apparent IUP by ultrasound.⁹

FIG. 113-20. Ectopic pregnancy. TVS showing a tubal ring (*left*) and adnexal free fluid (FF) (*right*). Loops of bowel are clearly outlined by the hypoechoic free fluid (*center*).

FIG. 113-21. Pelvic free fluid. TVS showing a moderate amount of free fluid (FF) in the posterior cul-de-sac (pouch of Douglas) behind an empty uterus. This was the only abnormal finding in this patient with an ectopic pregnancy.

Heterotopic Pregnancy

Usually the presence of an IUP is sufficient evidence that an EP does not exist. However, in the case of patients who are taking progestational/fertility agents, this assumption should not be made. The incidence of simultaneous intrauterine and extrauterine pregnancy (heterotopic pregnancy) in the general population is now thought to be as high as 1 per 4000 pregnancies, although historically this was only reported in 1 per 30,000 pregnancies. Those taking medications to enhance fertility are at much higher risk for heterotopic pregnancy. Patients who have a history of in vitro fertilization may have an incidence as high as 1 per 100 to 200 pregnancies. For this reason, sonographic imaging of the entire pelvis should be completed even after identification of an obvious IUP in such patients.

ABNORMAL FIRST-TRIMESTER INTRAUTERINE PREGNANCY

Spontaneous Abortion

Abortion is discussed in Chap. 106. Most pregnancy losses occur early in the first trimester, and few are lost after fetal cardiac activity is

FIG. 113-22. Complex mass (CM). TVS showing a complex mass/ectopic pregnancy (*right*) adjacent to an empty uterus (*left*).

FIG. 113-23. Pseudo-gestational sac. TVS showing a fluid collection (pseudo-gestational sac) inside the uterus (*right*) and a tubal ring associated with an ectopic pregnancy (*left*).

noted sonographically.⁷ After a completed abortion, an empty uterus should be visualized sonographically; thus a postpartum endometrial stripe greater than 10 mm in a symptomatic patient suggests the presence of retained products of conception (see Figure 113-10).

Threatened Abortion and Viability of an Early IUP

The pivotal step in the evaluation of a patient with first-trimester vaginal bleeding is pelvic sonography. If a live IUP is seen and there is a single gestation, expectant management is the rule.

There are several sonographic criteria that can be used to decide whether an early IUP is viable or whether early fetal demise has occurred. Major criteria are those which uniformly predict fetal demise. Inability to visualize a yolk sac or embryo in a large gestational sac is a major criterion for demise; this is referred to as a *blighted ovum* (Figure 113-24). Specifically, absence of a yolk sac when the MSD is 10 mm or greater with TVS or when the MSD is 20 mm or greater with TAS indicates certain fetal demise.⁷ In addition, absence of an embryo when the MSD is 16 mm or greater with TVS or when the MSD 25 mm or greater with TAS predicts fetal demise with confidence.⁷ Visualization of a grossly distorted gestational sac uniformly predicts fetal demise but is somewhat subjective (Figure 113-25). A gestational sac located in the lower portion of the uterus adjacent to the cervix is probably in the process of aborting.⁷ An irregular, thin, or weakly echogenic choriodecidual reaction surrounding the gestational sac, decreased amniotic fluid volume, or a fetal heartbeat below 90 beats/min after 6 weeks' gestational age are all suggestive but not diagnostic of a failing pregnancy.

FIG. 113-24. Blighted ovum. TVS showing a large empty intrauterine gestational sac (ex = cervix).

FIG. 113-25. Fetal demise. TVS showing a large gestational sac (GS) that is grossly distorted. There is some debris inside the sac but no clear yolk sac or embryo.

Subchorionic Hematoma

An intrauterine hematoma is present in about one-fourth of patients with threatened abortion. In the first trimester, blood may accumulate in the endometrial cavity between the chorionic membranes and the uterine wall; this is known as a *subchorionic hematoma* or *implantation bleed* (Figure 113-26). The presence of a subchorionic hematoma may more than double the chances of pregnancy loss in threatened abortion. The size and location are important factors in judging the significance of such bleeding. Small hematomas under the placenta are more important than larger hematomas elsewhere.

Vaginal Bleeding with No IUP

The sonographic finding of an empty uterus in a patient with vaginal bleeding and a positive pregnancy test poses a difficult diagnostic dilemma. Very early IUP or completed spontaneous abortion are possible, but 25 percent of these patients will have an EP.¹⁶ When echogenic material is seen within the uterus, retained intrauterine products from an incomplete abortion or from partial resorption after fetal demise may be present (see Figure 113-10); this should not be confused with intrauterine blood and clots, which can occur with an

FIG. 113-26. Subchorionic hemorrhage. TAS midline sagittal view showing an intrauterine pregnancy. The placenta is posterior, and the lower placental margin is displaced by an anechoic hemorrhage.

EP. Completed spontaneous abortion is confirmed only by passage of obvious products of conception or identification of chorionic villi pathologically. Serial quantitative serum p-hCG determinations may be helpful in this setting. After spontaneous abortion, serum (3-hCG levels fall rapidly during the first 7 days. Close follow-up with serial sonography and serum P-hCG determinations may be needed before a final diagnosis can be ascertained.

Molar Pregnancy

Gestational trophoblastic neoplasia is a proliferative disease of the trophoblast. It is discussed in Chap. 106. Most cases (80 percent) present as a hydatidiform mole and follow a benign course. More malignant forms of the disease are invasive mole (12-15 percent) and choriocarcinoma (5-8 percent). Patients with a hydatidiform mole most commonly present with vaginal bleeding but may present with early preeclampsia or hyperemesis gravidarum. A larger than expected uterus for gestational age and a markedly elevated serum P-hCG level ($> 100,000$ mIU/mL) are risk factors for malignant disease and are important clues to making this diagnosis. Most cases of molar pregnancy involve the entire placenta, but molar disease involving only part of the placenta or fetus also has been described. Pelvic ultrasound is the initial study of choice when a molar pregnancy is suspected.¹ A hydatidiform mole appears as an intrauterine echogenic mass with multiple small hypoechoic vesicles interspersed (Figure 113-27). It is said to have a characteristic appearance of grapes. However, the appearance of first-trimester moles may be confused with a blighted ovum or threatened abortion. A theca lutein cyst may be seen on examination of the ovaries in as many as half the cases of gestational trophoblastic disease (GTD). They are large, multiseptated ovarian cysts caused by markedly high levels of serum (3-hCG. A benign mole usually resolves after evacuation of the uterus. Choriocarcinoma may metastasize to the lung, vagina, brain, or liver and is very sensitive to chemotherapy.

SECOND- AND THIRD-TRIMESTER PREGNANCY

Ultrasound evaluations of second- and third-trimester pregnancies are often done in order to evaluate fetal age and well-being when maternal problems arise. Maternal vaginal bleeding, preeclampsia, diabetes, drug abuse, and trauma all may compromise the fetus. Ultrasound can be used to quickly evaluate several important structures that may have a bearing on the final outcome of the pregnancy. Although emergency physicians are not relied on to perform routine ultrasound examinations during late preg-

nancy, many of the structures and abnormalities seen in late pregnancy are easily recognizable, even to those with little ultrasound training.

Immediate Fetal Viability

The visualization of fetal movements and fetal heart rate (normal = 120 to 160 beats/min) takes priority in the acute setting.¹ The diagnosis of fetal death is established by careful sonographic imaging of the fetal chest for at least 3 min with lack of cardiac activity. Two experienced sonographers should confirm the diagnosis.

Oligohydramnios and Polyhydramnios

The amount of amniotic fluid should be estimated. Subjective estimates of amniotic fluid volumes are best left to experienced sonographers, but extremes of polyhydramnios and oligohydramnios may be obvious to the neophyte. Amniotic fluid volume is large compared with fetal volume in normal early pregnancy; this should not be mistaken for polyhydramnios. A single measurement of the length of the deepest pocket of amniotic fluid gives a gross estimate of the volume and may be the best method of measurement for the inexperienced sonographer. A pocket more than 8 cm deep indicates polyhydramnios, and a pocket less than 1 cm deep indicates oligohydramnios. A four-quadrant index also can be used to estimate the volume of amniotic fluid. The uterus is divided into four quadrants, and the deepest pocket in each quadrant is measured. If the sum of the four measurements is less than 5 cm, oligohydramnios is present. If the sum is greater than 20 cm, polyhydramnios is present. An obstetrician should be consulted immediately when oligohydramnios is found because it is associated with fetal renal malformation, severe growth retardation, and fetal death. Polyhydramnios may be associated with fetal anomalies, preterm labor, and premature rupture of membranes, but it is generally considered less serious.

Umbilical Cord

Sonographic examination of the umbilical cord should reveal two arteries and a single larger vein. A cord that contains only one artery is associated with a 25 to 50 percent chance of fetal abnormalities. The cord vessels are best counted at the cord insertion into the fetus because the two umbilical arteries may normally fuse at the placental end of the cord.

Fetal Gender

Both male and female genitalia are easily recognizable but should be clearly identified before the gender of the fetus is revealed. Lack of visualization of the penis and scrotum without clearly identifying the female labia is not adequate, and in this case no estimate of fetal gender should be made. Errors in sonographic sex determination occur relatively frequently; thus emergency physicians should avoid forecasting gender because it adds little to emergency care.

Fetal Structures and Abnormalities

Fetal anatomy such as fetal head, chest, abdomen, and extremities can be visualized quite easily in the second and third trimesters, even for those with little ultrasound experience. Most routine fetal ultrasound examinations and detection of anomalies should be performed by physicians who specialize in fetal sonography.

COMPLICATIONS IN THE SECOND HALF OF PREGNANCY

Placenta Previa

During the evaluation of third-trimester bleeding, the greatest utility of sonography is to establish the presence or absence of placenta previa.

FIG. 113-27. Molar pregnancy. TVS showing a large complex intrauterine mass with cystic regions that have the characteristic appearance of grapes.

OTHER CONDITIONS

Pelvic Inflammatory Disease and Tubo-Ovarian Abscess

The diagnosis of pelvic inflammatory disease (PID) is usually made clinically, without the aid of ancillary studies. Ultrasound findings are unlikely to be noted early in the course of PID. In cases of severe PID, the ultrasound examination may demonstrate free fluid in the cul-de-sac or pyosalpinx. Pyosalpinx is a swollen, pus-filled fallopian tube, which appears sonographically as a distinct circular structure with low-level echoes in the lumen when imaged in cross section. Pyosalpinx may appear to be a multicystic mass if multiple loops of distended tube are lying adjacent to one another. Sonographic evidence of pyosalpinx has been shown to be specific for the diagnosis of PID. Tubo-ovarian abscess (TOA) is a complication of PID that can be diagnosed accurately using pelvic ultrasound. An abscess will appear as a complex mass with both cystic and solid components (see Figure 113-30). Percutaneous or transvaginal drainage of a TOA may be facilitated by ultrasound guidance.

Ovarian Torsion

Doppler ultrasound is used commonly for the evaluation of suspected ovarian torsion; however, the diagnostic accuracy of Doppler studies for ovarian torsion is poor. When torsion is present, the lack of internal ovarian blood flow on Doppler examination probably indicates that an ovary is beyond salvage. Also, the absence of blood flow to the ovary can be seen in a variety of cystic ovarian lesions when torsion is not present. Massive ovarian edema is an entity caused by intermittent or partial adnexal torsion. Doppler flow is present, and resolution of the edema often occurs after detorsion of the adnexa. Simple gray-scale pelvic sonography is helpful when adnexal torsion is suspected because most patients with ovarian torsion have a significantly enlarged ovary.¹⁷ Finding normal-sized ovaries makes adnexal torsion unlikely.

tus should be evaluated. Placental abruption and direct fetal injury must be suspected following significant maternal trauma in the second and third trimesters.

Fetal Sonographic Evaluation

Ultrasound can be used to assist in the initial evaluation of the fetus after maternal trauma.¹ First, ultrasound can aid in making a quick estimate of gestational age. Knowledge of the gestational age is important because subsequent management decisions may be influenced by its determination. Next, immediate fetal viability can be ascertained by sonography. If the fetus is dead (no cardiac activity and no fetal movement), management of the mother will become the sole priority. Gross injury to the fetus, placenta, or uterus may be apparent on the initial ultrasound examination. Oligohydramnios following maternal trauma suggests uterine injury or premature rupture of the membranes. Large placental abruptions may be visualized, and fetal distress (fetal heart-beat above 180 or below 120 beats/min) may indicate unrecognized maternal, fetal, or placental injury. Urgent delivery of the significantly compromised fetus is indicated if the gestational age is at least 24 to 26 weeks (see Chap. 254). Traumatic uterine rupture is usually accompanied by massive bleeding and requires repair or hysterectomy regardless of gestational age. Although sonographic imaging may detect some large abruptions and gross fetal injury, cardiotocographic monitoring is a much more sensitive indicator. Fetal bradycardia, late decelerations, and loss of beat-to-beat variation are signs of distress. Fetal distress and frequent uterine contractions nearly always appear within 4 h of significant traumatic placental abruption.

PELVIC MASSES

Uterine Masses

A leiomyoma (uterine fibroid) is a benign proliferation of the smooth muscle and connective tissue of the uterus. It is the most common cause of uterine enlargement not related to pregnancy. Fibroids have a variety of sonographic appearances, ranging from hypoechoic masses with irregular uterine contours to echogenic structures with distinct calcified borders (Figure 113-29). When a fibroid degenerates, multiple small cystic spaces are visualized within the fibroid. Fibroids can be intramural, submucosal, subserosal, or pedunculated. A fibroid may outgrow its blood supply, leading to necrosis and severe pain, espe-

cially during pregnancy. Rarely, a fibroid degenerates into a uterine sarcoma. In addition, endometrial or ovarian carcinoma may invade the myometrium. Therefore, complex or cystic uterine masses require further investigation.

Cervix and Vagina

The vagina and cervix are best visualized with TAS. Visualization of the cervix with the transvaginal probe requires that the probe be withdrawn into the distal vagina. Nabothian cysts are benign growths that are seen commonly in the region of the cervix (see Figure 113-6). Gartner duct cysts are also benign and may be seen at the anterior and lateral walls of the vagina. Imperforate hymen causes primary amenorrhea, lower abdominal pain, and urinary symptoms during puberty. A tender lower abdominal mass may be palpable on physical examination, and pelvic sonography will confirm that the vagina is filled with blood; this is called *hematocolpos*. A distended urinary bladder and a blood-filled distended uterus, or *hematometra*, also may be noted. Perineal examination will reveal a bulging hymen; incision and drainage are required.

Adnexal Masses

Developing ovarian follicles may measure up to 2 cm at midcycle. Functional ovarian cysts measure greater than 2.5 cm and are well defined, thin-walled, and anechoic. Most simple ovarian cysts resolve spontaneously, and serial sonographic examinations are helpful to follow their progression. In postmenopausal patients, even well-defined anechoic ovarian cysts require further workup, especially if they are greater than 5 cm in diameter. Sonographically, polycystic ovary disease appears as bilaterally enlarged ovaries with multiple small follicles or a small number of very large follicles. In some cases, the follicles are so tiny that they cannot be seen sonographically; thus a normal appearance of the ovaries does not rule out the diagnosis.

Complex Adnexal Masses

Hemorrhagic ovarian cysts, endometriomas, tubo-ovarian abscesses, benign ovarian tumors, and malignancies all can present as a complex adnexal mass (Figure 113-30). Dermoids have the appearance of focal bright echoes inside a complex adnexal mass. Adnexal tumors that are hyperechoic, septated, and very irregular are more likely to be malignant and require further investigation. When a large complex adnexal mass and ascites are present, the likelihood of ovarian carcinoma high.

FIG. 113-29. Leiomyoma (fibroid). TAS showing a calcified mass on the anterior wall of the uterus with distal shadowing. An intrauterine gestational sac and yolk sac are seen in the uterine fundus.

FIG. 113-30. Complex adnexal mass. TAS showing a large, well-demarcated mass with both hypoechoic and hyperechoic regions. This is a tubo-ovarian abscess, but a hemorrhagic ovarian cyst or ovarian tumor could have a similar appearance.

OTHER CONDITIONS

Pelvic Inflammatory Disease and Tubo-Ovarian Abscess

The diagnosis of pelvic inflammatory disease (PID) is usually made clinically, without the aid of ancillary studies. Ultrasound findings are unlikely to be noted early in the course of PID. In cases of severe PID, the ultrasound examination may demonstrate free fluid in the cul-de-sac or pyosalpinx. Pyosalpinx is a swollen, pus-filled fallopian tube, which appears sonographically as a distinct circular structure with low-level echoes in the lumen when imaged in cross section. Pyosalpinx may appear to be a multicystic mass if multiple loops of distended tube are lying adjacent to one another. Sonographic evidence of pyosalpinx has been shown to be specific for the diagnosis of PID. Tubo-ovarian abscess (TOA) is a complication of PID that can be diagnosed accurately using pelvic ultrasound. An abscess will appear as a complex mass with both cystic and solid components (see Figure 113-30). Percutaneous or transvaginal drainage of a TOA may be facilitated by ultrasound guidance.

Ovarian Torsion

Doppler ultrasound is used commonly for the evaluation of suspected ovarian torsion; however, the diagnostic accuracy of Doppler studies for ovarian torsion is poor. When torsion is present, the lack of internal ovarian blood flow on Doppler examination probably indicates that an ovary is beyond salvage. Also, the absence of blood flow to the ovary can be seen in a variety of cystic ovarian lesions when torsion is not present. Massive ovarian edema is an entity caused by intermittent or partial adnexal torsion. Doppler flow is present, and resolution of the edema often occurs after detorsion of the adnexa. Simple gray-scale pelvic sonography is helpful when adnexal torsion is suspected because most patients with ovarian torsion have a significantly enlarged ovary.¹⁷ Finding normal-sized ovaries makes adnexal torsion unlikely.

THE NORMAL CHILD

Peter Mellis

Children account for approximately 30 percent of visits in most EDs. The majority have minor or self-limited illnesses that may optimally be cared for in a nonemergent setting. However, the differentiation of critically ill pediatric patients from the larger number of less ill children with similar complaints represents one of the most important and challenging diagnostic skills for emergency physicians. The key to mastering process of identifying ill children is a knowledge of child development as applied to the emergency setting.

GENERAL PRINCIPLES OF THE DEVELOPMENTAL APPROACH

Although there are many specific aspects of the developmental approach, a few general principles are applicable to all age groups of children and their families.

Communicate with the Child

Children are best approached in a positive and gentle manner, with an awareness that the first impression sets the tone for the encounter. Review the emergency record for patient's name and age so that an introduction and a developmentally structured interaction may be planned. An awareness of the child's age-related communication skills and perspective will result in a more meaningful evaluation. Whenever possible, look at the child from his or her own eye level. Use the child's motor skills, vocabulary, and specific life experiences as reference points. Hunger, discomfort, fear of separation or pain, and feelings of loss of control should be addressed directly. Recognize that the ED is a strange and threatening environment and, whenever possible, isolate the child from the sights and sounds of other patient care experiences that may heighten the child's own anxiety. Most importantly, be honest with children regarding expectations for their experience so that trust can be established.

Communicate with the Family

Assess and treat the child in the context of his or her family, avoiding separation whenever possible. ED policy should encourage parental accompaniment of children to the clinical area. It is optimal to consider that there are two patients, child and parent(s), each with expectations that must be addressed. Caregivers have essential historical information and, in the case of infants and toddlers, are physically necessary to the performance of a meaningful physical assessment. At all ages, children watch their parents for cues with respect to how to respond to the medical staff. Parents who understand and accept the sequence of events involved in emergency care become allies in enlisting their child's cooperation. Whenever possible, parents should be encouraged to remain present during procedures and maintain visual and physical contact from a sitting position. Appropriate exceptions include parental discomfort and critical illness. Because parents are intimately familiar with their child's range of verbal and nonverbal behaviors, the examiner must take the phrase "this is not my child" as parental concern for an abnormal level of consciousness. This reliance on parental knowledge is particularly applicable to the assessment of a child with developmental delay.

Assess by Means of Observation

Every effort should be made to gain information regarding a young child before interacting with him or her directly. Infants and young children communicate a normal level of consciousness through age-appropriate motor and social responses to their environment. Observe the child's behavior from a distance, preferably without his or her awareness. This can often be accomplished while obtaining the history from the caretakers. Antipyretic therapy and satisfying hunger are often crucial to achieving this period of optimal observation. Often more is learned regarding neurologic status from a brief period of observation than from the traditional physical examination. Nonemergent, uncomfortable examination components and procedures should be performed last.

Obtain Meaningful Vital Signs

Normal ranges for heart rate, respiratory rate, and blood pressure differ significantly with age and must be interpreted in the context of a child's activity at the time (Table 114-1). Anxiety, pain, fever, and crying will increase all values, and these states should be documented, if present. Optimal vital signs are obtained without eliciting an adverse reaction to the examiner (e.g., respiratory rate taken by observing abdominal movements and heart rate auscultated through clothing). If fever is a concern, temperature should be obtained rectally in infants, toddlers, and uncooperative children, because the oral, axillary, and tympanic routes are less reliable. Temperature measured by the oral route is likely to be feasible and accurate in children by 4 to 5 years of age. Blood pressure should be measured on previously well children who are 5 years and older (school age), children with chronic disease associated with hypertension (e.g., renal disease), and all children who are critically ill. Oxygen saturation should be determined for those in respiratory distress. Weight is a pediatric vital sign, because of dosing considerations and the importance of growth as an indicator of chronic disease in children. Appropriate scales and growth charts should be available in EDs. For resuscitation purposes, bedside estimates of weight are frequently inaccurate, and length-based resuscitation resources (e.g., Broselow tapes) are recommended.

GROWTH AND DEVELOPMENTAL STAGES

The process of development is not unique to children, but the pace at which change occurs and the implications for patient care are maximal during this period of life. *Developmental stages* are described with associated age ranges, but these are best viewed as a sequence of events with significant individual variations in rate of progression. For purposes of facilitating patient care in the ED, two aspects of each developmental stage must be considered. *Physical aspects* include growth and physiologic parameters unique to a given developmental stage, a knowledge of which is essential to provide excellent care. *Neurologic aspects* include motor, language, and social and psychological milestones that affect patient assessment and responses during acute illness or injury. These milestones and their related strategies are summarized in Table 114-2. Based on a knowledge of these principles, the examiner is well equipped to proceed with a developmentally *age-specific approach*.

Early Infancy (0 to 6 Months)

PHYSICAL ASPECTS Rapid growth rate is a characteristic feature of young infants, for whom the major work is eating. After a 5 to 10 percent

TABLE 114-1 Pediatric Vital Signs (Awake and Resting)

Age	Heart Rate/min, Upper Limit	Respiratory Rate/min, Upper Limit	Blood Pressure, * Lower Limit	Weight, † kg
0–1 mo	180	60	60/40	3–4
2–12 mo	160	50	70/45	5–10
12–24 mo	140	40	75/50	10–12
2–6 y	120	30	80/55	13–25
6–12 y	110	20	90/60	25–40
>12 y	100	20	90/60	40–60

*May be estimated by
systolic blood pressure (5th percentile) = $70 + [2 \times (\text{age in years})]$

†May be estimated by
≤12 mo; weight (kg) = $4 + (\text{age in months}/2)$
1–12 y; weight (kg) = $10 + [2 \times (\text{age in years})]$

loss over the first 3 days of life, term infants regain birth weight by 10 days of age. A 20- to 30-g per d weight gain is the best overall sign of health. Normal infants double their birth weight by 5 months. Young infants have a high ratio of surface area to body mass, with a proportionally large head, resulting in a high rate of heat loss and risk of hypothermia. The normal anterior fontanelle is slightly depressed when a child is upright. Young infants are obligate nose breathers and may experience partial airway obstruction with abnormal positioning or viral upper respiratory tract infections. Normal neonates may exhibit periodic breathing, or 5- to 10-s pauses followed by tachypnea due to immature central control of respiration. Cardiac output and minute ventilation are relatively rate dependent in early infancy. A heart rate faster than 180 beats/min and a respiratory rate faster than 60 breaths/min should be considered abnormal. Blood pressure is well maintained by compensatory mechanisms at this age, with hypotension a very late finding in shock. The pulmonary vascular bed dilates over the first 6 weeks of life, so that congenital heart lesions resulting in a left-to-right shunt, for example, ventricular septal defect, will present after this age. The primary series of immunizations, including

diphtheria-pertussis-tetanus (DPT), oral poliovirus, pneumococcal conjugate vaccine (PCV), and *Haemophilus influenzae* type b (Hib), are completed by age 6 months (Table 114-3). The rotavirus vaccine had been added to the primary immunization series, but possible association with intussusception has resulted in cessation of its use.

NEUROLOGIC ASPECTS Motor development is the major indicator of neurologic health and proceeds in a cephalocaudal fashion. Neonates demonstrate involuntary "primitive" reflexes, such as the suck, grasp, and Moro (startle) responses, which may be elicited to demonstrate muscle tone and should always be symmetric. By 1 month of age, infants can lift their heads, follow a moving object, and demonstrate a social smile. By 4 months, head control is steady, the child will reach for and grasp objects with the whole hand, a cooing response may be elicited, and rolling over has begun. During this period, normal infants learn trust from their parents and will respond positively to a gentle examiner. This is the period of least parental confidence, and many ED visits are made because of lack of knowledge and a need for reassurance.

TABLE 114-2 Developmental Stages and Emergency Department Assessment Strategy

Stage Milestone	Strategy
Early infancy (0–6 mo) Motor: lifts head, reaches Verbal: cooing Social: responsive smile	Observation Examine in parent's arms Direct approach
Late infancy (6–18 mo) Motor: reaches/obtains, sits, walks Verbal: jargon, few words Social: stranger anxiety/dependence	Observation Examine in parent's arms Indirect approach
Toddler (18–36 mo) Motor: walks well, scribbles Verbal: speaks in phrases Social: stranger anxiety/autonomy	Observation Indirect approach
Preschool (3–5 y) Motor: runs well, colors Verbal: speaks in sentences Social: magical thinking	Indirect or direct approach Explain briefly just before procedures
School age (5–12 y) Motor: schoolwork, sports Verbal: concrete reasoning Social: task oriented	Direct approach Explain in detail before procedures
Adolescence (12–17 y) Motor: adult Verbal: abstract reasoning Social: autonomy, rebellion	Direct approach Confidentiality Treat as adult

TABLE 114-3 Recommended Schedule of Childhood Immunizations

Age	DTaP	IPV	Hib	PCV	MMR	HepB	VZV
Birth						HepB	
2 mo	DTaP	IPV	Hib	PCV		HepB	
4 mo	DTaP	IPV	Hib	PCV			
6 mo	DTaP	IPV*	Hib	PCV		HepB*	
12–15 mo			Hib	PCV	MMR		VZVf
15–18 mo	DTaP						
4–6 y	DTaP	IPV			MMRj		
11–12 y	Td						

*Third dose of IPV and HepB may be given at any time at ages 6 to 18 mo. tVZV may be given at any time at ages 12 to 18 mo. JSecond dose of MMR may be given at any time at ages 4 to 12 y. *Abbreviations:* DTaP = diphtheria-tetanus-acellular pertussis, HepB = hepatitis B (live), Hib = *Haemophilus influenzae* type b conjugate, IPV = inactivated polio virus, MMR = measles-mumps-rubella (live), PCV = pneumococcal conjugate vaccine; Td = tetanus toxoid with diphtheria adjuvant (adult), VZV = varicella zoster virus (live).

AGE-SPECIFIC APPROACH Assessment is optimally made by direct interaction with the use of a pleasant, confident tone of voice and smiling face directed toward the infant. Observation of muscle tone, spontaneous activity, eye contact, responsive smile, and recognition of parents is most important. Examination of the infant is best performed when the infant is in the parent's lap, with use of brightly colored or pleasant-sounding objects to elicit a motor response. Feeding the infant or eliciting the sucking reflex with a finger often will result in greater cooperation. Optimal examination is done in order of least to most invasive interactions, that is, observation, auscultation, and palpation, being careful to avoid uncomfortable procedures such as ear and throat examination until the remainder of the exam is complete. Parental confidence should be directly reinforced. Young infants should be carefully monitored during procedures involving sedation or abnormal positioning, because of the risk of airway compromise. The motor abilities of young infants result in a limited potential for self-inflicted accidental injury. Whenever an injury is developmentally inconsistent with the stated mechanism, the potential for child abuse must be investigated.

Late Infancy (6 to 18 Months)

PHYSICAL ASPECTS Normal infants triple their birth weight by 1 year of age, but the rate of growth slows during this period. The primary teeth begin to erupt by 6 months of age, with an average acquisition rate of one per month. Head size, center of gravity, and ratio of body surface area to body mass remain large in comparison with those of adults. The anterior fontanelle is closed by 18 months of age. The measles-mumps-rubella vaccination is given at 12 to 15 months of age, and the varicella vaccine is given at 12 to 18 months of age. The DPT and Hib boosters are given during this same period (see Table 114-3).

NEUROLOGIC ASPECTS The normal infant sits with minimal support, transfers objects from hand to hand, and babbles by 6 months. By 9 months of age, the infant is crawling, pulling to a standing position, and verbalizing with nonspecific jargon. By 12 months, the infant has a mature pincer-type grasp, begins to walk, and acquires specific words. The developmental combination of mobility and grasp results in increasing risk of toxic and foreign-body ingestion. Between 9 and 12 months, a strong sense of "stranger anxiety," related to fear of separation from parents, is acquired and complicates every aspect of physical assessment. Conversely, the failure of an older infant or toddler to recognize and preferentially respond to parents suggests significant disease.

AGE-SPECIFIC APPROACH Assessment of an older infant and toddler begins with observation, preferably without the child's awareness of the examiner's presence. The child should be undressed to obtain a meaningful respiratory rate and to observe the work of breathing. Spontaneous motor activity, such as sitting and pulling up, and purposeful responses to parental overtures, such as reaching for objects and smiling, are indicators of a normal level of consciousness. The child should see the examiner approach gradually and engage his or her caretakers first. An entire examination requiring any degree of cooperation is best performed while the child is held on the parent's lap or shoulder so that perception of separation is avoided. As for younger infants, the examination proceeds from least to most invasive interactions. Procedures in this age group require adequate physical restraint. Although parental restraint is acceptable for nonpainful examination procedures, parents should not be asked to immobilize their child for invasive procedures. Caretakers should be encouraged to remain present to reassure their child during procedures, if it is their desire to do so. The high level of anxiety at this age frequently results in persistently uncooperative behavior despite adequate analgesia. Sedation for

procedures may require a significantly higher per-kilogram dose of an anxiolytic or analgesic drug to achieve the desired effect.

Toddler (18 to 36 Months)

PHYSICAL ASPECTS Decelerating growth rate and decreased appetite are seen during this period, although the head approaches its adult size. The 20 primary teeth are in place by 36 months, and dental caries are common. High center of gravity, mobility, and curiosity lead to increasing risk for head and orthopedic injuries. A toddler's open growth plates are far more likely to sustain epiphyseal fracture than ligamentous injury. Traction injuries to the arm will frequently result in subluxation of the annular ligament of the radial head (i.e., "nursemaid's elbow").

NEUROLOGIC ASPECTS By 18 months of age, most children can walk well, feed themselves, follow simple commands, and use four to six words to indicate their desires. Stranger anxiety peaks at this age but remains important throughout the toddler period. By 24 months, most children can run, climb stairs, and speak with three-word phrases, although only 50 percent of speech is intelligible to nonfamily members. Toddlers understand far more than their spontaneous speech would indicate and learn by imitating the behavior of their family members. When given opportunity to draw, a toddler will scribble with a brief attention span. Parents consistently underestimate the mobility and problem-solving ability of a toddler, resulting in a peak risk for falls and ingestions at this age.

AGE-SPECIFIC APPROACH An examination strategy of indirect observation followed by direct interaction in the safety of the parent's arms should be followed, as described for older infants. The examiner should encourage the parent to have the toddler walk and follow commands as an important component of the assessment for acute systemic or neurologic disease. Allow the child a favorite object, such as a doll or blanket, for comfort during the examination. Talk to the child in simple language about what you will do and offer to let the child touch or hold the examination instruments to gain their trust. Older toddlers may indicate the site of pain specifically, but many will be unable to communicate localized pain or tenderness. As described above, perform the physical assessment in order of least to most invasive examination components. As for older infants, restraint is routinely indicated for painful procedures and a higher per-kilogram dose of an anxiolytic or analgesic drug may be required. Because of likelihood of epiphyseal fracture, a young child with tenderness over the growth plate after injury should be immobilized with a splint, even if x-ray films are negative.

Preschool Age (3 to 5 Years)

PHYSICAL ASPECTS Growth rate slows significantly during this period, and appetite decreases further. Children develop a more lean body habitus. The incidence of injuries increases with increasing activity. The preschool child is no longer restrained in a car seat and is at risk for defined injury complexes from improperly fitting lap and shoulder belts. A DPT booster is given shortly before beginning school, between the ages of 4 and 6 years (see Table 114-3).

NEUROLOGIC ASPECTS Preschool children develop progressive autonomy in terms of mobility and self-care. Attraction to books, drawing, and coloring is common. Expressive language skills expand rapidly, and children this age are often able to identify site(s) of specific complaint. However, a strong sense of fear of pain remains, and the level of anxiety remains high in the emergency setting. Preschool children live in the present and have a limited sense of time and history, so that prior symptoms are frequently forgotten. Self-centered

"magical" reasoning is the rule, so that many preschool children believe that ED care is punishment for misbehavior. This is occasionally reinforced by parents who state they will "have the doctor give you a shot," which should be discouraged.

AGE-SPECIFIC APPROACH Many preschool children may be directly approached and examined in the traditional systematic fashion. However, some will require the indirect approach described for toddlers, and the nearby presence of a parent is typically essential for cooperation. The examiner should always talk directly with the preschooler to establish rapport and confirm the general complaint. Identification of recent positive experiences such as birthdays or favorite cartoon characters is frequently helpful in gaining cooperation. However, preschool children should be expected to identify only the current complaint, and reliance on parental history should remain. Cooperation during the physical examination is likely, although less comfortable components are still best performed at the end. The performance of painful procedures requires a careful approach. It is always best to be honest regarding discomfort, but information should be given immediately before performing the procedure to minimize the effects of fantasy regarding pain and causality and delaying tactics. Comfort and distraction by the parent are frequently effective for minor procedures; however, restraint, as for toddlers, is typically necessary. Rewards such as verbal praise and a sticker for bravery often significantly enhance the memory of the experience for the child and family.

School Age (5 to 12 Years)

PHYSICAL ASPECTS The school years represent the slowest period of growth in childhood, and the body habitus is typically slender. The primary teeth are loosening and the secondary teeth erupt. The lymphatics reach maximal dimensions relative to body size by 6 years of age. There is increased physical activity, including organized sports, during this period, and injuries become common.

NEUROLOGIC ASPECTS School-age children experience rapid language growth and maturing motor ability. Concrete reasoning ability emerges with an ability to understand cause and effect. The child is increasingly aware of his or her body and develops a sense of modesty. Task-oriented behavior is common, and school and sports activity are typically the central events of the child's life. School-age children are eager to please and often reluctant to express their fears of pain and death.

AGE-SPECIFIC APPROACH The direct examination approach is typically successful for school-age children. Parental accompaniment and respect for modesty should be maintained. Historical information should be elicited from child and parent. An effort to inquire about school or extracurricular interests will enhance rapport. Change in school performance is a helpful indicator of chronic disease. Painful procedures are best preceded by explanations to both parent and child, given well in advance with honesty regarding discomfort. The child should be given some degree of choice in the manner in which the procedure is completed, such as a comfortable position, to minimize the sense of loss of control.

Adolescence (12 to 17 Years)

PHYSICAL ASPECTS The teen years mark a second period of rapid growth, beginning at age 10 in girls and age 12 in boys. Secondary sexual development begins shortly after beginning the growth spurt, with menarche starting between 10 and 16 years in girls. Sexual activity and drug use are common during adolescence, and many teens are parents themselves, complicating the differential diagnosis and issues of maturity and reliability in carrying out the follow-up plan.

NEUROLOGIC ASPECTS Abstract reasoning ability progressively develops during adolescence, paired with a self-centered world view and self-consciousness regarding appearance. Feelings of immortality and denial of the consequences of risky behavior are common. Loss of autonomy is the greatest fear of an adolescent, and mistrust of and rebellion toward authority is normal. Previously well-controlled chronic disease frequently becomes unstable as a result of these developmental issues. Psychiatric disease and suicidal behavior are increasingly recognized in this age group. The parents of teenagers are frequently angered by these changes and may project these feelings on the ED staff.

AGE-SPECIFIC APPROACH The traditional history and physical examination with respect for modesty are effective in the assessment of adolescents. The examiner should communicate to the teenager that he or she will be treated "like an adult." Choices must be allowed, such as parental presence during the examination, with proper limit setting regarding cooperative behavior. The parent's concerns must be addressed individually and, if necessary, in private. Confidentiality should be stressed, particularly as the law requires with respect to pregnancy and sexually transmitted disease.

MEDICAL CONSENT AND THE TREATMENT OF MINORS

Consent for evaluation and treatment must be obtained for medical care to be delivered in a lawful manner. State laws vary regarding the age of majority at which consent may be given by a patient, varying between 18 and 21 years of age. In the case of minor children, consent must be obtained from the legal guardian (typically a parent, unless custody has been removed) before initiation of treatment. This does not apply, however, to triage and examination, and children should be evaluated without delay to determine the nature of the illness or injury.¹ If the child is not accompanied by persons able to provide consent, the parent or guardian should be contacted by phone and witnessed consent obtained. Such attempts should be documented in the medical record. Written documentation from the parent or legal guardian granting consent may suffice in many states, but this should not obviate attempted phone contact for permission to treat. In the absence of consent, the patient should be evaluated sufficiently to determine the presence or absence of an emergent situation. In the setting of an emergency situation in which delay in treatment may threaten the life or health of the child, consent can be assumed and care initiated with ongoing attempts to locate the parent or guardian. If any doubt exists, the emergency physician and patient are best served by providing treatment with documentation of efforts to determine the presence of an emergency and obtain consent for treatment. In the absence of an emergency, further care should not be provided unless specifically permitted under state law (Table 114-4). Most states permit minors to seek treatment for child abuse, substance abuse, sexually transmitted diseases, and pregnancy-related complaints without parental consent. Most states consider a child "emancipated" and able to provide consent if a member of the armed forces, married, or self-supporting and living independently. Some states permit older minors to give consent for nonemergent care. Many states have a process for obtaining concurrent judicial review and consent. Emergency physicians are encouraged to become familiar with the specific state laws applicable to consent issues.¹ As a matter of courtesy and necessity, verbal consent should be obtained from older minors, typically at age 12 years and older.

Parental refusal of consent for care in the setting of possible life-threatening emergency or child abuse presents emergency physicians with a significant challenge. If parental consent cannot be obtained, a court order should be obtained through the appropriate local mechanism to allow the provision of necessary care for the well-being of the child.

TABLE 114-4 Consent for Treating Minors

Age of consent is typically 18 y but may vary by state. A minor should be evaluated but not receive treatment in an emergency department without consent obtained from a parent or legal guardian, with the following exceptions:

- Life- or limb-threatening emergency
- State-protected right to treatment
 - Child abuse
 - Pregnancy-related complaints
 - Sexually transmitted disease
 - Substance abuse
 - Outpatient mental health (some states)
- State-defined "emancipated minor" status
 - Married
 - Member of armed forces
 - Self-supporting and living independently

FEVER

Carol D. Berkowitz

Fever is the most common chief complaint of children presenting to the ED and accounts for approximately 30 percent of pediatric outpatient visits. Physicians evaluating febrile children must differentiate mildly ill from seriously ill children, a challenge that may be compounded when no focus of infection is apparent. The extent of the diagnostic workup and the institution of appropriate management, including the use of antibiotics and the need for hospitalization, must be determined. Many factors, such as clinical assessment, physical findings, age of the patient, immunization status, and height of the fever, influence the evaluation and management decisions.

PATHOPHYSIOLOGY

Fever is defined as a rise in deep body temperature associated with a resetting of the body's thermostat. This thermostat is located in the preoptic region of the anterior hypothalamus, near the floor of the third ventricle. Exogenous fever-producing substances (pyrogens), such as bacteria, bacterial endotoxin, antigen-antibody complexes, yeast, viruses, and etiocholanolone, may stimulate the formation and release of endogenous pyrogens. Endogenous pyrogens are produced by neutrophils, monocytes, hepatic Kupffer cells, splenic sinusoidal cells, alveolar macrophages, and peritoneal lining cells and are believed to induce the synthesis of prostaglandins in the hypothalamus. Endogenous pyrogens include interleukin 1, interleukin 6, and tumor necrosis factor.¹ The body's thermostat is then reset at a higher setting, and the patient, whose own temperature is below that of the body's thermostat, experiences a chill. Peripheral vasoconstriction, shivering, central pooling, and behavioral activity (e.g., putting on a sweater or drinking hot tea) lead to an increase in body temperature.

CLINICAL FEATURES

The possible beneficial effects of fever have been debated for many years. Aside from these considerations, it is important to recognize that fever represents a symptom of some underlying disease, and one must determine what this disease is.

An initial question is, "What degree of temperature elevation represents a fever?" One survey conducted among pediatric training programs revealed a wide variability in the temperature considered a "fever" in infants younger than 2 months. This figure has ranged from 38°C to 39.4°C (100.4°F to 103°F). It is important to recognize that oral temperatures are generally 0.6°C (1°F) lower than rectal temperatures and axillary temperatures are 0.6°C (1°F) lower than oral temperatures. Temperatures taken with infrared thermometers that scan the tympanic membrane are of variable reliability and reproducibility.² Body temperature normally varies from morning to evening with the body's circadian rhythm. The degree of variation, which is greater in young women and small children, is approximately 1.1 °C (2°F).

Current practice guidelines suggest a temperature of 38°C as a sufficient fever to warrant an evaluation. The relation between height of fever and incidence of bacteremia is discussed below. In general, higher temperatures are associated with a higher incidence of bacteremia. The incidence of meningitis is about twice as high in children with fevers above 41.1°C (105.9°F) than in children with fevers between 40.5°C and 41.0°C (104.9°F and 105.8°F). The incidence of pneumonia and bacteremia is about the same in both groups.

Some studies, many of which have also been retrospective, have produced variable results and have indicated that children with higher temperatures have more diagnostic studies ordered but the same incidence of different diseases.

INFANTS UP TO 3 MONTHS

Diagnosis

The age of the patient influences the extent of the workup. Early studies suggested that infants younger than 3 months were at high risk for life-threatening infection. Recent studies based on outpatients showed that the incidence of serious bacterial infection, including bacteremia and meningitis, is about 3 to 4 percent, although serious nonbacterial infections (e.g., aseptic meningitis) are a frequent cause of fever in this age group (Table 115-1).

Presentation History

The history often provides a clue to the diagnosis. When evaluating infants younger than 1 to 2 months, it is critical to review the birth history, because the etiology of the infant's infection may be birth related. The key points to consider include the length of the gestation, the use of antibiotics in the mother or infant, and the presence of any neonatal complications, such as fever or tachypnea. Although an organ-specific list of inquiries may be helpful in treating older infants, it is less useful in younger ones, because the signs and symptoms of sepsis may be very nonspecific. For instance, vomiting and diarrhea accompany many problems, including gastroenteritis, otitis media, urinary tract infections, and meningitis. Cough or respiratory symptoms would be consistent with a respiratory infection. Frequency of urination is important to assess as a measure of the state of hydration.

TABLE 115-1 Incidence of Serious Bacterial Infection with Fever in Infants <3 mos of Age

Infants up to 3 mo old with temperature of $\geq 38^{\circ}\text{C}$	
Rochester criteria for low-risk bacteremia Nontoxic appearance No soft tissue infection WBC	0.2%
Normal urinalysis Stools	
	500-15,000/ μL
	<5 WBC/hpf with diarrhea

Abbreviations: hpf = high power field; WBC = white blood cell count.

Physical Examination

Infants should be undressed completely to enable a full assessment. Vital signs are important to evaluate. For instance, tachypnea may be a clue to lower respiratory tract infection. Crying and the ease of consolation should be evaluated. Inconsolable crying, or increased irritability when handled, is frequently seen in infants with meningitis. Although fullness of the anterior fontanelle may be noted in some of these infants, other signs of meningeal irritation, such as nuchal rigidity, are most often absent. A head-to-toe evaluation should be carried out to determine whether there is a focus of infection, such as an inflamed eardrum or evidence of cellulitis.

Clinical assessment of the severity of illness of young, febrile infants is, however, problematic. Young infants lack social skills, such as the social smile, and their ability to interact with examiners is limited. There is a report in the literature of an infant with group B streptococcal bacteremia who was judged by house staff and faculty to be clinically well. The absence of any diagnostic abnormalities in the medical history or on physical examination suggests the need for extensive laboratory tests to detect occult infection. These tests would include a complete blood count (CBC) and differential, erythrocyte sedimentation rate (ESR), blood culture, lumbar puncture, chest x-ray, urinalysis and culture, and a stool culture if there is a history of diarrhea, particularly if leukocytes are noted on a stool smear. Some authors also recommend a quantitative C-reactive protein as an index of serious bacterial infection. Urinary tract infections may not produce symptoms other than fever, so urinalysis and culture should be included routinely in the evaluation. Urinary tract infections may be associated with bacteremia in up to 30 percent of infected infants⁴ and are the most common bacterial infection in this age group.

The recognition of occult serious infection in well-appearing young, febrile infants is problematic. Most investigators agree that no single variable can correctly identify these infants. Combinations of variables are more helpful in the differentiation process. Criteria have been identified by a number of investigators but are generally referred to as the Rochester criteria for low risk for serious bacterial infection in infants younger than 3 months. These criteria include nontoxic appearance, no soft tissue infection, white blood cell counts (WBCs) between 5000 and 15,000/ μ L, fewer than 1500 bands/ \times L, normal urinalysis, and stool with fewer than 5 WBCs/high power field in infants with diarrhea.³ The risk of serious bacterial infection in the absence of these variables is about 0.2 percent.

Management

The appropriate management of young febrile infants presents another area of disagreement.⁵ There appears to be no "community standard of practice" regarding the need for hospitalization; some physicians hospitalize all febrile infants younger than 3 months, and others hospitalize only those younger than 1 month. Some have attributed this difference in management to a difference in bias, with physicians in practice having a bias toward wellness (the infant is basically healthy) and those working in the ED having a bias toward illness (worst-case scenario approach).⁶ Because the differentiation between sick and well infants is so difficult, especially to less experienced examiners, all such febrile infants need extensive septic workups. The decision not to hospitalize a small febrile infant must be made after careful clinical and appropriate laboratory assessment and after ensuring the reliability of follow-up.

Current management strategies include the administration of ceftriaxone at a dose of 50 mg/kg to febrile infants between 1 and 3 months of age who are judged to be at low risk for serious bacterial infection when the above criteria are used.⁷ A caretaker with a telephone is an additional criterion for such outpatient management. Similarly, Baskin and colleagues⁸ proposed parenteral ceftriaxone and 24-h observation for inpatient management of febrile infants between

2 and 4 weeks of age and also judged to be at low risk. Infants could be discharged if cultures were negative after 24 h. In the future, the ready availability of rapid viral assays may alter the use of expectant antibiotics in this age group.^{9,10}

INFANTS OF 3 TO 24 MONTHS

Diagnosis

Many of the considerations noted in the evaluation of infants younger than 3 months apply for older infants. Children between 3 and 36 months have been the focus of considerable research, because this group appears to be at higher risk for occult bacteremia (Table 115-2). These studies have sought to identify clinical and laboratory characteristics of bacteremic patients.

Clinical judgment appears to be more reliable in the assessment of older infants. Characteristics that evaluating physicians should note are willingness of patients to make eye contact, playfulness and positive response to interactions, negative response to noxious stimuli, alertness, and ease of consolation. Toxic infants will not respond appropriately.

Presentation History

The medical history and physical examination frequently will reveal the source of infection. Viral illnesses, including respiratory infections and gastroenteritis, account for most febrile illnesses and usually have system-specific symptoms, such as vomiting, diarrhea, rhinorrhea, cough, or rashes. In this age group, such symptoms are more often indicative of an organ-specific infection. Bacterial infections of the respiratory tract most notably include otitis media, pharyngitis, and pneumonia. Otitis media is generally caused by *Streptococcus pneumoniae* or nontypable *Haemophilus influenzae*, and antibiotic therapy, such as amoxicillin, should be directed at these organisms. Although pneumonia is commonly of viral etiology, it is appropriate to institute antibiotic therapy with amoxicillin or erythromycin. The physical signs of meningitis, such as nuchal rigidity and Kernig or Brudzinski signs, may be inapparent in children even up to the age of 2 years. A bulging fontanelle, vomiting, irritability that increases when the infant is held, inconsolability, or a febrile seizure may be the only signs suggestive of meningitis. Infants with aseptic meningitis generally should be hospitalized and ensured adequate long-term follow-up, because they are at greater risk for subsequent neurologic and learning disabilities.

The presence of petechiae on physical examination should alert physicians to the potential presence of a serious underlying infection.¹¹ Up to 20 percent of children may have bacteremia or meningitis, most frequently with *Neisseria meningitidis* or *H. influenzae*. Petechiae in association with high fever ($>40^{\circ}\text{C}$), ESR at or above 30 mm per h, and WBCs of at least 15,000/pi are most frequently correlated with bacteremia. The pneumonic ILL, for irritability, lethargy, and slow capillary refill (>2 s or hypotension), has been proposed as a clue to bacteremia associated with petechiae.¹²

Bacteremic infants may or may not have an obvious focus of infection. The height of the fever is a clue to bacteremia in infants. Al-

TABLE 115-2 Incidence of Serious Bacterial Infection with Fever in Infants Aged 3-24 Months

Infants 3–24 mo old with temperature of $\geq 39.5^{\circ}\text{C}$	5% before pneumococcal vaccine
Higher risk of bacteremia	$>15,000/\mu\text{L}$
WBC	$>500/\mu\text{L}$
Bands	$>10,000/\mu\text{L}$
ANC	

Abbreviations: ANC = absolute neutrophil count; WBC = white blood cell count.

though bacteremia may be seen at lower temperatures, a temperature above 39.5°C (103.1°F) in infants aged 3 to 36 months is associated with a higher incidence of bacteremia. **Specifically, occult pneumococcal bacteremia was reported with the following prevalences: 1.2 percent with temperatures from 39.0°C to 39.4°C, 2.5 percent with temperatures from 39.5°C to 39.9°C, 3.2 percent with temperatures from 40.0°C to 40.4°C, and 4.9 percent with temperatures above 40.5°C.**¹³

Certain laboratory tests have been recommended to assist further in identifying bacteremic patients. WBC counts of at least 15,000/ μ L, band counts of at least 500/ μ L, total polymorphonuclear counts of at least 10,000/ μ L, and band plus polymorphonuclear counts equal to or more than 10,500/ μ L are associated with an increased incidence of bacteremia, although bacteremia also occurs without these findings. An absolute neutrophil count equal to or more than 10,000/ μ L is associated with an increased likelihood of bacteremia and is an indication for a blood culture and the initiation of expectant antibiotic therapy.¹³ Other studies, such as an ESR, quantitative C-reactive protein, antigen assays, cytokine levels, and polymerase chain reaction are more expensive, not readily available, and offer no advantage over the WBC.

The incidence of bacteremia in children 3 to 24 months of age with a temperature of 39.5°C (103.1°F) or over was about 5 to 6 percent before the widespread use of the conjugated heptavalent pneumococcal vaccine. **The incidence was 12 to 15 percent in patients with WBCs of at least 15,000/ μ L.** An ESR at or above 30 mm per h had the same significance as WBCs of 15,000/ μ L or more. The organism most commonly causing bacteremia in this age group had been *S. pneumoniae*. *Haemophilus influenzae* has been rarely implicated in cases of occult bacteremia since the availability of *H. influenzae* vaccine. It is anticipated that the heptavalent pneumococcal vaccine will have a similar impact on the incidence of occult pneumococcal bacteremia, because 83 to 92 percent of *S. pneumoniae* recovered in bacteremic children involves one of the seven serotypes contained in the vaccine.^{14,15} Is it important to perform a blood culture to detect occult bacteremia? Opinions differ, especially since the advent of the heptavalent pneumococcal vaccine. It is apparent that bacteremic patients do better if they receive antibiotics early in the course of the disease. Many bacteremic children do have a focus of infection and, hence, are treated anyway. In addition, in at least 25 percent of bacteremic patients with no focus of infection, the bacteremia is resolved without antibiotics. Others develop soft tissue infections, which are then appropriately managed. The ability of oral antibiotics to prevent the development of meningitis in bacteremic children is still unclear. The blood culture appears to be useful for following patients who may not be returning for periodic evaluations. Some physicians who support the continued acquisition of blood cultures have speculated on the emergence of *N. meningitidis* as the most prevalent pathogen once *H. influenzae* and *S. pneumoniae* have been eliminated through immunization. Kuppermann and colleagues cited the devastating effects of meningococcemia.¹⁶ Conversely, as the prevalence of occult bacteremia is reduced, the rate of contaminated blood cultures will exceed that of truly positive blood cultures, thereby increasing the cost of health care without providing any benefit. The prevalence of blood cultures positive for *N. meningitidis* before *H. influenzae* and *S. pneumoniae* immunizations was 1 to 5 percent. The decision to obtain a blood culture should take into account the immunization status of the child and of other children in the community and whether the child is at high risk for an infection for any reason.

Management

Is there a role for the use of expectant antibiotics in children suspected of having occult bacteremia? Retrospective studies have shown that early antibiotics diminish the incidence of persistent bacteremia. In a prospective, randomized study comparing oral penicillin with no antibiotics, no improvement was reported in any bacteremic child who did not receive antibiotics. Other investigators reported more equivocal results.

Outpatient daily injections of ceftriaxone are being used by some physicians for children at increased risk of occult bacteremia. Controlled trials investigating the efficacy of this therapy have demonstrated a reduction in the incidence of meningitis in bacteremic children treated with ceftriaxone compared with those treated with oral or no antibiotics. Parenteral ceftriaxone should never be initiated without appropriate antecedent diagnostic studies. Treatment should be discontinued if cultures are negative. The risk from the overuse of ceftriaxone is the emergence of resistant organisms, a phenomenon that has been reported.^{17,18}

Current recommendations suggest the following approach to well-appearing infants between 3 and 36 months of age: for those 2 to 3 years with a temperature below 39.5°C, no blood testing should be done, because the incidence of occult bacteremia is less than 1 percent; for those 2 to 3 years with a temperature above 39.5°C or those 3 to 24 months with a temperature above 39°C, a CBC with an automated differential count should be obtained, because the incidence of occult bacteremia is 2.6 percent. If the absolute neutrophil count is more than 10,000/ μ L, obtain a blood culture and initiate expectant antibiotics with ceftriaxone at a dose of 50 mg/kg given twice 24 h apart.¹³ If cultures are negative after 48 h, no further treatment is needed. Any child who appears ill or toxic should be admitted to the hospital.¹⁹ Likewise, children who are felt to be at risk for a serious bacterial infection and do not have reliable follow-up or the ability to return to the hospital should also be admitted for inpatient management.

Another dilemma surrounds the management of positive blood culture results. All patients with positive blood cultures should be recalled for repeat evaluation. If they are receiving appropriate antibiotics, are clinically well, and have been afebrile, they should be instructed to complete the course of therapy. If they are afebrile and clinically well but have never been treated with antibiotics, opinions differ regarding the need for additional blood cultures and antibiotic therapy. In general, neither is necessary unless the child has developed a specific focus of infection. However, any patient who remains febrile or does poorly even if on antibiotics should receive complete septic evaluation (CBC, blood culture, lumbar puncture, chest film, and urine culture), be hospitalized, and receive parenteral antibiotics (Figure 115-1).

OLDER FEBRILE CHILDREN

Diagnosis

Children older than 3 years are easier to evaluate. They can specify their complaints and have illnesses similar to those of younger children, in particular upper respiratory infections and gastroenteritis. The risk of bacteremia appears lower in this age group, but the incidence of streptococcal pharyngitis is higher, especially in children between the ages of 5 and 10 years and those with hyperpyrexia. Infectious mononucleosis may present with fever, tonsillar hypertrophy, and exudate, as does streptococcal pharyngitis. Marked lymphadenopathy or hepatosplenomegaly would support the diagnosis. Pneumonia in this age group may be caused by *Mycoplasma pneumoniae*. These children present with cough and fever. Rales may not be apparent early in the illness, although the chest film would show evidence of an infiltrate. Bedside cold agglutinins, if positive, provide a clue to the correct diagnosis. Children with pneumonia secondary to *mycoplasma* should be treated with a macrolide such as erythromycin at 30 to 40 mg/kg per d (maximum dose, 1 g), or azithromycin at 10 mg/kg on day 1, and then 5 mg/kg on days 2 to 5, or clarithromycin at 7.5 mg/kg every 12 h.

EMERGENCY DEPARTMENT CARE

Managing the Fever

Once the issue of fever as a symptom has been addressed, it is appropriate to determine the need for fever-reducing measures.

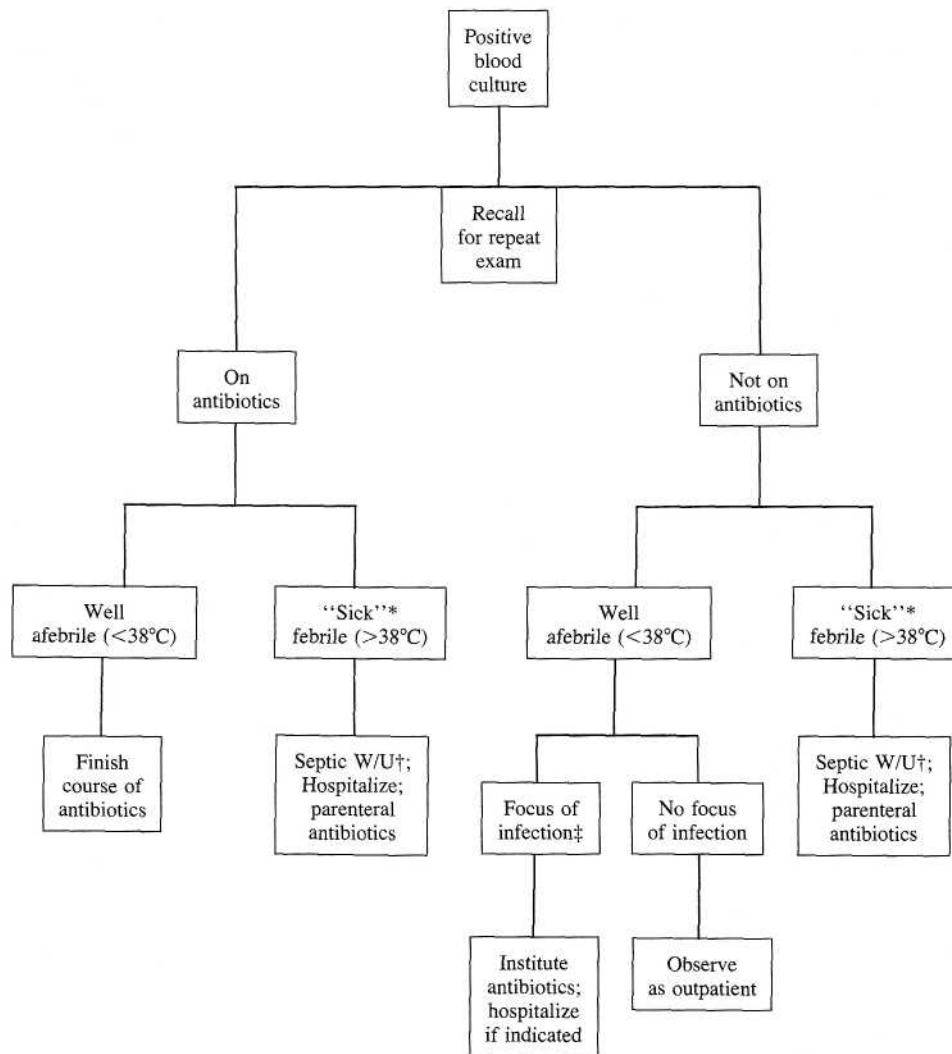

FIG. 115-1. Management of bacteremic children. *"Sick" = irritable, lethargic, anorexic, or vomiting. †Septic W/U (workup) = blood culture, lumbar puncture, chest x-ray, complete blood count, differential, urinalysis, and urine culture. ‡Focus of infection = otitis media, pneumonia, or cellulitis.

Many parents are concerned about the harmful effects of the fever; many are aware of the risk of febrile seizures. Children who are prone to febrile seizures are not benefited by antipyretics alone because the seizure frequently occurs early in the illness, often before the parents are aware that the child is ill. Aside from febrile seizures, fever is not known to produce any harmful effects in children. Many children, however, feel uncomfortable during the fever, so it is appropriate to institute measures directed at symptomatically reducing the fever.

The body loses heat in four ways: (1) radiation (60 percent), that is, heat loss from the body to the air in the surrounding environment; (2) evaporation (25 percent), that is, heat loss through the evaporation of perspiration, water, or any liquid applied to the body surface; (3) convection (10 percent), that is, heat loss when air currents blow over the skin; and (4) conduction (approximately 5 percent), that is, heat loss through contact with a solid surface. Heat loss through conduction is increased by the use of cooling blankets.

One can facilitate heat loss in children by using any combination of these measures. Unwrapping a bundled child increases heat loss through radiation, and rehydrating a dehydrated child increases the heat loss through evaporation. Sponging also helps to reduce fever by evaporation. Sponging should be done slowly and only with tepid water. Very rapid cooling by sponging can result in peripheral vascular collapse, and death among small, critically ill infants has been reported. Sponging with ice water is uncomfortable for children and results in shivering, and sponging with alcohol carries the risk of intoxication, hypoglycemia, and coma. Vigorous rubbing of the skin induces vasodilatation and improves heat loss.

Studies have shown that sponging and antipyretics used together are more effective than either modality used alone. Acetaminophen, ibuprofen, and aspirin are equally effective and appear to work centrally to block prostaglandin synthesis. Heat is lost through peripheral vasodilatation and sweating.

Drug dosage for aspirin or acetaminophen is 10 to 15 mg/kg per dose at 4-h intervals (maximum dose, 600 mg). Increasing the dose does not result in a better or more sustained effect. Administration of either drug by rectal suppository slightly delays absorption. No studies have evaluated the efficacy of alternating the two drugs at 2-h intervals to avoid the recrudescence of fever. Administration of the drugs simultaneously at the usual dosage produces a reduction in temperature that is sustained for 6 h rather than for 2 to 4 h. The dosage of ibuprofen is 5 mg/kg for fevers below 39°C (102.2°F) and 10 mg/kg for fevers above 39°C (102.2°F). Ibuprofen may be given every 6 to 8 h, with a maximum daily dose of 40 mg/kg. The key to assuring a good outcome is judicious management, follow-up, and reassessment. It is not appropriate to simply administer ceftriaxone and assume that any infection an infant may have has been appropriately treated. Emergency physicians must be certain that infants can be reevaluated to ensure that other problems have not emerged.

The use of aspirin has been curtailed after reports linking aspirin and Reye syndrome. Aspirin should not be used in children with chickenpox or with influenza-like illnesses. The effects of aspirin are cumulative, and over half of the reported overdoses involves therapeutic misuse. Other side effects of aspirin include gastrointestinal upset and hemorrhage and coagulation disturbances. Acetaminophen is also

toxic if taken in inappropriate doses, but there is minimal likelihood of any cumulative effect, and children are less prone than adults to hepatotoxicity. Side effects of ibuprofen are similar to those of aspirin and include gastrointestinal ulceration, bleeding, and perforation. Platelet disturbances have been reported but are felt to be reversible with cessation of therapy.

self-limited viral or minor focal bacterial infection, a subset will have serious bacterial disease with potential for morbidity and mortality. This chapter provides an overview of the presentation, diagnosis, and management of bacteremia, sepsis, and meningitis in pediatric patients in the ED. Although each is discussed separately, it must be kept in mind that these entities represent different points along a spectrum and may occur concurrently as a result of progression of disease.

BACTEREMIA AND SERIOUS BACTERIAL INFECTION

Pathophysiology

Children between the ages of birth and 3 years are at relatively increased risk for bloodborne bacterial disease due to immaturity of the reticuloendothelial system. The term *bacteremia* refers to the presence of a positive blood culture without reference to specific clinical symptomatology. Bacteremia may resolve spontaneously, progress to *septicemia* with clinical signs of abnormal perfusion parameters and altered mental status, or be associated with focal *serious bacterial infection* (SBI), most often involving the lung, kidney, meninges, bowel, bone, or joint. The risk of bacteremia and SBI decrease with age, with the greatest incidence in the first 3 months of life (Table 116-1). For purposes of discussion, the relative risks can be broken down into three age groupings: neonates (0 to 28 days), young infants (29 to 90 days), and children (3 to 36 months).

Neonates with fever have a 5 percent risk for bacteremia and a 15 percent incidence of SBI, predominantly due to pathogens encountered at the time of birth.¹ Bacteremia in this age group results in a fulminant septicemic process within hours to days of birth (*early-onset disease*) or a focal SBI developing weeks to months later (*late-onset disease*). Group B *Streptococcus* is by far the most common bacterial pathogen in this age group, followed by *Escherichia coli*, *Listeria monocytogenes*, and *Enterococcus* sp.

Infants 29 to 90 days of age are at a progressively lesser risk for late-onset infection from these neonatally acquired pathogens but are increasingly susceptible to community-acquired pathogens. This age group thus represents a transition period from neonates and those infants 3 months and older.

Children 3 months and older are susceptible to infection from community-acquired pathogens and are at relatively less risk for bacteremia and SBI in comparison with younger infants. Bacteremia in this age group is a result of SBI or may occur as a primary process and precede the development of focal serious infection. Focal SBI that may be associated with bacteremia includes meningitis, pneumonia, pyelonephritis, bacterial enteritis, facial cellulitis, septic arthritis, and osteomyelitis (Table 116-2). The reader is referred to subsequent chapters for descriptions of the pathogenesis and microbiology of these

TABLE 116-1 Age-Related Risk Groups and Causes of Bacteremia in Children

Group	Risk	Pathogens
Neonates 0-28 d	High risk	Group B <i>Streptococcus</i> <i>Escherichia coli</i> <i>Listeria monocytogenes</i> <i>Enterococcus</i> sp.
Young infants 29-90 d	Intermediate risk	Neonatal pathogens (above) Community-acquired pathogens (below)
Older infants 3-36 mo	Low risk	<i>Streptococcus pneumoniae</i> <i>Neisseria meningitidis</i> <i>Haemophilus influenzae</i> b (unimmunized) Group A <i>Streptococcus</i> <i>Escherichia coli</i> (pyelonephritis) <i>Salmonella</i> sp. (gastroenteritis) <i>Staphylococcus aureus</i> (osteomyelitis)

BACTEREMIA, SEPSIS, AND MENINGITIS IN CHILDREN

Peter Mellis

The identification and treatment of potentially life-threatening systemic infectious disease in children represents a continuing challenge for the emergency physician, most frequently in the setting of the evaluation of the febrile infant. Although most children with fever have

TABLE 116-2 Serious Bacterial Infections Associated with Bacteremia

Meningitis
Pneumonia
Pyelonephritis
Bacterial enteritis
Facial cellulitis
Septic arthritis
Osteomyelitis

infections in children. Pneumonia is most frequently viral in etiology in older infants and children, with a less than 3 percent incidence of associated bacteremia, most often due to *Streptococcus pneumoniae*. Urinary tract infection (UTI) is usually caused by *E. coli* ascending infection, with associated bacteremia most commonly noted in infants younger than 6 months. Bacterial enteritis caused by *Salmonella* sp. and facial cellulitis, septic arthritis, and osteomyelitis caused by *Staphylococcus aureus* and *S. pneumoniae* carry some risk of bacteremia in infancy. The development of generalized septicemia without a primary focus is quite rare in immunologically competent children, occurring primarily with *Neisseria meningitidis* infection.

Bacteremia may also occur in the 3- to 36-month age group without clinically recognized septicemia or focal SBI. This disease process, termed *occult bacteremia* (OB), most recently has been determined to have an incidence of 2 percent in children 3 to 36 months of age, with rectal temperatures of 39°C or higher, a well clinical appearance, and no major focal bacterial infection.² *Streptococcus pneumoniae* accounts for more than 80 percent of OB and carries a 5 percent risk of persistent bacteremia and a 10 percent risk of complicating SBI.² The recent introduction of a pneumococcal conjugated vaccine (PCV) has significantly decreased this risk. Based on clinical trials for this vaccine, the incidence of *S. pneumoniae* bacteremia and SBI are expected to decrease by up to 90 percent in fully immunized children.³ Because the PCV is not yet universally administered, is not protective against all serotypes of *S. pneumoniae*, and definitive studies after vaccine introduction have not yet been published, this organism is expected to continue playing a significant but declining role in OB and SBI. Although *Haemophilus influenzae* type b (Hib) historically accounted for a significant proportion of complicating SBI from OB, the impact of the Hib vaccine has been dramatic in virtually eliminating this organism as a potential pathogen in adequately immunized patients.⁴ Other organisms, such as *Neisseria meningitidis* and *Salmonella* sp., contribute a minority of cases of bacteremia but with a high rate of subsequent focal SBI. Although uncommon, group A *Streptococcus* has increasingly been reported as a cause of bacteremia. Primary varicella infection in immunocompetent children is a risk factor for group A *Streptococcus* bacteremia, particularly in the setting of fever persistent through the fourth day of illness.⁵

The primary issue with respect to identification and treatment of OB is the incidence of subsequent SBI. Studies conducted in the post-Hib vaccine era have demonstrated a less than 20 percent incidence of complicating SBI for those with OB. For all patients in this age group with fever but no SBI, given a 2 percent incidence of OB, this represents a less than 0.5 percent risk of complicating SBI.² However, no studies of complicating SBI after OB have been performed since the introduction of the pneumococcal conjugate vaccine. The present risk of OB and progression to complicating SBI in adequately immunized children is likely to be much lower.³

The widespread emergence of penicillin- and cephalosporin-resistant strains of *S. pneumoniae* has complicated the choice of optimal therapy for bacteremia, SBI, and meningitis in particular. Antibiotic treatment within the prior month has been demonstrated to be a risk factor for infection due to a resistant strain.⁶ The emergence of poly-drug-resistant organisms in community-acquired infections has led to a national effort to reduce the use of unnecessary antibiotics.

Clinical Features

Fever, defined as a temperature higher than 38°C (>104°F) measured by an age-appropriate route, is a frequent presenting complaint in the ED and may be a sign of potentially serious infection in children. However, the presence and degree of fever are nonspecific for purposes of identification of bacteremia and SBI. Indeed, the absence of fever does not exclude infection, and the finding of hypothermia (temperature < 36.8°C (<98°F)) may be a grave prognostic finding in the setting of sepsis.⁷ Infant temperatures should be obtained by the rectal route in the ED, because the axillary and auditory canal routes are less reliable in the identification of fever. Unlike the perception of tactile fever, a history of fever measured by the parent by the rectal route carries the same significance as fever detected in the ED. To facilitate the patient's comfort and the physician's assessment of mental status, antipyretic therapy (acetaminophen 10 to 15 mg/kg or, for children 6 months or older, ibuprofen 5 to 10 mg/kg PO or PR) should be administered early in the course of ED evaluation. However, the degree of defervescence in response to antipyretic therapy is not predictive of the risk of bacteremia and SBI.

Historical risk factors for neonatally acquired bacterial infection in infants younger than 3 months include premature delivery, ruptured amniotic membranes for more than 24 h before delivery, positive prepartum maternal vaginal culture for group B *Streptococcus*, and maternal amnionitis before or after delivery. Specific symptoms suggestive of a focus of infection in this age group are rare. High fever is uncommon in this age group, and serious infection most commonly presents with low-grade fever or normal temperature. **The symptoms and signs suggestive of bacteremia and SBI in neonates and young infants most frequently produce an overall ill appearance.** Parents may report poor feeding, decreased activity, or irritability in response to attempts to console ("paradoxical irritability"). Physical examination findings suggestive of an ill appearance include poor eye contact and muscle tone, including weak suck, poor head control, and indifferent response to stimuli. Signs of respiratory distress and poor perfusion parameters are suggestive of septicemia and should be specifically sought. Although uncommon, findings suggestive of a specific focus of infection, such as otitis media, skin, soft tissue, bone, or joint inflammation, place young infants in a higher-risk group for SBI. However, due to the nonspecific nature of the signs and symptoms of illness at this age, the history and physical examination alone are unreliable screening tools for bacteremia and SBI in neonates, with marginally improved predictive value in infants 30 to 90 days old.⁸

Children 3 months and older found to have bacteremia and SBI most often are noted to have fever with rectal temperatures of 39°C or higher, although serious infection can uncommonly occur without the finding of fever. As for younger infants, the most important historical and physical findings are related to overall appearance. **Parental report of persistent lethargy or irritability with associated fever raises significant concern for SBI with associated bacteremia.** Symptoms of respiratory, gastrointestinal, soft tissue, bone, or joint inflammation should be elicited. The reader is referred to subsequent chapters for a complete description of the symptoms suggestive of focal SBI in children. Historical risk factors of importance include incomplete immunization status, prior SBI, and underlying conditions that impair immune response, such as sickle cell anemia and human immunodeficiency virus. The physical examination is performed in two phases. The first is a global assessment of the child's appearance to categorize the child as "ill" versus "well," optimally after antipyretic therapy has been administered. This assessment should specifically include mental status, evaluated by observing response to parental physical and social stimulation, and perfusion and hydration parameters. A well appearance is demonstrated by an awake, responsive infant or child with good eye contact, developmentally appropriate social interaction with family members, normal muscle tone, and vigorous cry. An ill appearance is demonstrated by lethargy or irritability, failure to

respond to or be consoled by family members, weak cry, poor muscle tone, or abnormal peripheral perfusion parameters. If the examination findings are equivocal, the child should be reassessed within a short period and, if unchanged, considered "ill appearing." The performance of an overall assessment of appearance has been shown to improve the sensitivity of the history and physical examination in detecting SBI.⁹ The second phase of physical examination is devoted to eliciting signs of specific SBI and minor focal infection. Signs of meningitis may be subtle and are reviewed later in this chapter. **The finding of a minor focus of infection, such as upper respiratory infection, otitis media, pharyngitis, or gastroenteritis, does not exclude the possibility of bacteremia or SBI.**

The clinical presentation of the patient at risk for OB includes age of 3 to 36 months, rectal temperature of 39°C (102°F) or higher, well appearance by the above criteria, and no other signs of infection or signs of minor focal infection only. However, only 2 percent of patients with these findings will have a positive blood culture. Further, it is impossible to distinguish well-appearing febrile children with OB from those without bacteremia by clinical features alone.¹⁰ Conversely, a well-appearing child with an untreated rectal temperature lower than 39°C and no signs of focal SBI is at extremely low risk for bacteremia.

Diagnosis

Because of the relatively greater risk for bacteremic illness and lack of sensitivity of the clinical examination, the febrile or ill-appearing neonate, regardless of temperature, should be evaluated comprehensively for SBI by a *sepsis workup*. This workup should include complete blood count, blood culture, urinalysis and urine culture (catheterized or suprapubic technique), and cerebrospinal fluid (CSF) culture, cell count, Gram stain, and protein and glucose measurements. Respiratory symptoms or signs are indications for chest x-ray. The differential diagnosis for septic-appearing neonates includes congenital cardiac disease, metabolic disease, nonaccidental trauma, and bowel obstruction.

Infants 30 to 90 days of age are optimally evaluated by a *low-risk* versus *high-risk* stratification that combines clinical and routine laboratory assessments¹¹ (Table 116-3). Low-risk infants are those who were born at full term, have no underlying medical problems, and have not been treated previously with antibiotics. On physical examination, these young infants have a well appearance with no identified focus of possible bacterial infection to specifically include otitis media, skin, soft tissue, joint, or bone infection. To be considered low risk, these young infants also must have negative laboratory screening tests.

TABLE 116-3
Days of Age Low-Risk Criteria for Febrile Infants 30 to 90

History
Full term (≥37 wk of gestation)
No prior infections or underlying medical problems
No current antibiotics
Physical examination
"Well appearance"
No focus of infection (otitis, cellulitis, bone/joint)
Laboratory
WBC 5000-15,000/ μ L with <1500 bands/ μ X
Urinalysis <10 WBCs/hpf, negative for leukocyte esterase, nitrite
Stool smear <5 WBCs/hpf (if diarrhea present)
Normal chest x-ray (if respiratory symptoms/signs present)
Follow-up
Reliable parents
Home telephone and transportation

Abbreviations: hpf = high-powered field, WBC = white blood cell count.

Source: Dagan R, Powell KR, Hall CB, et al: Identification of infants unlikely to have serious bacterial infection although hospitalized for suspected sepsis. *J Pediatr* 107:855, 1985.

These are defined as white blood cell counts (WBCs) of 5000 to 15,000/ μ L with fewer than 1500 bands/ μ L, urinalysis showing fewer than 10 white blood cells per high power field, and negative findings for leukocyte esterase and nitrite, and, when diarrhea is present, a stool smear with fewer than 5 WBCs per high power field. Cultures of the blood and urine (suprapubic or catheterized) should be performed. Stool should be cultured if diarrhea is bloody or white blood cells are present, as above. A chest x-ray is indicated if there are significant respiratory findings, such as frequent cough, tachypnea, grunting respirations, rales, or wheezes. Lumbar puncture should be performed routinely in febrile infants younger than 60 days and strongly considered for those 60 to 90 days of age because of limited sensitivity of the clinical assessment at these ages for the detection of meningitis. Febrile infants 30 to 90 days of age who meet low-risk criteria have less than a 1 percent risk of bacteremia and less than a 2 percent risk of SBI. In contrast, young infants categorized as high risk with ill appearance are reported to have up to a 10 percent risk of bacteremia and a 15 percent risk of SBI.¹¹ Infants 30 to 90 days of age considered high risk by clinical or laboratory parameters should have a complete evaluation for sepsis, as for neonates.

The laboratory assessment of children 3 to 36 months and older should be individualized based on the overall appearance of the child, clues from the history and physical examination, and a knowledge of the incidence of bacteremia and SBI in this age group. Most importantly, an ill-appearing febrile child, regardless of age, should be stabilized and comprehensively evaluated for sepsis as just described. In contrast, the well-appearing febrile infant and child should have an directed laboratory evaluation based on clinically identified risk factors for bacteremia and associated SBI. Specifically, laboratory evaluation for pyelonephritis, pneumonia, bacterial enteritis, and bone or joint infection should be performed independently of the evaluation for bacteremia, sepsis, or meningitis.

Blood culture has limited usefulness in the outpatient management of radiographically identified pneumonia but should be considered in those patients ill enough to warrant admission. Similarly, blood cultures are indicated in febrile children 6 months or younger who have UTI and in those with clinical features of pyelonephritis requiring admission. Blood cultures are also appropriate for pediatric patients with presumed sepsis, meningitis, bacterial enteritis, facial cellulitis, septic arthritis, and osteomyelitis. All febrile patients who are immunocompromised, such as with sickle cell anemia and human immunodeficiency virus, also should have blood cultures obtained (Table 116-4). The identification of a clearly recognizable viral syndrome such as bronchiolitis or vesicular stomatitis or pharyngitis renders the yield of laboratory testing for bacteremic disease negligible.

The WBC is a nonspecific test that may assist in the identification of bacteremia and SBI but is not diagnostic and must be interpreted in the clinical context. Although the incidence of bacteremia rises with a WBC of 10,000/ μ L or more, there is no threshold value that distinguishes bacteremic from non-bacteremic patients or identifies patients with SBI with adequate sensitivity and specificity. A WBC of

TABLE 116-4 Indications for Blood Cultures in Children

Bacterial enteritis (age ≥24 mo)
Facial cellulitis
Septic arthritis
Osteomyelitis

5000/ μ L or fewer in ill-appearing infants is suggestive of overwhelming bacterial sepsis but in well-appearing infants suggests benign viral illness with transient bone marrow suppression. The choice of a WBC threshold of 15,000/ μ L or more for obtaining a blood culture in the setting of a well-appearing child with temperature of 39°C or higher and no or minor focus of infection represents a compromise, because this threshold will identify only 65 percent of those with OB. Moreover, only 7.5 percent of febrile, well-appearing children 3 to 36 months of age with a WBC of 15,000/ μ L or more will prove to be bacteremic. Decreasing the WBC threshold for obtaining a blood culture to improve sensitivity markedly decreases the specificity and predictive value of the test.¹² Other available screening tests, such as absolute neutrophil count, band count, erythrocyte sedimentation rate, and C-reactive protein, have failed to provide significantly greater sensitivity or specificity for the identification of bacteremia. Although the blood culture is the "gold standard" for the identification of bacteremia, its result usually cannot be predicted by a screening test with any degree of confidence at the time of initial ED evaluation. The pursuit of OB or finding of a minor focus of bacterial infection, such as otitis media, should not distract emergency physicians from evaluating febrile young children for symptoms or signs of focal serious bacterial infection.

Treatment

EMERGENCY The treatment plan for febrile infants, like the diagnostic evaluation, must be stratified by patient age and directed toward the age-related and organ system-specific probable pathogens (Figures 116-1 and 116-2 and Table 116-5). Febrile neonates, after being fully evaluated for sepsis, should be stabilized with supportive care and treated with broad-spectrum IV antibiotics to cover group B *Strepto-*

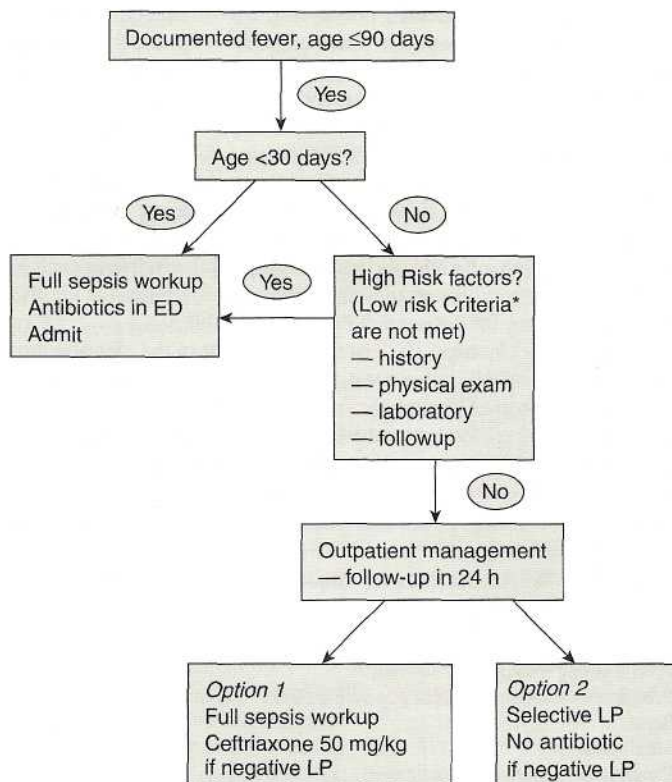

FIG. 116-1. Management scheme for febrile infants 0 to 90 days of

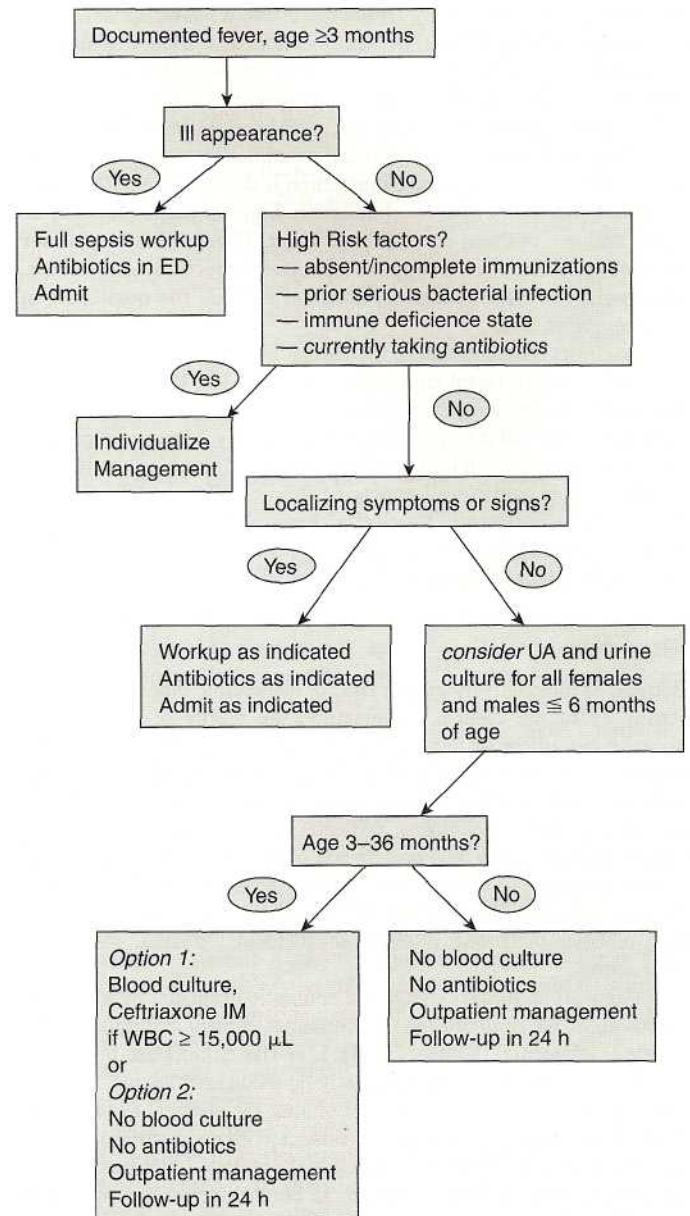

FIG. 116-2. Management scheme for febrile infants and children 3 months and older.

coccus, *E. coli*, *L. monocytogenes*, and *Enterococcus* sp. pending culture results. Optimal therapy includes ampicillin, 100 mg/kg per d, and cefotaxime or ceftriaxone, 50 mg/kg FV per d, with initial doses given in the ED before admission. Jaundiced neonates should not be treated with ceftriaxone, because this agent may displace protein-bound bilirubin.

Young infants 30 to 90 days of age considered to be high risk for SBI based on the foregoing clinical or laboratory parameters should be similarly evaluated for sepsis and treated with ampicillin and cefotaxime or ceftriaxone to cover neonatally and community-acquired pathogens. Young infants 30 to 90 days of age considered low risk for SBI based on clinical and laboratory parameters may be reasonably managed as outpatients in two ways, if follow-up is feasible based on the physician's judgment of parental reliability and availability of a home telephone and source of transportation. The more traditional and conservative approach is to perform a lumbar puncture on all such young infants to exclude bacterial and aseptic meningitis definitively and treat with ceftriaxone, 50 mg/kg per d intramuscularly, before discharge. Alternatively, it has been shown that well-appearing infants in

TABLE 116-5 Initial Intravenous Antibiotic Dosages for Bacteremia, Sepsis, and Meningitis

Age Group	Occult Bacteremia	Sepsis*	Meningitis
Neonates	Not applicable	Ampicillin, 100 mg/kg plus Cefotaxime, 50 mg/kg or Ceftriaxone, 50mg/kg	Ampicillin, 100 mg/kg plus Cefotaxime, 50 mg/kg or Ceftriaxone, 50 mg/kg
Young infants (30-90 d)	Not applicable	Ampicillin, 100 mg/kg plus Cefotaxime, 50 mg/kg or Ceftriaxone, 50 mg/kg plus consider Vancomycin, 15 mg/kg†	Ampicillin, 100 mg/kg plus Cefotaxime, 100 mg/kg or Ceftriaxone, 100 mg/kg plus Vancomycin, 15 mg/kg‡
Older infants and children	Ceftriaxone, 50 mg/kg§	Cefotaxime, 50 mg/kg or Ceftriaxone, 50 mg/kg plus consider Vancomycin, 15 mg/kg*	Cefotaxime, 100 mg/kg or Ceftriaxone, 100 mg/kg plus Vancomycin, 15 mg/kg‡

*Use meningitis doses if the patient is considered too unstable for lumbar puncture in the emergency department.

†Consider addition of vancomycin in sepsis only with critical illness.

‡Add vancomycin only if there is evidence of bacterial meningitis in the cerebrospinal fluid.

§May be given IM.

this age group considered low risk may be safely managed as outpatients with selective lumbar puncture and without antibiotics, provided strict adherence to clinical, laboratory, and follow-up criteria is maintained.¹³

The treatment of febrile infants 3 to 36 months of age remains a subject of considerable controversy. As for all infants, an ill-appearing febrile child should be stabilized with supportive care and fully evaluated for sepsis, and broad-spectrum IV antibiotics such as cefotaxime or ceftriaxone should be administered in the ED. Fortunately, most penicillin- and cephalosporin-resistant strains of *S. pneumoniae* demonstrate only intermediate resistance at this time and may be adequately treated with a third-generation cephalosporin. Treatment of focal SBI presumptively identified by diagnostic testing in the ED depends on the likely pathogens and is reviewed in subsequent chapters. Treatment of meningitis is reviewed later in this chapter. The optimal treatment for children at risk for OB has not been established. Published observational retrospective studies,¹⁴ prospective randomized trials,^{15,16} and meta-analyses of pertinent prior studies¹⁷ have concluded that expectant antibiotic treatment of patients at risk for OB results in a shorter duration of fever and a lower rate of subsequent focal SBI. However, no study has shown that oral antibiotics alter the rate of subsequent development of meningitis. Initial therapy for pediatric patients at risk for OB with ceftriaxone, 50 mg/kg IM, has been recommended because of a reported significant reduction in the incidence of subsequent culture-positive meningitis as compared with oral antibiotics or observation without therapy.^{14,17} However, critical reviews of these studies have shown significant methodologic flaws that seriously undermine the conclusion that antibiotic therapy prevents subsequent SBI, in particular the failure to include partially treated meningitis as an adverse outcome. At the present time, there is no standard of care for the treatment of well-appearing febrile children 3 to 36 months of age who are at risk for OB. Independent of other diagnostic considerations, reasonable approaches for treatment of possible OB include (1) blood culture if WBC is at least 15,000/ \times L, followed by ceftriaxone, 50 mg/kg IM, and (2) no blood culture and antibiotic therapy only for identified bacterial infection, in either case with follow-up within 24 h. The second approach is more completely justified if the patient is known to have had two or more doses of the PCV and Hib vaccines. If antibiotic treatment for OB is chosen, emergency physicians should be wary of the efficacy of antibiotic treatment in

preventing focal SBI and the potential for delayed diagnosis for partially treated infection with altered presentation, for example, UTI or meningitis.¹⁸

OUTPATIENT Follow-up within 24 h and clear instructions regarding indications for early return are the cornerstones of management of well-appearing febrile infants 3 to 36 months of age. Young infants 30 to 90 days of age may be similarly managed as outpatients if all "low-risk" clinical, laboratory and follow-up criteria are met. Communication with a patient's primary physician to facilitate such follow-up represents optimal management. In the absence of a primary physician, consideration should be given to performing such follow-up in the ED. The parents should be educated regarding the effective use of antipyretics and instructed to return with the child to the ED immediately for symptoms of ill appearance suggestive of SBI. Patients who return to the ED with the report of a positive blood culture for *S. pneumoniae* and who are afebrile and well appearing on follow-up may be managed as outpatients with repeat blood culture, oral antibiotic therapy, and follow-up in 24 h.

ADMISSION All febrile neonates and ill-appearing infants should be admitted for observation and parenteral antibiotic treatment pending culture results. Young infants 30 to 90 days of age who fail to meet "low-risk" criteria also should be admitted and treated. Infants 3 months or older who return to the ED with (1) a report of any gram-negative organism on blood culture or (2) persistent fever or ill appearance with a report of positive blood culture for *S. pneumoniae* should have a complete evaluation for sepsis, parenteral antibiotic therapy in the ED, and admission for continued treatment.

SEPSIS

Pathophysiology

Sepsis is a life-threatening clinical syndrome defined by bacteremia with clinical evidence of invasive, systemic infection that can progress with variable rapidity to circulatory failure. Sepsis can occur in isolation or with focal bacterial disease, such as meningitis. The pathophysiology of sepsis is related to (1) colonization with a bacterial pathogen, usually nasopharyngeal, (2) invasion of the blood by encapsulated

organisms and release of inflammatory mediators, and (3) host defense-response failure. This process results in systemic manifestations that are clinically detectable. Circulatory consequences may include alteration in systemic vascular tone and decreased myocardial contractility. Neurologic effects include decreased cerebral perfusion pressure and abnormal temperature homeostasis. Sepsis also may result in a microvascular angiopathy and disseminated intravascular coagulopathy involving the kidneys, lungs, skin, and central nervous system (CNS).

Host defense risk factors for sepsis include impaired splenic function (e.g., congenital absence, surgical removal, or functional impairment in sickle hemoglobinopathy) and congenital metabolic disease (e.g., galactosemia), and the rarer primary or acquired humoral and cellular immunodeficiency states. The presence of an indwelling foreign body or obstruction to drainage of a body cavity represents additional risk factors.

The likely pathogens for sepsis demonstrate an age-related distribution. In the first month of life, group B *Streptococcus* and *E. coli* dominate and can cause an explosive sepsis syndrome that may increasingly be recognized in the ED with the trend to early newborn discharge. The risk presented by these organisms falls dramatically by the third month of life. In infancy and early childhood, *N. meningitidis* predominates as the pathogen for sepsis, with life-long peak incidence during this age. *Streptococcus pneumoniae* is more likely to cause focal disease but may also result in sepsis syndrome, particularly with sickle cell disease and other causes of asplenia. In school-age children, *N. meningitidis* predominates as the cause of sepsis, but group A *Streptococcus* has increasingly been implicated. Rocky Mountain spotted fever, caused by *Rickettsia rickettsii* and acquired by tick bite in endemic areas of the United States, must not be overlooked as a possible cause of sepsis in the summer and fall seasons.

Clinical Features

The sepsis syndrome may present with a subtle or obvious, rapidly progressive clinical picture. Neurologic symptoms most frequently include altered mental status, with irritability, confusion, or lethargy. Poor feeding, lack of spontaneous motor activity, and hypotonia are common findings. Hyperpyrexia, defined as a rectal temperature higher than 41°C (106°F), may occur, although this is not specific for sepsis. Hypothermia also may occur in sepsis, particularly in infants younger than 3 months, and is a grave prognostic finding.⁷ Tachypnea and retractions may reflect hypoxia, metabolic acidosis, or underlying pneumonia. Early septic shock is accompanied by subtle findings of resting tachycardia, widened pulse pressure, warm distal extremities, and brisk capillary refill. Subsequently, classic signs of hemodynamic compensation occur, including weak distal pulses, delayed capillary refill, and cool extremities. Ultimately, these are followed by signs of decompensation with decreased sensorium and hypotension. Cutaneous findings may include petechiae, which may progress to coalescent purpura over hours to days.

Diagnosis

Sepsis represents a *clinical* diagnosis of exclusion in the ED, pending the results of cultures and treatment, because of the potential for rapid progression of disease. Obvious septic shock rarely presents a problem of diagnosis but rather of management. In more subtle cases, the combination of altered mental status and abnormal vital signs should suggest to the emergency physician the possibility of sepsis. Because of the characteristically nonspecific presentation, febrile or ill-appearing neonates should be considered septic until proven otherwise.

No laboratory test is diagnostic, although a WBC greater than 20,000/ μ L is supportive of bacterial sepsis. However, a WBC in the "normal" range in an ill-appearing child is not reassuring. A WBC smaller than 5000/ μ L or a platelet count smaller than 150,000/ μ L is a grave prognostic sign, particularly for disease due to *N. meningitidis*.¹

The diagnostic evaluation of septic-appearing infants in the ED should routinely include a complete blood count, electrolyte panel, blood glucose level, and urinalysis. Cultures of the blood and urine should be obtained by sterile technique. Diarrheal stool, if present, should be stained for white blood cells and cultured. A chest x-ray is indicated for signs of respiratory distress or critical illness, and arterial blood gas measurement should be considered. Liver and renal functions, coagulation studies, and fibrin split product analysis should be considered for critically ill children. Lumbar puncture should be performed to obtain CSF for culture, cell count, protein, and glucose. Lumbar puncture should be deferred if the patient has an unstable airway or a respiratory or hemodynamic status demanding resuscitation. Gram-stained smears made from CSF and petechial scrapings may provide immediate diagnostic information regarding the identity of the organism.

The differential diagnosis for a "septic-appearing" child includes infectious, cardiac, metabolic, and traumatic disease. Major focal bacterial infections, such as meningitis and pericarditis, and systemic viral disease (e.g., respiratory syncytial virus) may present with findings of fever, altered mental status, and cardiorespiratory compromise. Young infants with congenital heart disease or viral myocarditis may present in cardiogenic shock with respiratory distress and signs of poor perfusion. Toxic ingestion, diabetic ketoacidosis, and congenital metabolic disease may present with altered mental status as the major complaint. Child abuse with head or abdominal injury may present with altered mental status, temperature instability, and signs of poor perfusion without historical or cutaneous evidence of trauma.

Treatment

EMERGENCY Stabilization must take priority over completion of the diagnostic workup. Restoration of oxygenation and perfusion are the first priorities in the initial management of sepsis. An ill-appearing child should be provided high-flow oxygen and continuous monitoring of heart rate, respirations, and blood pressure, and oxygen saturation should be initiated. Attention to airway patency should continue throughout the assessment, with particular emphasis during procedures such as lumbar puncture. Secure vascular access should be obtained early, and, in the setting of signs of poor perfusion, fluid resuscitation should be done with multiple 20 mL/kg boluses of NS with serial reassessments. In such cases, an indwelling Foley catheter should be placed to ensure adequate response to fluid resuscitation by establishment of urine output of 1 to 2 mL/kg per h. In young infants in particular, hypoglycemia should be identified early by bedside testing and corrected with IV 25 percent dextrose (D25 or 25 g/100 mL) as a 0.5 g/kg bolus. Endotracheal intubation and mechanical ventilation are indicated if a patient is judged to have advanced respiratory or circulatory failure or neurologic compromise with potential for loss of airway control. Intubation also should be considered for septic-appearing patients who require interhospital transport. If serial fluid bolus therapy does not restore evidence of adequate perfusion, inotropic support with dopamine in the setting of normal blood pressure or epinephrine in hypotensive states is indicated.

Antibiotic therapy should be initiated in the ED as soon as possible and should not be withheld pending lumbar puncture if the patient is too unstable for this procedure. Antibiotic selection is made according to the likely age-related pathogens (see Table 116-5). In the first 2 months of life, ampicillin, 100 mg/kg, and cefotaxime or ceftriaxone, 50 mg/kg IV, are indicated. Adequate initial therapy for children 3 months and older is cefotaxime or ceftriaxone, 50 mg/kg IV. These doses should be doubled if meningitis has not been excluded by lumbar puncture, to facilitate CSF drug delivery. Because of the widespread emergence of penicillin- and cephalosporin-resistant strains of *S. pneumoniae*, vancomycin, 15 mg/kg IV, should be considered as part of the initial therapy for critically ill, septic children,

particularly in the setting of an underlying immune deficiency state.¹⁹ In endemic areas during the summer and early fall, doxycycline, 4 mg/kg IV, should be considered for septic children with possible Rocky Mountain spotted fever. Care must be taken to monitor patients after antibiotic administration for abrupt vascular collapse due to acute bacterial lysis with release of endotoxins.

ADMISSION All children with suspicion for bacterial sepsis should be admitted for monitoring and treatment pending culture results. Disposition decision-making for a possibly septic child must specifically include choice of the appropriate pediatric inpatient unit. A child with limited suspicion for sepsis who is alert and requires no cardiorespiratory stabilization in the ED may be admitted to a pediatric floor unit for antibiotic therapy pending culture results. A child with evidence of cardiorespiratory or neurologic compromise requiring stabilization in the ED should be admitted to a pediatric intensive care unit (PICU) because of the risk of progression of disease. If interhospital transfer to a PICU is necessary, a pediatric transport team should be used.

MENINGITIS

Pathophysiology

In most cases, bacterial meningitis occurs as a complication of a primary bacteremia. The inflammatory response to the products of bacterial multiplication may result in alteration of the permeability of the blood-brain barrier, with extension of infection and inflammation to the brain itself. The resulting brain edema, increased intracranial pressure, decreased cerebral blood flow, and vascular thrombosis produce neuronal injury. Less commonly, meningitis occurs by the hematogenous route from a distant primary focal infection, direct extension from adjacent infection, or after head injury with cribriform plate fracture. The incidence of meningitis is highest between the ages of birth and 2 years, with age-related peak risks during the neonatal period and between 3 and 8 months. Host defense factors resulting in impaired splenic function or immunodeficiency are associated with increased risk for sepsis and meningitis.

The pathogenic organisms responsible for bacterial meningitis parallel those responsible for sepsis. In the neonatal period, group B *Streptococcus* and *E. coli* predominate. In older infants and children, *S. pneumoniae* and *N. meningitidis* are the likely pathogens. Although penicillin-resistant strains of *S. pneumoniae* are increasing in frequency, there is no evidence that these organisms are more virulent.²⁰ Infants and children who have not received the Hib vaccine continue to be at risk for Hib meningitis.

Clinical Features

Because the presenting symptoms are subtle and overlap with those of less serious infection, a high index of suspicion for meningitis is crucial. Two modes of presentation are seen. The most frequently encountered pattern is an insidious progression of a febrile illness over several days. Less commonly, a fulminant progression to septic shock and meningitis may occur over hours, most commonly caused by group B *Streptococcus* in neonates and young infants and *N. meningitidis* in young infants and older children.

Symptoms and signs of bacterial meningitis depend on the patient's age, duration of illness, and pretreatment with antibiotics. No single complaint or physical finding is specific. However, the findings of fever associated with altered mental status constitute a reasonable basis for suspicion for meningitis. Infants typically present with non-specific symptoms including decreased responsiveness, poor feeding, and vomiting. Although common, fever is not universally present at the time of diagnosis. Symptoms and signs of "paradoxical irritability" despite parental comforting attempts, decreased responsiveness to

age-appropriate stimuli, vomiting, hypotonia, bulging fontanelle, or respiratory distress may be seen. Older children usually will complain of headache, photophobia, nausea, and vomiting. As for infants, signs of lethargy and confusion are primary indicators for suspicion of meningitis, and fever may not be consistently present. Nuchal rigidity and the classic findings of the Kernig sign (neck pain elicited with passive knee extension) and the Brudzinski sign (involuntary lower extremity flexion elicited with passive neck flexion) are helpful only if positive. Seizures occur early in 25 percent of patients with bacterial meningitis and are typically initially generalized but may be focal.²⁰ Focal neurologic findings, focal or prolonged seizures, and presentation with obtundation or coma suggest an adverse outcome. Pretreatment with oral antibiotics is associated with an altered presentation characterized by less consistent findings of fever or altered level of consciousness and longer duration of symptoms before diagnosis.¹⁸

Diagnosis

On the basis of reasonable clinical suspicion, a lumbar puncture must be performed to make or exclude the diagnosis of meningitis. The blood WBC is not an adequate screen for meningitis. In the absence of fever, computed tomography of the brain may be necessary to exclude intracranial mass lesion before lumbar puncture. If meningitis is strongly suspected, computed tomography should not delay antibiotic therapy. The CSF should be obtained for culture and sensitivity, protein and glucose levels, cell count, and Gram stain. Cerebrospinal fluid leukocytosis with a predominance of polymorphonucleocytes, CSF protein level greater than 100 mg/mL, and CSF glucose level less than 50 percent of blood glucose level are considered positive screening test results for bacterial meningitis. *Listeria* may be associated with CSF lymphocytosis. The Gram stain has a 70 percent sensitivity for preliminary identification of the offending organism and should be reported as soon as available. Because of the emergence of penicillin-resistant strains of *S. pneumoniae*, perform CSF latex agglutination for bacterial antigens on all patients with abnormal CSF to identify high-risk patients. If prior treatment with antibiotics has occurred, the emergency physician should have a lower threshold for performing a lumbar puncture, and bacterial antigen techniques are routinely indicated, because these are often essential to diagnosis. A complete blood count, electrolyte panel, blood glucose, urinalysis, and cultures of blood and urine should be obtained before performing the lumbar puncture. Indications for deferring lumbar puncture in the ED include cardiorespiratory compromise or risk of increased intracranial pressure. In such cases, antibiotic therapy should be given in the ED, and lumbar puncture should be performed as soon as possible in the inpatient setting.

The differential diagnosis for bacterial meningitis includes the same spectrum of systemic disease as described for sepsis. *Aseptic meningitis* refers to evidence of meningeal inflammation with negative CSF cultures and is more common than bacterial meningitis. Most frequently, this is due to viral meningeal infection, but other causes, such as tuberculosis or syphilis, should be considered. Parameningeal infection or brain abscess may rarely mimic the presentation and laboratory features of meningitis. Central nervous system mass lesion, nonaccidental head injury, and toxic drug ingestion also should be considered in afebrile patients.

Treatment

EMERGENCY As for clinically septic children, treatment for bacterial meningitis begins with stabilization of oxygenation, ventilation, and perfusion parameters. Provision of supplemental oxygen and monitoring of heart rate and oxygen saturation during and after lumbar puncture are appropriate, with careful attention to prevention of airway compromise during the procedure. Children with meningitis are often

septic and may require vigorous initial isotonic fluid bolus therapy to restore systemic and CNS perfusion. However, subsequent fluid should be provided at a maintenance rate to minimize brain edema. Neurologic complications are frequent and must be treated aggressively to prevent secondary CNS injury. Seizures are treated with lorazepam, 0.1 mg/kg IV, and, if necessary, phenytoin, 15 mg/kg, or phenobarbital, 10 mg/kg IV, with correction of hypoglycemia or other underlying metabolic disorder. Severe respiratory distress and decreasing mental status with risk of loss of control of airway protective reflexes should prompt elective endotracheal intubation. Increased intracranial pressure is treated with mannitol, 1 g/kg IV. Hyperventilation has fallen into disfavor.

Empirical antibiotic therapy for the likely age-related pathogens should be initiated as soon as possible in the ED. Recommended antibiotic dosages are higher with meningitis, because of poor drug penetration across the blood-brain barrier and concern for the possibility of antibiotic resistance. In the first 3 months of life, ampicillin, 200 mg/kg, and cefotaxime or ceftriaxone, 100 mg/kg IV are indicated. Children 3 months and older should receive cefotaxime or ceftriaxone, 100 mg/kg (maximum, 2 g) IV (see Table 116-5). Due to the widespread emergence of penicillin- and cephalosporin-resistant strains of *S. pneumoniae*, vancomycin, 15 mg/kg iv also should be administered routinely as initial therapy to children older than 1 month who have presumed bacterial meningitis.¹⁹

Steroid therapy has been shown to decrease the incidence of neurologic complications significantly in bacterial meningitis due to Hib, if given before or at the time of initial antibiotic therapy. However, this benefit has not been demonstrated for meningitis due to *S. pneumoniae* or *N. meningitidis*, and steroid therapy may actually worsen neurologic sequelae. Current guidelines are to consider steroid therapy in cases of suspected bacterial meningitis, specifically dexamethasone, 0.15 mg/kg IV before or immediately after the initial antibiotic dose to children 1 month or older (www.cisimmunize.org/application/TCM?file=/cispro/hib/hibjnf.html).^{19,21}

Prophylaxis of contacts to eliminate carriage of organisms from the upper respiratory tract is indicated after identification of an index case of meningitis caused by organisms capable of causing epidemic disease. For Hib disease, a regimen of rifampin, 20 mg/kg (maximum, 600 mg), once per day for 4 days is indicated for (1) household members if there is a home contact younger than 4 years and (2) day-care center staff and enrollees resembling households, defined as children younger than 2 years with contact of 25 h per week or more. For *N. meningitidis* disease, a regimen of rifampin, 10 mg/kg (maximum, 600 mg), twice per day for 2 days is indicated for all household members, day-care center contacts, and medical personnel who have had direct physical exposure to the index case before antibiotic therapy. There is no indication or effective prophylaxis for *S. pneumoniae* disease.

ADMISSION All pediatric patients with identified or presumed meningitis should be admitted for supportive care, monitoring for complications, and antibiotic therapy. As for sepsis, the disposition decision for children with meningitis also must include choice of the appropriate pediatric inpatient unit. Stable patients may be admitted to a monitored isolation bed on a pediatric floor unit for antibiotic therapy pending culture results. Children with evidence of cardiorespiratory or neurologic compromise should be admitted to a PICU, because of the risk of progression of disease. If transfer of such a patient is necessary, a pediatric transport team should be used for referral to a tertiary care center.

COMMON NEONATAL PROBLEMS

Tonia J. Brousseau Niranjan Kissoon

The assessment of neonates in the ED is more difficult than that of older children and adults. Symptoms are usually vague and nonspecific. Signs are usually subtle and, even when recognized, may not be helpful in pinpointing a diagnosis. For example, respiratory distress may be due to primary respiratory or cardiac disease, generalized sepsis, abdominal pathology, or metabolic derangements. Examination of neonates is time consuming and requires special skills in the approach to the infant and the anxious parent.

The prerequisites for the proper evaluation of neonates are a great deal of patience and an appreciation of the marked variations in nor-

mal vegetative functions. Many visits are initiated because of parental concerns related to feeding patterns; weight gain; stool frequency, color, and consistency; and breathing patterns. Physicians involved in the care of neonates in the ED therefore should be knowledgeable about patterns of normal vegetative functions in neonates. Routine early discharge from the newborn nursery has increased the number of ED visits for issues that previously would have been recognized and addressed before discharge. This trend requires a more thorough knowledge of neonatal issues by the emergency physician.¹

NORMAL VEGETATIVE FUNCTIONS

Feeding Patterns

The feeding of infants requires practical interpretation of specific nutritional needs and the widely varying limits of a normal baby's appetite and behavior regarding food. Variation in times between feedings is to be expected in the first few weeks during the establishment of a self-regulation plan. By the end of first month, more than 90 percent of infants establish a suitable and reasonably regular schedule. Most healthy bottle-fed infants want six to nine feedings every 24 h by the end of the first week of life; breast-fed infants prefer shorter intervals.²³

Feedings should be considered as having progressed satisfactorily if the infant is no longer losing weight by 5 to 7 days and is gaining weight by 12 to 14 days. Parents usually need reassurance that their infant is obtaining adequate nutrition because of the wide variation in the intakes of normal infants. It is important to appreciate that infants cry for reasons other than hunger and that they need not be fed every time they cry.

Weight Gain

Although it is difficult to precisely judge the caloric intake of breast-fed infants and feeding frequency varies widely, intake is adequate if the neonate is gaining weight appropriately and appears content between feedings. Normal newborns may lose 5 to 10 percent of their birth weight during the first 3 to 7 days of life. A weight loss of up to 10 percent is acceptable if the infant's examination and behavior are normal. On average, infants gain between 20 and 30 g per d in the first 3 months of life and between 15 and 20 g per d for the next several months. It is important to weigh the infant completely undressed.

An infant's weight between 3 and 12 months of age can be calculated approximately by the following formula:

$$\frac{\text{age (months)} + 9}{2} = \text{expected weight (kg)}$$

Although plotting the infant's weight on a growth chart is preferred, this formula provides a reasonable reference of expected weight between 3 and 12 months of age in the ED.

Stool Patterns

The number, color, and consistency of bowel movements can change greatly in the same infant and across infants regardless of diet or environment. Breast-fed infants frequently will produce six or seven stools per day, whereas formula-fed infants generally produce one to two stools per day. The stools of breast-fed infants are softer than those of elemental or breast-fed infants. An excessive intake of human milk or maternal use of laxatives further increases the water content of the infant's stool. Overfeeding or use of formula that is too concentrated or too high in sugar content also can produce loose stools.²

Stool color has no significance unless blood is present. Occasionally, an infant may not have a bowel movement on a given day. The first stool, which consists of meconium, is usually passed within the first 24 h after birth. Transition stools, which are greenish brown, ap-

pear after initiation of milk feeding and are replaced by typical milk stools 3 to 4 days later. Infrequent bowel movements do not necessarily mean constipation, because breast-fed infants may occasionally go 5 to 7 days without a bowel movement. A history of not passing meconium in the first 48 h of life may be suggestive of Hirschsprung disease.

Breathing Patterns

The normal respiratory rate is 30 to 60 breaths/min in infants. For premature infants, the rate is higher and fluctuates more widely. Because fluctuations occur rapidly, the respiratory rate should be counted for a full minute with the infant in full resting state, preferably asleep. A rate consistently over 60 breaths/min during periods of regular breathing should be evaluated further.

Because the breathing of newborn infants is almost entirely diaphragmatic, the soft front of the thorax usually is drawn inward during inspiration while the abdomen protrudes. In a quiet infant, this paradoxical pattern has no clinical significance; however, when it changes to predominantly thoracic breathing, intra-abdominal or intrathoracic pathology should be suspected. Alternatively, an increase in abdominal breathing suggests pulmonary disease.

Newborn infants, especially those born prematurely, may exhibit periodic breathing characterized by alternating periods of a normal rate and periods of a markedly slow rate of respiration, with pauses of more times for 3 s or longer. Such alternating respiratory patterns have been observed in 30 to 95 percent of premature babies during sleep, but less frequently in term infants. Periods of apnea longer than 20 s or accompanied by bradycardia or cyanosis should be evaluated.

Sleeping Patterns

Infants are not born with the ability to sleep through the night. Instead, they awaken every 20 min to 6 h, and sleep periods are spread evenly across the day and night. By 3 months of age, most of their sleep occurs at night, and by 6 months, most infants are sleeping through the night.

Night waking is defined as waking and crying once or more between midnight and 5 am for at least 4 of 7 nights per week for at least 4 consecutive weeks. This occurs in approximately 25 percent of infants usually younger than 12 months. This prevalence rises to about 50 percent among breast-fed infants. When the child cries during the night, parents can check to ensure that there is no physical reason for the crying. Having determined that there is no physical problem, parents should ignore the crying so that the child learns to fall asleep on its own. If parents usually feed the child at that time and the child is older than approximately 6 months, the volume of the night feedings should be tapered until they are discontinued and all nourishment is given during the daytime.³

REASONS FOR EMERGENCY DEPARTMENT VISITS

A review of presenting complaints in our pediatric ED, a tertiary-care referral center, over a 6-month period indicated the spectrum most likely to be seen by the emergency physician (Table 117-1). Complaints in neonates are usually not single; rather, they are often symptom complexes. Such symptom complexes reflect the nonspecific nature of signs and symptoms in neonates and the similar presentation of many diseases of diverse etiology.

Crying, Irritability, and Lethargy

The symptom complex of crying, irritability, and lethargy is fairly common yet difficult to treat, even in the presence of an identifiable cause. Most neonates exhibit varying degrees and periods of crying

TABLE 117-1 Common Presenting Complaints

Crying, irritability, lethargy (see Table 117-2)
Gastrointestinal tract symptoms
Feeding difficulties
Regurgitation
Vomiting
Diarrhea
Abdominal distention
Constipation
Cardiorespiratory symptoms
Rapid breathing
Cough and nasal congestion
Noisy breathing and stridor
Apnea, periodic breathing
Blue spells, cyanosis
Jaundice
Eye discharge, redness
Diaper rash, oral thrush
Fever and sepsis Sudden infant death

during a 24-h period. However, infants who present with an episode of acute, inconsolable crying should be observed closely for an underlying cause (Table 117-2).

Intestinal Colic

Colic is a paroxysm of crying for 3 h per d or more for 3 days/week or more over a 3-week period and causes significant parental distress. The incidence of colic is about 13 percent, with no seasonal variation. Colic is a symptom complex consisting of the sudden onset of paroxysmal crying lasting several hours, a flushed face, circumoral pallor, tense abdomen, drawn up legs, cold feet, and clenched fists. It may begin as early as the first week of life but seldom lasts beyond 3 to 4 months of age. A careful history is important in the diagnosis of colic; findings at physical examination are normal, and laboratory tests are not required. However, when the diagnosis is unclear, a careful history, physical examination, and appropriate laboratory investigations are necessary to rule out conditions listed in Table 117-2. In doubtful situations, admission for observation or return for reassessment is reasonable.

The cause of colic is unknown. Proposed causes include excessive intake of air, insufficient intake of fluid, allergy to protein, and mater-

nal stress. Just as the cause remains obscure, no single treatment has been proven effective for all infants who have colic. Applying heat to the abdomen, decreasing external stimulation, and rocking the infant have been advocated as useful interventions at various times. Administration of drugs (including sedatives) rarely is beneficial or indicated. A 1-week trial of hypoallergenic formula (non-cow's milk protein) may be beneficial and is occasionally a worthwhile intervention in severe cases. Reassuring the parents that colic is a common, self-limited problem in young infants and encouraging them to share caregiving responsibilities during this time can be helpful.

The emergency physician can also be helpful by making the following suggestions:

1. Changes in care-taking styles (e.g., increased soothing activities such as carrying and rocking, feeding more frequently, and use of a pacifier and less overstimulation)
2. Changes in environment (e.g., background music or car and stroller rides)
3. Changes in feeding for refractory cases (e.g., removal of cow's milk from the diet of an infant who has visible peristalsis, persistent regurgitation, and symptoms after ingesting cow's milk protein; removal of cow's milk from the diet of the mother of a breast-fed baby; but not switching to formula from breast milk or changing formula).⁴

Abuse and Trauma

Distinguishing between accidental and nonaccidental injuries is vital. The most common accidental newborn skin lesion is a scratch.⁵ By making an accurate determination, the practitioner achieves two equally important objectives: (1) protecting victims of abuse from future harm, which is often more severe than the present injuries; and (2) avoiding the damage done by unwarranted suspicion of abuse and the time-consuming investigative process that ensues.

Recognition of abuse and neglect (maltreatment) is likely only if the possibility is entertained in the differential diagnosis. The approach to the family should be supportive, empathic, and non-accusatory (see Chap. 297 for a detailed discussion).

If the diagnosis is suspected, the child should be admitted for protection, and the appropriate agencies should be notified for further investigation.

Infections

Neonatal infections are manifested by a variety of symptoms and signs, such as temperature instability, feeding difficulties, fever, jaundice, and respiratory distress. Neck rigidity and Kernig and Brudzinski signs are usually absent in neonates with meningitis. A septic neonate may present with a normal or subnormal temperature. Urinary tract infections are often associated with nonspecific signs, such as irritability, vomiting, diarrhea, or poor feeding, and diagnosis is established by urine culture rather than urinalysis. There is general consensus that all neonates (younger than 28 days) with possible sepsis should be hospitalized and given broad-spectrum antibiotic therapy pending results of appropriate cultures (e.g., urine, blood, and cerebrospinal fluid [CSF]). See Fever and Sepsis, below.

Surgical Lesions

Surgical conditions in neonates can present with a wide variety of symptoms, including respiratory distress, fever, lethargy, weight loss, poor feeding, feeding intolerance, or abdominal distention. Progression of symptoms can be helpful in decision-making but may not be easily or accurately elicited from an infant or poorly observant parent. The surgically correctable causes of respiratory distress in newborns are less frequent and include choanal atresia, congenital lobar emphysema, micrognathia (Pierre-Robin syndrome), laryngomalacia,

TABLE 117-2 Conditions Associated with Uncontrollable Crying, Irritability, and/or Lethargy in Neonates

Anal fissure
Intestinal malrotation/volvulus
Improper feeding practices
Cardiovascular
Heart failure
Metabolic abnormalities

tracheomalacia, tracheoesophageal fistula, and vascular rings. Most of these anomalies are identified in the newborn nursery, but in the ED these diagnoses should be considered in any infant with respiratory distress. In the neonate with abdominal symptoms, the most common diagnoses include necrotizing enterocolitis and congenital anomalies, such as malrotation with midgut volvulus, duplication, gastroschisis, and omphalocele.

Malrotation usually presents in the first month of life with sudden onset of bilious vomiting. The incidence is 1 in 500 live births and 50 percent are diagnosed in the first month of life. Bilious vomiting should always be considered a surgical emergency. These symptoms should prompt an immediate surgical evaluation or consultation. Delayed presentation or surgical correction results in an increased morbidity and mortality.

Pyloric stenosis classically presents between 2 and 6 months of age and is the most common surgically correctible cause of vomiting in newborns. With more sensitive evaluation using ultrasound, it is often diagnosed and corrected in the first month of life. In fact, more than 90 percent of newborns have no electrolyte disturbances at the time of diagnosis. A volumetric evaluation is an appropriate and effective tool to use in the ED if ultrasound is not immediately available. To perform a volumetric evaluation, place an 8-French naso- or orogastric tube and attempt aspiration of gastric contents 3 to 4 h after the last feed. If less than 5 mL is obtained, pyloric stenosis is unlikely. If more than 5 mL is obtained, pyloric stenosis is more likely, and a diagnostic ultrasound should be obtained to make the diagnosis.

Incarcerated inguinal hernias and intussusception are most common after 2 months of age. Incarcerated hernia and intussusception account for most abdominal surgical emergencies in the 2-month to 1-year age group; incarcerated hernia decreases in incidence after 1 year of age.

The diagnosis of abdominal emergencies is challenging in the ED. A systematic approach helps to minimize missed diagnoses. The most common signs are irritability and crying, followed by poor feeding, vomiting, constipation, and abdominal distention. Prudent use of laboratory and imaging studies will minimize misdiagnosis. The early involvement of a surgeon in the care of all pediatric patients who have significant abdominal symptoms is recommended.^{6,8}

Improper Feeding Practices

Improper feeding practices may result in an irritable infant with periods of inconsolable crying. These symptoms usually result from overfeeding without adequate burping during feedings. The infant swallows large amounts of air, resulting in bowel distention, reflux, and occasionally respiratory distress. Instruction in proper feeding practices usually alleviates the problem.

GASTROINTESTINAL TRACT SYMPTOMS

Common presenting gastrointestinal symptoms are listed in Table 117-1.

Feeding Difficulties

Most visits for feeding difficulties occur because parents perceive that the infant's food intake is inadequate. The neonate's pattern of intake is not fully established until about 1 month of age. If weight gain is satisfactory and the infant is satisfied after feedings, intake is adequate. Parents usually can provide accurate information of the intake of bottle-fed infants. Weighing breast-fed infants before and after feedings is not advised, because weights may be inaccurate. In addition, weighing may have adverse psychological effects on a mother whose infant is doing poorly.

Rarely, anatomic abnormalities may cause difficulty in feeding and swallowing. A careful history usually pinpoints such difficulties as having started at birth. The infants appear malnourished and dehydrated. The most likely causes are esophageal obstruction (e.g.,

stenoses, strictures, laryngeal clefts, or cleft palate) and compression of the esophagus or trachea by a double aortic arch. Infants with a recent decrease in intake have an acute disease, usually an infection, and should prompt an urgent evaluation.

Gastroesophageal Reflux

Regurgitation of small amounts is common in neonates due to reduced lower esophageal sphincter pressure and relatively increased intragastric pressure. Parents may confuse regurgitation with vomiting. Vomiting results from forceful contraction of the diaphragm and abdominal muscles, whereas regurgitation is independent of any effort and likely represents the ultimate degree of gastrointestinal reflux. If the neonate is thriving, parents can be reassured that regurgitation is of no clinical significance and will decrease as the infant grows. Such infants usually respond well to thickening of feedings. The infant's upper body should be elevated after feedings, if thickening of feedings alone does not resolve the regurgitation. Infants who are not thriving or having respiratory symptoms should be investigated for anatomic causes of regurgitation or chronic aspiration.

Regurgitation rarely results from pathologic processes, such as intrinsic compression of the esophagus or occasionally compression of the trachea, in which case it is usually accompanied by stridor and cough. Dysphagia, irritability, anemia, and malnutrition are sequelae of chronic regurgitation with esophagitis, but this condition is rare. Investigations such as scintigraphy, pH monitoring, endoscopy, and biopsy are used to confirm the diagnosis of reflux esophagitis. These invasive tests are not done on an emergency basis.

Vomiting

Vomiting results from many causes and is rarely an isolated symptom. During the first few weeks of life, vomiting is uncommon and is often confused with regurgitation. Vomiting beginning at birth is most likely due to an anatomic abnormality, such as tracheoesophageal fistula, upper gastrointestinal obstruction, or midgut rotation. More commonly, acute vomiting may be part of the symptom complex of some diseases, especially increased intracranial pressure, and infections (e.g., sepsis, urinary tract infections, and gastroenteritis).

Projectile vomiting is usually seen in infants with pyloric stenosis and usually assumes its characteristic pattern after the second and third weeks of life. This condition usually occurs in firstborn males and is characterized by projectile vomiting at the end of feeding or shortly thereafter. The vomitus does not contain bile or blood. Examination of these infants should be done with the infant relaxed and the stomach empty. Prominent gastric waves may be seen going from the left to right. A firm olive mass may be felt by palpating under the liver edge. Malnutrition and dehydration are rarely seen because of early diagnosis.

In any infant who is vomiting, signs of dehydration should be sought. Hepatobiliary, urinary tract, and central nervous system disease can also cause vomiting. Vomiting due to inborn errors of metabolism may present with hypoglycemia and metabolic acidosis. Infants who are vomiting should be admitted for evaluation and therapy.

Necrotizing Enterocolitis

Necrotizing enterocolitis remains incompletely understood, but the cause is multifactorial. It is a result of inflammation or injury to the bowel wall that has been associated with infectious causes and hypoxic-ischemic insults. Although there is a higher incidence in premature infants, it may be seen in the term newborn. Initial symptoms may range from feeding intolerance, abdominal distention, bloody stools, and apnea or shock. The classic x-ray findings include pneumatosis intestinalis (intramural air) and hepatic portal air. Free air in the abdomen may be seen, if perforation has already occurred. Management is directed by symptomatology. A pediatric surgeon should be ampicillin, cefotaxime, and clindamycin to cover gram-positive, gram-negative, and anaerobic organisms.

Blood in the Diaper

consulted or a transfer arranged to an appropriate facility after stabilization. Broad-spectrum antibiotics should be administered, including

Blood in the diaper or stool can be a difficult complaint to evaluate in the ED. In the first 2 to 3 days of life, blood in the diaper is most commonly due to swallowed maternal blood. This possibility may be confirmed by the Kleihauer-Betke or Apt-Downey test (see Chap. 254), which differentiates fetal from maternal hemoglobin in the stool. After the first few days of life, most causes are idiopathic, but coagulopathies, necrotizing enterocolitis, anal fissures, allergic or infectious colitis, and congenital defects should be considered. Visualization of a bleeding anal fissure on examination may be helpful, but not visualizing a fissure does not confirm or exclude the diagnosis. Cow's milk allergy is an IgE-mediated disorder causing changes in the bowel mucosa that result in bloody stools. Eosinophils may be present in the stool, and the diagnosis may be confirmed by resolution of the problem after cow's milk is removed from the diet. For unresponsive or severe cases, biopsy may be needed to make a diagnosis. A careful history and thorough examination of the infant, with focus on the abdomen and rectum, may be helpful. Blood in the stool should be confirmed by a guaiac test for occult blood. A single event in a newborn that has no other findings may be observed as an outpatient. Persistent symptoms or other findings should be evaluated on an inpatient basis with appropriate subspecialty care.

Diarrhea and Dehydration

Diarrhea refers to stools that are abnormally frequent and liquid. The modifier *abnormal* is critical because stools can normally be frequent and liquid in young children. In the United States, rotavirus predominantly affects infants between ages 3 to 15 months. The peak incidence is in the winter months, and rotavirus accounts for as many as 50 percent of the cases of acute diarrhea in winter. Enteric adenoviruses (serotypes 40 and 41) are the second most common viral pathogen in infants. In summer, most cases of diarrhea are caused by bacteria (including *Escherichia coli*, *Salmonella*, and *Shigella*). Parasitic causes of diarrhea are rare in neonates.

A history of bloody diarrhea strongly suggests a bacterial pathogen. A suspicion or diagnosis of *Salmonella* gastroenteritis in a newborn

should prompt a full sepsis evaluation and admission for antibiotic therapy. The history should assess the infant's state of hydration and possible causative agents. Information regarding oral intake, frequency and volume of stools, general appearance of the infant, mental status, and frequency of urination can help in assessing hydration. The parent should be asked about fever, antibiotic therapy, and exposure to infant day-care centers or other children and adults with diarrheal illness.

All children with diarrhea should be carefully weighed unclothed for comparison with previous weight and to provide a baseline for monitoring subsequent weights during the course of the disease. In an infant, the normal extracellular fluid volume is 25 percent of body weight; therefore, a loss of 8 percent of body weight as extracellular fluid would result in severe dehydration. The actual weight loss is usually greater than 8 percent because of concomitant loss of cellular water. A neonate with gastrointestinal losses may prompt further evaluation and should be considered for admission, because loss of seemingly small volumes of stool may cause significant dehydration.

The physical examination should begin with a general assessment, with particular attention to the state of hydration (Table 117-3). Mucous membranes should be evaluated for moistness. The appearance of the anterior fontanel and eyes should be assessed. Skin hydration and turgor may provide a sense of the degree of dehydration. The finding of doughy and tented skin is associated with hypernatremic dehydration. The child's mental status with regard to interaction with the examiner and the parent may reflect the severity of the illness and dehydration.

Temperature, pulse, and blood pressure also may provide information concerning the degree of illness. The rest of the physical examination should focus on signs of concurrent viral illness, such as upper respiratory tract infections and abdominal findings. A rectal examination is often useful in obtaining a stool sample for detection of occult blood, culture, examination for leukocytes, measurement of pH, and detection of reducing substances. It can also rule out anal fissures as the cause of bloody stools.

Serum electrolyte levels, in particular sodium and bicarbonate, should be assessed in any neonate with diarrhea and dehydration. A markedly elevated serum urea nitrogen with a relatively normal creatinine may indicate recent or rapid dehydration. Serum creatinine values tend to be low in infants and young children, and a creatinine value of 1 mg/dL may represent a doubling in the normal value. The rest of the evaluation should include a stool sample for the above-mentioned tests and a urine sample for culture and analysis.

Most newborns should be admitted to the hospital for rehydration. The loss of even seemingly small volumes of stool may cause severe

TABLE 117-3 Clinical Assessment of Severity of Dehydration

Signs and Symptoms	Mild Dehydration	Moderate Dehydration	Severe Dehydration
Body weight loss, %	3-5	6-9	≥10
General appearance and condition, infants and young children	Thirsty, alert, restless	Thirty; restless or lethargic but irritable to touch or drowsy	Drowsy; limp, cold, sweaty, cyanotic extremities; may be comatose
Radial pulse	Normal rate and strength	Rapid and weak	Rapid, feeble, sometimes impalpable
Respiration	Normal	Deep, may be rapid	Deep and rapid
Anterior fontanel	Normal	Sunken	Very sunken
Systolic blood pressure	Normal	Normal or low	Low, may be unrecordable
Skin elasticity	Pinch retracts immediately	Pinch retracts slowly	Pinch retracts very slowly
Eyes	Normal	Sunken	Grossly sunken
Tears	Present	Absent or reduced	Absent
Mucous membranes	Moist	Dry	Very dry
Urine flow	Normal	Reduced amount and dark	Anuria, severe oliguria
Capillary refill	Normal	±2s	>3 s
Estimated fluid deficit, mL/kg	30-50	60-90	>100

dehydration in the neonate. Oral hydration may be attempted in the hospital, depending on personnel and cardiovascular stability of the patient. Oral rehydration should be attempted in children who are less than 5 percent dehydrated. If the infant is breast fed, rehydration should be continued and an oral electrolyte and glucose solution supplement should be given until diarrhea subsides. An age-appropriate diet should be resumed after initial feedings, with oral rehydration solutions as tolerated. A lactose-free or elemental formula should not be substituted unless stools are positive for reducing substances. The total fluid intake of oral electrolyte solution and regular diet should be approximately 150 mL/kg per d.^{9,10}

However, if there are any indications of significant peripheral vascular compromise or shock, or if vomiting is persistent, or if there is more than 5 percent dehydration, intravenous hydration is recommended (see Chap. 132).

Abdominal Distention

Abdominal distention may be normal in neonates and is usually due to lax abdominal musculature and relatively large intra-abdominal organs. It may also be accentuated by excessive gas within the bowel. If the infant is comfortable and feeding well and the abdomen is soft, there is no need for concern. Abdominal distention may also occur in association with bowel obstruction, constipation, necrotizing enterocolitis, or ileus due to sepsis or gastroenteritis. Congenital organomegaly (e.g., hepatomegaly, splenomegaly, or renal enlargement) undetected in the perinatal period also may present as abdominal distention.

Constipation

Infrequent bowel movements in neonates do not necessarily mean that the infant is constipated. Infants occasionally may go without a bowel movement for 5 to 7 days and then pass a normal stool. However, if the infant has never passed stools, especially if there has not been a stool in the first 48 h of life, the possibility of intestinal stenosis or atresia, Hirschsprung disease, or meconium ileus or plug should be considered. Constipation occurring after birth but within the first month of life suggests Hirschsprung disease, hypothyroidism, or anal stenosis. The diagnosis of Hirschsprung disease is supported by absence of feces on rectal examination and an abrupt change in bowel luminal size on barium enema, and is confirmed by a rectal biopsy demonstrating absence of ganglion cells. Infants with hypothyroidism present with feeding problems, a weak or hoarse cry, hypothermia, hypotonia, and peripheral edema. The child should be admitted for further evaluation and treatment. Hypothyroidism is part of the routine newborn metabolic screening but varies from state to state. Emergency physicians should be familiar with the diseases that are screened for in their state and how they may obtain the results.

CARDIORESPIRATORY SYMPTOMS

Neonates are prone to respiratory problems for a variety of reasons. Anatomic predisposing factors are a barrel-shaped chest, a flattened diaphragm, limitation of diaphragmatic movement by abdominal compression, smaller airway diameter, and higher closing volumes. The high compliance of the chest wall, low compliance of the lungs, and less fatigue-resistant fibers in the diaphragm and intercostal muscles are other significant contributory factors. Cardiorespiratory symptoms are also more common in neonates, because structural and functional abnormalities of the airway and heart are more likely to present early in life. A cardiorespiratory arrest should be considered due to respiratory pathology until proven otherwise.

Cardiorespiratory symptoms in neonates are nonspecific and may be due to primary organ failure (cardiovascular or respiratory) or secondary to a variety of systemic diseases, such as sepsis, metabolic aci-

dosis, abdominal pathology, and severe meningitis. Regardless of the cause, the assessment and stabilization of the cardiac and respiratory systems are priorities and should be accomplished before or concurrently with establishing a diagnosis.

Rapid Breathing

Rapid breathing can be due to minor problems, such as abdominal distention, or to life-threatening illnesses, such as sepsis. **Rapid breathing or grunting should always be considered a medical emergency.** Physical examination should include observation for grunting during feeding. Admission for investigations, monitoring, and therapy should be considered in all but the mildest cases. When a cause cannot be identified on initial presentation, a full sepsis workup (full blood count, blood culture, urinalysis, chest x-ray, and CSF examination) should be done, and broad-spectrum antibiotics should be administered (Table 117-4).

Pneumonia

The lungs are the most common sites of infection in neonates, with group B *Streptococcus* being the most common cause of lower respiratory infection. The infection is most likely acquired in utero from a contaminated amniotic fluid environment. Affected infants frequently develop fulminant illness within hours of birth. Other common bacterial pathogens in newborns and infants include *Streptococcus pneumoniae* and *Haemophilus influenzae* serotype B. Chlamydial pneumonia usually occurs after 3 weeks of age and is accompanied by conjunctivitis in 50 percent of cases. Infants with bacterial and viral pneumonia may present with fussiness, stuffy nose, decreased appetite, abrupt onset of high fever, nasal flaring, grunting, retraction, tachypnea, and tachycardia.

Patients with chlamydial pneumonia are usually afebrile, tachypneic, and have a prominent "staccato" cough. Wheezing is uncommon, but the chest x-ray may demonstrate hyperinflation with bilateral interstitial infiltrates. The definitive diagnosis is by a nasopharyngeal swab for culture, but the peripheral blood count may reveal an eosinophilia.

Respiratory syncytial virus (RSV), adenovirus, and parainfluenza virus can also cause, pneumonia in otherwise well infants.

TABLE 117-4 Causes of Rapid Breathing in Neonates

Pneumonia
Bacterial
Viral
<i>Chlamydia</i>
Aspiration
Bronchiolitis
Illness in other organ systems
Septicemia
Central nervous system (e.g., meningitis)
Abdomen (e.g., distention, gastroenteritis)
Metabolic acidosis
Congenital diseases
Respiratory disease
Delayed presentation of diaphragmatic hernia
Tracheoesophageal fistula
Lobar emphysema
Tracheal stenosis, webs
Heart disease
Cardiac failure (e.g., hypoplastic left heart, critical coarctation of aorta, aortic stenosis, patent ductus arteriosus)
Cyanotic disease (e.g., transposition of great arteries)
Vascular ring
Neuromuscular disease
Infant botulism
Muscle weakness

In addition to pneumonia, infections with *Bordetella pertussis* may cause paroxysms of cough accompanied by cyanosis in an otherwise well-appearing infant. The cough is not accompanied by the characteristic whoop in neonates. Pertussis always must be considered in infants who have severe, paroxysmal cough and post-tussive vomiting. Apnea also may be the only presenting symptom. Because many adults are susceptible to infection with pertussis, such an infection should be considered if the caretaker also has a persistent cough. Infants younger than 6 months who are suspected of having pertussis should be admitted to the hospital. Pertussis is diagnosed through culture of the nasopharynx, but because special culture medium is required, the laboratory should be consulted about proper technique when this culture is required. A lymphocytosis of the peripheral blood count is nonspecific but may support the diagnosis.

The approach to the febrile neonate with suspected bacterial pneumonia should include a full evaluation for sepsis (blood and urine cultures, chest radiographs, and complete blood count). The blood culture results are typically negative, but obtaining two culture samples instead of one during the initial evaluation may increase the diagnostic yield fourfold. A lumbar puncture should be done if there are no contraindications.

Infants who have fever and pneumonia should be hospitalized and receive parenteral antibiotics. The most common organisms include group B *Streptococcus*, *Listeria*, and *Haemophilus influenzae*. A premature infant who has recently been in the neonate intensive care unit may have a nosocomial cause such as *Staphylococcus aureus* or *Pseudomonas aeruginosa*. Chlamydial or *B. pertussis* pneumonia should be treated with erythromycin or sulfamethoxazole. Infants with pneumonia who are afebrile may be treated as outpatients when a viral pathogen is suspected. Inability to eat, respiratory distress, and hypoxemia are criteria for hospitalization. Outpatients should be seen daily until symptoms resolve.¹¹

Bronchiolitis

Bronchiolitis is an acute lower respiratory tract illness in early life preceded by signs and symptoms of an upper respiratory infection or apnea. Bronchiolitis is a highly seasonal disease, comparatively few cases are seen during the summer months, and activity peaks during winter months. Serious cases of bronchiolitis occur most commonly in infants younger than 1 year and in those who are premature (<34 weeks of gestational age) or have an underlying medical problem. The greatest risk of a complicated course is in the first 3 months of life. Bronchiolitis is seen more commonly in families of low socioeconomic status or infants who have not been breast fed.

Respiratory syncytial virus is the most common cause, accounting for more than 60 to 90 percent of bronchiolitis cases. Transmission is by direct contact with nasal secretions of infected individuals much more frequently than by aerosol spread. Shedding of the virus can be documented 1 to 2 days before symptoms onset and for 1 to 2 weeks thereafter. Those exposed are probably not contagious for the entire period of time but should be considered contagious 24 to 48 h before the onset of symptoms and for several days thereafter.

Many other viral agents also can cause bronchiolitis, although the illness is milder. The parainfluenza viruses are the second most common cause of bronchiolitis and are responsible for autumn and spring epidemics, usually before and after RSV outbreaks. Influenza type A virus, adenovirus, rhinovirus, and *Mycoplasma pneumoniae* also can precipitate bronchiolitis.

Acute bronchiolitis presents in infancy with serous nasal discharge accompanied by sneezing. These symptoms are followed by diminished appetite, cough, dyspnea, irritability, and, commonly, periods of apnea. **Apnea is more common in neonates and preterm infants younger than 34 weeks of gestational age and usually presents within the first 3 days of illness.** Physical examination reveals a rapid respiratory rate (>60 breaths/min), cyanosis, air hunger, wheezing,

hyperinflation, intercostal and subcostal retractions, and a palpable liver and/or spleen due to hyperinflation of the lungs. Fever is usually low grade or absent, except in the presence of otitis media, when a temperature as high as 40°C may be present. Chest x-rays usually show hyperinflation with patchy atelectasis.

The diagnosis of bronchiolitis is usually made clinically. There is no need to send nasopharyngeal washings for diagnosis unless the infant is younger than 2 months, when washings may obviate a sepsis evaluation. A wheezing infant with a history of the aforementioned symptoms for several days, particularly during the peak season for RSV can be assumed to have bronchiolitis. Immunofluorescence or enzyme-linked immunosorbent assays performed on respiratory secretions are very sensitive and specific for detection of RSV. Other diagnostic tests, such as blood gas analysis or cell counts, are directed by clinical assessment but are rarely necessary.

Most cases of bronchiolitis are mild and can be managed without hospitalization. Infants usually recover without (3-adrenergic agents or other medications used for relief of wheezing. The decision to hospitalize an infant with bronchiolitis should be based on a number of clinical criteria in addition to other considerations, such as reliability of parents and the likelihood of obtaining acceptable follow-up. **Infants who are born prematurely, have underlying heart or lung disease, are younger than 3 months, or have low initial oxygen saturation (<92 percent) are at greater risk to develop progressive or life-threatening illness.** In addition, infants who are not feeding well or are dehydrated should be hospitalized.

Infants for whom hospitalization is being considered may receive a course of a nebulized (3-adrenergic agent (albuterol 0.1 to 0.15 mg/kg per dose, up to 5 mg). The drug should be continued only if the infant shows improvement. Racemic epinephrine has demonstrated more consistent beneficial results than (3-adrenergic agents and warrants a trial in sicker patients. The continued use of such agents in the absence of an initial beneficial response is not routinely recommended. It is not possible to predict which individuals with bronchiolitis may respond to (3-adrenergic agents. The use of corticosteroids is not useful in the treatment or outcome of bronchiolitis. The use of antibiotics generally does not affect the clinical course of bronchiolitis, but the presence of a high fever or severe course of illness may be an indication for temporary antibiotic coverage.^{12,13}

ILLNESS INVOLVING OTHER ORGAN SYSTEMS

The search for pathologic conditions in other organ systems is mandatory, because the presence of respiratory symptoms does not preclude pathology in another organ. For example, generalized sepsis, meningitis, gastroenteritis, and metabolic acidosis may present with respiratory distress as the predominant symptom.

CONGENITAL DISEASES

Respiratory Disease

Occasionally an H-type tracheoesophageal fistula may present in the first month of life or later with recurrent pneumonia, respiratory distress after feedings, and problems in clearing mucus. Tracheal stenosis may present initially with noisy breathing or a high-pitched cry and tremendous respiratory difficulty even after mild upper respiratory infections. Similarly, neonates with chronic respiratory insufficiency, such as bronchopulmonary dysplasia, may present as respiratory failure even after mild upper respiratory infections.

Heart Disease

Rapid breathing due to cardiac disease is usually not associated with significant retractions and use of accessory muscles. As a general rule,

a well-developed neonate who presents with unexplained cyanosis and tachypnea should be suspected of having congenital cardiac disease. In neonates with transposition of the great arteries and ventricular septal defect or critical coarctation of the aorta, congestive cardiac failure may be the presenting feature. Infants with underlying cardiac disease may present to the ED in the first few weeks of life after the ductus arteriosus closes. Emergency physicians should be familiar with the simple but potentially life-saving administration of prostaglandins. Prostaglandin E₁ is started at 0.05 to 0.1 µg/kg per min and titrated according to improvement of partial pressure of oxygen. Signs of heart failure may be very subtle but are life threatening and require emergency referral¹⁴ (see Chap. 120).

Neuromuscular Disease

Any form of muscle weakness may be associated with shallow breathing and a compensatory increase in respiratory rate. Infantile botulism is a possible cause and usually preceded by constipation, and the infant may have a poor cry and feeding difficulties. Ocular palsy, apnea and weakness or hypotonia, and lethargy are later symptoms. Other causes of hypotonic neuromuscular diseases include Down syndrome, hypoxic-ischemic encephalopathy, spinal cord lesions such as myelomeningocele, and peripheral nerve diseases such as myasthenia gravis, metabolic disorders, and myotonic dystrophy.

Cough and Nasal Congestion

Cough may be a prominent feature of most of the primary respiratory conditions listed in Table 117-4. It also may be the initial presentation of a variety of congenital anomalies, including cleft palate, laryngeal tracheomalacia, laryngotracheal cleft, tracheal webs, tracheoesophageal fistula, tracheal hemangiomas, and vascular rings. Although congenital malformation resulting in cough and nasal congestion is more likely to occur in neonates, in most instances, cough is due to a viral upper respiratory infection and may be associated with sneezing and nasal congestion. It also may be a prominent feature of bronchiolitis and chlamydial and pertussis infections. Treatment of the underlying condition is required. Cough suppressants should be avoided in neonates. The focus should be the diagnosis of the etiology, not suppressing the cough. Over-the-counter cough medications usually are not effective and may contain ingredients that increase mucus production or cause drowsiness or irritability. Nasal congestion is best treated with instillation of saline drops and suction, when necessary.

Noisy Breathing and Stridor

Noisy breathing is a common presenting complaint in neonates and is usually benign. Stridor is usually due to congenital anomalies (e.g., webs, cysts, atresia, stenosis, clefts, or hemangiomas) anywhere from the nose to the trachea and bronchi. Infants who were intubated in the neonatal period may develop subglottic stenosis. Infection (e.g., croup, epiglottitis, and abscess) as a cause of stridor in neonates is rare. Stridor worsening with cry or increased activity suggests laryngomalacia or subglottic hemangioma; stridor and feeding difficulties suggest vascular ring, laryngeal cleft, or tracheoesophageal fistula; stridor with hoarseness or weak cry suggests vocal cord paralysis. Laryngomalacia is the most common cause of stridor in the neonate. It is characterized by noisy, crowing, inspiratory sounds, which usually decrease during the first year of life. When the diagnosis is in doubt, the infant should be admitted for evaluation.

Apnea and Periodic Breathing

Periodic breathing, which may occur in normal neonates, should be differentiated from apnea. However, periodic breathing may precede apnea, and both may occur in the same patient. Apnea is a cessation of

respiration for 20 s or bradycardia and cyanosis. It signifies critical illness and warrants prompt investigation and admission for monitoring and therapy.

Apnea may be precipitated by any of the disease conditions listed in Table 117-4 and usually indicates respiratory muscle fatigue and impending respiratory arrest. Resuscitation, including airway support and ventilation, should be followed by a thorough search for the inciting condition. If no obvious cause is found, the neonate should be assumed to be septic or have meningitis. Cultures should be obtained and broad-spectrum antibiotics started.¹⁵

Cyanosis

An infant with cyanosis usually presents a diagnostic challenge, because such findings may be due to many disorders. If cyanosis is associated with rapid but unlabored breathing, the most likely cause is cyanotic congenital heart disease with a right-to-left shunt. Methemoglobinemia, although rare, may mimic cyanotic heart disease and could be easily diagnosed by ordering an arterial blood gas with a co-oximeter. Irregular or shallow breathing may be associated with sepsis, meningitis, cerebral edema, or intracranial hemorrhage and also may be accompanied by cyanosis. If breathing is labored (e.g., grunting or retractions), pulmonary disease (e.g., pneumonia or bronchiolitis) is likely. All infants with cyanosis should be admitted for monitoring and further investigation.

Jaundice (Hyperbilirubinemia)

Jaundice (Table 117-5) may appear at different times during the neonatal period and may require a complete diagnostic evaluation. This is the most common reason for re-evaluation and admission as a result of earlier discharge from the newborn nursery. Jaundice during the first 24 h rarely presents to the ED. The most common causes of jaundice seen in the ED are physiologic jaundice, jaundice due to sepsis, or breast-milk jaundice. Occasionally, infants with hemolysis due to autoimmune disease may present to the ED.

Physiologic jaundice is due to the hemolysis of fetal red blood cells. It is characterized by bilirubin rising at a rate of less than 5 mg/dL per 24 h, with a peak of 5 to 6 mg/dL during the second to the fourth days of life, and a decrease to less than 2 mg/dL by 5 to 7 days. Septic infants with hyperbilirubinemia may have an increase in bilirubin by greater than the acceptable 5 mg/dL per 24-h period, and other features of sepsis, such as vomiting, abdominal distention, respiratory distress, and poor feeding. Jaundice associated with breast feeding is thought to be due to the presence of substances that inhibit

TABLE 117-5 Causes of Jaundice in Neonates

<24 h	ABO, Rh incompatibility Sepsis Congenital infections (e.g., rubella, toxoplasmosis, cytomegalovirus infection) Excessive bruising from birth trauma (cephalhematoma or intramuscular hematoma)
2-3 d	Physiologic
3 d to 1 wk	Septicemia Syphilis, toxoplasmosis, cytomegalovirus infection
> 1 wk	Septicemia, congenital atresia of bile ducts, serum hepatitis Congenital hemolytic anemias (sickle cell anemia, spherocytosis) Hemolytic anemia due to drugs (e.g., in glucose-6-phosphate dehydrogenase deficiency) Rubella, herpetic hepatitis Hypothyroidism Breast-milk jaundice

glucuronyl transferase in breast milk; it may start as early as the third to fourth day and reaches a peak of 10 to 27 mg/dL by the third week of life. Although cessation of breast feeding will result in a rapid decline of bilirubin over 2 to 3 days, it is not routinely recommended. Breast feeding jaundice is unlikely to cause kernicterus and usually can be treated with phototherapy, when necessary.

A proper history and physical examination provide clues to the causes of jaundice. A well-looking child who is gaining weight and feeding well is unlikely to be septic. Laboratory evaluation should include a full blood count to test for anemia, a smear for hemolysis, direct and total bilirubin determinations, a reticulocyte count, and a Coombs test. Admission to the hospital, appropriate cultures, and antibiotics are ordered for neonates who are unwell and have any of the signs or symptoms listed in Table 117-5. In all cases, arrangements should be made for monitoring of bilirubin and hemoglobin levels. Whereas most well infants can be monitored and receive phototherapy as outpatients, infants who have anemia or have bilirubin levels approaching exchange transfusion levels should be admitted. The American Academy of Pediatrics recommends initiation of phototherapy based on age. **Infants 25 to 48 h old with bilirubin levels of at least 15 mg/dL, 49 to 72 h old with levels of at least 18 mg/dL, or older than 72 h with levels of at least 20 mg/dL should receive phototherapy. These recommendations are for healthy newborns, not ill-appearing or premature newborns.**¹⁶

Eye Discharge, Redness, and Conjunctivitis

Neonates with red eyes most likely have conjunctivitis. Neonatal conjunctivitis occurs in 1.6 to 12 percent of newborns during the first month of life. The chemical irritation from antimicrobial prophylaxis against bacterial infection is the most frequent cause occurring in the first 24 h of life, followed by *Chlamydia trachomatis* infection. Other important pathogens in this setting are *H. influenzae* and *Streptococcus pneumoniae*. *Neisseria gonorrhoeae* is no longer a major cause of neonatal conjunctivitis in the United States, because of the use of neonatal ocular prophylaxis. The failure rate of antimicrobial prophylaxis is 1 percent. However, because *N. gonorrhoeae* can damage the eye severely, it is important to always test for this pathogen as the possible cause of neonatal conjunctivitis. Viruses rarely cause isolated neonatal conjunctivitis as an isolated problem. They usually cause conjunctivitis as part of a generalized viral syndrome affecting many organs. For example, herpes simplex virus causes neonatal keratoconjunctivitis as part of a generalized viremia, with infection at other sites such as skin or mucous membranes, or with disseminated disease. The finding of vesicles anywhere on the body in association with neonatal conjunctivitis suggests herpes simplex infection. This finding warrants a full sepsis evaluation with CSF cultures for herpes simplex virus and treatment with acyclovir.

An important consideration in the evaluation of neonatal conjunctivitis is the time of onset. Chemical conjunctivitis due to ocular prophylaxis usually occurs on the first day of life. Gonococcal conjunctivitis generally has its peak time of onset between 3 and 5 days after birth. By the end of the first week of life and throughout the first month of life, *Chlamydia* becomes the most frequent cause of conjunctivitis. These times of onset presume rupture of amniotic membrane at or near the time of delivery. However, the conjunctiva can be inoculated before birth by an ascending bacterial infection.

Chlamydial conjunctivitis can vary in severity, ranging from mild to severe hyperemia with a thick mucopurulent discharge and pseudomembrane formation. Gonococcal conjunctivitis can present as a typical bacterial conjunctivitis. However, in its full-blown form, it presents as hyperacute conjunctivitis with profuse discharge. There often is severe edema of both lids. In marked contrast to other forms of bacterial conjunctivitis, *N. gonorrhoeae* has the capacity to invade superficial layers of the conjunctiva, causing ulceration of the cornea. If it is not treated, it can result in permanent loss of vision from corneal complications.

A Gram stain and culture should always be obtained in instances of neonatal conjunctivitis to look for *N. gonorrhoeae*. Because isolation of *C. trachomatis* requires specialized tissue cultures, proper technique should be used in collecting culture specimens (e.g., Dacron swabs) and specimens for antigen detection.

Gonococcal ophthalmia neonatorum is treated best with ceftriaxone (25 to 50 mg/kg per d IV or IM, not to exceed 125 mg) given once or as a single dose of cefotaxime (100 mg/kg IV or IM). Disseminated disease should be suspected until CSF cultures are negative. Admission is necessary, and ophthalmology consultation should be sought. Cefotaxime is recommended for hyperbilirubinemic infants. Infants with gonococcal ophthalmia should have their eyes irrigated with saline solution immediately and at frequent intervals until the discharge is eliminated. Topical antibiotic treatment alone is inadequate and unnecessary when systemic antibiotic treatment is given.

Chlamydial conjunctivitis and pneumonia in young infants are treated with oral erythromycin (50 mg/kg per d in four divided doses, for 14 days). Oral sulfonamides may be used after the immediate neonatal period for infants who do not tolerate erythromycin. Topical treatment of conjunctivitis is ineffective and unnecessary. Because the efficacy of erythromycin therapy is approximately 80 percent, a second course is sometimes required. A specific diagnosis of *C. trachomatis* infection in an infant should prompt the treatment of the mother and her sexual partners.

The neonate with a red eye and irritability also may have a corneal irritation or abrasion, usually due to an eyelash or scratch from a fingernail. Fluorescein evaluation with Wood's lamp or a slit lamp is helpful. Acute glaucoma, although rare, also presents as a red, teary eye. In these instances, the cornea may be stained or cloudy, the anterior chamber may be shallow, and the intraocular pressure may be increased. Prompt ophthalmologic referral of all suspected cases of glaucoma is needed. Infectious causes should be treated (Table 117-6) and follow-up care ensured.^{17,19}

Diaper Rash and Oral Thrush

Candidal diaper dermatitis is an erythematous plaque with a scalloped border and a sharply demarcated edge that is studded by satellite lesions. It usually occurs in the moist, occluded diaper area and intertriginous zones and usually results from the action of organisms harbored in the gastrointestinal tract. Treatment consists of a topical anti-candidal agent with each diaper change or four times daily. Protection of the area with zinc oxide paste overlying the cream will prevent friction, and local treatment with nystatin cream will prevent spread of the infection. An oral course of fluconazole is warranted in a candidal diaper rash that is unresponsive to topical therapy (see Table 117-6). More serious conditions such as *S. aureus* superinfection require oral antibiotics. Staphylococcal scalded skin syndrome or toxic epidermal necrolysis should be considered in the more severe or atypical presentations. These conditions require prompt recognition, treatment, and admission.

Oral candidal lesions are white and flaky and may involve the tongue, lips, gingiva, and mucous membranes. These lesions are common in normal newborns, debilitated infants, and those on antibiotics. Oral lesions may affect oral intake, because of pain and discomfort. Treatment of ill infants consists of treating the underlying pathology, topical oral mucosa antifungal therapy, or oral fluconazole (Diflucan) and an anesthetic gel before feeding. Cool liquids may prevent discomfort and pain.^{20,21}

Fever and Sepsis

Fever is most commonly due to acute infections. Fever is present when an infant's rectal temperature is 38°C (100.4°F) or higher as measured by a caretaker or a health care professional. Although the height of the temperature in infants older than 4 weeks suggests a bacterial etiology,

TABLE 117-6 Antibiotic Therapy for Neonatal Infections

Indication	Organisms	Antibiotic
Sepsis and meningitis	Group B <i>Streptococcus</i> <i>Escherichia coli</i> <i>Listeria</i>	Ampicillin, 200-300 mg/kg per d, div q6h IV, and Cefotaxime 200 mg/kg per d div q6h IV or Ceftriaxone 100 mg/kg per d Gentamycin 2.5 mg/kg per d IV for infants younger than 7 d or div q12h IV for infants older than 7 d
Pneumonia	Group B <i>Streptococcus</i> <i>Listeria</i> <i>Chlamydia trachomatis</i> <i>Bordetella pertussis</i>	Same as for sepsis Same as for sepsis Erythromycin 40-50 mg/kg per d div q6h PO for 14 d Erythromycin 40-50 mg/kg per d div q6h PO for 14 d or Azithromycin 10-12 mg/kg per d PO for 7 d
Conjunctivitis	<i>Chlamydia trachomatis</i> <i>Neisseria gonorrhoeae</i>	Same as chlamydia pneumonia Ceftriaxone 25-50 mg/kg per d IV or IM Cefotaxime 100 mg/kg per d IV or IM (in hyperbilirubinemia)
Necrotizing enterocolitis	Associated with <i>Escherichia coli</i> , <i>Pseudomonas</i> , and <i>Staphylococcus epidermidis</i>	Ticarcillin 300 mg/kg per d div q6h IV or IM and Gentamycin 2.5 mg/kg per d IV for infants younger than 7 d or div q12h IV for infants older than 7 d
Oral thrush	<i>Candida albicans</i>	Oral nystatin suspension 100,000 U 1-2 drops to each side of mouth q4-6h after feedings for 7-14 d Fluconazole 10 mg/kg PO loading and then 3-6 mg/kg per d for 14 d
Dermatitis	<i>Candida albicans</i>	Nystatin cream 100,000 U/g to affected area q4-6h Fluconazole 10 mg/kg PO loading and then 3-6 mg/kg per d for 14 d

there is no such correlation between height of fever and possible bacterial etiology in neonates. The risk of bacterial infection rises with the height of the temperature in infants older than 4 weeks (about 3 percent with fever above 39.4°C, 6 percent with fever above 40°C, 13 percent with fever above 40.5°C, and 26 percent with fever above 41.1°C).²²⁻²³

Recognizing neonatal bacterial sepsis early is a difficult task. Neonates have about twice the risk of serious bacterial infection as do infants 4 to 8 weeks of age. Neonatal sepsis tends to appear as an "early-onset" or a "late-onset" syndrome, with some overlap. Early-onset disease is seen in the first few days of life, tends to be fulminant, and is usually associated with maternal or perinatal risk factors, such as maternal fever, prolonged rupture of membranes, and fetal distress. Late-onset disease usually occurs after 1 week of age, tends to develop more gradually, and is less likely to be associated with risk factors. Septic shock and neutropenia are more common with early-onset syndrome, and meningitis is more common in late-onset disease.

Clinical signs of either type of sepsis are not specific (Table 117-7). Septic infants may exhibit any of a variety of symptoms, including lethargy, poor feeding, vomiting, temperature instability (hypothermia more often than hyperthermia), unexplained apnea, respiratory distress, seizures (with or without meningitis), cyanosis, tachycardia, bleeding diathesis, and hypotension.

The bacterial causes of neonatal sepsis tend to reflect the organisms that colonize the female genital tract and nasal mucosae of caregivers. In general, the two groups of pathogens most frequently encountered are gram-positive cocci, such as *p*-hemolytic streptococci, and enteric organisms, such as *E. coli* and *Klebsiella* species, and *H. influenzae*. *Listeria monocytogenes* also causes sepsis and meningitis in neonates. Viral infections comprise another common cause of fever and are most likely due to enteroviruses (coxsackievirus and echovirus) acquired at the time of delivery or RSV and influenza A virus acquired postnatally.

When a neonate is thought to be septic, microscopic analysis of CSF, blood, and urine, and cerebrospinal cultures should be obtained.

All neonates should be admitted, and intravenous antibiotics should be started. Initial treatment of a neonate with suspected bacterial septicemia or meningitis entails a combination of ampicillin and an aminoglycoside. An alternative regimen of ampicillin and cefotaxime or ceftazidime is active against gram-negative bacilli and can be used in cases when gram-negative meningitis is strongly suspected. An infant with a maternal history of herpes or suspicious CSF findings (predominance of lymphocytes and erythrocytes in a nontraumatic lumbar puncture) or ill appearance should also receive intravenous acyclovir. Febrile infants 4 to 8 weeks of age who satisfy the following criteria are at low risk and may be candidates for outpatient management:

1. No focus of bacterial infection (middle ear, skin, soft tissue, bone, or joint) on physical examination
2. Term, well appearing (alert, active, and with good muscle tone), well hydrated, and tolerating oral fluids adequately, and no respiratory distress (respiratory rate <60 breaths/min, no grunting respiration or retractions)
3. Total white blood cell counts fewer than 10/uL for CSF, fewer than 15,000/(xL for complete blood count, fewer than 10 cells/high power field for urinalysis, and negative results for bacteriuria, leukocytes, esterase, and nitrite
4. No pulmonary infiltrates on chest radiograph
5. Reliable caretaker ensuring close outpatient follow-up

The decision to administer ceftriaxone empirically pending culture results in newborns younger than 28 days or infants who do not meet low-risk criteria is routine, because potentially serious complications, such as bacteremia and septicemia, and seeding of central nervous system can result. *Streptococcus pneumoniae* is the most common cause of occult bacteremia. Routine use of the pneumococcal vaccine polyvalent, Pneumovax (intramuscular or subcutaneous injection), or the pneumococcal 7-valent conjugate vaccine, Prevnar (intramuscular injection only), has been instituted and may decrease the risk of occult bacteremia, but data are not yet available to change our current standards

TABLE 117-7 Signs and Symptoms of Neonatal Sepsis

Temperature instability
 Central nervous system dysfunction
 Respiratory distress
 Feeding disturbance
 Jaundice
 Rashes
 Fever, hypothermia
 Lethargy, irritability, seizures
 Apnea, tachypnea, grunting
 Vomiting, poor feeding, gastric distention, diarrhea

for empiric treatment. Therefore, the therapeutic benefit of administering ceftriaxone pending culture results decreases risk and outweighs cost considerations. Thorough and frequent reevaluations of these infants are essential to monitor changes in the clinical course and culture results.^{22,24}

NEONATAL SEIZURES

Recognition of seizures in the newborn period is important, because their management and implications are different than at any other age. Seizures usually indicate a severe underlying problem that is rarely idiopathic. Newborns are more likely to present with subtle manifestations, such as eye deviation, tongue thrusting, eyelid fluttering, apnea, or pedaling movements rather than generalized activity. Neonatal seizures are discussed in detail in Chap. 125.

THE NICU GRADUATE

Daniel G. Batton

Graduates of the neonatal intensive care unit (NICU) may be frequent visitors to the ED and often require rehospitalization during the year following discharge.^{1,2} Most NICU graduates are low-birth weight infants who may have a variety of complications related to prematurity. **These infants should be evaluated based on their corrected gestational age, not their chronologic age.** For example, a 32-week-gestation premature infant who is 8 weeks old should be evaluated as a term infant.

Premature infants are usually discharged from the hospital at a corrected gestational age of 33 to 38 weeks, although a few infants will be well beyond 40 weeks. The normal respiratory rate at this age is 30 to 40 breaths/min, but an infant with bronchopulmonary dysplasia usually breathes 60 to 70 times per min. The heart rate ranges from 120 to 160 beats/min while awake and is considerably lower during quiet sleep. Most laboratory values are similar to adult values, although the hematocrit can be as low as 20 to 25 percent following discharge because of physiologic anemia. By 3 to 4 months corrected age the hematocrit should have increased significantly from this nadir. When caring for NICU graduates, attention must be paid not only to the presenting signs and symptoms of the acute illness, but also to general problems related to prematurity.

GENERAL CONSIDERATIONS

Cold Stress

Following hospital discharge, premature infants remain susceptible to cold stress when exposed to lower environmental temperatures, primarily because of decreased subcutaneous tissue.⁴ Infants who are cold-stressed are not capable of responding by shivering, but instead attempt to maintain body temperature by increasing the metabolism of brown fat, which results in heat production. However, this process increases oxygen consumption and can lead to hypoglycemia. If this compensatory increase in metabolic rate is insufficient to overcome the low environmental temperature, then body temperature will fall. A normal body temperature, however, does not eliminate the possibility of cold stress, since body temperature may be maintained at considerable metabolic expense. The best way to avoid cold stress is for the ED to provide an adequate environmental temperature for the infant who is being evaluated. If the room temperature cannot be adjusted appropriately, a heat lamp should be available. Commercial heat lamps with automatic timers are available and can be adjusted to provide varying amounts of heat. Such lamps should be standard equipment in EDs that treat infants and children.

Hypoglycemia

Premature infants are at risk of developing hypoglycemia with an acute illness. This risk may be due in part to increased glucose consumption, cold stress, poor enteral intake during the illness, or suboptimal glycogen stores.⁴ Since hypoglycemia can have serious consequences, **glucose testing is necessary for all premature infants presenting with an acute illness.** If the blood sugar is less than 45 mg percent, intravenous glucose therapy (D10W at 100 mL/kg per d) may be required.

Hypertension

Longitudinal studies of convalescing premature infants have demonstrated that systemic hypertension may develop in as many as 9 percent.⁵ The possible causes include thromboembolic renal artery occlusion following umbilical artery catheterization, and bronchopulmonary dysplasia.⁶ Although the normal range is age dependent, a systolic blood pressure greater than 120 mm Hg or a diastolic pressure greater than 75 mm Hg warrants consideration of systemic hypertension.⁷

Fractures

Because of decreased bone mineralization (osteopenia), fractures of the long bones and ribs are not uncommon in premature infants during their initial hospitalization. Usually by the time of hospital discharge, bone mineralization has improved to such an extent that new fractures are uncommon, but evidence of healing fractures on x-ray examination may still be present. This fact should be kept in mind if fractures are incidentally noted on an x-ray, to avoid possible misinterpretation as a sign of child abuse. Comparison of current x-rays with previous films may help to clarify the issue.

Failure to Thrive

The establishment of consistent weight gain with oral feedings is a standard criterion for hospital discharge for most premature infants. However, this does not ensure that adequate weight gain will continue following discharge. Failure to thrive may occur either because of an ongoing chronic disease (e.g., bronchopulmonary dysplasia, malabsorption, or central nervous system disease) or because of dysfunctional parenting. NICU graduates should be consuming at least 150 mL/kg per d of a standard formula if not breast feeding and should be consistently gaining approximately 20 to 30 g/d. If appropriate growth curves⁸ are unavailable, a comparison of the current weight with the discharge weight (which parents usually remember) allows for a quick evaluation of this problem. Any infant with failure to thrive requires a thorough diagnostic evaluation and often hospitalization for accurate documentation of caloric intake. Prematurity itself is not an adequate explanation for postdischarge failure to thrive.

Immunizations

The recommendation by the American Academy of Pediatrics is to immunize premature infants on the same schedule as normal full-term infants in most cases.⁹ However, because of prolonged hospitalization and complicated follow-up, it is possible that immunizations might be missed. Inquiry about the immunization status may uncover such a situation. Although it may not be desirable to immunize an infant during an acute illness, appropriate recommendations for follow-up should be made.

ACUTE RESPIRATORY DETERIORATION IN INFANTS WITH BRONCHOPULMONARY DYSPLASIA

Although acute respiratory deterioration can occur in any NICU graduate, this discussion focuses on those infants with ongoing pulmonary

disease, such as bronchopulmonary dysplasia (BPD). BPD is usually a sequela of prematurity, hyaline membrane disease, and mechanical ventilation, although it may be associated with other conditions.¹⁰ Features of BPD include tachypnea, hypercarbia, suboptimal oxygenation, and sometimes reactive airway disease. In more severe cases, pulmonary hypertension, pulmonary edema, and cor pulmonale are prominent. The cornerstones of therapy for BPD are oxygen and nutrition. It is essential to take a medication history, since some infants will be treated with chronic diuretics, bronchodilators, or systemic steroids, although their value remains poorly defined.

Acute respiratory deterioration in patients with BPD is usually manifested by an increase in respiratory rate and effort, a decrease in oxygenation, and poor feeding. The most common causes of acute respiratory deterioration in infants with BPD are listed in Table 118-1. A careful history can usually delineate the likely etiology. For example, a history of an upper respiratory infection or fever suggests an infectious cause, which is the most common reason for an acute respiratory deterioration in a patient with BPD. Although many viruses and bacteria can be responsible for such infections, **respiratory syncytial virus (RSV) infection is particularly common in premature infants with BPD.**^{2,11} **Infants with BPD can quickly deteriorate during an RSV infection due to acute bronchospasm and airway obstruction from increased secretions.** Such infants usually require rehospitalization for close observation since many worsen to the point of requiring mechanical ventilation. Although the current recommendation of RSV immunoglobulin prophylaxis for premature infants may decrease the frequency of RSV infection requiring hospitalization,^{12,14} this is likely to remain an important cause of acute respiratory deterioration in NICU graduates, particularly for those with underlying BPD.

Sudden respiratory deterioration in a patient with BPD is usually due to aspiration, either from gastroesophageal reflux or to a poorly coordinated suck/swallow reflex. Exposure to cigarette smoke or other environmental pollutants may also precipitate acute bronchospasm. Congestive heart failure is usually accompanied by the development of peripheral edema and excessive weight gain. Dehydration is an important cause of acute respiratory deterioration, since many infants have an altered myocardial compliance (Starling curve shifted to the right), making cardiac output more dependent on end-diastolic filling. Therefore, if an infant becomes dehydrated secondary to vomiting and diarrhea or to aggressive diuretic therapy, cardiac output will decrease and secondary respiratory deterioration will follow. When evaluating and treating an infant with BPD who acutely deteriorates, there is often a temptation to initiate or increase the use of diuretics. However, if the infant is already volume depleted, diuretics will make the infant worse. Anemia may also exacerbate respiratory distress in an infant with BPD and is suggested by the presence of pallor. Infants who are not on adequate iron supplementation could have iron deficiency anemia. Acute cor pulmonale can develop secondary to hypoxemia from any of the above-mentioned causes, and deterioration can be very rapid. Effective treatment of acute cor pulmonale in infants with BPD includes treatment of the hypoxemia and its underlying cause.

TABLE 118-1 Causes of Acute Respiratory Deterioration in Infants with BPD

Respiratory infection
Sepsis
Aspiration
Gastroesophageal reflux
Incoordinate sucking or swallowing
Bronchospasm
Pulmonary edema or congestive heart failure
Dehydration
Gastroenteritis
Diuretic therapy
Anemia

The usual evaluation of an infant with BPD who has acute respiratory deterioration includes a complete blood count, arterial blood gas determination, appropriate cultures, and a chest x-ray. Since the chest x-ray can be difficult to interpret because of chronic abnormalities, it is essential to compare the current x-ray with previous films to identify acute changes. The interpretation of blood gases can also be difficult as these infants often have a compensated respiratory acidosis with P_{CO_2} values from 50 to 70 mm Hg. If a worsening respiratory acidosis is accompanied with hypochloremia, overaggressive diuretic use may be responsible. Infants who become hypochloremic from diuretics will retain bicarbonate and have a secondary increase in P_{CO_2} since they have a limited ability to compensate.

Therapy for acute respiratory deterioration should be directed toward the specific cause, but oxygenation is the cornerstone of treatment. Although BPD infants often have chronic CO_2 retention, there is no evidence that respiratory drive is decreased with oxygen administration. Therefore, oxygen should be used liberally while definitive diagnosis and treatment are contemplated. Specific therapies for BPD have recently been extensively reviewed.¹¹ Care in an ED often centers on the treatment of acute bronchospasm. Although bronchospasm may be a prominent feature, the treatment of acute respiratory deterioration in an infant with BPD is not the same as that for a child with asthma. The majority of infants with BPD who need acute bronchodilator therapy require hospitalization and observation because of the potential to require mechanical ventilation.

APNEA AND HOME APNEA MONITORS

Most infants resolve apnea of prematurity before discharge and do not require apnea monitoring at home.¹⁵ However, home monitoring is sometimes utilized for premature infants with severe apnea or if apnea persists beyond 38 weeks' gestational age.^{16,17} Infants may be brought to the ED because of an apneic episode or because the parents are not sure of the significance of an alarm. Studies have demonstrated that the majority of alarms at home are not associated with a change in cardiorespiratory status and probably represent monitor malfunction, such as that caused by loose leads.¹⁶ However, caution must be exercised before attributing an alarm to a mechanical problem with the monitor. All episodes associated with cyanosis or bradycardia, directly observed episodes of apnea (of sufficient duration, i.e., >15 s), and any episode requiring intervention, such as stimulation or mouth-to-mouth resuscitation, should be thoroughly evaluated and usually require admission. A recurrence of apnea in a premature infant who was discharged apnea-free warrants admission and a thorough search for the cause. The differential diagnosis (Table 118-2) includes respiratory infection (especially with RSV or pertussis), sepsis, gastroesophageal reflux and aspiration, aspiration during feedings, anemia, and metabolic problems such as hypoglycemia. Other more unusual causes include seizures, cardiac dysrhythmias or heart failure, and posthemorrhagic hydrocephalus. Therapy is directed toward the specific cause.

TABLE 118-2 Most Common Causes of Apnea and Bradycardia at Home in NICU Graduates

Respiratory infection (RSV or pertussis)
Sepsis
Gastroesophageal reflux and aspiration
Aspiration with feedings
Anemia
Hypoglycemia
Seizures
Cardiac arrhythmias
Posthemorrhagic hydrocephalus

POSTHEMORRHAGIC HYDROCEPHALUS

Premature infants who have had an intraventricular hemorrhage may develop posthemorrhagic hydrocephalus in the newborn period.¹⁸ Hydrocephalus can progress during the initial hospitalization, in which case the infant is usually discharged with a ventriculoperitoneal shunt in place. Hydrocephalus may also develop gradually following discharge. Such infants may present to an ED because of progressive hydrocephalus if unshunted, or shunt obstruction and/or infection. Infants with infection usually have nonspecific signs, such as poor feeding, lethargy, irritability, fever, and vomiting, similar to those of any other child with central nervous system infection. An infant with an obstructed shunt most often has a tense fontanel and a history of vomiting, although the infant usually does not appear particularly ill. A comparison of the current head circumference with the head circumference at discharge (if available) is helpful in evaluating for progressive hydrocephalus. A imaging study such as a computed tomography scan or cranial ultrasound may be necessary to fully evaluate the size of the ventricles. Empiric antibiotic therapy should be utilized whenever a shunt infection is suspected, pending culture results. Shunt infections usually require removal of the foreign body, although successful treatment without removal has been reported for *Staphylococcus epidermidis* infections. For both shunt infections and hydrocephalus, neurosurgical consultation is required.

THE EXPECTED HOME DEATH

Some infants are discharged from the NICU with lethal conditions for which further medical intervention is not indicated, and the parents are expecting the child to die at home. In many cases the parents are instructed to take the infant to the ED to be pronounced dead by a physician. The parents should be given a letter at the time of the original hospital discharge by their physicians delineating the infant's problems to provide guidance to the emergency physician facing such a situation. This is a very traumatic time for the parents. A futile resuscitation effort is not appropriate and can prolong the parents' agony. It is very important to request autopsy permission in such cases to completely delineate the infant's problems and to provide optimal counseling for future pregnancies.

SIDS (SUDDEN INFANT DEATH SYNDROME) AND ALTE (APPARENT LIFE-THREATENING EVENT) Carol D. Berkowitz

Sudden death may affect persons of any age, but it is especially devastating when it affects previously healthy individuals. In the past, between 5000 and 10,000 infants (1 to 2 per 1000 live births) succumbed yearly to sudden infant death syndrome (SIDS), also known as *crib death*. With recent changes related to infant position during sleep, the number of deaths has decreased to about 3000 and the rate to about 0.8 deaths per 1000 infants.

The term *sudden infant death syndrome* was officially designated in 1963 to describe a syndrome of unexpected death in infants younger than 1 year for which no pathologic cause could be determined by a thorough postmortem examination. The syndrome has been a leading cause of death of infants between 1 month and 1 year of age.

An understanding of SIDS is essential for emergency physicians so that they can recognize the syndrome, initiate resuscitation, manage infants who have experienced an apparent life-threatening event (ALTE; previously termed *near-miss SIDS*), and counsel the family of the victim.

PATHOPHYSIOLOGY

More than 70 different theories for SIDS have been proposed, including suffocation from sleeping with a parent, milk allergy, and thymic enlargement (status thymicolymphaticus). The main disturbance in some victims appears to be with the infant's ventilatory response, and SIDS and infantile apnea appear related, although the exact nature of this relation is uncertain. There are multiple causes of infantile apnea for which the final pathway involves respiratory muscle fatigue. Death is due to respiratory rather than to cardiac arrest, and some potential SIDS victims may be successfully resuscitated with ventilation alone. Dysrhythmias probably occur only as a terminal event, and syndromes such as prolonged QT interval or Wolff-Parkinson-White syndrome are rare associations.¹ Prospective studies monitoring normal infants showed no antecedent dysrhythmias in infants who eventually succumbed to SIDS. Conversely, approximately 2 percent of premature and low-birth-weight infants experienced bradycardia (fewer than 50 breaths/min) without apnea 1 week after discharge.

Information implicating ventilation disturbances and hypoxemia has been obtained from two sources: autopsies of infants who succumbed to SIDS, and studies of those who experienced an ALTE but survived. The ALTE group comprises infants who were found limp, cyanotic, pale, and lifeless, showed no respiratory effort, but who were successfully resuscitated.

Autopsies of some SIDS victims showed pathologic changes initially felt to be indicative of longstanding hypoxemia. These changes included smooth muscle thickening in small pulmonary arteries, right ventricular hypertrophy, hematopoiesis in the liver, increase in peri-adrenal brown fat, adrenal medullary hyperplasia, and abnormalities of the carotid body. Markers now reported with regularity include brainstem gliosis and increased neuronal apoptosis in the brainstem and hippocampus.

Recently, much attention has been given to SIDS and sleeping in the prone position.^{2,3} Epidemiologic studies indicated that the incidence of SIDS is lower in countries where infants sleep supine or in the side-down position, and that a reduction in the incidence of SIDS follows a reduction in prone sleeping. Concern about aspiration in infants sleeping in the supine position are unfounded. Two mechanisms linking SIDS to prone sleeping are noted. With prone sleeping, infants will assume a face-down position, particularly in response to a cold stimulus on the face. This may result in upper airway obstruction. However, upper airway obstruction has not been observed in clinical trials; rather, infants were found to rebreathe expired air and experience hypercarbia.⁴ Because of these observations related to the prone position, the American Academy of Pediatrics now recommends a supine or side-sleeping position for normal infants.

The link between child abuse, SIDS, and ALTE has also received renewed interest.⁵ Familial cases of SIDS raise the possibility of abuse. Some investigators reported that 10 percent of SIDS cases are due to abuse. Some children with ALTE have been purposefully asphyxiated, and in some cases the complaints have simply been fabricated. These problems are referred to as *Munchausen syndrome by proxy*. The use of in-hospital covert video-surveillance cameras has sometimes facilitated substantiating this diagnosis. Child abuse is the diagnosed cause of death in about 2000 cases a year. The presence of bruises, long-bone fractures, rib fractures, internal hemorrhages, evidence of physical neglect, or trauma around the nares suggests abuse. Rib fractures in infants are not induced by cardiopulmonary resuscitation. A history inconsistent with the usual events surrounding a SIDS death also may raise the suspicion of abuse. In addition, some infants with abusive head trauma may present with nonspecific symptoms including apnea.⁶ Appropriate diagnostic studies should be initiated to establish the correct diagnosis. An interesting report on death-scene investigations found circumstantial evidence of accidental death in 23 of 26 infants studied.⁷ It is beyond the scope of emergency physicians to conduct such investigations. However, more and more communities have extensive databases that are filled in when SIDS is suspected. In addition, Child Death Review Boards are convened to ensure the full evaluation of sudden and unexpected death among children. It is important, however, to be aware of the possible role of accidental or intentional trauma in some SIDS victims.

SIDS and Apnea

Four groups of infants who appear at increased risk of SIDS have been identified: (1) term infants who have had an ALTE, (2) premature infants of low birth weight, (3) siblings of infants who have succumbed to SIDS, and (4) infants of substance-abusing mothers.⁸

Studies of infants with ALTE may reveal (1) hypoventilation (partial pressure of carbon dioxide > 45 mm Hg) and chronic hypoxemia, (2) a depressed ventilatory response to CO₂ breathing, (3) prolonged sleep apnea (>15 s, associated with cyanosis or pallor), (4) bouts of frequent short apnea, (5) increased periodic breathing (characterized by repeated 3-s pauses in breathing followed by normal breathing for shorter than 20 s with bradycardia), (6) obstructive apnea, and (7) mixed obstructive and central apnea.

Southall⁹ described three separate components associated with respiratory abnormalities in infants.

First, there is central apnea, in which immaturity, tumor, head injury, infection, or congenital malformation leads to primary failure of

respiratory center control. In addition, peripheral chemoreceptors act abnormally, particularly in response to hypercarbia and hypoxia. The dive reflex may contribute to apnea on a central basis. Young monkeys receiving a cold or wet stimulus to the face in the area of the trigeminal nerve stop breathing. This situation may be analogous to a young infant lying in a regurgitated feeding. Alternatively, this stimulus may lead to a face-down sleeping position and airway obstruction.

Airway obstruction is a second component. Obstructive apnea may occur in response to nasal occlusion, as with an upper respiratory infection, and is noted with tonsillar enlargement, hypotonia of the hypopharynx, or glossoptosis. It is a contributing factor in about 5 percent of ALTE episodes. It is detected by the presence of increased chest wall movement, with bradycardia and decreased partial pressure of oxygen (by surface oximeter). It is a contributing component to SIDS in infants with upper respiratory infection.

The third and most significant component is expiratory apnea. Prolonged expiratory apnea is associated with sudden atelectasis. Ventilation perfusion inequalities, hypoxia, and sudden cyanosis occur within 5 to 10 s. There is a rapid loss of consciousness. These episodes may occur even in the face of nasotracheal intubation. In older children, they may occur with crying, as cyanotic breath-holding spells.

Acute hypoxic episodes are felt to occur in 80 percent of SIDS cases.

EPIDEMIOLOGIC FACTORS

The diagnosis of SIDS is confirmed by autopsy, but many clinical and epidemiologic features characterize the syndrome. Although the overall incidence is now about 0.8 per 1000 live births, there is variation among different ethnic groups, with an incidence of 0.51 per 1000 among Asian Americans and 5.93 per 1000 among Native Americans. Some of the current ethnic variability in the incidence of SIDS may be related to compliance of caregivers' placing infants in the supine position. Victims range in age from 1 month to 1 year, with peaks at 2 months 2 weeks and at 4 months. The infant frequently has been premature or small for gestational age. Although initial reports suggested a higher incidence of SIDS among premature infants with bronchopulmonary dysplasia, this association has not been confirmed by more recent studies.

The syndrome is rare in the first month of life, probably because the neonate has a better anaerobic capacity for survival, and with a gasp may be able to raise his or her arterial partial pressure of oxygen over 20 mm Hg and continue breathing. Of the infants who are otherwise healthy, 30 to 50 percent have some acute infection, usually of the upper respiratory tract, at the time of the event. Infection with respiratory syncytial virus has been associated with apnea, particularly in premature infants and those with an antecedent history of apnea. Otitis media and gastroenteritis also have been associated with SIDS. Infected infants tend to be older than noninfected infants, and males outnumber females in the infected group by 2:1. The sex ratio is equal in the noninfected group. There is a disproportionate number of babies from the lower socioeconomic group, although this is true for deaths in infancy from all causes. Mothers frequently are younger than 20 years and unwed, smoke, use drugs, and have made few prenatal and postpartum visits. Prenatal and postnatal maternal smoking increase the incidence of SIDS. Sudden infant death syndrome is more likely to occur during the winter months and when the infant is asleep.

A disproportionate number of infants succumb to SIDS while with a babysitter.¹⁰ Many of these infants have been found in the prone position. For some infants, this is the first time they have been placed in the prone position, and investigators have proposed that these infants have poor strength and tone in their neck muscles. Further, some infants may have acquired an upper respiratory infection in day-care centers, a phenomenon that is well described for that setting.

The issue of the relation between co-sleeping and SIDS is controversial.^{11,12} Several studies have reported an increased incidence of co-sleeping or sleeping on an inappropriate surface among SIDS victims.

Parental intoxication or substance abuse appears to be a related factor. In one study, only 1 of 40 children who had died from SIDS while co-sleeping had been supine on an appropriate surface at the time of death.

CLINICAL FEATURES

A number of scenarios may confront physicians in the ED. These scenarios mirror the range of problems that may be broadly categorized under the heading of SIDS or of ALTE (Table 119-1).

Some infants appear completely well at the time they are examined, and the parents may relate a history of cessation of respiration. The physician must then determine whether the event represented an episode of apnea, was severe enough to be life threatening, or represented a different disorder.

The sequence of events before the episode may be a clue to the cause (Table 119-2). If the infant stiffened or exhibited clonic movements, the cessation of respiration may have been postictal apnea after a seizure. With a seizure, an infant is frequently awake before becoming apneic. Gastroesophageal reflux may lead to apnea and also may occur in awake infants after a feeding. A history of an upper respiratory infection followed by paroxysmal cough with an apneic episode suggests pertussis. Hypoglycemia also may be associated with apnea, with or without a seizure. The differential diagnosis also includes infection (sepsis or meningitis) and cardiomyopathy. Infantile botulism may be the cause in 5 to 10 percent of SIDS victims.

The evaluation of healthy-appearing infants with a history of apnea is problematic. Occasionally, parents may have misinterpreted acrocyanosis, postprandial regurgitation, or skin color change with stooling as an episode of apnea. The parents should be carefully questioned about what they did to revive the baby, for example, stimulation or mouth-to-mouth resuscitation. No resuscitative efforts suggest a benign event. Conversely, the need for mouth-to-mouth resuscitation indicates a more serious event. The finding of irregular respiration or poor muscle tone on physical examination would assist in the diagnosis of an ALTE.

Some infants who have experienced an ALTE have not been fully resuscitated in the field. They should receive the benefit of vigorous cardiopulmonary resuscitation, unless signs of irreversible death (livedo reticularis, blood pH of 6, or boxcar venous pooling in the fundi) are apparent. Frequently the heart will resume beating after prolonged arrest. The infant heart is a remarkably resistant organ and may be revived after irreversible brain damage.

DIAGNOSIS

The evaluation of an infant who has experienced an ALTE should include a complete medical history, particularly of the event itself, and

TABLE 119-1 Risks for SIDS and ALTE

SIDS risks

Term infants with an episode of ALTE
Premature low-birth-weight infants
Siblings of an infant who died of SIDS
Infants of substance-abusing mothers

ALTE risks

Respiratory center immaturity
Hypoventilation and chronic hypoxemia
Depressed ventilatory response to CO₂
>15 s of sleep apnea, with cyanosis or pallor
Increased periodic breathing: 3-s pauses, apnea >20 s, and bradycardia
Prolonged expiratory apnea
Obstructive apnea
Apnea related to upper respiratory infection

Abbreviations: ALTE = apparent life-threatening event, SIDS = sudden infant death syndrome.

TABLE 119-2 Conditions That May Present as an Apparent Life-Threatening Event

Child abuse
Gastroesophageal reflux
Infantile botulism
Inborn errors of metabolism
Intracranial hemorrhage
Pertussis
Respiratory syncytial virus infection
Seizure
Sepsis

take into account the perinatal and epidemiologic factors associated with SIDS and ALTE. A history of other infant deaths in the family should be obtained because of the familial incidence of SIDS. Familial cases of SIDS suggest the possibility of child abuse or of inborn errors of metabolism, such as disorders of fatty acid metabolism.¹³ Autopsy results in a small subset of infants who succumbed to SIDS showed findings such as microvesicular steatosis of the liver, a sign of a disorder of fatty acid metabolism. Sometimes, sudden unexpected death has occurred in other siblings within these affected families. Initial reports suggested that siblings of SIDS victims are at increased risk (about 10-fold) for subsequent SIDS. More recent studies showed at most a twofold increase in the incidence of SIDS among SIDS siblings.

The physical examination should be complete, with special emphasis on the neurologic evaluation and the presence of any injuries. The initial laboratory assessment should include a complete blood cell count; determination of levels of serum electrolytes, blood sugar, calcium, phosphate, and magnesium; and a 12-lead electrocardiogram. A septic workup, including blood culture, cerebrospinal fluid analysis, urine culture, and chest x-ray, is indicated in most cases, although studies have shown a negligible yield in the absence of associated findings such as fever. Nasopharyngeal washings for respiratory syncytial virus or other viral assays are indicated if there are signs of an upper respiratory infection. In an infant with an ALTE, the stool should be sent for clostridial culture and botulinum toxin testing, especially if hypotonia is present. Other studies should be done when suggested by the history and physical examination; these include determination of serum ammonia, urinary organic acids, sleep and awake electroencephalograms, skull x-rays, barium swallow, and computed tomography.

TREATMENT

Initial treatment in the ED involves continued resuscitation of the infant, if necessary, and stabilization. In general, all ALTE victims and infants with a history of apnea and/or cyanosis should be admitted to the hospital. The evaluation of these infants is designed to rule out treatable causes of apnea and to determine whether, in the absence of these other causes, the infant is at risk for SIDS, an event reported in 20 to 100 percent of infants with an ALTE.

Apnea should be monitored in the hospital. Most hospitals can obtain pneumograms, which provide evidence of abnormalities related to periodic breathing or episodes of apnea. Polysomnography measures the amount of air flowing in at the mouth and nose and can detect obstructive apnea; the test is complicated and generally done in a sleep laboratory. Certain tertiary care centers are equipped to evaluate responses to CO₂ breathing and diminished inspiratory oxygen.

HOME MONITORING

Two major treatment modalities are recommended for infants who have experienced an ALTE or are at risk for SIDS. Xanthine derivatives such as caffeine and theophylline are used frequently in treating apnea of prematurity because of their central excitatory effect. Their use is asso-

ciated with the normalization of the respiratory pattern in more than 80 percent of such children. Their efficacy in the prevention of SIDS is unclear. A pragmatic approach to the use of xanthine derivatives would be to limit them to infants with abnormal pneumograms. Reversal of these abnormalities with either medication would be an indication for its use. Theophylline is given at 6 mg/kg per d and caffeine at 5 to 7.5 mg/kg per d, and a serum level of 5 to 15 mg/mL should be maintained.

Home apnea monitoring is the second modality that can be offered. Three groups were defined in a National Institutes of Health Consensus Statement in 1986 as being candidates for home monitoring. The first group consists of term infants with unexplained apnea of infancy, usually manifested by a life-threatening episode and/or abnormal pneumogram. The absence of an abnormal pneumogram does not preclude home monitoring. The second group consists of preterm infants who have continued to manifest apnea beyond term (i.e., after 40 weeks postconception). The third group consists of subsequent siblings of two or more SIDS victims, but not of one SIDS victim. Twins of SIDS victims were reported to have a 20-fold increase in their risk for SIDS. More recent studies suggested their chance is the same as for non-twin siblings. Additional candidates for home monitoring include infants with bronchopulmonary dysplasia, especially if oxygen dependent, and infants who require tracheostomy for airway support.

Home-monitoring devices usually measure chest wall movement and heart rate. The detection of bradycardia is particularly important in infants with an obstructive component, because chest wall movement is not diminished with obstructive apnea. Parents must be instructed in equipment maintenance, interpretation of the alarm, and cardiopulmonary resuscitation. Home monitoring does not mean simply supplying a family with a mechanical device. It involves the development of a medical team to support the family, interpret any episodes of apnea, and decide when home monitoring can be discontinued. Technicians who are available 24 h a day to maintain the equipment are also required.

Emergency physicians are frequently consulted about monitor alarms. Infants are brought to the ED because of alarm triggering. Physicians must be able to differentiate a false alarm from a true episode. The need for vigorous stimulation or mouth-to-mouth resuscitation suggests a serious episode. If there is concern about equipment malfunction, technical assistance should be obtained from the monitoring company.

The use of home monitors has increased dramatically in recent years. The estimated cost of monitoring (including initial assessment) ranges from \$3000 to \$5000 per infant, with monthly rental and maintenance costs ranging from \$150 to \$300. Although parental anxiety is frequently reduced, the reduction in the incidence of subsequent SIDS in monitored infants is questioned. Reports found a mortality rate as high as 50 percent among infants on home monitoring. In many cases, technical errors and parental noncompliance contributed to the infant's demise. Some infants, however, simply failed to respond to aggressive cardiopulmonary resuscitation.

The decision to discontinue monitoring is usually made by an infant's primary physician. In general, most infants remain on a monitor for 6 to 8 months. Criteria for discontinuing the monitor include 2 to 3 months with no episodes requiring stimulation or resuscitation, 3 months without apnea of 20 s or longer, no apnea associated with an upper respiratory infection or immunization, and an improvement in any neurologic problem for which the monitoring was instituted (e.g., apnea associated with seizures).

THE SIDS VICTIM

The management of a nonresuscitative SIDS infant and the infant's family is equally challenging for a physician. The emergency physician is confronted by the distraught mother who had fed her infant several hours earlier, went to check the sleeping infant, and found the baby cold, blue, and lifeless. Frequently, valiant albeit unsuccessful

efforts are carried out in the ED, or the infant is revived briefly, only to succumb after several hours in the intensive care unit.

The major responsibility of the physician is then to notify, counsel, and educate the family. In most jurisdictions, victims of sudden and unexplained deaths must be referred to the coroner's office, where an autopsy is performed at the coroner's discretion. Some jurisdictions have infant death teams that fully evaluate the circumstances surrounding the unexpected death of young infants. If the physician believes the infant is a victim of SIDS, the family should be so advised but told that the final confirmation awaits the autopsy report. The emergency physician should assure the family about their lack of responsibility for the infant's death and assuage their feelings of guilt. The physician should then serve as a facilitator by maintaining contact with the family to advise them of the autopsy results. The hospital chaplain or social worker may provide additional support, but the physician's empathy is especially supportive to the family. Most communities have organizations for parents of SIDS victims, and information about these organizations can be obtained from the SIDS Alliance, 10500 Little Patuxent Parkway, Suite 420, Columbia, MD 21044, 1-800-221-SIDS. Parents also may be referred to Web sites such as <http://www.sidsfamilies.com>.

bilization, and appropriate tertiary referral a challenge. In the ED, problems may range from an asymptomatic discovery of a murmur to the life-threatening presentation of a cyanotic infant in cardiogenic shock.

Congenital heart disease is usually classified based on physiology (presence or absence of cyanosis, with or without persistent fetal circulation) or on the nature of the anatomic defect (shunt, obstruction, transposition, or complex). Most pediatric heart disease is congenital, but acquired conditions also occur and include complications secondary to rheumatic fever, Kawasaki disease, and severe chronic anemias, as well as myocarditis, pericarditis, endocarditis, and the tachy dysrhythmias.

Pediatric heart disease can also be classified by clinical presentation. The six common clinical presentations to primary care physicians are cyanosis, congestive heart failure, pathologic murmur in asymptomatic patients, abnormal pulses, hypertension, and syncope. Table 120-1 lists the most common lesions in each category. While this is informative in the formation of a broad differential diagnosis in very ill pediatric patients, it is perhaps best to classify heart disease according to the clinical presentation in the ED. Most often, this presentation is in children with previously undiagnosed heart disease and to a lesser degree in those with previously diagnosed heart disease or reparative surgery for the same.

Children with previously undiagnosed heart disease can be broadly classified into three categories: unstable, stable but symptomatic, and stable and asymptomatic. Unstable infants usually require immediate and decisive stabilization and aggressive management before diagnostic studies or tertiary referral can be made. Pediatric cardiology consultation should be emergently sought from the regional tertiary care center before pharmacologic intervention, if at all possible. Stable and symptomatic infants require less-aggressive measures, so there is time to focus on physiologic derangement and correction of abnormalities of oxygenation and metabolism and time for tertiary referral. A baseline electrocardiogram (ECG) and chest radiograph are indicated in such infants, particularly when a murmur appears to be pathologic (grade 3 or louder, holosystolic or diastolic in timing, and/or radiating away from the heart). Stable but asymptomatic infants can easily be referred routinely based on findings on general examination. Such infants can be electively evaluated without specific testing in the ED. Recent, well-publicized cases of pediatric sudden death from unrecognized pediatric heart disease are rare, but such infants arrive in extremis at the ED. This represents a final presentation type of pediatric heart disease that is tragic because such infants cannot often be resuscitated, even by physicians with expertise in pediatric heart disease.

Children with known heart disease arrive at the ED for treatment of routine illnesses, as well as for problems related to their unique disease. Rarely, they arrive with acute life-threatening cardiovascular complica-

TABLE 120-1 Clinical Presentation of Pediatric Heart Disease

Cyanosis	TGA, TOF, TA, Tat, TAVR
Congestive heart failure	See Table 115-3
Murmur/symptomatic patient	Shunts: VSD, PDA, ASD Obstructions Valvular incompetence
Abnormal pulses	
Bounding	PDA, AI, AVM
Decreased with prolonged amplitude	Coarctation, HPLV
Hypertension	Coarctation
Syncope (see Chap. 131)	
Cyanotic	TOF
Acyanotic	Critical AS

Abbreviations: AI = aortic insufficiency; AS = aortic stenosis; ASD = atrial septal defect; AVM = arteriovenous malformation; HPLV = hypoplastic left ventricle; PDA = patent ductus arteriosus; TA = truncus arteriosus; Tat = tricuspid atresia; TAVR = total anomalous venous return; TGA = transposition of the great arteries; TOF = tetralogy of Fallot; VSD = ventricular septal defect.

PEDIATRIC HEART DISEASE C.

James Corrall

Pediatric cardiovascular disorders are decidedly uncommon in emergency medicine. The combination of the low incidence and the age-related differences in clinical presentation make timely recognition, sta-

tions. Once the knowledge of preexisting heart disease is known, the physician can anticipate complications related to the unique disease, such as hemoconcentration caused by polycythemia, bacterial endocarditis, or embolism. Only infrequently do such infants have abnormal immune systems, and most handle routine pediatric illnesses well.

CARDIOVASCULAR PHYSIOLOGY

It is important to understand the interplay between normal cardiovascular dynamics in pediatric patients and the age-related changes that occur during transition to the extrauterine environment. This understanding is necessary in order to recognize the signs and symptoms of pediatric heart disease and to plan therapy appropriate to the physiologic derangement.

Perhaps the most dramatic change that occurs at birth is the transition from fetal to postnatal circulation. Immediately following birth, flow through the umbilical arteries ceases and the venous flow through the cord slows and then stops. These vascular changes are mediated by the rapid increase in partial pressure of arterial oxygen (P_{aO_2}) that occurs during lung inflation. Following lung expansion, pulmonary vascular resistance falls and pulmonary blood flow increases. The pulmonary vascular resistance will continue to fall with increases in blood flow over the next 30 to 45 days of extrauterine life. The ductus arteriosus also closes with the rise in P_{aO_2} , and blood shunted through a patent foramen ovale ceases. In time, these shunt channels permanently close but, until then, may reopen under conditions of decreased partial pressure of oxygen (P_{O_2}) or other stresses.¹

Because neonates and small children have limited ability to increase stroke volume because of the relatively noncompliant ventricular walls, they rely on changes in heart rate to adjust the cardiac output. Thus, sinus tachycardia is usually the first response to stress in infants and children and is mediated by the intrinsic pacemaker in the sinoatrial node and by various adrenergic, hormonal, and neural mediators.

Preload is the amount of blood that the heart receives to distribute to the body. Decreasing the amount of blood flowing into the heart lowers the cardiac output. Preload can be reduced by pharmacologic means such as by the use of intravenous nitrates or by blood loss. Similarly, increasing the amount of blood into the heart will increase the cardiac output in accordance with Starling forces, until the point of maximum compliance of the ventricular wall. At this point, cardiac output decreases dramatically and congestive heart failure occurs.

Afterload is the resistance to blood flow out of the heart. Afterload may be increased anatomically in neonates by an obstructive lesion, such as aortic stenosis or critical coarctation of the aorta. Afterload depends on the size of the ventricle and its compliance or elasticity. The compliance in the neonatal heart is limited, so afterload reaches critical values early. Afterload also depends on the amount of arteriolar resistance in the case of pediatric hypertension unrelated to obstructive lesions in the proximity of the heart and great vessels. Treatment of afterload problems is directed at arterial vasoconstriction or vasodilatation.

Contractility or inotropy, which is the ability of the cardiac muscle to pump blood out of the heart, refers to the force or power of the contraction and determines the amount of work that the heart can perform. Increasing the cardiac contractility increases the stroke volume and hence the cardiac output. Cardiac contractility is normally regulated by neural or humoral mechanisms. It may be altered pharmacologically by such medications as digoxin or dobutamine.

Cardiac rate or chronotropy is the ability of the heart muscle to pump blood out of the heart per fixed unit of contraction. In the typical circumstance, chronotropy and inotropy cannot be differentiated with regard to therapeutic maneuvers. Typically, both the cardiac rate and the relatively fixed contractility of the neonatal heart contribute to the overall cardiac output, with the former contributing more of the output. In pediatric hearts older than 4 to 5 years, there is a more balanced contribution to cardiac output, with the contractility playing a much more prominent role.

THERAPEUTIC PRINCIPLES

All of the medical management provided to children with heart disease is directed toward increasing cardiac output in low-output states by alteration of the heart rate, preload, afterload, or inherent contractility. As mentioned previously, some of these parameters may be rather fixed due to the inherent limitations of the neonatal ventricular noncompliance.

Heart rate is the most malleable of the cardiac physiologic parameters. Symptomatic bradycardias of all types are treated with oxygenation, atropine and, in severe cases, with epinephrine and/or isoproterenol followed by transthoracic pacemaker and transvenous pacemaker usage. Symptomatic tachycardia must be differentiated into sinus, supraventricular, or ventricular before specific therapy can be initiated.

Preload disorders are common in children and are most frequently caused by shock states with resultant hypovolemia that causes the decreased preload. Hypovolemia may be a result of increased loss of total body water, such as occurs in excessive diarrhea or vomiting, or it may be a relative loss of volume because of maldistribution. In the latter circumstance, distributive forms of shock such as in sepsis, neurogenic spinal shock, or anaphylaxis produce relative hypovolemia secondary to increased vasodilation and decreased venous return to the heart. In congestive heart failure, preload is markedly increased when the left atrial pressure becomes elevated. The resulting Starling forces produce pulmonary edema and its resultant hypoxemia. The hypoxemia reduces contractility, further increasing the left atrial pressure and accentuating the increased preload state. Treatment of such a state requires diuretics and vasodilation to reduce preload.

Adequate oxygen delivery is necessary for the myocardium during the diastolic filling phase. The oxygen supply depends on the P_{O_2} of the blood, the hemoglobin concentration, and the coronary perfusion pressure. Hypoxemia results from deoxygenated venous blood entering the systemic circulation by vascular shunts that may be present at any location. Hypoxemia caused by most vascular shunts responds poorly to increasing ambient inspired oxygen. In contrast, most respiratory causes of hypoxemia respond to increasing oxygen.

Anemia profoundly decreases the amount of oxygen available to the tissues by decreasing the amount of oxygen bound to hemoglobin per unit of cardiac output. Transfusions of 10 mL packed red cells per kg will raise the hemoglobin approximately 1.5 g/dL and provide improved oxygen-carrying capacity to the tissues. In special circumstances, other competing agents, such as methemoglobinemia and carboxyhemoglobinemia, with increased affinity for oxygen must be excluded.

Myocardial perfusion can only occur during the relaxation phase provided during diastole. The perfusion is markedly impaired under conditions of low cardiac output. Because the coronary perfusion pressure is the difference between the diastolic pressure minus the coronary sinus venous pressure, it follows that any situation that lowers diastolic pressure to 30 to 40 mm Hg can lead to poor coronary perfusion, myocardial ischemia, and subsequent ECG changes reflecting injury. Treatment of low diastolic pressure includes infusion with α -adrenergic agents such as phenylephrine, norepinephrine, and epinephrine to raise the diastolic pressure and coronary artery perfusion. Other factors are also important to augment perfusion, but are not as amenable to therapy by emergency physicians.

Severe acidosis adversely affects myocardial contractility and may be persistent after hypovolemia has been corrected. Sodium bicarbonate may rapidly improve contractility in such situations. If acidosis is caused by respiratory failure, airway control with endotracheal intubation and mechanical ventilation is useful to correct the hypercapnia and to decrease the metabolic demand generated by trying to overcome respiratory failure. Temperature control is also important because elevations cause an increase in oxygen consumption, causing a marginal cardiovascular system to fail. Ideally, a neutral thermal environment should be maintained to avoid such stress. Hypoglycemia frequently occurs during stressful events, and neonates are less able to

respond because of decreased glycogen stores and minimal fat necessary for gluconeogenesis. Low serum glucose of less than 40 mg/dL should be corrected with an infusion of either D25 or D10 solution. Electrolyte disturbances can interfere with both inotropic and chronotropic responses to decreased cardiac output. Appropriate monitoring of concentrations of potassium, calcium, magnesium, sodium, chloride, phosphate, and bicarbonate is prudent. Finally, attempts must be made to minimize stress in ill neonates. Alleviation of external stressors such as tubing manipulation or skin care should be minimized to increase oxygen availability by decreasing agitation. Phlebotomy should be minimized, and parents should be present to console the child.

ASSESSMENT OF CHILDREN SUSPECTED OF HAVING HEART DISEASE

Children with heart disease may present with symptoms unrelated to the underlying disease, and careful neurologic, pulmonary, and cardiac assessment must be performed to determine the stability of patients and the need for supportive care. From a cardiovascular perspective, this assessment determines whether the cardiac output is low, normal, or hyperdynamic. Concurrent conditions often exist, making definition of physical findings challenging. For instance, the symptoms and signs of increasing pulmonary venous pressure and the signs of a viral upper respiratory tract infection appear similar. What appears to be a feeding disorder with easy fatigue during routine feeds may represent congestive heart failure, particularly if diaphoresis is present with labored breathing.

The physical examination of children with significant congenital heart disease is often not as dramatic as the diagnosis of congestive heart failure in adolescents. In the author's experience, unrecognized congenital heart disease in small infants is often not diagnosed until the second or third visit to the emergency department for the same illness. Most often, that illness is misdiagnosed as a viral upper respiratory illness or a feeding intolerance.

When a child with known cardiac problems presents to the ED, the historical information that must be obtained by the emergency physician is problem focused and directed toward known complications of the congenital defect. A detailed history of medications administered and recent changes in dosages and timing of administration are important in such children. New illnesses, particularly of the upper respiratory tract, should be identified. Simple common pediatric illnesses such as croup, pneumonia, or bronchiolitis may cause sudden decompensation in a child with limited cardiac reserve. These illnesses may be difficult or impossible to differentiate clinically from an exacerbation of known cardiac disease. The symptoms and signs of increased right heart failure and critical pulmonary venous pressure states and respiratory illness often overlap and are indistinguishable without echocardiography.

Exertional dyspnea is often present, but overlooked, in older children with cardiac disease. In infants, feeding intolerance is the most reliable marker of exercise tolerance. Historical evidence of slow feeding, increased tachypnea with feeding, persistent staccato cough with feeding, and diaphoresis at midfeeding all suggest borderline cardiac reserve.

In small infants, tachypnea is often the first sign manifested, followed by rales that are more typical of congestive heart failure. Hepatomegaly usually develops late and is more marked than splenomegaly. In small infants, edema is usually generalized and not associated with jugular venous distention. Accurate blood pressure measurement in infants requires an appropriately sized cuff (approximating two-thirds of the extremity). Blood pressure should be measured in both upper and lower extremities. Cardiac murmurs should be graded according to location, timing in the cardiac cycle, and loudness. There may be significant cardiac pathology in the absence of murmur and, conversely, a very loud murmur may be innocent. The

pediatric-sized stethoscope bell and diaphragm should be used to discern the exact location of murmurs. Heart sounds should also be assessed particularly for fixed splitting of the second heart sound.

Focused cardiac examination must address the difference between pathologic and innocent cardiac murmurs. In one study of newborns 1 to 5 days with a murmur, 86 percent had structural heart defects.² Usually, innocent flow murmurs are of low intensity and do not radiate. They are brief in the cardiac cycle and usually systolic in timing. They are never holosystolic and are usually accentuated by head position or Valsalva maneuver.³

The Still murmur, which is the most common innocent murmur, is usually early systolic in timing, located at the apex or the lower left sternal border, and is often confused with the murmur of a ventricular septal defect (VSD). It usually does not radiate to the back like the murmur of a VSD. Pulmonary systolic ejection murmur, which is equivalent to the Still murmur, is extremely harsh and is usually heard loudest in the second and third intercostal spaces on the left. A unique murmur, often heard in neonates, is that of peripheral pulmonic stenosis. This murmur is usually of low intensity, is usually heard in both axillae and the back, and usually vanishes by 3 to 6 months of age. It is often misdiagnosed as a congenital lesion in sick infants and results in inadvertent administration of cardiotonic medication. Significant cardiac murmurs are usually holosystolic, continuous or diastolic in timing and usually associated with radiation.^{3,4}

Laboratory studies are usually not initially helpful in acutely ill, hemodynamically unstable patients, but may be of some benefit in more stable pediatric patients. Such studies are usually confined to chest radiograph, ECG and, in some centers, bedside emergency ultrasonography.

Chest radiographic studies are essential in assessing the size and shape of the heart, and in evaluating pulmonary blood flow. The chest radiograph also provides some information about the position of the aortic arch, which should be normally left sided. In the normal left-sided aortic arch, there is rightward displacement of the esophagus and trachea to the right. An abnormal right position of the aortic arch may be a clue to the diagnosis of the congenital cardiac lesion. Right-sided aortic arches are seen in truncus arteriosus, transposition of the great vessels, tetralogy of Fallot, tricuspid atresia, and total anomalous pulmonary venous return. The chest radiograph is critical to the assessment of pulmonary vascularity. In small left-to-right shunts, the pulmonary vascularity is normal. Pulmonary vascularity can also be normal in conditions that cause pulmonary stenosis, such as valvular pulmonic stenosis or functional pulmonic stenosis associated with tetralogy of Fallot. Increased pulmonary vascularity may be seen with any cause of left-to-right shunting or in any cause of left-sided failure, such as ischemia or outflow obstruction.

The ECG is useful to evaluate cardiac conduction and, in particular, the rhythm, electrical axis, chamber size. Such information is clearly age related and will require one to have access to a standard text of normal values of pediatric ECG voltages and criteria for ventricular hypertrophy.⁵ The electrical force axis most often defines abnormal chamber diameters and usually does not suggest cardiac ischemia as in the adult population.

Hemodynamically Unstable Patients

Clinical signs of low cardiac output are manifested by signs of dysfunction of one or more organ systems. Shock is diagnosed by determination of skin perfusion and mental status appropriate for age. Additional information may be obtained by assessment of the distal pulse quality, amplitude, and duration. Pallor, cyanosis, and skin mottling are usually present. The infant's hands and feet appear cold, and there is delayed capillary refill that is very distinct from acrocyanosis present in some infants. Mental status changes appear as fluctuating signs of apathy, irritability, or failure to respond to painful stimuli or to parental presence. Body positioning is that of prostration with loss of

head control and is preferred to that of upright sitting or standing. Sinus tachycardia is the first response to maintenance of cardiac output, followed by tachypnea in an attempt to correct the acidosis of poor perfusion and oxygen delivery. Hypotension occurs late, is dramatic in its onset, and can occur without warning. Laboratory studies are unhelpful because their results are usually normal.

Noncardiac causes of shock and low cardiac output states must be considered, diagnosed, and treated in tandem with delineation of the possibility of congenital heart disease. Congenital heart lesions that present with low cardiac output are usually classified as shunt dependent and must be treated definitively and quickly. Up to 1 percent of infants are born with one or more congenital heart anomalies. Many of these lesions are of trivial or mild consequence, but a significant number are severe enough to become incompatible with life once the ductus arteriosus begins to close. As this occurs, blood can no longer reach the lungs and distal circulation. These infants present in shock within the first 2 weeks of life. Both cyanotic and acyanotic lesions may present in this fashion. The former include severe coarctation of the aorta, critical aortic stenosis, and hypoplastic left ventricle. Transposition of the great vessels, pulmonary atresia, and hypoplastic right heart syndrome are examples of the latter presentation.

Shunt-dependent lesions mandate immediate surgical referral for repair or palliation of the anatomic condition. It may be necessary to stabilize and restore some function to the shunt-dependent lesion while awaiting transport to a tertiary care facility. One method of providing this care is with the use of prostaglandin infusion to reopen the shunt pharmacologically. Prostaglandin E_1 infusions are successful in reopening the ductus arteriosus in nearly 95 percent of such patients and may allow for less emergent repair of the underlying defect. It is infused at a rate of 0.05 to 0.1 $\mu\text{g}/\text{kg}$ per min initially. If there is no improvement within several minutes, it is increased progressively in 0.2 $\mu\text{g}/\text{kg}$ per min increments. The minimal effective dosage should be used, because of adverse effects that include fever, skin flushing, diarrhea, and periodic apnea. Intubation and ventilatory support are often necessary as well.

Cardiogenic shock can also occur as a result of dysfunctional myocardium and may mimic the signs and symptoms seen with shunt-dependent anatomic lesions. Such cardiomyopathies are uncommon in pediatric patients, but can be easily confused with anatomic lesions. Cardiomyopathies are usually defined into two groups in children: dilated and hypertrophied. Presentation varies from asymptomatic cardiomegaly discovered on routine chest radiograph to congestive heart failure, cardiogenic shock, or sudden death. Typically, such children self-limit their activities at home and then, during an acute febrile illness, decompensate rapidly and arrive in profound shock. The dilated cardiomyopathies more often cause congestive heart failure, whereas the hypertrophied cardiomyopathies cause sudden death. Emergent medical management includes supportive care as previously outlined in an attempt to enhance contractility. Tragically, little can be done to assist those unfortunate children who suffer sudden death.

TETRALOGY OF FALLOT Although not in itself a cause of hemodynamic instability because of sudden loss of blood flow, tetralogy of Fallot often presents in a dramatic fashion as a consequence of hypercyanotic episodes or "tet spells" that mimic other more significant structural lesions. Tetralogy of Fallot is the most common cause of cyanotic congenital heart disease in children older than 4 years of age. Anatomically, it is characterized by obstruction of the right ventricular outflow tract, VSD, dextroposition of the aorta, and right ventricular hypertrophy. Functionally, obstruction of the right ventricular outflow tract and the presence of VSD have the greatest physiologic consequences. Because of the outflow tract obstruction, blood is forced from right to left, resulting in desaturation and compensatory polycythemia and hyperviscosity.

The other cardinal features on physical examination are a holosystolic VSD murmur in the third intercostal space at the left sternal border and a diamond-shaped systolic murmur of pulmonary stenosis in

the second intercostal space at the left sternal border. The history may reveal exercise intolerance relieved by squatting. The main radiographic findings are a boot-shaped heart with decreased pulmonary vascular markings. A right-side aortic arch is present in 25 percent of tetralogies. Right ventricular hypertrophy with right axis deviation is the primary ECG abnormality.

The greatest threat to these patients is the hypercyanotic or tet spells. These episodes, dramatic in presentation, are characterized by episodes of paroxysmal dyspnea with labored respiration, increased cyanosis, and syncope. These episodes in concert with polycythemia lead to seizures, cerebrovascular accidents, and death. They occur as a consequence of the exertion of feeding, crying, or straining at stool, and last from a few minutes to hours. The rapid, deep hypernea results from an increase in cardiac output with exertion against fixed right ventricular outflow tract obstruction. The fixed obstruction causes increased shunting across the VSD and increased hypoxia, hypercarbia, and acidosis. The hypoxia and acidosis cause a decrease in systemic vascular resistance that further potentiates the shunt and stimulates the respiratory center to maintain and deepen the hypernea.⁶

Management of hypercyanotic spells consists of positioning and pharmacologic management. Infants should be placed in a knee-chest position. This positioning allows for an increase in venous return to the heart and an increase in systemic vascular resistance. Pharmacologic management includes administration of oxygen to decrease the hypoxemia, and injection of morphine sulfate SC or IM at a dosage of 0.2 mg/kg per dose. Many consider the administration of propranolol a contraindication to bypass surgery, so it should not be given without consultation. In extreme cases, phenylephrine infusion 10 $\mu\text{g}/\text{kg}$ initial infusion, followed by infusion of 0.5 to 2 ($\mu\text{g}/\text{kg}$ per min, is used to increase the systemic vascular resistance and increase blood pressure.

Lack of recognition of the hypercyanotic episode and timely intervention could result in significant complications, including seizures, cerebral thrombosis, profound lactic acidosis, deterioration in cardiac rhythm, and subsequent death.

TRANSPOSITION OF THE GREAT VESSELS This is the most common cyanotic defect that appears in the first week of life. Infants with this defect who are brought to the ED usually have dusky lips noted by parents or have an increased respiratory rate or feeding difficulty. While not as dramatic in presentation as a hypercyanotic spell of tetralogy of Fallot, the defect is easily missed on a single ED visit because of the lack of cardiomegaly or murmur.

Anatomically, in transposition of the great vessels, the aorta originates from the right ventricle, and the pulmonary artery originates from the left ventricle. The systemic veins drain as they usually do into the anatomically correct right atrium, and the pulmonary veins drain into the left atria. Thus, in transposition, the systemic and pulmonary blood flows are not admixed and exist in parallel unless alternative flow is established. To maintain life, mixing of blood occurs either at the level of the atria via an atrial septal defect or at the level of the ventricles by a VSD. If neither of these is present, flow must be maintained by a persistent ductus arteriosus.

Clinically, cyanosis and tachypnea appear within the first several days of life, but may be prolonged when a patent ductus arteriosus fails to close. Ironically, cardiomegaly is often absent and no murmur is noted. The chest radiograph is usually normal, but may show a narrow, small heart because of the overlapping of the abnormally positioned aorta and pulmonary artery. The ECG shows normal right-sided-force dominance. Rarely, depending on the anatomy, will frank congestive heart failure be present.

Treatment of this condition is initially palliative in the cardiac catheterization laboratory and involves the creation of a large artificial atrial septal defect by using a balloon catheter (Rashkind septoplasty). Initially, most emergency physicians who suspect this entity are justified in beginning an infusion of prostaglandin E_1 , as previously outlined, while arranging transport to a facility capable of palliation. The

definitive surgery that is performed later is the Mustard operation, in which an artificial baffle is created at the atrial level to direct systemic venous return into the left ventricle and the pulmonary return to the right ventricle. The left ventricle then pumps blood to the lungs, and the right ventricle pumps blood to the systemic circulation.⁷

LEFT VENTRICULAR OUTFLOW OBSTRUCTION SYNDROMES

No clinical presentation can match the rapidity of onset of cardiogenic shock, hypotension, and acidosis as seen in infants with this group of disorders. In these infants, systemic blood flow depends on a large contribution of shunted blood via a patent ductus arteriosus. When the ductus closes, cardiac output falls, perfusion becomes negligible, and a state of profound cardiogenic shock ensues. Such lesions are often complex, but include hypoplastic left heart syndrome, tricuspid atresia, and critical coarctation of the aorta. Other variants include transposition of the great vessels, as discussed previously, and some tetralogy of Fallot variants.⁸

Such infants present with decreased or absent perfusion, hypotension, and severe acidosis. When these infants present in the first week of life, they must be considered for an infusion of prostaglandin E₁, as outlined earlier. The infusion is begun at 0.1 (Jig/kg per min, preferably by a central line, although any access in such ill infants is acceptable. The dosage may be reduced as perfusion and color return. Side effects of the infusion include hypotension and mandate close observation of blood pressure. Other effects are apnea, focal seizures, and fever that may mimic sepsis. Because of the critical nature of these infants, immediate referral and transfer to a tertiary care facility are necessary.

Hemodynamically Stable, Symptomatic Patients

Some infants arrive at the ED with respiratory distress and are found on examination to have findings suggestive of congenital heart disease, usually with evidence of congestive heart failure. These infants have near-normal blood pressure and usually display normal skin perfusion, but may have cyanosis. Several congenital cardiac conditions may present in this fashion.

TRUNCUS ARTERIOSUS This congenital anomaly is characterized by a single, large arterial trunk originating from the ventricular portion of the heart. This common vascular trunk supplies blood to both the systemic and the pulmonary circulation. A large VSD is usually present and may account for the murmur that is often heard. Because of the large amount of flow from both ventricles into the single large arterial conduit, flow to the pulmonary tree is greatly enhanced due to decreased flow resistance. This results in little or no cyanosis until pulmonary resistance increases and then cyanosis appears.

Clinically, these infants present with signs of increased pulmonary blood flow, dyspnea, and, occasionally, overt congestive heart failure. Chest x-ray demonstrates cardiomegaly and increased pulmonary vascularity or pulmonary edema. The ECG is initially normal until pulmonary vascular resistance increases and then signs of strain, left ventricular hypertrophy, or biventricular hypertrophy are evident.

VENTRICULAR SEPTAL DEFECT This is the most common cardiac defect, and symptoms displayed depend on the size of the defect. Small defects are often found on routine physical examination. More than 60 percent of these close spontaneously in older childhood.

Moderate-sized VSDs cause elevated right ventricular pressure and subsequent increased pulmonary artery pressure. Infants with this defect present with increased cough with mild upper respiratory tract infections and may have mild increase in pulmonary vascularity and early congestive heart failure. Typically, the chest radiograph is interpreted as mild congestive heart failure, and treatment consists of furosemide and, occasionally, digoxin.

Large VSDs present with congestive heart failure early in infancy, resulting in early and severe pulmonary artery pressure that, if uncorrected, will result in pulmonary hypertension. Pulmonary hypertension

will result in reversal of left-to-right shunt and cyanosis in a condition known as the Eisenmenger complex.

COARCTATION OF THE AORTA This represents localized narrowing of the aortic lumen, most often distal to the origin of the left subclavian artery and in close proximity to the ductus arteriosus or its postnatal remnant, the ligamentum arteriosus.

In infancy, symptomatic infants present with congestive heart failure and feeding difficulty. Decreased pulse amplitude and duration are noted in the lower extremities, and hypertension is noted in the upper extremities. Cardiac examination reveals a systolic ejection murmur at the cardiac base, with interscapular radiation.

Older children present with decreased exercise tolerance and, occasionally, claudication to the lower extremities. In children older than 6 to 7 years of age, a characteristic rib notching of the inferior border of posterior ribs is evident. Such notching is bilateral and usually caused by hypertrophied collateral vessels.⁹

Hemodynamically Stable, Asymptomatic Patients

This class of patients presents to the ED for reasons that are not referable to the heart and are discovered to have findings suggestive of cardiac disease. Some of the more common cardiac defects have already been mentioned including mildly affected tetralogy of Fallot, small- to moderate-sized VSDs, and coarctation of the aorta. Several common structural defects warrant mention here.

ATRIAL SEPTAL DEFECT Most children remain symptomatic throughout childhood until adolescence, when signs of increased pulmonary hypertension develop. Characteristically, the physical examination of such children reveals a split second heart sound that does not vary with inspiration. Often a soft systolic murmur heard at the upper left sternal border may mimic the pulmonary flow murmur mentioned earlier. Initially, the chest radiograph is normal but, with time, shows an increased size of the right atria and later the right ventricle. The ECG shows a characteristic prolongation of the PR interval and a incomplete or complete right bundle-branch block pattern. Cardiomegaly represents a late finding that is usually seen in adults.¹⁰

CONGENITAL AORTIC STENOSIS This is a less dramatic form of left-sided outlet obstruction than described previously. Children with this defect usually arrive at the ED with fatigue, decreasing exercise tolerance, exertional dyspnea, or syncope. The diagnosis is suspected based on the greatly diminished pulse amplitude and duration and the characteristic murmur, which is usually systolic in timing and loud with radiation to the neck. Treatment consists of decreasing activities, particularly sports, and referral for evaluation of surgical intervention. In all circumstances, these children should refrain from any significant physical activity, as sudden death can result.

CONGESTIVE HEART FAILURE

Clinical Features

The most common cause of congestive heart failure (CHF) in children is congenital heart disease, which often masquerades as, or coexists with, pneumonia or sepsis. Pneumonia can cause a previously stable cardiac condition to decompensate, so that both problems exist simultaneously. The predominant symptoms include poor feeding, excessive diaphoresis, irritability or lethargy with feeding, weak cry, and, in severe cases, grunting and nasal flaring. Pulmonary congestion with rales, rhonchi, and wheezing may mimic common lower respiratory viral infections. Gallop rhythms may be difficult to ascertain because of the presence of tachycardia. Table 120-2 outlines the common symptoms and signs of an infant with congestive heart failure.

TABLE 120-2 Recognition of Congestive Heart Failure in Infants

	Right-Sided Failure	Left-Sided Failure	Both
Cardinal signs	Hepatomegaly	Tachypnea Dyspnea and sweating on feeding Rales	Cardiomegaly Failure to thrive Tachycardia
Unusual signs	Jugular venous distention Peripheral edema Anasarca		

Both increased pulmonary blood flow in left-to-right shunts and pulmonary edema decrease lung compliance, causing tachypnea in an attempt to maintain minute ventilation. Tachypnea is a cardinal sign of left-sided failure in infants. Unlike tachypnea caused by respiratory viruses, this tachypnea is usually effortless in children with congestive heart failure, because of lack of airway obstruction. Because feeding is the infant's primary form of exertion, dyspnea and sweating during feeding can often be elicited in the history. Peripheral edema, jugular venous distention, and rales are unusual and late signs in infants.

Hepatomegaly appears long before ascites, anasarca, or peripheral edema in right-sided failure in infants, but is usually a late sign. Hepatomegaly exists when the liver is more than 2 cm below the right costal margin in the absence of downward displacement by hyperexpanded lungs. In hepatomegaly, the liver border is rounded rather than sharp.

In congestive heart failure, the details of any murmur detected on physical examination contribute to the diagnosis. The chest radiograph may reveal cardiomegaly, increased or decreased vascular markings, or pulmonary edema. Often, as a consequence of the presence of a thymic shadow, the cardiac size is not readily apparent on routine posterior-anterior radiographs of the chest, but can be assessed on the lateral view by obliteration of the retrocardiac window by the enlarged heart. On the posterior-anterior view, the thymic shadow can be distinguished from the cardiac silhouette by the "sail sign," if present, and by the scalloped border that is produced by compression of the thymus against the rib cage. The ECG is often nonspecific, but may reveal only evidence of abnormal electrical axis, rhythm disturbances, or, more often, chamber hypertrophy.

Physiology of Congestive Heart Failure

Typically, most cases of CHF in children are caused by afterload increases in the pressure dynamics of one or both chambers of the heart. In these conditions, pressure builds in one chamber of the heart because of an obstructive lesion in the outflow tract of the affected chamber. Several of the more common entities early in the first weeks of life are the left ventricular outflow obstruction syndromes, followed by congenital aortic stenosis and moderate-to-severe coarctation of the aorta. With these lesions, the systemic circulation has inadequate perfusion, and renal flow is diminished. The combination of increased fluid retention and chamber dilatation results in cardiac failure. Treatment of afterload increases is aimed at vasodilatation with either specific load-altering medications, such as nitroprusside or nitroglycerin, or the use of furosemide, which has both a diuretic effect and a vasodilatory effect.

Less often, CHF can be related to increases in preload representing an overall volume overload without obstructive pressure consequences. Typical entities include large VSDs, and persistent patent ductus arteriosus in premature infants. Anemias of different etiologies should be considered, especially iron deficiency anemia in small cow

milk-fed infants. Sickle cell anemia and thalassemia variants should also be considered. In the former group of conditions, decreasing the vascular volume with diuretics is beneficial. In addition, the use of digoxin may be beneficial prior to surgical repair. In the latter cases, transfusion is warranted along with judicious use of fluid restriction and diuresis.

Poor contractility is not usually considered a major cause of CHF in small infants, because the ventricular walls are still relatively non-compliant. In older pediatric patients, however, poor contractility becomes an issue. Kawasaki syndrome, idiopathic endocardial fibroelastosis, pulmonary hypertension associated with Eisenmenger syndrome, and toxic-metabolic causes should be considered in adolescent patients with CHF. Less-frequent inflammatory causes include myocarditis, constrictive pericarditis, and collagen vascular diseases. Treatment is geared toward increasing contractility with dobutamine or digoxin.

Differential Diagnosis

CONGENITAL ANATOMIC HEART DEFECTS Once CHF is recognized, age-related categories simplify further differential diagnosis as outlined according to time of development in Table 120-3. In the first few minutes of life, CHF occurs from a variety of noncardiac origins such as asphyxia, acidosis, hypoglycemia, hypocalcemia, anemia, and sepsis. In critically ill premature neonates, a patent ductus arteriosus is the most common cause of CHF. Among full-term newborns, a hypoplastic left ventricle is the most common cause in the first week of life and coarctation of the aorta is the most common cause in the second week of life. Transposition of the great arteries presents within the first 3 days of life, with either cyanosis or CHF.¹¹

VSDs alone do not cause CHF in the first weeks of life but, when complicated by transposition of the great arteries, truncus arteriosus, critical aortic stenosis, or coarctation can present with failure at any time during the first few weeks of life. Large, uncomplicated VSDs can present with CHF after weeks 3 to 4 of life as pulmonary artery pressure continues to fall, increasing the left-to-right shunt. Onset of failure is insidious between 1 and 3 months of age, when the left-to-right shunt increases as the pulmonary vascular resistance decreases further from the high fetal values.

Clinical assessment also involves estimation of the degree of severity of the congestive heart failure. For example, depending on the size of the defect, a VSD may present in a variety of ways, ranging from mild tachypnea to chronic compensated CHF accompanied by growth

TABLE 120-3 Differential Diagnosis of Congestive Heart Failure Based on Age of Presentation

Age	Spectrum	
1 min	Noncardiac origin: anemia, acidosis, hypoxia, hypoglycemia, hypocalcemia, sepsis	Acquired
1 hour		
1 day	PDA in premature infants	Congenital
1 week	HPLV	
2 weeks	Coarctation	
1 month	Ventricular septal defect	
3 months	Supraventricular tachycardia	Acquired
1 year	Myocarditis	
	Cardiomyopathy	
	Severe anemia	
10 years	Rheumatic fever	

Abbreviations: HPLV = hypoplastic left ventricle; PDA = patent ductus arteriosus.

failure and frank pulmonary hypertension in later years. The finding on clinical examination of a small VSD is often out of proportion to the size of the VSD: a small VSD may have with a loud holosystolic murmur that is hemodynamically insignificant, and a large defect may produce no murmur initially.

In contrast to the gradual onset of heart failure with a VSD, coarctation of the aorta can present with abrupt onset of CHF precipitated by a delayed closure of the ductus arteriosus during week 2 of life. The severity of the symptoms is directly proportional to the degree of obstruction and can vary from mild tachypnea to cardiogenic shock. Milder degrees of coarctation, on the other hand, present later in life with isolated hypertension and diminished pulses in the lower extremities.

The onset of CHF after 3 months of age usually signifies acquired heart disease as opposed to congenital heart disease. The exception to this rule occurs when pneumonia, subacute bacterial endocarditis, or other complicating factors cause a previously stable congenital lesion to decompensate. Before 2 years of age, myocarditis, cardiomyopathies, and severe anemia are the most common diseases in the differential diagnosis. Rheumatic fever, once a common cause of CHF, is seen among children who are 8 to 12 years of age. Except in certain ethnic groups, it is now unusual.

MYOCARDITIS AND CARDIOMYOPATHIES Myocarditis affects children of all ages and is the leading cause of end-stage cardiomyopathy requiring transplantation. Viral etiologies include enteroviruses (coxsackie, echovirus, and poliovirus), as well as mumps, influenza virus, and varicella-zoster. An emerging cause is HIV-associated myocarditis and chronic Epstein-Barr myocarditis. Many bacterial species have been associated with myopericarditis, but not myocarditis alone. Noninfectious causes include lupus erythematosus, toxins such as tricyclic antidepressants, and cocaine. Myocarditis is often preceded by a viral respiratory illness and needs to be differentiated from pneumonia. As with the latter diagnosis, presenting signs and symptoms are often respiratory distress, fever, tachypnea, and tachycardia. Clues that suggest myocarditis include generalized malaise, fever, and myalgias in age-appropriate children.

Cardiomyopathies are uncommon, but significant because of the high mortality and severe disability that they produce. They are usually classified into two groups: either dilated or hypertrophic. The dilated cardiomyopathies display impaired cardiac contractility and ventricular dilation. Most cases are idiopathic or viral in etiology. Most infants who arrive at the ED have respiratory symptoms, and a chest radiograph reveals an enlarged heart and vascular congestion. In a small percentage of these infants, acute cardiovascular collapse can result from severe CHF or dysrhythmia. Infants become acutely symptomatic when their disease is accentuated by intercurrent febrile illness. The hypertrophic cardiomyopathies display thickened myocardium and very plastic immobile contractile state.

Chest radiographs show cloudy lung fields either from inflammation or pulmonary edema. ECG may reveal ST-T segment changes that are generalized to all leads or rhythm disturbances. Evidence of ectopy signals severe diffuse disease and a high risk of sudden death. Cardiomegaly with poor distal pulses and prolonged capillary refill, however, distinguish it from common pneumonia. Once cardiomegaly is discovered, admission and echocardiogram are warranted. The latter will show a dilated, poorly contracting left ventricle with a low ejection fraction with or without a pericardial effusion. In dilated cardiomyopathies, both ventricles are usually affected and substantial dilatation is apparent at diagnosis.

At this point, the cause of myocarditis must be further delineated in a hospital, and endomyocardial biopsy may be warranted to do so. Parents must be thoroughly versed in cardiopulmonary resuscitation and be aware that a lethal dysrhythmia could cause sudden death. Infants are best kept comfortable in an upright position in an infant seat.

Oxygen is administered in a nonthreatening fashion appropriate for age, and a neutral thermal environment is established. If CHF is apparent, a diuretic is administered. Severe CHF is initially treated with inotropic infusions (for example, dopamine hydrochloride or dobutamine) along with fluid restriction, diuresis, and supplemental oxygen. Intubation and mechanical ventilation often become necessary during the hospital phase of the illness. Treatment is directed to the underlying cause in addition to the supportive therapy outlined earlier.

PERICARDITIS Usually, this presents as cardiomegaly that is discovered incidentally on chest radiograph. Clinical signs, such as chest pain, muffled heart sounds, and a friction rub, may be present. In older patients and adolescents, classic pleuritic or positional chest pain, abdominal pain, and tachycardia may be seen. An echocardiogram is performed on an urgent basis to distinguish a pericardial effusion from dilated or hypertrophic myocarditis. The most common etiology is in association with coxsackie viral myocarditis. Bacterial pericarditis from *Haemophilus influenzae* is rare today and was uncommon even before the availability of *H. influenzae* type B conjugated vaccines. Typically, most cases of bacterial pericarditis present with profound toxicity and muffled heart sounds and jugular venous distention. If not appropriately drained in addition to antibiotic treatment, constrictive pericarditis will result in tamponade. Pericarditis that accompanies rheumatic fever, lupus erythematosus, or chronic renal failure is usually secondary and does not produce the main symptomatology. Because diagnostic pericardiocentesis can be complicated by hemorrhage, cardiac tamponade, and arrest, it is usually deferred to a pediatric cardiologist or intensivist for drainage. Pericardiocentesis with an 18-gauge over-the-needle catheter is indicated in the ED if an infant with large heart becomes rapidly unstable with loss of pulse. As in adults, the needle is placed in the sub-xiphoid region and aimed toward the left shoulder.

Typically, uncomplicated pericarditis responds to a prolonged course of anti-inflammatory medication and decreased activity or bed rest. Most cases are self-limited and require specialty consultation only for the initial evaluation.

COR PULMONALE If an infant presents in pure right-sided CHF, the primary problem is most likely to be pulmonary in origin. Hepatomegaly and anasarca may be present, but most often, in early stages, lid edema is the first noticeable sign. Moreover, the lid edema is likely to be appreciated by the parents more than by the physician and must be specifically searched for on examination. Often it will have to be elicited by asking "Do your child's eyes look puffy?" If the underlying problem is bronchopulmonary dysplasia resulting from prematurity and infantile respiratory distress syndrome, the infant may already be on appropriate home oxygenation and diuretic therapy. Upper airway obstruction from hypertrophied adenoidal and tonsillar tissue can produce cor pulmonale, presenting as edema or anasarca. The clinical features of airway obstruction, however, are subtle; a careful history will reveal continuous mouth breathing while awake and sleeping, with or without snoring. Sleep studies and tonsillectomy are indicated. Cor pulmonale from upper airway obstruction in infants usually responds to diuresis and oxygen alone, without the need for digoxin.

Treatment

The degree and severity of CHF dictate the initial treatment. Infants who present with mild tachypnea, hepatomegaly, and cardiomegaly simply need to be seated upright in a comfortable position and kept in a neutral thermal environment to minimize preload and to avoid metabolic stress. If the work of breathing is appreciably increased by an increased pulmonary blood flow, 1 to 2 mg/kg furosemide parenterally is indicated. If pulmonary edema is present, then the hypoxemia can

usually be corrected by fluid restriction, diuresis, and an increase in ambient oxygen.

Severe degrees of CHF can present with signs of low cardiac output or cardiogenic shock. Aggressive management is often necessary in secondary derangement, including respiratory insufficiency, acute renal failure, lactic acidosis, disseminated intravascular coagulation, hypoglycemia, and hypocalcemia.

For definitive diagnosis and treatment of congenital lesions presenting in CHF, cardiac catheterization followed by surgical intervention is often necessary. Stabilization and improvement of left ventricular function can often first be accomplished with inotropic agents. Digoxin is used in milder forms of CHF. Initial digitalization is performed IV, giving one-half the daily dosage followed by one-fourth of the daily dosage IV at 6- to 8-h intervals. Maintenance digoxin consists of one-eighth the daily dosage given IV or PO at 12-h intervals. For full-term infants up to 2 years of age, the dosage is 0.03 to 0.05 mg/kg per d. Hence, 0.02 mg/kg would be the appropriate first digitalizing dose to be given in the ED.

At some point, congestive heart failure progresses to cardiogenic shock, in which distal pulses are absent and end-organ perfusion is threatened. In such situations, continuous infusions of inotropic agents such as dopamine or dobutamine are indicated instead of digoxin. The initial starting range is 5 to 10 μ g/kg per min. The "rule of six" simplifies the necessary calculations. A total of 6 mg/kg of body weight of either dopamine or dobutamine is placed in a microdrip chamber and filled to 100 mL with D5W or NS; 1 mL per h equals 1 μ g/kg per min, so it is administered via a pump initially at 5 mL per h (5 μ g/kg per min). Prior to starting a continuous inotropic infusion such as this, the acid-base status should be checked by arterial blood gas analysis. Any abnormality should be corrected with 1 to 2 mEq/kg of sodium bicarbonate as needed and cautious volume expansion with 10 mL/kg of NS if necessary.

If inotropic support is inadequate, the use of combination therapy with vasodilatory therapy is warranted. The combination of dopamine and nitroprusside has been used extensively in situations of low cardiac output and low ejection fraction states. Another combination is nitroglycerin, which is readily available to even the smallest EDs.

When pharmacologic management is unsuccessful, other measures must be considered. Typically, most emergency physicians will be able to support ventilation with endotracheal intubation and positive end-expiratory pressure. Further care after tertiary referral includes balloon-assist counterpulsation devices or membrane oxygenation until definitive surgical care of the underlying cardiac defect can be undertaken.

DYSRHYTHMIAS

In general, children are able to tolerate higher rates without the usual ischemic phenomenon often present in adults. The treatment in children is usually directed at the underlying structural aspect of the intracardiac conduction system and less at prevention of cardiac ischemia related to rate.

Dysrhythmias can occur in the absence of underlying structural heart disease or metabolic condition. Many conditions that occur in the adult population—such as hypoxia, electrolyte imbalance, collagen vascular diseases, and overzealous use of sympathomimetic agents—rarely occur in children. Because much of the prognosis with regard to the reoccurrence of a dysrhythmia depends on the nature of any underlying structural cardiac defect, cardiologic evaluation is needed for all first-time occurrences of dysrhythmias.

Recognition of dysrhythmia is age dependent, and dysrhythmia often masquerades as other cardiac entities. In small infants, poor feeding and irritability may be the only signs of illness, with signs of poor cardiac output at higher rates evident later as edema and poor capillary refill. Older children may have more specific symptoms because of their increased ability to verbalize. In such instances, more classic

adult symptoms of palpitations may be elicited, as well as syncope due to increased rate.

Slow Cardiac Rates

FIRST- AND SECOND-DEGREE ATRIOVENTRICULAR BLOCKS First-degree atrioventricular (AV) block is seen frequently and has no real serious consequence unless it occurs in the presence of another cardiac anomaly such as an atrial septal defect. Second-degree AV block requires a more thorough evaluation. Mobitz type I second-degree AV block can be a normal variant. Mobitz type II, however, is always of significance and always requires an evaluation and prolonged monitoring.

COMPLETE ATRIOVENTRICULAR BLOCKS Complete AV block can occur and can be either congenital or acquired. Congenital complete AV block is associated with congenital heart disease or may occur independently. In the former, the prognosis is extremely guarded until the underlying defect is corrected. Often the associated congenital defect is so severe (common AV canal) that it is uncorrectable. In the latter condition, AV block occurs during gestation and is usually secondary to maternal connective tissue disease with autoimmune destruction of the AV tracts in infants. The diagnosis is usually suspected prenatally, and treatment is instituted during gestation. Postnatal therapy includes transthoracic pacemaker and transvenous pacemaker use. Acquired AV block can occur without cause in older children, occur as a manifestation of inflammatory diseases of the myocardium, or occur postpartum in adolescent patients. In this category, syncope is usually the initial presenting complaint, and prompt recognition and referral are mandatory. Treatment is with an implantable pacemaker to prevent sudden death.

Fast Cardiac Rates

SINUS TACHYCARDIA Although usually a benign event, the differentiation from the more significant supraventricular tachycardia (SVT) is difficult. Typically, ventricular rates in excess of 230 beats/min are highly unusual and should be presumed to be the latter entity. The rate in SVT is usually fixed, with little variability with manipulation of the infant. Vagal maneuvers may be attempted to try to slow the cardiac rate. If slowing can be accomplished, P waves may be visible. The presence of P waves during slowing supports the diagnosis of sinus tachycardia. Other causes of sustained high-rate sinus tachycardia must be sought, including diarrheal dehydration, febrile illness, hyperthyroidism, sepsis, and drug effect from substance abuse or iatrogenic medication administration.

SUPRAVENTRICULAR TACHYCARDIA This is the most common dysrhythmia in the pediatric age range. In infants, SVT presents with a 4- to 24-h history of poor feeding, tachypnea, pallor, and lethargy. In older children, palpitations and chest pain can be prominent in the symptomatology. Physical examination reveals weak pulses and a tachycardia that can be too rapid to be counted accurately. Depending on the time since onset of SVT, other physical signs can vary from CHF to cardiogenic shock with pending arrest. Low cardiac output is secondary to inadequate ventricular diastolic filling time.

Most children younger than 3 or 4 months of age will have no easily identifiable cause for the tachycardia. Children older than 4 months often have underlying structural defects or precipitators, such as fever or exposure to sympathomimetic cold remedies. Older children and adolescents are more likely to have accessory pathways. Recurrence rates for accessory pathway disease are as high as 90 percent, and recognition allows for more directed therapy at the AV node.

An ECG rhythm strip shows an unvarying ventricular rate between 220 and 360 beats/min, as opposed to a range of 150 to 200 beats/min

in adults with SVT. The QRS complexes are narrow and regular. P waves are absent or abnormal. Any wide-complex rhythm that is seen is considered ventricular in origin, because SVT with aberration is usually extremely rare in children.

SVT must be distinguished from sinus tachycardia, which is the most common tachyarrhythmia in children. In sinus tachycardia, P waves are present. The normal range for heart rate in newborns is 120 to 200 beats/min. In children younger than age 5 years, it is not unusual to find a sinus tachycardia up to a rate of 200 beats/min caused by fever, stress, or hypovolemia. The latter requires prompt recognition and adequate volume expansion.¹²

Initial management of *unstable* patients with narrow or wide complex tachycardia consists of immediate synchronized cardioversion at 0.5 J/kg with increases in power output to 2 J/kg as needed. Cardioversion should be undertaken at the lowest possible output in children on digoxin. There is a greater risk of subsequent ventricular fibrillation in such patients, so prophylactic lidocaine hydrochloride should be administered in a dose of 1 mg/kg before cardioversion. If cardioversion is unsuccessful, overdrive pacing is indicated. Once cardioversion is completed, suppressive therapy with digoxin is required.

Intravenous adenosine (0.1 mg/kg followed by 0.3 mg/kg boluses every 1 to 2 min until tachycardia resolves) is the drug of choice for both wide and narrow complex supraventricular tachycardia.¹³ Because the half-life of adenosine is a matter of seconds, it is administered as a rapid bolus via a peripheral IV line. Two syringes can be timed in delivery of the medication: the first syringe contains the adenosine, and the second contains 5 to 10 mL of saline flush. Both syringes can be sequentially emptied in less than 5 s. A brief (3 to 10 s) period of asystole is sometimes seen before return of a normal sinus rhythm. If necessary, the dosage can be doubled, tripled, or quadrupled to convert the rhythm (maximum dosage, 12 mg).¹³

Vagal maneuvers to convert SVT can be attempted, but are usually not successful until after the first dose of digoxin. The diving reflex, which is elicited by submersing the face in ice water, usually produces the greatest vagal tone. An alternative to submersion is to place the ice water in a plastic bag that can be lowered briefly on the infant's face.

Digoxin has been the time-honored standard of medical management of SVT in infants. Because it takes 4 to 6 h before the rhythm converts, however, it is used more for chronic management than for acute conversion. The dosage is the same as that previously listed for CHF.

Verapamil should not be used in neonates and children <5 years of age because it can result in electromechanical dissociation.¹³ The dose of verapamil in older children is 0.1 mg/kg bolus, with preparation for any associated hypotension with calcium chloride at 10 mg/kg ready at the bedside. If verapamil fails or is contraindicated, then chemical cardioversion with either propranolol, procainamide, or flecainide may be attempted.¹⁴ Propranolol administration prolongs conduction at the AV node in both antegrade and retrograde fashion and thus is extremely useful in Wolff-Parkinson-White syndrome. It is administered at a dosage of 0.1 mg/kg per dose every 6 h. Procainamide blocks only retrograde conduction and may be beneficial if the rhythm appears to be ventricular in origin. It is administered as a 5- to 15-mg/kg bolus over 20 to 30 min.¹⁴

ATRIAL FLUTTER This is associated with congenital heart disease approximately 90 percent of the time. The atrial rates generated typically range from 200 to 300 beats/min in practice, but rates as high as 500 beats/min have been reported. With such high rates, the flutter waves are often difficult to visualize unless vagal maneuvers result in slowing long enough to capture the flutter waves. Conduction to the ventricles is variable and can be as high as 1:1 to a more usual 3:1 or 4:1 block.

In stable patients, control of rate is a first priority and can usually be accomplished by the use of digitalization to slow the ventricular response. The ultimate goal of therapy is to eliminate the flutter waves and to decrease the conducted response of the atria. If digoxin alone is

effective, procainamide can be given. Combination therapy is usually never appropriate for emergency physicians to undertake, because slowed junctional bradycardia or asystole may occur.¹⁵

ATRIAL FIBRILLATION Unlike adult atrial fibrillation, which is usually secondary to ischemic heart disease or pulmonary disease with chamber dilatation, childhood disease is secondary to rheumatic heart disease or dilated cardiomyopathy. Atrial fibrillation in children usually manifests as an irregular rhythm with variable conduction. Rate control is rarely problematic unless rates are in excess of 200 beats/min. In unstable patients, immediate cardioversion is usually successful at energy levels of 0.5 J/kg. Overdrive pacing is useful for those that do not convert.

Unlike adult cardioversion, anticoagulation is never necessary prior to the termination of atrial fibrillation. Medical therapy with digoxin is rarely effective, and not enough experience is available with newer agents such as diltiazem¹⁶ or ibutilide. Even in stable patients, cardioversion is usually required. Rarely, electrophysiologic studies are warranted and ablation of the focus is required.¹⁷

VENTRICULAR TACHYCARDIA This is usually seen in the presence of underlying congenital heart disease. Intentional or inadvertent drug overdose should also be suspected. Occasionally, ventricular tachycardia may be idiopathic and discovered on routine examination in asymptomatic children. In the latter case, complete investigation should include a search for myocarditis, cardiomyopathy, or the prolonged QT syndrome.

Despite the poor prognosis that this rhythm holds in adults, stable asymptomatic children are usually left untreated if the heart is normal. Symptomatic children who present with syncope or chest pain require further study, but treatment should not be instituted by emergency physicians until after these studies are performed.

If patients are unstable in any way, synchronized cardioversion should be performed at an energy of 1 to 2 J/kg. If stability for transfer is uncertain, medical management with lidocaine hydrochloride is warranted. The dosage is usually a 1 mg/kg loading dose followed by a 0.5 mg/kg reload in 20 to 30 min, and then a maintenance infusion of 0.01 to 0.04 mg/kg per min infusion. Procainamide can also be used, but must be given over 30 to 60 min at a dose of 15 mg/kg IV. Other considerations include phenytoin, propranolol, or amiodarone.^{18,19}

VENTRICULAR FIBRILLATION The initial energy for defibrillation is 2 J/kg and can be doubled, if necessary. Hypoxia and acidosis should be corrected to increase the success of defibrillation. A trial of amiodarone given as a 5 mg/kg infusion over 5 to 20 min followed by defibrillation may be warranted. If defibrillation is successful a continuous infusion of 5 to 15 µg/kg per min is warranted. Failure to respond after an initial infusion of amiodarone followed by three defibrillation attempts and a second 2 mg/kg bolus infusion usually indicates that the heart is unresuscitable.¹⁹

ANTICIPATING PROBLEMS IN CHILDREN WITH CONGENITAL HEART DISEASE

Children with congenital heart disease are brought to the ED for routine accident care, as well as for childhood illnesses. Some childhood illnesses may predispose patients to acute cardiovascular complications. A significant number of these children are treated with digoxin, diuretics, and anticoagulants that can make care of acute problems difficult. Special problems must be anticipated and complications of therapy for other conditions avoided.

Hypoxemic Spells

Most ED procedures involve fear and apprehension, as well as pain in the preparation of wounds and fracture splint placement or reduction.

Infants with uncorrected tetralogy of Fallot can have hypoxemic episodes when total oxygen demand during painful procedures exceeds that which the restricted pulmonary blood flow can support. Strain also increases the right-to-left shunt through a VSD, as well as the reduced pulmonary blood flow. As described previously, loss of consciousness can result. Pediatric consultation should be obtained, if at all possible, before attempting conscious sedation.

Surgical Shunt Dysfunction

Because of palliative shunt procedures performed in the neonatal period prior to definitive operative repair of complex congenital heart disease, shunts can malfunction. Typically, infants in such a situation are in acute distress with increasing cyanosis. Although not as dramatic as with ductus-dependent lesions, symptoms develop when the shunt flow narrows to less than 50 percent of usual. Ordinarily, a continuous murmur is heard over the side of the shunt. Diminution or disappearance of the murmur suggests occlusion of the shunt. Typically, emergency physicians can do nothing for these infants. Palliative therapy with 100 percent oxygen is used, and transfer to a tertiary center is expedited. The use of thrombolytic therapy has been tried, but should be used by only pediatric cardiologists by direct shunt instillation or systemically. In all cases, possible replacement of the shunt or definitive surgical repair might be the only option.

Pulmonary Hypertensive Crisis

Many children with congenital heart disease have increased pulmonary artery pressure, particularly those with large VSDs. With painful procedures, these patients can experience pulmonary vasospasm. In such conditions, cyanosis and lethargy can develop and can mimic the hypercyanotic episodes of tetralogy of Fallot. Treatment is directed toward alkalinization with IV sodium bicarbonate and 100 percent oxygen to facilitate pulmonary vasodilation. Anxiolysis and analgesia are useful.

Diuretic Complications

Diuretics may be inadequate for the weight of the child because of normal growth and present as CHF. Conversely, during times of excess extraneous losses such as diarrhea or vomiting, dehydration can occur with subsequent hemoconcentration that could compromise cardiac function or shunt integrity. Careful monitoring of potassium levels is imperative during such losses.

Digoxin Toxicity

Because of the narrow therapeutic window between treatment and toxicity, digoxin toxicity can easily develop. In infants, toxicity is manifested most often by bradycardia and occasionally by other dysrhythmias. The usual adult patterns of atrial and ventricular tachycardia are not seen, except in adolescents. It is always good practice to monitor digoxin concentrations expectantly during any visit where blood will be drawn.

Usually, increased serum concentrations can be managed by withholding dosages of digoxin. Rarely, pharmacologic intervention is required for bradycardias. Ventricular dysrhythmias are managed medically with lidocaine or phenytoin. For severely intoxicated children, the use of digoxin immune globulin (Digibind) is indicated and will reverse toxicity rapidly. Usually, the dosage can be calculated readily based on the amount of digoxin elevation in nanograms above normal (see Chap. 174). A 1-ng increase in digoxin is assumed to reflect a burden of 1 mg digoxin. Each vial of digoxin-specific antibody binds 0.4 mg digoxin. Therefore, a digoxin level that is 5 ng above expected would require 12.5 vials of digoxin-specific antibody. Care should be taken to avoid volume overload.

Anticoagulation Problems

Some children with congenital heart disease are on anticoagulant therapy to prevent shunt occlusion or thrombosis of surgically implanted valves or grafts. The risk of serious bleeding is small with routine ED visits, but must be considered for any elective repair of fractures or lacerations. Prothrombin time and the international normalized ratio (INR) must be monitored. Reversal of anticoagulation with the administration of either vitamin K or fresh-frozen plasma should be undertaken only after consultation with a pediatric cardiologist.

Anemia and Polycythemia with Cyanotic Congenital Heart Disease

Children with this problem require an increase in hemoglobin concentration to compensate for hypoxemia. Children develop tachycardia, feeding difficulty, or congestive heart failure when hemoglobin concentrations fall to normal. Often, anemia will be compensated for by polycythemia, which will cause increased viscosity and the potential for cerebrovascular complications. Iron supplementation is important for prevention of anemia. When polycythemia occurs, therapeutic phlebotomy may be warranted.

Viral Infections with Congenital Heart Disease

Although few normal children have problems with common viral pathogens such as influenza virus, parainfluenza virus, or respiratory syncytial virus, children with congenital heart disease are at unique risk for major sequelae. Distinguishing minor early infections with these agents and differentiating them from the symptoms of congestive heart failure is a challenge, even for seasoned clinicians. Children with lesions that increase pulmonary blood flow are far more at risk because of pooling of alveolar secretions. The pooled secretions allow for stasis and secondary bacterial overgrowth. Dramatic increases in mortality and morbidity are evident among affected infants. No effective therapy is available for parainfluenza and influenza virus, and prophylaxis against influenza B with amantadine analogues is not approved for small children. Hospitalization and specific treatment of infants affected by respiratory syncytial virus has been difficult to justify because of conflicting studies regarding efficacy of the antivirals and ribavirin and the expense of respiratory syncytial virus-specific immune globulin. Most infants will benefit from admission for bronchodilator therapy, but the prophylactic use of antibiotics to prevent secondary bacterial pneumonia is not justified. Admission may help sort out the distinction between congestive heart failure and underlying pulmonary infection.²⁰

Subacute Bacterial Endocarditis

Children with congenital heart disease are at great risk of developing endocarditis. Transient bacteremia produced by iatrogenic procedures such as dental work or gastrointestinal or urologic manipulation can lead to localized colonization and infection. Although the thrust of most primary care providers is toward prevention of this disease, cases still occur. Typically, the usual presentation is of unexplained fever in children with known congenital heart disease. Appropriate evaluation includes multiple blood cultures, urine culture and analysis, and complete blood count. Parenteral or oral antibiotics should be administered in consultation with a pediatric cardiologist familiar with the child's history. In cases of known source of infection, such as otitis media or pneumonia, multiple blood cultures should be obtained, and appropriate therapy should be directed at the site of primary infection.

Acutely ill children with high fever mandate hospitalization, multiple blood cultures, and echocardiographic study of the heart. Usually, treatment is instituted following the obtainment of cultures and is directed toward the most common pathogens. Established diagnosis is followed by 4 to 6 weeks of intravenous antibiotic therapy.²¹

ENDOCARDITIS PROPHYLAXIS PRIOR TO PROCEDURES

Prophylactic treatment is recommended for patients with congenital heart malformations and rheumatic fever with valvular disease who are undergoing surgical or dental procedures and instrumentation involving mucosal surfaces. The administration of the medication should be timed such that an effective serum level will be present during the 15 min after the mucosal manipulation, when the transient bacteremia occurs. Amoxicillin 50 mg/kg (maximum, 2 g) is given 1 h before the procedure and 25 mg/kg (maximum, 1.5 g) 6 h later. For patients with valvular disease, 2 mg/kg gentamicin is given IV or IM 30 min before the procedure and 8 h later, in addition to the amoxicillin. Erythromycin 20 mg/kg PO (maximum, 800 mg erythromycin ethylsuccinate or 1 g stearate) can be given 2 h before the procedure, with half the dose given 6 h later.

The indications for prophylaxis and treatment options are well outlined in the American Heart Association guidelines for prophylaxis of endocarditis. Cases of endocarditis can occur despite appropriate prophylaxis. Vigilance in performing appropriate blood cultures is warranted in any children with symptoms suggestive of endocarditis.²²

EVALUATION OF FEVER IN INFANTS WITH HEART DISEASE

Infants and children with known heart disease are prone to the same illnesses as other children. When they are brought to the ED for treatment of febrile illnesses, they are most likely to be hemodynamically stable and capable of handling the illness. Any signs of congestive heart failure are indications for an admission. Otherwise, blood cultures should be obtained, as well as a complete blood count, as would be performed for any infant between the ages of 6 months and 24 months. Although occult bacteremia has the same probability for occurrence in a child with congenital heart disease, concern for bacterial endocarditis must be greater. Oral or parenteral antibiotics should be administered with great care if presumptively treating early bacteremia or subacute bacterial endocarditis. It is more prudent to arrange admission, repeated cultures, and expectant therapy for such infants than to begin antibiotic therapy blindly simply because of the presence of congenital heart disease. A follow-up visit is mandatory in 12 to 24 h for any children who are discharged home without hospital admission.

EVALUATION OF INFANTS WITH CARDIAC TRANSPLANTATION

Increasingly, infants with complex congenital heart disease are surviving and undergo cardiac or cardiopulmonary transplantation. Many of these special infants are being returned to their homes of origin after a period of intensive recovery close to the transplant hospital. As a result, these infants are often instructed to seek care in EDs far removed from the transplant hospital for "evaluation." Many emergency medicine practitioners have had no experience with infants of this complexity and are unsure of what the evaluation will entail.

Most patients are sufficiently stable and beyond the period of acute rejection of the cardiac or cardiopulmonary transplant, but may rarely present with acute, life-threatening deterioration. Allograft rejection is the leading cause of severe hemodynamic compromise in the pediatric heart or heart-lung transplant recipient. Most patients are maintained on a complex immunosuppressive regimen to suppress the immune system at multiple sites. Therapeutic monitoring of the immunosuppressive regimen is usually beyond the scope of most hospitals, but may be collected and forwarded to the transplant hospital after appropriate telephone consultation and transfer arrangements are made.

These patients are extremely ill and require careful optimization of cardiac output. All the parameters that define cardiac output (heart

rate, preload, contractility, and afterload) that were previously discussed require pharmacologic manipulation to stabilize the circulation until the rejection can be reversed. Careful administration of volume, diuretics, inotropic, and afterload-reducing agents are required for stabilization prior to transfer to the transplant hospital. Corticosteroids are paramount in treatment for both cellular and vascular rejection, but should only be undertaken by direction of the transplant hospital and is probably not warranted acutely unless used to treat acute secondary adrenal insufficiency.²³

Fortunately, most cardiac transplant recipients more commonly seek ED care for complaints that are not acutely life-threatening. The most common complaints are related to the respiratory tract, and the most common diagnoses are related to infectious processes. Fever is the presenting complaint in 25 percent of the visits, which result in positive blood cultures in approximately 10 percent of cases. By reason of severe immunocompromise, infections from opportunistic organisms and bacteremia must be considered. Surprisingly, most infections are similar to those in the nontransplanted child.^{24,25} In one series drawn from an ED experience at a transplant hospital, admission was required for approximately 30 percent of the ED visits.²⁴ No pediatric heart transplant recipients should be considered for discharge unless consultation with the transplant hospital occurs. In all but the most unusual of circumstances, these children require transfer to the transplant hospital for more definitive care after stabilization.

OTITIS AND PHARYNGITIS IN CHILDREN

Kimberly S. Quayle
Susan Fuchs David M. Jaffe

OTITIS MEDIA

Otitis media, or inflammation of the middle ear, is one of the most common pediatric diagnoses. Each year there are 25 to 30 million office visits, with direct costs of more than \$5 billion a year.¹ Acute otitis media (AOM; acute suppurative, purulent, or bacterial) is associated with signs and symptoms of inflammation of the middle ear, such as otalgia, otorrhea, fever, irritability, anorexia, or vomiting.¹ Otitis media with effusion (OME; secretory, nonsuppurative, serous, or mucoid) is a relatively asymptomatic collection of fluid in the middle ear. The duration (not the severity) of OME can be divided into acute (<3 weeks), subacute (3 weeks to 3 months), and chronic (>3 months). The most important distinction between OME and AOM is that the signs and symptoms of acute infection (otalgia, otorrhea, and fever) are lacking in OME, but hearing loss may be present in both conditions.¹

Acute Otitis Media

Infants and young children are at greatest risk for the development of otitis media, with the peak incidence occurring between 6 and 18 months.² In fact, in the United States, up to 50 percent of children will have had at least one episode of AOM by age 1.¹ The incidence is higher in males, Native Americans, Alaskan and Canadian Eskimos, and children who attend day care, are exposed to tobacco smoke, have a cleft palate or other craniofacial anomaly (e.g., Down syndrome), sleep in a prone position, use a pacifier, have older siblings or parents with a history of ear infections, had their first episode of AOM at younger than 6 months, or have congenital or acquired immunodeficiency.^{1,2} The incidence is lower in breast-fed infants.¹

Middle ear effusion may persist for weeks to months after an episode of AOM. Antibiotic therapy generally sterilizes the effusion but does not clear it from the middle ear space. After the first episode of AOM, 70 percent of children still have a middle ear effusion at 2 weeks, 40 percent at 1 month, 20 percent at 2 months, and 10 percent at 3 months.³

ETIOLOGY Bacteria are the most common cause of AOM and can be isolated in a pure culture from the middle ear exudate in 60 to 75 percent of cases. These organisms colonize the nasopharynx and enter

the middle ear via the eustachian tube. *Streptococcus pneumoniae* and *Haemophilus influenzae* are the most common pathogens (*S. pneumoniae*, 40 to 50 percent, and most common serotypes are 19, 23, 6, 14, 3, and 18; *H. influenzae*, 30 to 40 percent, primarily nontypable strains), and *Moraxella catarrhalis* is the third most common organism (10 to 15 percent).^{1,4} Of importance is a major change in the increased prevalence of (3-lactamase-producing *M. catarrhalis* (almost 100 percent) and *H. influenzae* (35 to 40 percent), which affects antibiotic therapy decisions.¹ *Streptococcus pyogenes* (group A) and *Staphylococcus aureus* each are found in 2 percent of cultures.⁴ *Chlamydia pneumoniae* also may be a causative organism, especially in those younger than 6 months. However, in infants 6 weeks or younger, gram-negative enteric bacilli and *S. aureus* account for 10 to 20 percent of isolates.⁵ Although viruses are rarely recovered from middle ear effusions, recent studies have shown an increased risk of OME after an upper respiratory tract infection due to rhinovirus, respiratory syncytial virus, adenovirus, and influenza virus A or B.

PATHOPHYSIOLOGY Abnormal function of the eustachian tube appears to be the dominant factor in the pathogenesis of middle ear disease. Two types of tube dysfunction may result in otitis media: obstruction and abnormal patency. Obstruction can result from persistent collapse of the eustachian tube due to increased tubal compliance, an inadequate active opening mechanism, or both. Infants and younger children are susceptible to eustachian tube obstruction, because the cartilage that supports the eustachian tube is less stiff than in adults. In addition, an upper respiratory tract infection or allergies can obstruct the eustachian tube and decrease its function. The obstructed eustachian tube prevents equilibration of air pressure between the middle ear and the atmosphere and creates conditions favorable to the development of purulent or sterile effusions. The other type of dysfunction is abnormal patency, which may allow reflux of nasopharyngeal secretions.⁵

CLINICAL FEATURES Classic signs and symptoms of AOM include ear pain (otalgia), otorrhea, and fever; however, ear pulling and irritability may be the only clues in an infant. The most important diagnostic tool is the pneumatic otoscopic examination. Before adequate visualization of the external canal and tympanic membrane (TM) can be achieved, cerumen must be removed from the canal by blunt curettage or by irrigation with warm water.⁵ The presence or absence of discharge and the position or contour (normal, bulging, retracted), color (pink, grey, red, yellow), and degree of translucency (translucent, opaque, non-opaque) and mobility (normal, increased, decreased, absent) of the TM must be assessed.⁶ The light reflex is of no diagnostic value. The normal eardrum is translucent and pearly gray but may become reddened with crying. The eardrum should be freely mobile in response to positive and negative pressure by the pneumatoscope; however, retracted TMs have reduced mobility. The TM of AOM is usually opaque, pale yellow, red, and sometimes bulging, and bony landmarks (long and short process of the malleus) are not easily discernible. However, the most significant sign is the loss of or decrease in mobility of the TM, which implies the presence of a middle ear effusion.

Tympanometry is a noninvasive diagnostic technique used to determine the compliance of the TM and the middle ear. A fixed tone at a given intensity is delivered through a probe snugly placed in the external ear canal as the air pressure in the canal is changed from positive to negative. The tympanogram is a recording of the acoustic compliance of the middle ear, and patterns obtained are useful in distinguishing a normal ear from one with an effusion.⁶ Spectral gradient acoustic reflectometry is a technique that in the uncooperative infant or child is easier to perform than tympanometry, because the instrument does not need to seal the auditory canal. It assesses the response of the TM to a sound stimulus, and a microprocessor analyzes the data into spectral gradient angles that indicate the likelihood of a

middle ear effusion.⁵ However, it cannot be used to distinguish the presence of an effusion due to AOM from that caused by OME.⁶

Aspiration of the middle ear is the most definitive method of verifying the presence and type of middle ear effusion and infecting organism; however, its use for this purpose in the ED setting is rarely practical. It may be beneficial in (1) children with overwhelming sepsis, (2) immunologically deficient children, (3) neonates, (4) children with persistent symptoms of AOM after more than 48 to 72 h on antimicrobial therapy, or (5) otitis media with confirmed or potential suppurative complications.^{5,6} Diagnostic tympanocentesis may be performed by inserting an 2.5- to 3-in. 18-gauge spinal needle or catheter over a needle attached to a syringe through the anterior inferior or posterior inferior quadrant of the TM. The aspirate should be cultured in blood culture broth, on blood and chocolate agar plates, and sent for Gram stain.⁶ When therapeutic drainage is required, a myringotomy should be performed. The incision should be made in the lower half of the TM and should be large enough to allow adequate drainage and aeration of the middle ear. Myringotomy may relieve unusually severe otalgia at initial examination or at any time during the course of the disease. In addition, it should be performed when a suppurative complication (e.g., meningitis, facial paralysis, or mastoiditis) is present.^{5,6}

TREATMENT Selection of the appropriate antibiotic is based on several factors: (1) knowledge of the likely etiologic agent or recovery of a specific pathogen from middle ear fluid, (2) the efficacy of certain antibiotics against the organism responsible for AOM, (3) antibiotic penetration into middle ear fluid, (4) a history of drug allergy, (5) compliance issues, (6) drug side effects, and (7) treatment failure or success of previous drug regimens for that child.¹ There are also patient factors that influence therapy, including age, attendance at day care, and the use of antibiotics within the past 3 months.¹⁴

Despite the approval of 16 antibiotics by the US Food and Drug Administration (FDA) for the treatment of AOM (see Table 121-1 for doses and frequency) and the changing antibiotic susceptibility pat-

terns that have emerged over the past few years, amoxicillin remains the drug of choice. However, due to the prevalence of drug-resistant *S. pneumoniae* (DRSP) (Table 121-2), a Centers for Disease Control and Prevention (CDC) working group has developed a new management scheme.⁴ **There are now two doses of amoxicillin (Amoxil): the standard dose (40 to 45 mg/kg per d) and the high dose (80 to 90 mg/kg per d).** The recommendation to use a high dose is based on the fact that amoxicillin has the longest time above the MIC₉₀ against DRSP than any of the other antibiotics.⁴ The high-dose amoxicillin is recommended as first-line treatment for those patients with a high risk of DRSP. These patients include children younger than 2 years, those in day care, and those who have used antibiotics within the previous 3 months. Although this high dose is not approved by the FDA, it was felt that amoxicillin had a long safety record and a history of efficacy in treating AOM.⁴

Other potential choices include high-dose amoxicillin-clavulanate (Augmentin; 80 to 90 mg/kg per d of the amoxicillin component with 6.4 mg/kg per d of clavulanate, which requires the new 7:1 formulation) or cefuroxime axetil (Ceftin; 30 mg/kg per d). For those children not in the high-risk group, first-line treatment options include standard- or high-dose amoxicillin.⁴

If after 3 days the infant or child still has evidence of AOM (clinical failure including persistence of signs and symptoms such as ear pain, fever, or TM findings consistent with AOM), it is necessary to provide coverage against P-lactamase-producing *H. influenzae* and *M. catarrhalis* and penicillin-resistant *S. pneumoniae*. Antibiotics that are appropriate are based on the initial agents used but include high-dose amoxicillin-clavulanate, cefuroxime axetil, and intramuscular ceftriaxone (Rocephin) for the low-risk group. For the high-risk group, intramuscular ceftriaxone, clindamycin, and tympanocentesis are options.⁴ The caveats are as follows. (1) Whereas the FDA has approved a single dose of intramuscular ceftriaxone for penicillin-susceptible strains, the CDC working group has recommended treatment on 3 consecutive days for those in whom high-dose amoxicillin was unsuccessful, because one dose may be insufficient in curing AOM due to

TABLE 121-1 Treatment Options for Otitis Media

Generic Name (Trade Name)	Oral Dose Unless Otherwise Noted	Frequency*
Amoxicillin (Amoxil)	40-45 mg/kg per d, standard dose 80-90 mg/kg per d, high dose	tid
Amoxicillin—clavulanate (Augmentin)	40-45 mg/kg per d, standard dose 80-90 mg/kg per d, high dose, but limit clavulanate to 6.4 mg/kg per d	4:1 formula tid, 7:1 formula bid
Trimethoprim-sulfasoxazole (TMP-SMX; Bactrim, Septra)	TMP, 8-12 mg/kg per d SMZ, 40-60 mg/kg per d	bid
Erythromycin and sulfasoxazole (Pediazole, Eryzole)	40-50 mg/kg per d of erythromycin	qid or tid
Second-generation cephalosporins Cefaclor (Ceclor) Cefuroxime axetil (Ceftin) Cefprozil (Cefzil) Cephalexin (Keflex, Kefab) Loracarbef (Lorabid)	40 mg/kg per d 30 mg/kg per d 30 mg/kg per d 25-50	tid or bid bid bid
Third-generation cephalosporins Cefixime (Suprax) Cefibuten (Cedax) Cefpodoxime (Vantin) Cefdinir (Omnicef) Ceftriaxone (Rocephin)	mg/kg per d 30 mg/kg per d 8 mg/kg per d 9 mg/kg per d 10 mg/kg per d 14 mg/kg per d 50 mg/kg per d, IM only	qid or tid bid qd or bid qd qd or bid qd or bid qd for 1-3 d
Macrolides		
Azithromycin (Zithromax)	10 mg/kg per d on day 1, then 5 mg/kg per d for 4 d	qd
Clarithromycin (Biaxin)	15 mg/kg per d	bid

* Prescription duration is 10 days, unless otherwise noted. Please see text for discussion of appropriate patients for 5-7 versus 10 days of therapy.

TABLE 121-2 High-Risk Features for Otitis Media Due to Drug-Resistant *Streptococcus pneumoniae*

Antibiotics within past 3 mo
Day-care attendance
Age <2 y

penicillin-resistant *S. pneumoniae*.⁴ (2) The use of clindamycin may be appropriate for those exposed to recent antibiotics, but it is important to realize that clindamycin is not active against *H. influenzae* or *M. catarrhalis* and, hence, should be given as the sole agent in culture-confirmed *S. pneumoniae* otitis media.⁴ (3) Since the report of the CDC working group, another cephalosporin, cefdinir (Omnicef), has been approved for AOM. Because its spectrum of activity is similar to that of cefuroxime axetil and it has a better taste, it may be another appropriate choice.⁷ (4) The use of diagnostic tympanocentesis is another option to guide the choice of therapy.⁴

If the child is not found to have a treatment failure on day 3, but rather returns for a re-check between days 10 and 28 and is found to still have AOM (not just a middle ear effusion), then the treatment options include high-dose amoxicillin-clavulanate, cefuroxime axetil, or intramuscular ceftriaxone for the low-risk group and high-dose amoxicillin-clavulanate, cefuroxime, intramuscular ceftriaxone, or tympanocentesis for the high-risk-group, after taking into account the caveats listed above⁴ (Figure 121-1).

Although there are many other (3-lactamase agents effective and approved for the treatment of AOM [including cefaclor (Ceclor), cefixime (Suprax), ceftibuten (Cedax), cefprozil (Cefzil), cefpodoxime (Vantin), loracarbef (Lorabid), azithromycin (Zithromax), and clarithromycin (Biaxin)], the CDC working group did not include them due to lack of clinical efficacy.⁴ Cefprozil has less p-lactamase stability than do cefuroxime, cefdinir, and cefpodoxime. Cefaclor, loracarbef, cefixime, and ceftibuten have inadequate activity against penicillin-resistant *S. pneumoniae*.^{1,6}

Some of the traditionally used first- and second-line antibiotics, including trimethoprim-sulfamethoxazole [TMP-SMZ (Bactrim or Septra)] and erythromycin and sulfasoxazole (Pediazole), are not in the algorithm, because resistance to TMP-SMZ is more common than resistance to penicillin and 10 percent of isolates are resistant to erythromycin. Therefore, patients who have already failed high-dose amoxicillin are likely to fail to respond to these drugs.⁴ In addition, pneumococci that are resistant to erythromycin are also resistant to the newer macrolides, azithromycin and clarithromycin, and they are not as effective against *H. influenzae* as the (3-lactams⁴ (see Figure 121-1).

Patients who are allergic to P-lactam agents should not be given cephalosporins, so alternatives such as clindamycin, erythromycin and sulfamethoxazole in combination, TMP-SMZ, clarithromycin, or azithromycin are recommended.¹

In infants 6 weeks or younger, several factors should be taken into account (Table 121-3). If the infant is younger than 2 weeks (or is older but has remained in a newborn nursery for a prolonged period), group B *Streptococcus*, *S. aureus*, and gram-negative bacilli are the most likely pathogens. A child of this age warrants a full septic workup (complete blood count, blood culture, urinalysis, urine culture, lumbar puncture with cerebrospinal fluid analysis and culture, and possibly a chest radiograph) and admission for parenteral antibiotics (ampicillin plus gentamicin, cefotaxime, or ceftriaxone). For infants between 2 and 6 weeks of age who have been discharged for more than 2 weeks from a nursery, *S. pneumoniae* and *H. influenzae* are the most likely culprits.⁵ Although a full septic workup is warranted, decisions about admission and treatment options are based on the results of these tests, the appearance of the infant, availability of close follow-up, and prevailing policies.

In the numerous trials of antibiotics in the treatment of otitis media, adverse reactions requiring the discontinuation of the drug have occurred in fewer than 5 percent of patients. With ampicillin, amoxi-

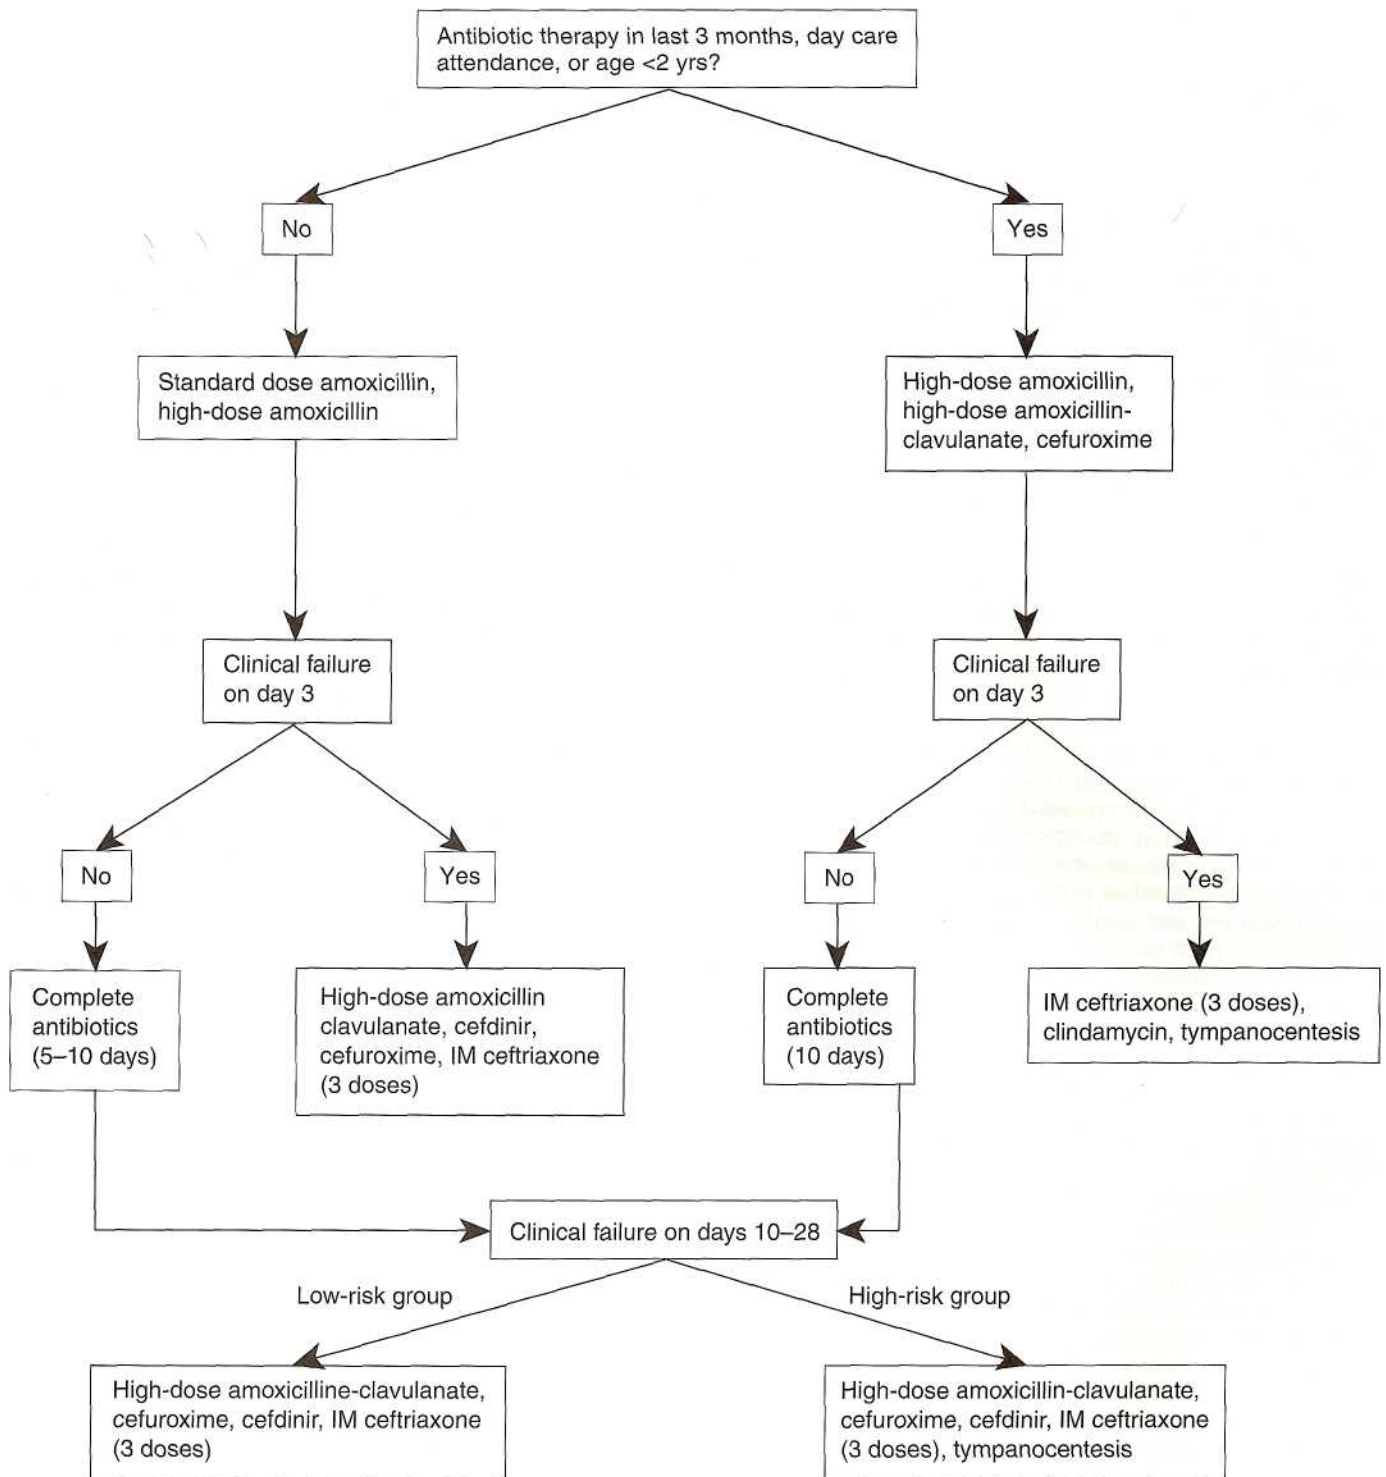

cillin, and amoxicillin-clavulanate, diarrhea is the most common side effect, followed by rash. Trimethoprim-sulfasoxazole can also cause diarrhea and skin rash (including Stevens-Johnson syndrome), but the major concern is the development of neutropenia and thrombocytopenia. In addition, a patient with glucose 6-phosphate dehydrogenase deficiency should not receive sulfonamides. Erythromycin often causes gastrointestinal symptoms, including abdominal cramps, nausea, vomiting, and diarrhea. Aside from possible cross-sensitivity in patients with penicillin allergy, cefaclor can cause a serum sickness-like reaction consisting of a rash, arthralgia or arthritis, and fever.¹

DURATION OF THERAPY Although the CDC working group did not address the issue of duration of therapy, recent data support the use of a 5- to 7-day course of antibiotics in older children (>2 years) with mild AOM. For children younger than 2 years, any patient with perforation of the TM, those with underlying medical problems, those at higher risk of treatment failure, and those with chronic or recurrent otitis media should receive a full 10 days of treatment (except for azithromycin, which is given for 5 days).³⁻⁸

ADDITIONAL THERAPY Antipyretics and analgesics may be helpful in alleviating some of the acute symptoms. A topical analgesic [antipyrine, benzocaine, and glycerin (Auralgan)] instilled into the external ear canal often provides some relief from otalgia, but it should not be used when a TM perforation is present. Decongestants, antihistamines, or glucocorticoids have no demonstrable role in the treatment of AOM. With appropriate antimicrobial therapy, most children with AOM are significantly improved within 48 to 72 h. Persistent or recurrent pain or fever after 48 to 72 h indicates a need for reexamination of the child and the possible selection of another antimicrobial agent. Reasons for response failure include a resistant organism, non-compliance, and host-related structural or immunologic abnormalities. Standard practice has been that children with an uncomplicated course should be reexamined within 10 to 14 days of the completion of antibiotic therapy. Studies have demonstrated that this visit may be delayed to 3 to 6 weeks in certain cases. However, in view of the fact that an emergency physician is not usually providing long-term follow-up care for such patients, telephone contact with the patient's physician to arrange for a follow-up visit is recommended.

Recurrent Acute Otitis Media

Many children have repeated episodes of AOM. Recurrent AOM is defined as three or more episodes of AOM in 6 months or four episodes in 12 months, with at least one episode within the past 6 months^{3,9} (Table 121-4). Some children develop symptoms and a new ear effusion, often associated with an upper respiratory tract infection, after a previous effusion has resolved, whereas others develop symptoms of AOM with no documented resolution of a previous effusion. There is a correlation between such "otitis-prone" children and the onset of AOM before 1 year of age. Other risk factors include day-care attendance and genetic susceptibility: a sibling or parent with a history of severe or recurrent AOM. The key factor is distinguishing AOM from OME via pneumatic otoscopy and even tympanocentesis.⁹ Due to the risk of long-term sequelae, such as hearing loss and speech impairment, prevention of further episodes is desirable.⁹ A more thorough physical examination and laboratory x-ray studies should be performed to rule out sinusitis, allergies, immune deficiencies (C3 and C5 deficiencies), submucous cleft palate, or a tumor of the nasopharynx. If none of these is present, the preferred method of prevention for this particular group of patients is prophylaxis with antibiotics: amoxicillin, 20 mg/kg per d at bedtime, or sulfasoxazole, 75 mg/kg in one or two divided doses, for 3 to 6 months, with rechecks every 1 to 2 months. Prophylaxis is especially important during the fall and winter, when respiratory tract infections tend to occur; for children younger than 2 years; and for those in day care. Although there is concern that

TABLE 121-3 Otitis Media Neonates

Age	Organisms	Workup
<2 wk or prolonged care in a nursery	Group B <i>Streptococcus</i> , <i>Staphylococcus aureus</i> , gram-negative bacilli	Full septic workup including lumbar puncture
2-6 wk or discharged ≤2 wk from a nursery	<i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i>	Full septic workup, lumbar puncture is usual

the use of prophylaxis results in increased nasopharyngeal carriage of resistant pneumococci in this population, the benefits must be weighed against the risks and other options.³

Myringotomy with tympanostomy tube insertion is the next step for children who fail antibiotic prophylaxis, although some physicians might have chosen myringotomy instead of antibiotic prophylaxis. Adenoidectomy is recommended at the time of myringotomy tube placement for children with severe nasal obstruction.⁵

Persistent Acute Otitis Media

Persistent AOM is defined as the persistence of AOM within 3 days of initiating therapy or the recurrence of signs and symptoms within a few days of completing a 10-day course of antibiotics. This condition may be caused by the same pathogen (relapse) or a new bacterial species (reinfection).⁵ The treatment of this problem is covered in the algorithm for AOM (see Figure 121-1). If the child still has AOM after two courses of treatment, tympanocentesis for culture and identification of the organism should be performed, although this is not always feasible. A search for a suppurative complication of otitis media (e.g., mastoiditis) or a concurrent infection (e.g., meningitis) should be performed at this time.

Chronic Suppurative Otitis Media

The persistence (>6 weeks) of a chronic inflammation of the middle ear and mastoid in the presence of a perforated or non-intact TM is known as chronic suppurative otitis media (CSOM). Purulent ear discharge may or may not be present.¹⁰ It is thought to be a sequela of partly treated or untreated AOM or recurrent AOM. The organisms responsible for infection depend on the patient's age. In young children who develop AOM and then have a perforation or those with a tympanostomy tube, the common organisms are those that cause AOM, including *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*. In older children or in those with water contamination of the middle ear, *Pseudomonas aeruginosa* and *S. aureus* are the most common causative organisms, although anaerobes have also been cultured.¹⁰ It is thought that the organisms gain access to the middle ear through the perforated TM and become pathogens in the middle ear. A thorough examination is imperative, because chronic ear drainage can be a manifestation of a cholesteatoma (which requires surgery). In the absence of a cholesteatoma, the following steps result in a more rapid improvement in ear drainage and a decreased need for tympanomastoid surgery. (1) Meticulous daily cleaning and aspiration of the external and middle ear followed by instillation of ear drops. Polymyxin B, neomycin, and hydrocortisone (Cortisporin, Pediotic suspension), topical tobramycin and dexamethasone (TobraDex), or gentamicin ophthalmic drops (Garamycin) are falling out of favor, because they may be ototoxic. Ofloxacin (Floxin otic) is FDA approved for use in CSOM in children older than 12 years and for cases of AOM in children older

than 1 year with tympanostomy tubes. Ofloxacin (Floxin otic) is currently the only FDA-approved drug for children with non-intact TMs. Ciprofloxacin with hydrocortisone (Cipro HC) is FDA approved for children and adults for the treatment of otitis externa and with an intact TM, not for CSOM. Alternatives to antibiotics include the use of ototopical antiseptic agents such as acetic acid and aluminum subacetate (Burow's solution), acetic acid (2%) otic (VoSoL), or acetic acid (2%) in aqueous aluminum acetate otic solution (Otic Domeboro).^{5,10} (2) Oral antibiotics (amoxicillin-clavulanate) in addition to otic drops can be prescribed, if the organism is thought to be *P. aeruginosa*, although this is unlikely to be effective. For adults and children older than 18 years, oral ciprofloxacin is another alternative.¹⁰ (3) If ototopical drops with or without oral antibiotics is not successful, the next step is the use of parenterally administered broad-spectrum, antipseudomonal antibiotics [ticarcillin, ticarcillin-clavulanate (Timentin), piperacillin, or ceftazidime (Fortaz, Tazicef, or Tazidime)] on an inpatient or an outpatient basis.^{5,10}

Complications and Sequelae of Otitis Media

The complications and sequelae of otitis media predominantly involve the middle ear and adjacent structures within the temporal bone, but in rare instances intracranial complications may occur. The aural or intratemporal complications and sequelae include hearing loss, perforation or retraction pocket of the TM, tympanosclerosis, adhesive otitis media, ossicular discontinuity and fixation, CSOM, cholesteatoma, mastoiditis, petrositis, labyrinthitis, and facial paralysis.¹¹ Suppuration in the middle ear, mastoid, or both may extend into the intracranial cavity, producing the following intracranial complications: meningitis, extradural abscess, subdural empyema, focal encephalitis, brain abscess, lateral (sigmoid) sinus thrombosis, and otitic hydrocephalus.¹¹ These complications are uncommon except in neglected cases.¹¹

Prevention of Acute Otitis Media

Because *Pneumococcus* is the most common bacterial pathogen in AOM, the use of a vaccine could decrease the incidence of AOM. A heptavalent pneumococcal conjugate vaccine is now available in the United States. It contains separate conjugates for serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F. Large-scale evaluations of this vaccine in northern California and Finland have demonstrated a reduction in all AOM cases by 6 to 8.9 percent and culture-proven pneumococcal cases by 34 percent.¹² The routine use of this vaccine (recommended to be given at ages 2, 4, and 6 months, with a booster at age 2 years) could reduce the number of visits for otitis in the United States by 1 million!¹²

Otitis Media with Effusion

Otitis media with effusion is defined as a collection of fluid in the middle ear, without acute clinical signs and symptoms, which often follows an episode of AOM.¹³ Hearing loss is by far the most prevalent complication and morbid outcome of OME. The extent of hearing loss depends on the volume of the effusion rather than the physical properties of the effusion, and OME is associated with a mild to moderate conductive hearing loss of 20 dB or more. Audiometry is of limited value as a diagnostic method for the identification of OME, but it

TABLE 121-4 Recurrent Acute Otitis Media

- ≥ 3 episodes in 6 mo
- or
- ≥ 4 episodes in 12 mo, with 1 in past 6 mo

can be helpful in the evaluation of the effect of middle ear disease on hearing. The relation between persistent or episodic conductive hearing loss and impairment in the cognitive linguistic and speech development of children has been reported. However, the degree and duration of the hearing loss required to produce such deficits have not been defined.¹³

Other factors that should be considered in addition to hearing loss when deciding whether to treat OME include (1) occurrence in young infants, because they are unable to communicate their symptoms and may have suppurative disease; (2) an associated acute purulent upper respiratory infection; (3) permanent conductive or sensorineural hearing loss; (4) vertigo; (5) alterations in the TM (severe atelectasis and/or a deep retraction pocket in the posterosuperior quadrant or the pars flaccida); (6) middle ear changes, such as adhesive otitis or ossicular involvement; (7) persistence of the effusion for more than 3 months (chronic OME); (8) occurrence of episodes so close together that the child has OME for 6 of 12 months; (9) the presence of craniofacial abnormalities; and (10) impaired or deficient immunologic status.¹³ A thorough search for an underlying cause (e.g., sinusitis, allergy, submucous cleft, or tumor) should be attempted before treatment is begun.

There are several management options for children 1 to 3 years of age with OME that persists for less than 3 months: observation (no treatment) or treatment with an antibiotic for 10 to 14 days.¹³ Because most episodes of OME clear spontaneously and because of the concern for antibiotic resistance, the no-treatment option is currently preferred.¹³ However, if antibiotic therapy is chosen, because bacteria that cause OME are similar to those found in AOM, the antibiotics used are the same: amoxicillin, amoxicillin-clavulanate, TMP/SMX, cefaclor, erythromycin, and sulfasoxazole.¹³

For children with OME of 3 months' duration and a hearing loss of 20 dB or more, the Agency for Health Care Policy and Research recommends referral to an otolaryngologist for myringotomy with tympanostomy tube placement as another option (in addition to the options described above).¹³ However, many reserve myringotomy and tube placement for patients who have failed an antibiotic trial.

The other nonsurgical methods available, including the use of decongestants, antihistamines, and immunotherapy, have not been shown to be effective in clinical trials.¹³ The addition of an oral corticosteroid (prednisone, 1 mg/kg per d in two doses for 7 days) to the use of oral antibiotics for 14 to 21 days remains controversial. Steroids should not be used in a susceptible child who has been exposed to Varicella in the past month, due to a risk of disseminated disease.

Myringotomy with tympanostomy tube placement improves the conductive hearing loss for longer periods than does myringotomy alone.⁵ Tympanostomy tubes remain in place from a few weeks to several years, with an average of 6 months. Possible complications of myringotomy tubes are scarring (tympanosclerosis), localized atrophy, persistent perforation, and the rare development of a cholesteatoma.⁵ For children 4 years or older who have recurrent chronic OME and who have had one or more myringotomy and tympanostomy tube operations in the past, adenoidectomy is a reasonable option.¹¹ The presence of upper airway obstruction, recurrent acute or chronic adenoiditis, or both is another indication to consider adenoidectomy.⁵

OTITIS EXTERNA

External otitis (OE) is any inflammatory condition of the auricle, external ear canal, or outer surface of the TM. It can be caused by infection, inflammatory dermatoses, trauma, or combinations of the three.

Pathophysiology

The flora of the normal ear canal are the same as those of normal skin. They include *Staphylococcus epidermidis*, *Corynebacterium* species, and *ct-hemolytic streptococcus*.¹⁴ Compromise of any of the protective

features of the ear canal (e.g., shape, cerumen, or acidic pH) can lead to OE due to colonization and invasion by pathogenic organisms, especially *P. aeruginosa*, *S. aureus*, and fungi.¹⁴ Causes include (1) high environmental temperature and humidity, (2) hyperhydration and maceration of epithelial tissue in the canal, (3) absorption of moisture by the stratum corneum, (4) lack of cerumen through blocked gland ducts and/or mechanical removal (scratching), (5) obstruction of gland ducts by edema and keratin debris, (6) invasion by exogenous or endogenous organisms through breaks in the damaged epithelial surface, and (7) trauma.¹⁴

Clinical Features

The mildest form of acute inflammatory OE is characterized by itching or a sense of fullness in the ear. As it progresses, increasing pain, itching, redness, edema, tenderness of the canal, and cheesy or purulent discharge occur. Inward pressure on the tragus or pulling the auricle up and back usually results in discomfort. If the TM can be visualized, it is often red, thick, and covered with the flat vesicles or areas of desquamating epithelium.¹⁴ In the severe stage, pain is intense and can be caused by any movement of the jaw or the ear. There is often disseminated infection, with the presence of enlarged and tender lymph nodes. Further anterior spread of the infection affects the parotid gland and subcutaneous tissue. Posterior spread involves the mastoid, and medial spread involves cranial nerves IX through XII, with possible osteomyelitis of the skull.¹⁴

When there is acute localized OE (furunculosis), although pain, itching, and signs of infection, such as erythema, are present, a localized abscess is often seen. The organism responsible is usually *S. aureus*.¹⁴ When OE is caused by fungi (otomycosis), most commonly *Aspergillus niger*, there is intense itching. Otomycosis is more common in those with underlying immune disorders and diabetes mellitus.¹⁴

Diagnosis

The hardest part of the diagnosis is to distinguish between OE and otitis media. Ideally, clinical inspection of the TM with a pneumatic otoscope helps establish the diagnosis; however, the TM of a child with OE may be as red and distorted as that of a child with otitis media, although mobility of the TM is normal or slightly decreased in OE. In addition, visualization of the TM may be difficult, because of edema of the canal in OE. Tympanometry can be helpful if the canal is clear, and a tight seal for the earpiece can be formed without too much discomfort. Parotitis, periauricular adenitis, mastoiditis, dental pain, and temporomandibular joint dysfunction should be considered when the discomfort is poorly localized and the ear canal and TM appear normal. In addition, pain can be referred from pharyngitis or tonsillitis, but such pain is often made worse by swallowing or eating. Foreign bodies in the ear also can cause OE.¹⁴

Treatment

A thorough and atraumatic cleaning of the ear canal is the most important part of therapy. For mild infections, dry mopping with a small tuft of cotton attached to a wire applicator is sufficient and may be curative. If the canal is inflamed, edematous, and occluded by debris, cleaning can be done with gentle suctioning: a soft plastic infant feeding tube (with an opening at the tip) can be used.

Mild OE can be treated with cleaning and acidifying agents alone. Acetic acid eardrops are the easiest and least expensive way to eliminate the infecting agent. A 2% solution is effective and available commercially in aqueous (Otic Domeboro) or alcohol-based (VoSoL or Orlex) solutions. These drops should be used three to four times a day for at least 1 week.¹⁴

Moderate OE should be treated with cleaning and antibiotic drops. If the canal cannot be cleaned sufficiently, an Oto-Wick can be placed

in the canal to act as a passage for the use of drops. It can be left in place for 2 to 3 days, at which point reexamination and removal can be performed. Antibiotic preparations containing neomycin and polymyxin B (Cortisporin Otic, Otocort, and Pediotic) have been reported to cause ototoxicity.¹⁴ Cortisporin is available as a solution and a suspension. The solution contains an acidifying agent, so it may cause more burning or stinging than the suspension. Another option is the use of Cortisporin ophthalmic suspension, which is free of acid and alcohol. Consequently, fluoroquinolone otic drops such as ofloxacin (Floxin otic) or ciprofloxacin with hydrocortisone (Cipro HC otic) are now preferred.¹⁴ Floxin otic is approved for use with a non-intact TM. Cipro HC otic is approved for use with an intact TM. Although fluoroquinolones are not approved for children younger than 18 years via the oral route, otic fluoroquinolone drops can be used in children older than 1 year. Fluoroquinolone drops are used twice a day, as opposed to the polymyxin/neomycin drops, which must be used three to four times a day.¹⁴ Otic chloramphenicol (Chloromycetin) should be avoided because of the risk of aplastic anemia.

Children who fail to respond within 48 h of treatment should be reexamined. If the ear is not clear and dry, other causes, such as cellulitis, abscess, CSOM, cholesteatoma, sensitization to the antibiotic, local dermatoses, or even noncompliance, should be excluded.¹⁴ In some cases, oral antibiotics active against *S. aureus* (e.g., dicloxacillin or cephalexin) may be required. Oral ciprofloxacin, an effective antipseudomonal drug, is not approved for children younger than 18 years.

Patients with progressive, unresponsive, or severe infection may require parenteral (intravenous) therapy. Cultures of canal secretions should be taken, and a combination of an aminoglycoside (gentamicin or tobramycin) and an antipseudomonal penicillin (ticarcillin or piperacillin) should be started. If the clinical findings and course of the illness suggest an infection due to *S. aureus*, a penicillinase-resistant antibiotic [nafcillin, oxacillin, vancomycin, or ampicillin-sulbactam (Unasyn) for those older than 1 year] also should be given.¹⁴

The basic treatment of otomycosis is similar to that for acute bacterial OE, with cleaning followed by 2% acetic acid or M-cresyl acetate (25%) preparations. Patients who do not respond can be treated with topical antifungal medications, including suspensions of miconazole, nystatin, clotrimazole, or amphotericin B. Glucocorticoids are present in many topical otic preparations, but their value is unproven. Topical benzocaine and lidocaine may be useful to reduce the itching, but they are inadequate for the relief of moderate to severe pain, for which oral analgesics may be required.¹⁴

Prevention of Otitis Externa

Swimming should be prohibited during the course of treatment. Even after therapy, earplug use is suggested. If there is no perforation of the TM, irrigation with 2% acetic acid in Burow's solution (Otic Domeboro) or other acidic solutions, to return the pH to an acidic level, is helpful. Acidified isopropyl alcohol (equal parts vinegar and alcohol) or hydrogen peroxide also can be used, followed by drying with suction, compressed air, or a hair dryer set on low, 1 ft. from the ear for 1 min. The use of cotton swabs to clean the ears should be strongly discouraged,¹⁴ because injury to the TM or ear canal can result.

PHARYNGITIS

Pharyngitis, infection of the pharynx and the tonsils, is a very common pediatric problem. Despite physicians' longstanding familiarity with pharyngitis, there remains wide variability in approach. Controversies and new developments pertain to (1) selection of patients for throat culture and antibiotic treatment, (2) use of rapid diagnostic tests for group A *p*-hemolytic *Streptococcus* (GABHS), (3) increased incidence of serious systemic streptococcal disease, and (4) occurrence of bacteriologic and clinical failure with penicillin treatment of GABHS.

Non-Streptococcal Pharyngitis

ETIOLOGY Most cases of acute pharyngitis in children are caused by viral infections. Examples include adenovirus, Epstein-Barr virus (EBV; see below), influenza virus, parainfluenza virus, rhinovirus, herpes simplex virus, and enterovirus. Although many of these viruses cause symptoms in addition to sore throat and fever, such as cough, coryza, conjunctivitis, or mucosal ulcerations, some viral infections can be clinically difficult to distinguish from GABHS.

Mycoplasma and *Chlamydia* have been suggested as uncommon causes of pharyngitis in adults and adolescents; however, neither organism appears to be an important cause of pharyngitis in children.¹⁵ Many organisms, viral, bacterial, fungal, and even protozoal, have been associated with pharyngitis; however, only a relatively few are of practical significance to the emergency evaluation of pharyngitis in the immunocompetent child. Recent studies have suggested that *Arcanobacterium haemolyticum* (formerly *Corynebacterium haemolyticum*) might be a cause of non-GABHS tonsillopharyngitis with or without a scarlatiniform rash. Erythromycin is the treatment of choice when this organism is identified.¹⁵ Among bacterial pathogens, GABHS is clearly the most important, accounting for 15 to 30 percent of all pharyngeal infections in school-age children. GABHS pharyngitis is unusual in children younger than 3 years, and rheumatic fever is rare in this age group.¹⁶

DIAGNOSIS AND TREATMENT The few non-GABHS organisms that occasionally require specific diagnosis are *Corynebacterium diphtheriae*, *Neisseria gonorrhoeae*, EBV, and human immunodeficiency virus (HIV) type 1. Despite the many etiologic possibilities, in school-age children the diagnostic task is most often reduced to distinguishing GABHS, which requires specific antibiotic therapy, from non-streptococcal pharyngitis.

Diphtheria is a rare but serious cause of pharyngitis in developed countries. Immunization in infancy has been effective in nearly eliminating diphtheria in childhood, but it can occur in crowded conditions where there are socioeconomic barriers to immunization. Morbidity occurs because of infectious and toxic reactions. Infectious invasion and spread occur with enough tissue necrosis to produce a pseudomembrane that can progress to cause airway obstruction. The *C. diphtheriae* bacteria also produce an exotoxin that can cause widespread organ damage, including myocarditis and cardiac dysrhythmia, neuritis with bulbar and peripheral paralysis, nephritis, and hepatitis. Diagnosis must be clinical to expedite effective therapy; however, the bacteria can be grown on Loeffler medium. Treatment is directed at killing the bacteria and neutralizing the exotoxin. Therefore, antibiotic (penicillin or erythromycin) and horse serum antitoxin must be given.

Neisseria gonorrhoeae is an infrequent but important cause of pharyngitis in sexually active adolescents. Gonococcal pharyngitis in younger children strongly suggests child sexual abuse. Gonococcal pharyngitis may be asymptomatic or cause very mild symptoms with occasional exudative tonsillitis and/or cervical lymphadenopathy. Pharyngeal throat swabs should be plated on Thayer-Martin medium to recover the organism. Rectal and vaginal or urethral cultures and serum to test for syphilis and hepatitis B should be obtained whenever gonorrhea is suspected or documented. Gonococcal pharyngitis in children and adolescents should be treated with ceftriaxone (125 mg IM once). Children who cannot tolerate ceftriaxone may be treated with a 5-day regimen of TMP/SMX. Children 9 years or older also should receive oral doxycycline (100 mg twice daily for 7 days) for presumptive *Chlamydia* infection. Children 8 years or younger should receive erythromycin, 40 mg/kg per d in divided doses. Azithromycin (20 mg/kg, 1 g maximum) PO in a single dose is an alternative treatment for *Chlamydia* in all age groups.¹⁷

Epstein-Barr virus is a herpesvirus that is a common cause of infection in childhood and adolescence. Although EBV has been associated with a variety of clinical syndromes, most children infected with

EBV are asymptomatic or have only mild, nonspecific symptoms. Epstein-Barr virus can cause isolated tonsillopharyngitis and pharyngitis as a manifestation of infectious mononucleosis (IM). Clinically, the classic IM syndrome begins with malaise, fatigue, and sore throat. Fever and adenopathy are the most common signs. Splenomegaly and hepatomegaly are also present in the majority of infected children, whereas skin rash, enanthem, eyelid edema, and jaundice occur much less commonly. Pharyngitis occurs in nearly all children with IM. The appearance of the throat can resemble that of bacterial GABHS disease. Dual infection with EBV and GABHS has been documented. Classic IM is much less common in children younger than 2 years, when EBV tends to cause a nonspecific febrile illness. However, IM has been reported recently to occur in toddlers more commonly than was once thought. These younger children most often have a syndrome characterized by fever, tonsillitis, lymphadenopathy, and hepatosplenomegaly.

The laboratory can be helpful in establishing the diagnosis of IM. There is an increase in the proportion and the absolute number of atypical lymphocytes in the peripheral blood smear (generally >50 percent lymphocytes and a 10 percent atypical lymphocytes). Liver transaminase levels show moderate elevation (in general, aspartate aminotransferase < 600 U/dL). The heterophil antibody is present (and can be demonstrated by rapid slide test methods) in more than 90 percent of children older than 5 years with IM but in only 75 percent between the ages of 2 and 4 years, and in fewer than 30 percent younger than 2 years. Serologic testing specific for EBV can provide information as to the likelihood of acute, postacute, old quiescent, and reactivation-type infections. These determinations are made on the basis of the presence of specific patterns of IgM and IgG responses to viral capsid antigen and IgG responses to EBV early antigen and the EBV nuclear antigen.

Infectious mononucleosis is generally a benign, self-limited, but somewhat prolonged illness. In general, treatment involves nonspecific supportive modalities (fluids, acetaminophen, and rest). Fatal complications are rare. Death can be caused by neurologic complications (e.g., meningoencephalitis or Guillain-Barre syndrome), splenic rupture and hemorrhage, and bacterial and fungal sepsis. Immuno-compromised children may have unusual susceptibility to fulminant EBV infection. Airway obstruction secondary to tonsillar hypertrophy also can occur. This complication responds rapidly to glucocorticoid administration (dexamethasone, 1 to 10 mg/kg maximum and then 0.5 mg/kg every 6 h) and rarely requires intubation. Airway obstruction is the only complication for which the use of steroids is widely accepted.

Human immunodeficiency virus type 1 is a recently recognized cause of acute pharyngitis.¹⁵ Primary retroviral infection can produce an IM-like illness with fever, sore throat, and lymphadenopathy that can last for a few days or a few weeks. Findings such as gastrointestinal symptoms or mucocutaneous lesions occur more commonly with acute HIV infection and are very unusual with IM caused by EBV. Primary HIV infections should be considered in high-risk populations.

Streptococcal Pharyngitis

Pharyngitis caused by GABHS is the most common treatable cause of pharyngitis in children. The peak months of infection are January to May, but, because of the high frequency of occurrence in school-age children, the beginning of school in the fall is also associated with GABHS pharyngitis in many areas. The peak ages are 4 to 11 years, with GABHS infection being uncommon before age 3 years.

DIAGNOSIS No set of symptoms or signs is completely specific for GABHS (Table 121-5). Nonetheless, there are findings that are typically, but not exclusively, associated with GABHS. In general, the infected child experiences sudden onset of sore throat and fever. The tonsils and pharynx appear markedly red and have a moderate to large amount of exudate. The soft palate and uvula are also red and may have petechiae. The anterior cervical lymph nodes are enlarged and

TABLE 121-5 Characteristic Signs of Streptococcal Pharyngitis

Erythema of tonsils and pharynx
Exudate of tonsils and pharynx
Erythema and edema of uvula
Petechiae of the soft palate
Enlarged, tender anterior cervical lymph nodes
Scarlatiniform rash

tender. The presence of a scarlatiniform rash and pharyngitis is virtually diagnostic of GABHS. Headache, vomiting, abdominal pain, meningismus, and torticollis also can occur. These are of little diagnostic importance but must be recognized as possibly attributable to GABHS. The presence of significant coughing, rhinorrhea, or ulcerations suggest an alternative diagnosis.

There is general agreement that clinical diagnosis alone would result in an unacceptably high rate of misdiagnosis.

The mainstay of laboratory diagnosis is still the throat culture, although rapid antigen-detection techniques are gaining popularity in pediatric offices and EDs. The tonsil or posterior pharyngeal wall should be swabbed vigorously. In many centers, the swab is sent to the laboratory in appropriate culture medium for further handling. The sample is plated on a blood agar culture medium with neomycin and nalidixic acid added. Colonies that show β -hemolysis are identified as group A by bacitracin disk tests, fluorescent antibody staining, or latex agglutination. The rate of false-negative results from single throat culture is about 10 percent. Recovery rates are maximized by good swabbing technique, multiple cultures (rarely actually performed), and incubation in a carbon dioxide-enriched environment. Positive cultures may indicate an acute GABHS infection or the carrier state. Rates of GABHS carriage change with the season but have been reported to be as high as 15 percent. There is imperfect correlation between the amount of growth (generally reported on a scale of 1+ to 4+) and the likelihood of true infection. Chronic carriers of GABHS are not at increased risk for developing true GABHS pharyngitis or suppurative and nonsuppurative (e.g., rheumatic fever and nephritis) sequelae, nor do they pose an increased risk for disease transmission.

Incubation of throat cultures takes 24 to 48 h, during which time management must occur with uncertainty as to the diagnosis. Antigen-detection procedures are often available in EDs and practitioners' offices. The tests involve extraction of group A carbohydrate antigen from a throat swab and then combining the antigen with a latex agglutination, coagglutination, or enzyme-linked immunosorbent assay. More recently, a chemiluminescent DNA probe test and optical immunoassay have become commercially available. The nonculture tests take 10 to 30 min to perform and are generally more expensive per test than direct plate culturing. Sensitivity under controlled laboratory conditions when using the culture as the gold standard ranges from 85 to 90 percent, and specificity ranges from 98 to 100 percent. Unfortunately, when measured in the field under less well-controlled circumstances, sensitivity of the latex agglutination test has been as low as 50 percent.¹⁸ In other words, the false-positive rate is low, but the false-negative rate may be unacceptably high. The newer optical immunoassay tests are nearly as sensitive as blood agar plate culture and more sensitive than other rapid tests for GABHS; however sensitivities for these tests have varied from 79 to 95 percent when performed in office or ED settings.^{18,19} Any ED or office planning to use a rapid diagnostic test must assess the performance of the test on site. A safe and commonly used approach is to obtain swabs for throat culture and rapid test simultaneously. Children with positive rapid test results are treated for GABHS. If the results are negative, the throat culture is processed and the children are managed according to an acceptable strategy while awaiting throat culture results. An important role of the rapid tests is to decrease the indiscriminate use of antibiotics in children with sore throats, most of whom do not have streptococcal pharyngitis.

TREATMENT The objectives of treatment for GABHS are (1) to prevent rheumatic fever, (2) to prevent suppurative complications (e.g., peritonsillar abscess and cellulitis, suppurative cervical lymphadenitis, and retropharyngeal abscess), and (3) to hasten clinical recovery. Group A (3-hemolytic *Streptococcus* is highly sensitive to penicillin, and there has been no evidence of development of resistance in vitro despite decades of use. A single dose of intramuscular penicillin G benzathine (600,000 units if the patient weighs 27 kg or less, and 1.2 million units if the patient weighs more than 27 kg) is effective but causes significant local discomfort in more than 50 percent of recipients. A preparation containing penicillin G benzathine, 900,000 units, and penicillin G procaine, 300,000 units (CR Bicillin 900/300, introduced in 1976), is effective for children who weigh 64 kg or less and significantly reduces the magnitude and frequency of local reactions. Oral penicillin V is a popular alternative. A regimen of 250 to 500 mg two times daily for 10 days effectively eradicates infection and prevents rheumatic fever.^{16,20} Amoxicillin suspension (at the same dosage as penicillin) is a more palatable alternative for children unable to swallow pills. Variable levels of compliance have been reported. Improvements in compliance can be achieved with careful parent education at the time of discharge. If compliance or follow-up are problematic, the intramuscular route should be used. Alternatives to penicillin for children with penicillin allergy include erythromycin or cephalosporins (Table 121-6). Treatment with antimicrobials, such as azithromycin, cefuroxime, cefdinir, cefixime, and cefbodoxime, for 5 days has been reported to eradicate *Streptococcus* as effectively as the traditional 10-day courses; however, the cost of medication and the effects on antimicrobial resistance also must be considered.²¹

Research also has clearly demonstrated the beneficial effects of early antibiotic therapy on reduction of signs and symptoms of GABHS pharyngitis.¹⁵ In addition, because it is recommended that children with GABHS receive antibiotics for 24 h before returning to school or day care, early treatment benefits the children and their parents, especially parents who work outside the home. Based on these considerations, many strategies for testing and treatment have been proposed, ranging from treating all children with pharyngitis with antibiotics to withholding antibiotics from all pending culture results. Cost-effectiveness studies employing decision-analysis methods have compared some of these strategies.^{22,23} The best strategy for a given institution depends on the local prevalence of GABHS, the availability and accuracy of rapid antigen testing, and the ability to follow up successfully in untreated children found to have positive culture results. A widely accepted strategy that incorporates the latest technology is to perform rapid antigen testing on all

children with pharyngitis and to treat all with positive results. In addition, children with classic clinical findings or a scarlatiniform rash should be treated regardless of the result of rapid testing. Those with a negative rapid test result and equivocal or atypical clinical features for GABHS should have a throat culture performed, but treatment may be withheld pending culture results. Positive culture results indicate the need for treatment. It is not necessary to reculture to test for eradication of GABHS in asymptomatic children. Children with recurrent or persistent symptoms and those with previously documented rheumatic fever do require reculturing. Children with persistent positive culture results in this context can be treated with a different antibiotic such as amoxicillin-clavulanate, a cephalosporin, or clindamycin.²⁰ The asymptomatic carrier state need not be treated except in certain circumstances. These exceptions include a family history of rheumatic fever, an outbreak of rheumatic fever or glomerulonephritis, or multiple documented symptomatic episodes of streptococcal pharyngitis occurring within a family or closed community. Clindamycin, amoxicillin-clavulanate, or a combination of penicillin and rifampin have been shown to be effective in eradicating GABHS in carriers.¹⁷

COMPLICATIONS An increased number of apparent treatment failures with penicillin has been reported.²¹ Group A p-hemolytic *Streptococcus* remains susceptible to penicillin in vitro. Alternative explanations for these findings may involve children who are carriers of GABHS and develop a viral pharyngitis, patients who reacquire the organism from a family member or another close contact, or patients who are noncompliant with the prescribed penicillin. Other proposed mechanisms include development of GABHS penicillin tolerance and the production of p-lactamase from other normal pharyngeal flora. The evidence does not support the diminished efficacy of penicillin therapy for GABHS pharyngitis. Reports of the proposed therapeutic failures have prompted many recent studies comparing the efficacy of penicillin with that of other antibiotics. In general, penicillin remains the recommended antibiotic of choice based on past experience, cost, and historically successful prevention of rheumatic fever.^{16,20,21}

The overall incidence of rheumatic fever has been declining in the developed countries and is now less than 1 per 100,000 in the continental United States. A number of scattered outbreaks of acute rheumatic fever were reported in the United States during the latter part of the 1980s. There is ample justification for adherence to the American Heart Association's recommendations that one of the above-mentioned antibiotic regimens for documented GABHS pharyngitis must be provided. Antibiotic treatment begun within 9 days of the onset of infection is effective in preventing rheumatic fever.

Post-streptococcal glomerulonephritis is a nonsuppurative complication of GABHS disease that is not preventable with antibiotic therapy. Its occurrence is related to infection with nephritogenic strains of streptococci.

Indications for tonsillectomy remain uncertain and controversial. For children with many recurrent episodes of pharyngitis, tonsillectomy reduces the incidence of pharyngitis. The decision regarding tonsillectomy for such children should be individualized to account for various considerations of risks, benefits, and quality of life, including the quality of available anesthetic and surgical services, impact of recurrent illness versus surgery on the child and parents, school performance, and comparative costs to the family.

Recent outbreaks of pharyngitis caused by group G and C streptococci have been reported, often associated with contaminated food sources.¹⁵ Although the acute clinical syndromes associated with these organisms are identical to those of GABHS pharyngitis, they are unlikely to cause preventable nonsuppurative sequelae. However, rare cases of acute glomerulonephritis after infection with group G *Streptococci* have been described.

A recent resurgence of invasive GABHS infections has been noted.²² Serious illnesses include septicemia, toxic shock-like syndrome, pneumonia, cellulitis, lymphangitis, and necrotizing fasciitis.

TABLE 121-6 Antibiotic Choices Streptococcal Infections for Group A

Drugs	Dosage
Penicillin V*	250-500 mg bid PO for 10 d
Amoxicillin†	250-500 mg bid PO for 10 d
CR Bicillin 900/300^	1.2 million units, IM, single dose
Benzathine penicillin G#	1.2 million units, IM, single dose
If allergic to penicillin§	40 mg/kg per d PO bid for 10 d
Erythromycin ethyl succinate	12 mg/kg per d for 5 d
Azithromycin	

*250 mg for children, 500 mg for adolescents and adults.

†Amoxicillin suspension is a better tasting alternative if the child is unable to swallow pills.

‡For patients <64 kg (140 lb).

#For patients >64 kg (140 lb).

§Cephalosporins also may be considered for penicillin-allergic patients.

Such systemic infections may produce an extraordinarily virulent syndrome progressing rapidly to shock and death. Data suggest an appearance of new serotypes of GABHS but also an increased strain-associated virulence, rather than virulence related to a given serotype. The pathogenetic mechanism by which these virulent strains produce severe disease is not well understood.

Symptomatic therapy for GABHS and non-streptococcal pharyngitis includes acetaminophen for analgesia. A throat spray (e.g., Chloraseptic) can be used before meals and bedtime, if further analgesia is required. Lozenges should be avoided in children younger than 5 years because of the possibility of aspiration.

SKIN AND SOFT TISSUE INFECTIONS

Richard Malley

This chapter discusses several of the more common skin and soft tissue infections of childhood, including conjunctivitis, impetigo, sinusitis, and cellulitis. Because of its particular severity, orbital/periorbital cellulitis is highlighted in a section separate from the general discussion of cellulitis; however, the pathophysiology and clinical manifestations that are shared are not repeated.

CONJUNCTIVITIS

Definition

Conjunctivitis is an inflammation of the conjunctivae, the membranes that line the surface of the eye. This inflammation may be the result of infection, allergy, or mechanical or chemical irritation. Keratoconjunctivitis involves the cornea as well as the conjunctivae.

Etiology

The etiology of infectious conjunctivitis differs between the newborn and the older child (Table 122-1). In the newborn, pathogens that reside in the birth canal play a major role in ocular infections. *Chlamydia trachomatis* is the most frequent, but *Neisseria gonorrhoeae* poses the greatest threat to the integrity of the eye. Later in childhood, the respiratory tract pathogens predominate, particularly *Haemophilus* species. Trachoma, a recurrent chlamydial conjunctivitis seen in tropical regions, is not discussed.

Epidemiology

Conjunctivitis is the most common ocular infection of childhood. It may occur at any age. Neonates acquire most infections during passage through colonized birth canals; in older children, respiratory tract pathogens spread from person to person. Conjunctivitis is usually a sporadic disease, but epidemics of viral illness may occur.

Pathophysiology

Pathogens introduced into the conjunctival sac may proliferate and produce hyperemia and an inflammatory exudate. This exudate may be purulent, fibrinous, or serosanguineous. With certain organisms, corneal involvement (keratitis) also may occur.

TABLE 122-1 Etiology of Infectious Conjunctivitis

Frequency	Neonate	Child
Very frequent	<i>Chlamydia trachomatis</i>	Adenoviruses <i>Haemophilus</i> species
Moderately frequent	<i>Streptococcus pneumoniae</i> <i>Enterococcus faecalis</i> or <i>faecium</i> <i>Neisseria gonorrhoeae</i>	<i>Streptococcus pneumoniae</i>
Infrequent	<i>Haemophilus influenzae</i> Herpes simplex <i>Staphylococcus aureus</i>	<i>Neisseria gonorrhoeae</i> <i>Neisseria meningitidis</i> <i>Chlamydia trachomatis</i> Herpes simplex <i>Staphylococcus aureus</i> <i>Corynebacterium diphtheriae</i>

Clinical Features

Older children with conjunctivitis may complain of photophobia, ocular pain or pruritus, a sensation of a foreign body in the eye, crusting of the eyelids, or conjunctival erythema. Infants and young children are usually brought by their parents for "pink eye" or crusting. The duration of symptoms with infectious conjunctivitis is most often 2 to 4 days but may be longer in cases which are untreated or resistant to therapy.

As with any ocular complaint, the physician should perform a thorough examination of the structure and function of both eyes, including, when age appropriate, examination of visual acuity, visual fields by confrontation, extraocular muscle function, periorbital area, eyelids (with eversion), conjunctivae, cornea with fluorescein staining, pupillary reflex, anterior chamber, and fundus. Erythema and increased secretions characterize conjunctivitis. Chemosis may be seen. Intense erythema and purulent discharge are more common with an infectious rather than an allergic cause. The cornea does not stain with fluorescein in children with conjunctivitis unless an associated keratitis has developed, as with herpes simplex or adenoviruses. Most importantly, visual acuity is normal.

Fever and other systemic symptoms do not occur with isolated conjunctivitis. However, conjunctivitis may be only one manifestation of a viral upper respiratory tract infection, in which case the temperature may be elevated. Conjunctivitis may be only one manifestation of a systemic disorder, such as measles and Kawasaki disease.

Diagnosis

The diagnosis is primarily clinical. A Gram stain, which should be performed in neonates or in confusing cases, usually shows more than 5 white blood cells per oil immersion field and, in many cases, bacteria. The finding of gram-negative intracellular diplococci presumptively identifies *N. gonorrhoeae* in the first few weeks of life. Conjunctival scrapings and/or cultures may be performed in selected circumstances to diagnose *C. trachomatis* or specific viral and bacterial pathogens.

Once the diagnosis of conjunctivitis is established on the basis of diffuse injection, purulent discharge, and normal vision, infectious and noninfectious causes are next separated. *Allergic conjunctivitis* is usually distinguished by chronicity, seasonality, pruritus, and associated symptoms of allergic rhinitis; if the physician is uncertain, a Gram stain should be done (Table 122-2).

Differential Diagnosis

The differential diagnosis of the "red (or pink) eye" includes conjunctivitis, orbital/periorbital infection, foreign body, corneal abrasion, uveitis, and glaucoma. Periorbital and orbital infections cause obvious swelling and tenderness around the eye and/or loss of ocular mobility.

TABLE 122-2 Differential Diagnosis of Allergic and Infectious Conjunctivitis

	Allergic	Infectious
History		
Pruritus	Yes	No
Chronic	Yes	No
Recurrent	Yes	No
Seasonal	Yes	No
Sneezing, rhinorrhea	Yes	Variable
Examination		
Discharge	Watery	Watery or purulent
Chemosis	Present	Usually absent
Fluorescein	Negative	Negative, except keratitis
Laboratory tests		
Gram stain	Negative	White cells, bacteria

Foreign bodies should be visible on direct examination, often only following eversion of the upper eyelid. Thus the differential diagnosis usually revolves around four conditions: conjunctivitis, corneal abrasion, uveitis, and glaucoma (Table 122-3). Both uveitis and glaucoma are uncommon. The erythema in these conditions is concentrated around the limbus, and the discharge consists primarily of tears. Additionally, the vision is decreased in glaucoma, and the cornea may be cloudy. A corneal abrasion is easily identified by the uptake of fluorescein.

Complications

Conjunctivitis is generally self-limited, with the notable exceptions of herpes simplex and *N. gonorrhoeae*. The potential complications are corneal ulceration and scar formation leading to visual impairment.

Treatment

In approaching infectious conjunctivitis (Figure 122-1), the physician must decide whether the ocular disorder is one manifestation of a systemic illness such as measles, or is occurring in relative isolation. Isolated conjunctivitis may be caused by various viruses and bacteria, of which herpes simplex and *N. gonorrhoeae* are particularly severe, or by *C. trachomatis*, especially in the first 3 months of life.

Fluorescein staining always should be performed in an effort to identify the dendritic corneal ulcerations characteristic of herpetic disease. If they are identified, treatment is with acyclovir or other antiviral agents under the supervision of an ophthalmologist. Because *N. gonorrhoeae* is usually acquired during passage through the birth canal, infants younger than 1 month of age must always be tested for this pathogen with a Gram stain and culture. If gram-negative intracellular diplococci are seen on smear, a single intramuscular injection of ceftriaxone (125 mg) is indicated.

Infants older than 1 month of age and older children with an obvious clinical diagnosis of conjunctivitis do not routinely require smears or cultures. In patients younger than 3 months of age, treatment is instituted with erythromycin (50 mg/kg per d) PO for *C. trachomatis* (Table 122-4). Older children require only topical antibiotic instillation into the conjunctival sac. A child who has unusually severe disease or who fails to respond to therapy within 48 h may benefit from a laboratory investigation. Appropriate studies in the infant younger than 1 month of age includes a Gram stain and bacterial culture and either a scraping or culture for *C. trachomatis*. Older children require only a Gram stain and bacterial culture. Diagnostic tests for herpes simplex are not usually rewarding in the absence of corneal ulceration; culture for adenoviruses may be helpful in persistent or severe hemorrhagic infections to avoid unnecessary additional testing, but there is no specific treatment. All children with conjunctivitis should be reevaluated within 48 h. Failure to improve warrants further investigation and continued, careful follow-up.

IMPETIGO

Impetigo is a superficial bacterial infection of the skin confined to the epidermis. Deeper spread to the dermis leads to ecthyma. There are two varieties of impetigo: impetigo contagiosa and bullous impetigo.¹ Impetigo is the most common skin infection seen in the pediatric ED. The prevalence is greatest in children younger than age 6 years. Impetigo may be sporadic or epidemic. Conditions favoring epidemic spread include warm weather, overcrowding, and poor hygiene. Bullous impetigo is less common than impetigo contagiosa.

Pathophysiology

Group A β -hemolytic streptococcus (GABHS) or *Staphylococcus aureus* often are the primary infecting agents and therapy should cover

Abbreviations: JRA = juvenile rheumatoid arthritis; URI = upper respiratory infection.

both organisms. In particular, in bullous impetigo, the primary pathogen is *S. aureus*.

The intact epidermis forms a relatively impervious barrier to bacteria. The development of impetigo follows a breach in the integument; this may be an obvious abrasion or an inconspicuous insect bite. Bacteria then invade the skin and elaborate toxins, such as streptolysins, which promote local spread.

Clinical Features

The chief complaint of children with impetigo is most often that of sores on the body. There are no associated systemic manifestations such as fever or malaise. Regional lymph nodes may be minimally enlarged.

The typical lesion of impetigo contagiosa begins as an erythematous papule. Small vesicles may follow transiently, but rapid progression to crusted lesions occurs. These crusts, which are initially honey-colored and fine in consistency, may appear on any area of the body; between the upper lip and the nose is a very characteristic site. The lesions enlarge over days to weeks, and the crusts become thicker. Erythema is mild. No induration is present.

In bullous impetigo, the characteristic skin lesions are superficial bullae filled with purulent material. The bullae range in size from 0.5 to 3 cm and have minimal, if any, surrounding erythema.

The diagnosis of impetigo is clinical, and laboratory tests are not needed. Where the diagnosis is uncertain, Gram stain of the lesions is

helpful, showing abundant polymorphonuclear leukocytes and gram-positive bacteria. Local culture may be obtained from patients whose disease does not respond to standard therapy.

Several dermatologic disorders may resemble either impetigo contagiosa or bullous impetigo. These include tinea corporis, nummular eczema, small burns or abrasions, allergic contact dermatitis, eczema herpeticum (with underlying atopic dermatitis), and scalded skin syndrome.

Impetigo may spread locally or, in the case of streptococcal infections, lead to remote, nonsuppurative sequelae. Occasionally, impetigo may progress to cellulitis or lead to lymphadenitis in the regional nodes. The attack rate for acute poststreptococcal glomerulonephritis has been as high as 1 percent in certain epidemics; however, the disease is unusual following sporadic skin infections.

The treatment of impetigo is oral antibiotic therapy or an appropriate topical antibiotic for limited eruptions. A first-generation oral cephalosporin such as cephalexin (50 mg/kg per d) provides effective oral therapy. Mupirocin is the only topical agent with proven efficacy. Combination topical and systemic therapy is unnecessary. Vigorous scrubbing, in addition to topical or systemic antibiotic agents, offers no advantage; routine cleanliness is sufficient.

Antibiotic therapy hastens the resolution of impetigo and limits suppurative complications. Although the incidence of glomerulonephritis may be reduced, it has not been possible to demonstrate this effect with certainty in clinical studies because of the low incidence of this disease.

SINUSITIS

Sinusitis is an inflammation of the paranasal sinuses: maxillary, ethmoid, frontal, or sphenoid. This inflammation may be on the basis of infection or allergy; it may be acute, subacute, or chronic.

The major pathogens in acute bacterial sinusitis in childhood are *Streptococcus pneumoniae*, *Moraxella catarrhalis*, and nontypeable *Haemophilus influenzae*.² The incidence of *H. influenzae* type B (Hib) sinusitis in children has likely declined with Hib vaccination, but other nontypeable *H. influenzae* are still important causative pathogens. Other potential etiologic agents found in a minority of infections include group A streptococcus, group C streptococcus, (3-hemolytic streptococcus, and *Peptostreptococcus*. Similar clinical investigations in adults have been in general agreement, finding nontypeable *H. influenzae* and *S. pneumoniae* in 60 to 70 percent of the cases. Although *S. aureus* and anaerobic organisms are isolated occasionally, they rarely play a role in acute infections in childhood. Severe sinusitis is not a common illness in children, but mild or subacute disease may occur more frequently.

Pathophysiology

The ethmoid and maxillary sinuses are present at birth, but the frontal and sphenoid sinuses do not become aerated until 6 or 7 years of age. The sinuses are lined primarily by ciliated columnar epithelium and connect with the nasopharynx via narrow ostia. Normally, the epithelium is coated by a double layer of mucus: a viscid gel layer superficially and a more fluid layer underneath. Resistance to infection depends on the patency of the ostia, the function of the ciliary mechanism, and the quality of the secretions.

Obstruction of the ostia results either from mucosal swelling or, less commonly, mechanical obstruction. By far the most frequent offenders are viral upper respiratory infection and allergic inflammation. Less-common causes include cystic fibrosis, trauma, choanal atresia, deviated septum, polyps, foreign body, and tumor.

Factors that impair normal mucociliary function include viral infections, cold or dry air, certain chemicals or drugs, and, rarely, inborn errors of motility. Alterations of the mucus occur in asthma and cystic fibrosis.

The bacteria that cause sinusitis often colonize the nasopharynx of healthy children. Disruptions in one or more of the barriers described above allow these organisms to ascend through the ostia and multiply within the sinuses.

Clinical Features

The spectrum of sinusitis has not been completely defined as it relates to clinical manifestations. However, there are two major types of infection, which can usually be distinguished on clinical grounds: acute, severe sinusitis, and mild, subacute sinusitis (Table 122-5).

Acute, severe infections of the sinuses are infrequent during childhood. Symptoms are headache and bilateral nasal mucopurulent discharge. Findings include fever, localized swelling and/or erythema, and facial tenderness.

The diagnosis of sinusitis in young children is usually made on clinical grounds without any laboratory or radiographic studies. In older children and adolescents, transillumination of the maxillary or frontal sinuses may provide assistance.

Standard radiographs or preferably CT if available, should be obtained in patients with an uncertain clinical diagnosis and in cases of severe sinusitis. The most diagnostic findings for purulence are an air-fluid level or complete opacification, although it is important to remember that certain sinuses (such as frontal) are not usually aerated in young children. Mucosal thickening greater than 4 mm is usually indicative of infection but may accompany viral upper respiratory disease, particularly in the first year of life. A normal radiograph suggests, but does not prove, that a sinus is free of disease.

TABLE 122-5 Severity of Signs and Symptoms in Children with Sinusitis

	Acute, Severe Disease	Mild, Subacute Disease
Headache	+++	++
Fever	+++	+
Facial tenderness	++	—
Facial swelling	++	—
Nasal discharge	+++	++++

Ultimate confirmation of infection within the paranasal sinuses rests with demonstration of organisms by Gram stain and quantitative culture of aspirated secretions. Aspiration is not routinely indicated but can be performed in selected cases of maxillary sinusitis by an otolaryngologist. Appropriate circumstances for aspiration include (1) life-threatening complications, (2) immunosuppressive conditions, (3) clinical unresponsiveness, and (4) unusually severe disease. The presence of organisms on Gram stain and a count of at least 104 colony-forming units point to bacterial infection.³

Differential Diagnosis

Nasal congestion lasting 3 to 7 days often accompanies viral upper respiratory infections, and should not be diagnosed as acute sinusitis and does not need treatment with antibiotics.

Other causes of facial swelling include superficial infection (cellulitis), trauma, cold injury, and allergic edema. Facial pain may be neurogenic, odontogenic, or related to the temporomandibular joint. Unilateral nasal discharge suggests a nasal foreign body.

Complications

The proximity of the paranasal sinuses to the brain sets the scene for the occurrence of life-threatening complications from sinusitis; however, the use of antibiotics has reduced the incidence of such complications. Infection may spread from the sinuses to surrounding structures through the diploic veins, which have no valves, or by erosion through bone.

The most commonly encountered complications are periorbital cellulitis and orbital cellulitis/abscess. Periorbital infection causes swelling around the eye, while intraorbital accumulation of pus may be recognized on the basis of proptosis and decreased ocular motion. Infection may also produce osteomyelitis of the surrounding bone; in the frontal region this is referred to as Pott puffy tumor. Less-common complications of intracranial extension are epidural, subdural, or brain abscess; meningitis; and cavernous sinus thrombosis. Meningitis rarely follows sinusitis; it more commonly occurs after bacteremia. Suspicion of an intracranial complication requires neuroimaging. Brain abscess and subdural empyema are demonstrated by contrast head CT scan, and cavernous sinus thrombosis or epidural empyema may only be visualized by magnetic resonance imaging (MRI).

Treatment

Sinusitis requires therapy with antibiotics (Table 122-6). Mild, subacute infections respond well to oral therapy for 10 to 14 days. Amoxicillin (80 mg/kg per d) remains the first-choice antimicrobial. Failure to improve with amoxicillin therapy suggests infection with pathogens that are often resistant to this drug, such as *M. catarrhalis* or *H. influenzae*, or perhaps with penicillin-resistant *S. pneumoniae*. A second course of treatment with newer oral second- and third-generation cephalosporins such as cefprozil or cefpodoxime, or amoxicillin-clavulanic acid should

TABLE 122-6 Antibiotic Therapy for Sinusitis

	Acute, Severe Sinusitis	Mild, Subacute Sinusitis
Initial	Ceftriaxone, 75 mg/kg per d IV or Ampicillin-sulbactam, 200 mg/kg of ampicillin per d IV	Amoxicillin, 80 mg/kg per d PO
Persistent	Antibiotics as above plus surgical drainage	Cefprozil, 30 mg/kg per d PO or Amoxicillin-Clavulanate 40 mg/kg per d PO
Penicillin allergic	Ceftriaxone, 75 mg/kg per d IV or Clindamycin, 40 mg/kg per d IV	Clindamycin, 10–30 mg/kg per d PO divided every 6–8 h

then be instituted; aspiration for culture may be useful for those patients in whom the infection still persists after a second course of therapy.

Acute, severe sinusitis may result in life-threatening complications and requires intravenous antibiotic therapy directed at *S. pneumoniae* (possibly penicillin-resistant), amoxicillin-resistant *H. influenzae*, and, less commonly, *S. aureus*. Ceftriaxone (50 to 100 mg/kg per d) represents a single-drug regimen effective for this disease; ampicillin-sulbactam (200 mg/kg per d) is a good alternative for the nonallergic patient. Failure of severe disease to respond promptly to antibiotic therapy or the occurrence of complications indicates the need for surgical consultation in regard to drainage procedures.

CELLULITIS

Cellulitis is an infection of the skin and subcutaneous tissues. It extends below the dermis, differentiating it from impetigo, but does not involve muscle (pyogenic myositis) or bone (osteomyelitis). Any region of the body may be involved, but two divisions are important in regard to predicting the most likely pathogens: (1) the trunk and extremities and (2) the face (buccal and periorbital cellulitis).

Children of any age may develop cellulitis, but, as noted above, disease caused by *H. influenzae* has become rare, affecting mainly infants younger than age 6 months.

The organisms that play an important role in the immunocompetent host under normal circumstances include *S. aureus*, *S. pyogenes* (group A (3-hemolytic streptococcus), and *H. influenzae* (Table 122-7). In general, *S. aureus* is the most common and *H. influenzae* the least common among the three major pathogens, particularly in children immunized against *H. influenzae* type B.⁴ However, in certain anatomic locations, particularly for young or unimmunized children, *H. influenzae* remains an important consideration. Additionally, unusual organisms may cause cellulitis in immunocompromised hosts or following their introduction in special types of wounds (see Table 122-7).

Pathophysiology

Cellulitis may occur either when a pathogen is directly inoculated into the subcutaneous tissue or following an episode of bacteremia. The majority of infections involve local invasion after a breach in the integument. The organisms responsible are usually *S. aureus* and *S. pyogenes*. In contradistinction, *H. influenzae* type B disseminates hematogenously.

TABLE 122-7 Etiology of Cellulitis

	Most Likely	Less Likely
IMMUNOCOMPETENT HOST

Any site/animal bite	<i>S. aureus</i>	<i>Pasteurella multocida</i>
Any site/human bite	Anaerobic organisms	<i>S. aureus</i>
IMMUNOCOMPROMISED HOST		
Any site	<i>S. aureus</i> , gram-negative rods	Anaerobic organisms

Clinical Features

The child with cellulitis manifests a local inflammatory response at the site of the infection, including erythema, edema, warmth, and tenderness. There may be a history of a preceding wound or a complaint related to loss of function, such as limp with an infection of a lower extremity. Fever is unusual except in infections caused by *H. influenzae* type B (Table 122-8).

Inspection of the area of cellulitis usually shows intense erythema. A violaceous hue suggests *H. influenzae*, but has been reported with other pathogens, including *S. pneumoniae*. Red streaks may radiate proximally along the course of the lymphatic drainage, and the regional nodes may enlarge.

The diagnosis of cellulitis is made by inspection. Laboratory studies including a WBC count, blood culture, and aspirate culture are obtained for specific indications: immunocompromise, fever, severe local infection, facial involvement, and failure to respond to therapy.

The WBC count is normal in most cases of infection caused by *S. aureus* or *S. pyogenes*, which are locally invasive. On the other hand, cellulitis caused by *H. influenzae* type B results from bacteremia and is usually accompanied by a WBC count > 15,000/⁶/L.

The blood culture is usually negative in infections caused by *S. aureus* and *S. pyogenes*. On the other hand, *H. influenzae* type B, as a rule, causes a bacteremic infection.

Aspirate cultures are best obtained close to the center of an infected lesion, as the periphery may consist primarily of edema fluid devoid of organisms. The needle should be sufficiently large to permit the evacuation of purulent material—22 gauge for the face and 19 gauge for the trunk and extremities. Using a 5- or 10-mL syringe prefilled with

TABLE 122-8 Usual Clinical and Laboratory Features of Children with Cellulitis

Characteristic	<i>H. influenzae</i>	<i>S. aureus</i>
Age	<3 years	Any
Fever	Yes	No
Color of lesion	Violaceous	Erythematous
Location	Cheek, periorbital	Trunk, extremity
Preceding wound	No	Yes
WBC count	>15,000/ ⁶ /L	<15,000/ ⁶ /L
Bacteremia	Yes	No

Abbreviation: WBC = white blood cell count.

1 mL of sterile, nonbacteriostatic saline, the needle is directed into the subcutaneous tissue to a depth of approximately 0.5 to 1.0 cm, and aspiration is attempted. If there is no return, the saline is injected and reaspirated. The material obtained is used for culture and Gram stain.

Differential Diagnosis

Cellulitis must be differentiated from other causes of erythema and edema, including trauma and allergic reaction. Allergic edema is not tender and usually only mildly erythematous. Traumatic lesions may be easily distinguished when there is a history of injury and absence of fever. Cold injury, especially on the cheeks ("popsicle panniculitis"), may be confused with cellulitis.

Complications

Cellulitis caused by *S. aureus* and *S. pyogenes* may at times spread locally or involve the regional lymph nodes; distant foci occur only rarely. Bacteremic *H. influenzae* type B infections (which are exceedingly rare since the advent of universal conjugate vaccination in the United States) are more likely to spread hematogenously, involving the central nervous system, epiglottitis, joints, or pericardium.

Treatment

The treatment of cellulitis is the administration of systemic antibiotic therapy. Although most patients respond rapidly to oral antistaphylococcal agents, the clinician must identify those individuals who require broad-spectrum or IV administered drugs. Obviously, signs of sepsis are indicative of hematogenous dissemination and demand treatment as an inpatient. Additionally, children younger than 6 months of age and those with impaired immunity are unable to contain local bacterial infections and will benefit from intravenous therapy.

Among otherwise healthy children older than 6 months of age, only those who are clinically ill appearing, or in whom bacteremic disease is suspected, need to be admitted to the hospital. Prior to the advent of the *Haemophilus* vaccine, physicians could identify patients at risk for invasive *H. influenzae* type B disease fairly reliably on the basis of anatomic location, presence of fever, and a WBC count greater than 15,000/ \times L. Although the incidence of this disease has dropped considerably, it is important to remember that young infants and underimmunized children are still at some risk of being infected with this organism.

The usual therapy for patients discharged from the ED is an antistaphylococcal antibiotic, such as dicloxacillin or cephalexin. Broad-spectrum therapy is recommended presumptively for patients who are immunocompromised or suspected to have bacteremia, pending a definitive isolate (Table 122-9).

PERIORBITAL/ORBITAL CELLULITIS

Cellulitis as previously defined may involve the tissues anterior to the orbital septum (periorbital cellulitis) or within the orbit (orbital cellulitis).

Children younger than age 3 years are more likely to become bacteremic than are those who are older; thus, they experience the highest incidence of periorbital disease. Orbital cellulitis may occur at any age.

S. aureus, *S. pneumoniae*, and *H. influenzae* are the principal etiologic agents, although the incidence of *Haemophilus influenzae* type B disease has declined significantly since the advent of universal immunization.⁴ Orbital infections are most often caused by *S. aureus*.

Pathophysiology

Organisms reach the periorbital area either hematogenously or by direct extension from the ethmoid sinus. In the case of orbital disease, contiguous spread is most common.

TABLE 122-9 Initial Antibiotic Therapy for Cellulitis

	Drug	Dose
Presumptive immunocompetent		
Extremity or buccal/periorbital		
Afebrile	Dicloxacillin	50-100 mg/kg per d PO
	or	
	Cephalexin	50-100 mg/kg per d PO
Febrile/leukocytosis	Ampicillin-sulbactam	200 mg/kg as ampicillin/per d IV
	or	
	Ceftriaxone	75 mg/kg per d IV
Immunocompromised		
Any site	Oxacillin	150 mg/kg per d IV
	or	
	Cefazolin	100 mg/kg per d IV
	and	
	Gentamicin	5-7.5 mg/kg per d IV
	or	
	Tobramycin	5-7.5 mg/kg per d IV
Specific organism		
<i>Streptococcus pyogenes</i>	Penicillin	100,000 units/kg per d PO or IV
<i>Staphylococcus aureus</i>	Dicloxacillin	50-100 mg/kg per d PO
	or	
	Oxacillin	150 mg/kg per d IV
<i>Haemophilus influenzae</i>		
Ampicillin-sensitive	Ampicillin	200 mg/kg per d IV
Ampicillin-resistant	Ceftriaxone	75 mg/kg per d IV

Clinical Features

Orbital and periorbital cellulitis cause the periorbital area to appear red and swollen. The periorbital edema is usually more prominent with preseptal infections. Proptosis or limitation of extraocular muscle function indicates orbital involvement. Fever is more common with periorbital cellulitis.

Periorbital and orbital cellulitis are distinguished from noninfectious disorders on the basis of the clinical findings and the WBC count. Leukocytosis occurs frequently with cellulitis, more often with bacteremic preseptal infections. A blood culture is often positive.

CT is performed when orbital involvement is likely. An inflammatory mass is easily demonstrated when present using this modality.

Differential Diagnosis

As for cellulitis in other regions, allergic and traumatic causes for edema must be considered. Additionally, tumors and metabolic disease may cause swelling, discoloration, and/or proptosis. Thyrotoxicosis usually occurs in adolescents. The most likely tumor is metastatic neuroblastoma. Pseudotumor occurs rarely.

Complications

Periorbital cellulitis may serve as a focus for metastatic bacterial disease; of particular concern is the occurrence of meningitis. Orbital cellulitis may evolve into a subperiosteal abscess; this condition threatens the integrity of the eye and should be considered a surgical emergency. Intracranial extension may occur rarely.

Treatment

Admission and treatment with intravenous antibiotics is the rule. Blood cultures should always be done, and an aspirate culture is indicated for

any ill child. In a child younger than 6 months of age, strong consideration of a lumbar puncture is indicated whenever infection with *H. influenzae* type B is suspected. Beyond 6 months of age, in the immunized child, although the possibility of meningitis remains, a decision regarding a lumbar puncture can be based on the clinical status and examination of the patient. Presumptive therapy of periorbital or orbital cellulitis is directed against *S. aureus*, pneumococcus (both penicillin-sensitive and resistant) and *H. influenzae* (see Table 122-9). Although medical management may be sufficient in some cases,⁵ surgical drainage is often necessary with abscess formation or sinusitis.

VIRAL AND BACTERIAL PNEUMONIA IN CHILDREN

Kathleen Brown Willie Gilford, Jr.

The diagnosis and management of pediatric pneumonia cases can present unique challenges to the emergency physician. However, having a heightened sense of awareness toward certain presenting signs and symptoms from the child or parent and the appropriate ED workup and management can serve to dismantle these challenges. Pneumonia is defined pathologically as an inflammation of lower tract lung tissue. Clinically, pneumonia is defined by the presence of pulmonary infiltrates on a chest radiograph, usually associated with a combination of clinical signs, such as cough, fever, chest pain, tachypnea, and a variety of abnormal auscultatory findings. This chapter does not discuss in detail the entities associated with the diagnosis of pneumonia, such as interstitial processes, foreign body aspiration, chemical inflammation, *Mycobacterium tuberculosis*, and certain protozoan infections (e.g., *Pneumocystis carinii*). Instead, this chapter focuses on viral and bacterial pneumonias, which are most commonly implicated as the causes of pneumonia.

EPIDEMIOLOGY

Pneumonia develops more often in early childhood than at any other age. The incidence of pneumonia in children decreases as a function of age. In North America it has been estimated at 40 per 1000 in preschool children and approximately 9 per 1000 in 10-year-olds.^{1,2} Infectious causes often display seasonal variation. Parainfluenza occurs predominantly in the fall, respiratory syncytial virus (RSV) in the winter, and influenza in the spring. Bacterial pneumonia is more common in the winter, when indoor crowding promotes respiratory transmission of microbes. Several risk factors increase the incidence or severity of pneumonia: prematurity, malnutrition, low socioeconomic status, passive exposure to smoke, and attendance at day-care centers. The mortality rate of childhood pneumonia is less than 1 percent in industrialized nations, but pneumonia accounts for up to 5 million deaths annually in children younger than 5 years in developing countries.³

PATHOPHYSIOLOGY

Most pneumonias are acquired through aspiration of infective particles into the lower respiratory tract. There are many protective mechanisms preventing infection with aerosolized infective particles. Aerosolized

particles are filtered in the nasal cavities or entrapped and cleared by the normal mucus and ciliated epithelium of the upper respiratory tract. Aspiration is further prevented by laryngeal reflexes and coughing. In the lower respiratory tract, alveolar macrophages and various immune mechanisms prevent further invasion by infectious agents. These defense mechanisms include the ingestion and killing of bacteria by macrophages, the activation of complement and antibodies that neutralize bacteria, and the transportation of particles from the lung by lymphatic drainage. Abnormalities in any of these protective mechanisms predispose patients to acquired pneumonia. Anatomic abnormalities of the respiratory tract, immune deficiencies, neuromuscular weakness, airway abnormalities that predispose the child to aspiration, and alterations in the quantity or quality of mucus secretion (e.g., cystic fibrosis) also predispose patients to acquired pneumonia. Passively acquired maternal antibodies may further prevent respiratory tract infection by pneumococcal and *Haemophilus influenzae* infections.

Suppression of the normal respiratory physiologic and anatomic defenses may occur secondary to a preceding viral infection of the upper respiratory tract. Coexistence of viral and bacterial pathogens in children has been demonstrated in 50 percent or more of cases.^{4,5} Bacteria that cause pneumonia include many of the same organisms that colonize the child's upper airway. In addition, organisms that are transmitted person to person by airborne droplet spread may cause pneumonia. Less commonly, bacterial and certain viral (e.g., herpes simplex virus, varicella, rubella, rubeola, and Epstein-Barr virus) microbes may cause pneumonia through hematogenous or contiguous spread. Parenchymal invasion by bacteria results in an acute inflammatory response that includes exudation of fluid, deposition of fibrin, and infiltration of the alveoli with fluids, polymorphonuclear leukocytes, and, soon, macrophages. Accumulation of excess alveolar fluid creates the characteristic consolidation seen on chest radiographs. Viral agents, mycoplasma, and chlamydia typically cause inflammation characterized by a predominately mononuclear infiltrate involving submucosal and interstitial tissues.

ETIOLOGY

The specific etiologic agent of pneumonia can be determined in about one-third to two-thirds of cases based on results, when available, of cultures, antigen detection, and serologic techniques.^{4,11} The predominant pathogens that cause pneumonia in pediatric patients are a function of the patient's age, the presence of underlying disease, the vaccination status, and attendance in day care. Because clustering of cases of pneumonia due to a particular microbe are common, it is helpful to be aware of recent local outbreaks. When an etiologic agent is not identified, the best predictor of the agent is age. The most common etiologic agents causing pneumonia according to age groups are listed in Table 123-1 and discussed below.

Newborns: Birth to 1 Month

The newborn age group is the only developmental period when bacterial infections are more common than viral agents as the leading cause of pneumonia. Most infections in this age group are caused by aspiration of the maternal genital organisms present during labor and delivery. The predominant pathogen is group B *Streptococcus*, followed by *Escherichia coli*, *Klebsiella* species, and other gram-negative enteric bacilli from the Enterobacteriaceae family. Other, less commonly encountered organisms include nontypeable *H. influenzae*, other streptococci (group A and (3-hemolytic species), enterococci, *Listeria monocytogenes*, *Bordetella pertussis*, and anaerobic bacteria.¹¹

Infants: 1 to 24 Months

During the first 2 years of life, viruses are the most common etiologic agent of pneumonia. Respiratory syncytial virus, parainfluenza virus, influenza virus, and adenovirus account for most lower respiratory tract infections, including pneumonia, in this age group.^{1,2,4,7} There

TABLE 123-1 Etiologic Agents and Empirical Antimicrobial Therapy for Pediatric Pneumonia in Otherwise Healthy Children*

Age Group	Frequent Pathogens (in Order of Frequency)	Patients in Hospital	Outpatients
Newborn	Group B <i>Streptococci</i> Gram-negative bacilli <i>Listeria monocytogenes</i> Herpes simplex Cytomegalovirus Rubella	Ampicillin plus Cefotaxime or Gentamicin	Not recommended
1–3 mo	<i>Chlamydia trachomatis</i> Respiratory syncytial virus Other respiratory viruses	Afebrile pneumonitis: erythromycin or clarithromycin Febrile pneumonia: cefuroxime	Initial outpatient management not recommended
3–12 mo	Respiratory syncytial virus Other respiratory viruses <i>Streptococcus pneumoniae</i> <i>Haemophilus influenzae</i> (type b,† nontypeable) <i>C. trachomatis</i> <i>Mycoplasma pneumoniae</i>	Ampicillin or cefuroxime	Amoxicillin or Erythromycin or Clarithromycin
2–5 y	Respiratory viruses <i>S. pneumoniae</i> <i>H. influenzae</i> type b† <i>M. pneumoniae</i> <i>Chlamydia pneumoniae</i>	Same as for 3–12 mo	Same as for 3–12 mo
5–18 y	<i>M. pneumoniae</i> <i>S. pneumoniae</i> <i>C. pneumoniae</i> <i>H. influenzae</i> type b† Influenza viruses A and B Adenoviruses Other respiratory viruses	Erythromycin or clarithromycin‡ With or without cefuroxime or ampicillin	Erythromycin or clarithromycin‡

*Duration of antibiotic treatment: outpatients, 7 to 10 days; hospitalized, 10 to 14 days.

†*Haemophilus influenzae* type b is uncommon where there is universal *H. influenzae* type b immunization.

‡Azithromycin can be substituted for clarithromycin with equal safety and efficacy for treating *M. pneumoniae*.

Source: Adapted with permission from Jadavji T, Lau B, Lebel MH, et al: A practical guide for the diagnosis and treatment of pediatric pneumonia. *CMAJ*, 156(suppl):S703, 1997.

are at least 14 other viral agents isolated in children with pneumonia, which include rhinoviruses, enteroviruses, coronavirus, measles, varicella, rubella, herpes simplex virus, and Epstein-Barr virus.^{7,8,12} Bacterial pneumonia due to *Streptococcus pneumoniae*, *Streptococcus pyogenes*, *Staphylococcus aureus*, and *H. influenzae* should be considered in infants and toddlers who are severely ill, have rapid onset and progression of symptoms, or have lobar or diffuse infiltrates, large effusions, or abscesses on radiograph.¹³

Very young infants (1 to 3 months) may present with what is often referred to as *afebrile pneumonitis*, or atypical pneumonia. This syndrome is typified by cough, tachypnea, and sometimes progressive respiratory distress in the absence of fever. **Apneic episodes can occur with RSV, chlamydia, and pertussis.** There is often radiographic evidence of bilateral diffuse pulmonary infiltrates with air trapping. The viruses listed above are the most common etiologic agents.¹⁴ *Chlamydia trachomatis* often is identified in this scenario.^{10,14} *Ureaplasma urealyticum*, *Mycoplasma hominis*, *P. carinii*, and *B. pertussis* also have been implicated in this syndrome, but the extent of their role is not as well defined.^{10,15}

Preschool: 2 to 5 Years

As age advances, the overall incidence of pneumonia decreases, but the relative frequency of bacterial pathogens, in particular *S. pneumoniae*, as etiologic agents increases. Nevertheless, respiratory viruses, in particular influenza viruses A and B and adenovirus, remain the most common cause of pneumonia in this age group. The most common bacterial pathogen encountered is *S. pneumoniae*. In the recent past, *H. influen-*

zae type b was encountered nearly as frequently; however, since implementation of widespread immunization against this agent, its incidence as an agent of invasive disease is thought to be much less.^{16,17} However, non-type b *H. influenzae*, which is not protected against by the vaccine, may be an increasingly common agent of bacterial pneumonia.¹⁸ Other bacteria that are isolated less commonly include *S. aureus*, group A *Streptococcus*, and *Moraxella catarrhalis*. *Mycoplasma pneumoniae* has been found more frequently in this age group in recent studies.^{19,20}

School Age and Adolescence

Once children reach school age, *M. pneumoniae* is the most frequent bacterial cause of pneumonia.^{1,20,21} The peak incidence is between 10 and 15 years of age.²² *S. pneumoniae* remains a common pathogen in this age group.¹ *Chlamydia pneumoniae* is estimated to be the cause of up to 19 percent of pneumonias in school-aged and adolescent

patients. These infections are usually mild or asymptomatic.

S. aureus pneumonia can occur at any age but tends to be most frequent in older children.²³ Respiratory viruses, especially adenovirus, also can cause pneumonia in this age group.

All Ages: Special Considerations

The most common etiologic agents causing severe pneumonia (requiring admission to an intensive care unit) in all age groups beyond the neonatal period include *S. pneumoniae*, *S. aureus*, group A *Streptococcus*, *H. influenzae* type b, adenovirus, and *M. pneumoniae*. *Staphylococcus aureus* is notorious for causing rapidly progressive disease,

often with pulmonic abscesses. A resurgence of virulent group A *Streptococci* has been associated with sporadic cases of invasive disease, including necrotizing fasciitis with pneumonia and empyema in children.²⁴ Increased severity of *M. pneumoniae* infections in children with sickle cell disease has been described.

Gram-negative bacilli, including *Pseudomonas*, should be considered in patients who have recently been hospitalized. Anaerobic infections should be considered in children with neurologic or anatomic defects that predispose them to aspiration. Unusual causes of bacterial pneumonia in children include *Mycobacterium tuberculosis*, *Legionella pneumophila*, *Chlamydia psittaci*, *Francisella tularensis*, and rickettsial infections. Children with progressive or unresponsive pneumonia should be evaluated for evidence of these microorganisms. An immunocompromised host is susceptible to all of these infections and to opportunistic infections, such as *Pneumocystis carinii*, cytomegalovirus, and fungal diseases.

CLINICAL FEATURES

Clinical findings in a child with pneumonia are highly variable and depend on the specific respiratory pathogen, age, the severity of the disease, and any underlying illnesses. Tachypnea is the most frequent sign of pneumonia in children and may be an otherwise isolated finding. The best physical examination finding for ruling out pneumonia in an infant or child is the absence of tachypnea.²⁵ However, tachypnea is a nonspecific symptom and may occur secondary to fever, anxiety, metabolic disease, cardiac disease, or other respiratory problems. Fever can increase an infant's respiratory rate by 10 breaths/min for each degree centigrade of elevation.²⁶ Respiratory rates should be counted past 1 min. Several studies have shown that rates counted over a shorter period tend to overestimate the rate.²⁷

Auscultation of the lungs may reveal localized rales, wheezing, and decreased air entry in the affected area. However, auscultatory findings may not be reliable in children. When a group of pediatricians was asked to examine children with lower respiratory tract symptoms, there was only fair agreement about most auscultatory findings.²⁸ In younger children, decreased breath sounds, rather than rales, are often heard, because the involved areas tend to be ventilated poorly. Observable findings, such as respiratory rate and work of breathing, are more reliable.²⁵ Signs of increased work of breathing may include retractions, chest indrawing in infants, or paradoxical (seesaw) breathing. Granting respirations are frequently present, particularly in infants with pneumonia.²⁹ Abdominal distention and pain may be present secondary to a paralytic ileus or diaphragmatic irritation in lower lobe pneumonias.³⁰

The clinical presentation may be suggestive of the etiologic agent (Table 123-2). Two classic presentations have been described for pneumonia: typical pneumonia and atypical pneumonia. Typical pneumonia is characterized by abrupt onset of fever, chills, pleuritic chest pain, and productive cough. Associated physical examination findings include high-grade fever, localized findings on chest examination, and a toxic appearance. Atypical pneumonia is characterized by gradual onset (over days) of headache, malaise, nonproductive cough, and low-grade fever. Associated physical examination findings may include wheezing, prolonged expiration, rhinitis, conjunctivitis, pharyngitis, and rash. The typical pattern is generally thought to be associated with a bacterial pathogen, and the atypical pattern is thought to be more characteristic of a viral infection; however, significant overlap exists, and identification of a causal agent based on clinical presentation is not always reliable.³¹

Typical clinical presentations have been described for some specific pathogens. Pneumonia due to *S. aureus* is notorious for being particularly rapid in the progression of clinical findings. Patients with *B. pertussis* pneumonia typically develop prodromal symptoms, including mild cough, conjunctivitis, and coryza, which lasts 1 to 2 weeks. A severe, paroxysmal cough often associated with emesis and

TABLE 123-2 Antibiotic Dosages for Pneumonia

Antibiotic	Dosage
Amoxicillin	40 mg/kg daily in 3 divided doses PO
Ampicillin	150 mg/kg daily in 4 divided doses IV, IM
Azithromycin	10 mg/kg daily, then 5 mg/kg daily PO
Cefotaxime	150 mg/kg daily in 3 divided doses IV IM
Ceftazidime	50 mg/kg daily in 3 divided doses <i>IV</i> , IM
Cefuroxime	150 mg/kg daily in 3 divided doses, <i>IV</i> , IM
Clarithromycin	15 mg/kg daily in 2 divided doses PO
Erythromycin	40 mg/kg daily in 4 divided doses PO, IV
Gentamicin	2.5 mg/kg daily in 3 divided doses IV, IM

dehydration, because coughing prevents eating and drinking, is characteristic of the catarrhal phase of pertussis infections. The inspiratory whoop is generally present only in older children. A history of maternal pelvic or conjunctival chlamydial infection is present in up to 50 percent of cases in which the infant develops *C. trachomatis* pneumonia. An infant with a chlamydial infection is usually afebrile, has a distinct staccato cough (i.e., short, abrupt onset), and diffuse rales on auscultation. Such infants rarely appear systemically ill. Chlamydial pneumonia in adolescents is usually insidious in onset and often includes complaints of sore throat and dysphagia. Mycoplasmal infections generally present with the gradual onset of malaise, fever, and headache. A hacking, nonproductive cough usually begins 3 to 5 days after the onset of illness and is present in up to 98 percent of children. Mycoplasmal infection may produce pharyngitis, and rales are present in approximately 75 percent of patients. A variable rash, which may be papular, vesicular, urticarial, or erythema-multiforme-like, is present in about 10 percent of patients with *M. pneumoniae*.

The age of the patient also may affect the clinical presentation. Pneumonia often occurs in association with a sepsis syndrome in neonates.^{11,22} Infants frequently lack the classic symptoms and present with a variety of nonspecific findings. Nonspecific symptoms and signs of pneumonia in infants include fever without a localizing source, apnea, poor feeding, abdominal pain, vomiting or diarrhea, hypothermia, grunting, bradycardia, lethargy, and shock. Sputum production is uncommon in non-tracheostomized children younger than 8 years.

The severity of pneumonia may be judged by clinical features. More severe pneumonia is associated with deterioration of the patient's mental status, the use of accessory muscles, and the presence of retractions, nasal flaring, splinting, and cyanosis. Infants with poor feeding and lethargy may have more severe disease. A patient with a history of immunosuppressive therapy, a history of primary immune deficiencies, or a history suggestive of an immune deficiency may have more severe pneumonia, often caused by unusual pathogens. Children with underlying illnesses, such as congenital heart disease, chronic pulmonary disease, or sickle cell disease, are often more severely compromised by pneumonia.

DIAGNOSIS

Initially it is important to differentiate pneumonia from noninfectious pulmonary conditions, such as congestive heart failure, atelectasis, primary and metastatic tumors, and congenital abnormalities, such as pulmonary hypoplasia or congenital lobar emphysema. The wide variety of conditions that may simulate pneumonia include radiologic imaging problems (e.g., poor inspiration or a prominent thymus), recurrent or acute aspiration, atelectasis, tumors, collagen vascular disorders, allergic alveolitis, chronic pulmonary diseases (e.g., cystic fibrosis or asthma), and congenital abnormalities (e.g., pulmonary se-

questration). A thorough history and physical examination usually help to exclude many of these conditions.

Radiographs

The chest radiograph is considered the pragmatic reference standard for making the diagnosis.²⁵ The finding of consolidation on radiograph is thought to be a reliable sign of pneumonia.³² Differentiating the various microbiologic causes of pneumonia is often more difficult. Typical patterns of clinical presentation and epidemiologic data on incidence have been described above but often overlap. Radiographically, viral pneumonias tend to appear as diffuse interstitial infiltrates, frequently with hyperinflation, peribronchial thickening, and areas of atelectasis. Bacterial pneumonias tend to have lobar or segmental consolidation. Pneumatocele formation and a combination of pneumothorax and empyema are highly suggestive of *S. aureus* infection. However, bacterial pneumonias with perihilar interstitial and nodular patterns on radiographs have been reported.^{33,34} *C. trachomatis* infections usually lead to hyperexpansion and diffuse alveolar or perihilar interstitial infiltrates.

Radiographic patterns in *M. pneumoniae* infections are variable and nonspecific.³⁵ Lower lobe, streaky or patchy infiltrates are the most common, but many other patterns are possible, including lobar infiltrates in 10 to 25 percent of cases. Viral pneumonias also can cause lobar or segmental consolidations.³⁴ Several studies have investigated the accuracy of the chest radiograph in differentiating viral from bacterial disease. A recent review of these studies found sensitivities ranging from 42 to 80 percent and specificities of 42 to 100 percent.²⁵

Laboratory Studies

The white blood cell count is usually elevated, with a left shift in bacterial pneumonia, especially early in the illness.³⁶ Typically, viral, chlamydial, and pertussis pneumonias produce lymphocytosis. However, it is not unusual for viral pneumonia to initially provoke a significant polymorphonuclear cell response. In patients with mycoplasma pneumoniae, the total white blood cell count and differential cell count are usually normal, but the erythrocyte sedimentation rate may be elevated. Chlamydial infections or parasitic infections often produce eosinophilia.

Blood culture results are rarely (5 to 10 percent) positive in children with pneumonia, even when it is proven to be bacterial.^{41,42} Blood cultures should be obtained in infants who have high fever, appear ill, or require hospitalization. Sputum cultures also may help in identifying the causative organism but are difficult to obtain from non-tracheostomized children, in particular those younger than 8 years.

Cultures of the nasopharynx and throat for viral pathogens, chlamydia, pertussis, and mycoplasma often reveal the causative agent in patients with pneumonia caused by these organisms. Bacterial cultures of these regions have no diagnostic value due to mixed oral flora. Fluorescent antibody tests for *C. trachomatis* and *B. pertussis* are preferable to culture in some settings. Rapid viral antigen tests exist for a number of organisms, including RSV and influenza. Bacterial antigen testing is available in some centers but has poor sensitivity and specificity in diagnosing the cause of pneumonia.^{42,3} Serologic testing can be done for viruses, mycoplasma, parasites, and fungi in persistent or puzzling cases. Skin testing for tuberculosis also should be considered in patients not responding to traditional therapy or with apical, cavitary pneumonia.

More invasive diagnostic procedures, such as obtaining endotracheal cultures, percutaneous lung aspiration, bronchoalveolar lavage, or open lung biopsy, may be necessary in patients with severe disease that is unresponsive to empiric therapy. Results of tests for cold agglutinins are positive in 72 to 92 percent of patients with *M. pneumoniae* infection. Cold agglutinin test results also may be positive in viral infections and are less consistently positive in young children. To perform

the bedside test for cold agglutinins, place several drops of blood in a blue-stopper coagulation profile tube and place it in ice water for 15 to 30 s. The presence of floccular agglutination is considered a positive result, and the agglutination should disappear after rewarming.

TREATMENT

All patients with actual or suspected pneumonia should have oxygen saturation determined with pulse oximetry.³⁷ There is no evidence-based pulse oximetry threshold for the administration of oxygen, or for admission to the hospital. For previously healthy, otherwise well young children with pneumonia who live at sea level, surveyed emergency physicians selected a median pulse oximetry threshold of 93 percent for admission.³⁸ In this survey 99.5 percent of emergency physicians practicing at sea level would have admitted a child with an oximetry value <90%. Physicians practicing at significant elevation may select lower oximetry values as the threshold for the admission of supplemental oxygen, as children at elevation have lower baseline oximetry values.^{38,39} Children with oxygen saturation levels >90% may require supplemental oxygen and admission in the presence of other factors such as age <3 months; toxic appearance; oxygen desaturation with crying, feeding, or exercise; the presence of grunting with respiration; and comorbidities such as pre-existing lung disease, prematurity, or dehydration; actual or potential ventilatory insufficiency from muscular or spinal disorders; or shock.

In patients requiring hospital admission for suspected bacterial pneumonia, intravenous antibiotics should be administered in the ED. Empiric coverage, whether outpatient or inpatient, should be guided by the age of the patient and the epidemiologic data discussed above. Tables 123-1 to 123-4 list likely organisms and suggested antibiotic therapies. In newborns, ampicillin (150 mg/kg daily) in combination with an aminoglycoside (gentamicin 2.5 mg/kg per dose) or a third-generation cephalosporin (cefotaxime 150 mg/kg daily) is preferred. The ampicillin provides coverage against *Listeria* and enterococcal species. For infants with pneumonitis syndrome or afebrile pneumonia, erythromycin (40 mg/kg daily in four divided doses) is the drug of choice. In children 3 months to 5 years of age, ampicillin (150 mg/kg daily in four divided doses) or cefuroxime (150 mg/kg daily in three divided doses) alone is usually sufficient. In children who are unresponsive to this therapy or who have a suggestive clinical presentation, mycoplasma and chlamydial infections should be considered. Appropriate coverage for these infections includes erythromycin (40 mg/kg daily in four divided doses) or clarithromycin (15 mg/kg daily in two divided doses). In children older than 5 years, erythromycin or clarithromycin alone is usually sufficient. In severely ill hospitalized children in this age group, the addition of cefuroxime should be considered. In all age groups, if resistant *S. pneumoniae* is suspected, vancomycin should be added.

Children with fulminant viral pneumonia, such as an immunocompromised patient with varicella, may require treatment with acyclovir. In RSV pneumonia, ribavirin therapy should be considered for selected high-risk children, such as those with significant underlying cardiopulmonary or oncologic diseases and those with severe RSV

TABLE 123-3 Agents for Treating Unusual Pneumonias

Cause	Drug
Varicella pneumonia	Acyclovir
Respiratory syncytial virus	Ribavirin, if high risk
Human immunodeficiency virus with interstitial pneumonia	Prednisone and zidovudine
Cytomegalovirus pneumonia	Ganciclovir and 7-globulin
Gram-negative pneumonias	Ceftazidime

TABLE 123-4 Typical Features for Some Pneumonia Pathogens

Organism	Features
<i>Staphylococcus aureus</i>	Very rapid progression
<i>Bordetella pertussis</i>	1–2 wk of cough, coryza, conjunctivitis Cough with emesis and dehydration Whooping cough in older children Lymphocytosis on complete blood cell count
<i>Chlamydia trachomatis</i>	Neonatal: maternal pelvic or conjunctival infection Infant: staccato cough, nontoxic appearance Adolescent: sore throat, dysphagia Lymphocytosis or eosinophilia on complete blood cell count
<i>Mycoplasma</i>	Gradual onset of fever, malaise, headache Hacking nonproductive cough with pharyngitis Positive for cold agglutinins

pneumonia. Lymphocytic interstitial pneumonia in children with human immunodeficiency virus should include a combination of prednisone and zidovudine. Patients with bone marrow and solid organ transplantation and cytomegalovirus pneumonia may require ganciclovir and γ -globulin. Ceftazidime or ceftriaxone should eradicate nosocomial pneumonia in most cases, but ceftazidime has improved efficacy against *Pseudomonas aeruginosa*. Children with cystic fibrosis often develop acute infectious exacerbations secondary to *Pseudomonas* and *S. aureus*, often with reduced antimicrobial resistance to standard antibiotics.

Most children with uncomplicated pneumonia can be treated as outpatients. If a bacterial cause is suspected, the patient should be placed on an appropriate antibiotic. The choice of oral antibiotic should be based on the considerations discussed above with regard to the most likely etiologic organisms based on the age and clinical presentation of the patient. For outpatient treatment, amoxicillin (40 mg/kg daily in three divided doses) is preferred for children between 3 months and 5 years. Alternatively, daily intramuscular ceftriaxone may be used.⁴⁰ After age 5 years and in penicillin-allergic children, erythromycin (40 mg/kg daily in four divided doses) or tetracycline (in children older than 9 years) is the preferred initial agent. Recent data have indicated similar cure rates, fewer side effects, and reduced termination of therapy with clarithromycin compared with erythromycin.^{41,42} Azithromycin also has been shown to have a cure rate equal to that of erythromycin in children with community-acquired pneumonia.⁴³ Both drugs are significantly more expensive than erythromycin or tetracycline.

If viral pneumonia is suspected, no specific antibiotic therapy is warranted. Symptomatic treatment should include fever control and hydration. Patients with viral pneumonia often have a mixture of airway and air-space disease. If the patient has prominent airway disease (bronchiolitis-like) symptoms, bronchodilator therapy should be considered.

All patients discharged with a diagnosis of pneumonia should have routine follow-up with a primary care provider within 1 to 2 days. The duration of therapy depends on the clinical response, predisposing host factors, and suppurative complications. Ten days of antimicrobial treatment should suffice for most uncomplicated cases.

Disposition

ADMISSION CRITERIA Children with hypoxia should be admitted to the hospital. There is no evidence-based definition of hypoxia, but physicians often choose a pulse oximetry threshold of <90-93% for

admission. Other factors include age <3 months; toxic appearance; respiratory distress; a history of apnea or cyanosis; impaired immune function; oxygen desaturation with crying, feeding, or exercise; the presence of grunting with respiration; the presence of pre-existing lung disease; prematurity; dehydration; the potential for ventilatory insufficiency; lack of response to oral antibiotics; or inability to provide close outpatient followup. **The presence of underlying disease and the ability of the caregivers should also be considered.** The finding of a pleural effusion or pneumatocele or findings suggestive of a bacterial infection in a child younger than 1 year suggest a pathogen other than *S. pneumoniae* (in particular *H. influenzae* type b or *S. aureus*). Because such infections can progress rapidly and are not well tolerated, hospitalization is generally required. Infants with suspected *B. pertussis* or *M. tuberculosis* should be admitted. Children with moderate or severe complications from pneumonia should be hospitalized. Indications for admitting patients with RSV pneumonia are the same as those for RSV bronchiolitis.

COMPLICATIONS Most viral pneumonias will resolve spontaneously without specific therapy. Complications are similar to those for bronchiolitis and include dehydration, bronchiolitis obliterans, and apnea. Apnea is commonly seen in very young infants with RSV, chlamydial, or pertussis infection. Pleural effusions can occur with viral pneumonias but are not common.

Uncomplicated bacterial pneumonia usually responds rapidly to antibiotic therapy. A delay in improvement or a worsening condition after therapy has begun should prompt an evaluation for possible complications. Complications of bacterial pneumonia include pleural effusions, empyemas, pneumothorax, pneumatoceles, dehydration, and development of additional infectious foci. Pneumococcal pneumonias are accompanied by pleural effusions in about 10 percent of cases. Pneumonia due to *H. influenzae* type b is complicated by pleural effusions in 25 to 75 percent of cases. Other foci of infection are frequently seen with *H. influenzae* type b and can include meningitis, septic arthritis, epiglottitis, soft tissue infections, and otitis media. Pneumonias secondary to *S. aureus* have a high rate of complications, including empyemas (80 percent) and pneumatoceles (40 percent). *Mycoplasma pneumoniae* is only rarely complicated by pleural effusions, meningitis, encephalitis, arthritis, and hemolytic anemia. Whenever pneumonia is complicated or prolonged, roentgenographic follow-up is recommended to assure complete resolution, which may take 4 to 6 weeks or longer.

PREVENTION Administration of the *H. influenzae* type b vaccine has nearly eliminated disease caused by this agent. A heptavalent pneumococcal (Prevnar) vaccine was approved recently for use in infants and toddlers and is expected to cause a similar reduction in pediatric pneumococcal infections.^{44,46} Thus, because of the significance of such interventions, the emergency physician should inquire about immunization status and refer to a primary care physician if the patient is unimmunized.

DISCHARGE INSTRUCTIONS All children discharged from the ED with a diagnosis of pneumonia should receive specific advice on the dosage and scheduling of medications and the signs of worsening respiratory distress. Children who become unable to ingest adequate amounts of fluid or prescribed antibiotics should be instructed to return for further care. All children discharged with the diagnosis of pneumonia should have follow-up scheduled with the primary care provider within 48 h.

ACKNOWLEDGMENT

The authors would like to acknowledge the contribution of Dr. Thomas Terndrup for his work on the prior edition of this chapter.

PEDIATRIC ASTHMA AND BRONCHIOLITIS

**Maybelle Kou
Thorn Mayer**

ASTHMA

Asthma is a chronic disease of the tracheobronchial tree characterized by airway obstruction, inflammation, and hyperresponsiveness. Triggers for cytokine-mediated inflammation and hyperresponsiveness are well known and can be as innocuous as changes in barometric pressure. The cascade of events leading to mucous plugging, airway edema, and obstruction is generally reversible with appropriate, aggressive therapy. Adequate and timely treatment is paramount to the care of children with asthma.

The National Institutes of Health (NIH) 1997 Expert Panel Report 2 (EPR-2), *Guidelines for the Diagnosis and Management of Asthma*,¹

is a publication with which all physicians should be familiar. It provides treatment algorithms for use in the acute-care setting and clear guidelines to outpatient management (see Figure 68-1). However, most institutions will need to tailor these protocols to meet regional, local, and individual hospital needs.

Epidemiology

Asthma affects 4.8 million children younger than 18 years of age.² The prevalence of asthma has increased in all age groups by 40 percent in the last decade. In 1995, there were about 570,000 ED visits for asthma in children aged 0 to 14 years,³ with an admission rate of nearly 70 per 10,000. An investigation of over 113,000 pediatric asthma admissions from 1986 to 1993 revealed that although the number of discharges paralleled the general increase in population, the percentage of patients with adverse outcomes [mainly intubation but also the need for CPR] as well as death almost tripled.⁴ Between 1993 and 1995, there were 170 deaths due to asthma in the age group from 0 to 14 years.⁵

Specific risk factors associated with the development of asthma in children include low birth weight, family history of asthma, urban household, low-income household, and race (children of African-American, Asian, and Hispanic descent).⁶⁻⁸ These factors also have an influence on when hospitalization might be required during exacerbation. Most children presenting with asthma do so before age 8, with male predominance in the prepubertal age group. During adolescence, this ratio equalizes.

Risk factors that contribute to the deaths of children with asthma include socioeconomic background, limited access to health care, improper medication administration, and unrecognized severe disease. Extreme lability of disease, nocturnal asthma, and history of respiratory failure with previous intubation also have contributed to these deaths.

Pathophysiology

Bronchial hyperreactivity appears to have a genetic basis; however, the difficulty in distinguishing atopy from asthma has resulted in limited studies of this area. Nonetheless, asthma is classified as extrinsic IgE-mediated, intrinsic (infection-induced), and mixed (both IgE- and infection-induced). Since environmental factors are strongly implicated in the initiation of bronchial hyperreactivity, it should come as no surprise that 66 to 75 percent of asthmatic children are "allergic," many with serum IgE elevation. Concurrent sinusitis and bronchospasm secondary to chronic postnasal drip may be present. Whereas allergens and irritants are the most common and preventable triggers of asthma in children older than 2 years of age, viral respiratory infections are felt to be predisposing in those below age 2. Respiratory syncytial virus is one of many viruses that can cause wheezing; this is discussed below under "Bronchiolitis" (Table 124-1).

Sympathetic β_2 -receptors cause bronchodilation, and parasympathetics govern bronchoconstriction. IgE-mediated inflammation is a contributor in the pathogenesis of an asthma attack. Mast cells release histamine, leading to the formation of arachidonic acid metabolites and the inflammatory cytokine cascade. Asthma is a two-stage process: (1) bronchoconstriction due to histamine and leukotriene release (early stage) and (2) airway mucosal edema with mucous plugging (late phase). Since resolution depends largely on the degree of mucosal inflammation, an asthma attack may persist from days to weeks.

Bronchospasm, mucosal edema, and mucous plugging cause variable and reversible airflow obstruction with subsequent air trapping and impaired oxygen exchange. While increased lung volumes and pulmonary overdistention may help maintain airway patency, the resulting tidal volume approaches the volume of the pulmonary dead

TABLE 124-1 Asthma Triggers

Trigger	Countermeasures
Environmental	
Air pollution	Keep indoors during high-ozone days
Temperature extremes	
High humidity	
Tobacco smoke	Adults stop smoking
Allergens	
Animal dander/feces	Minimize carpets, down/feather bedding; control animal dander
Molds	
Pollen	
Exercise	Pretreat before exercise
Viral respiratory infections	Simple infection control measures when others are ill
Rhinitis/sinusitis	Treat postnasal drip and sinusitis
Gastroesophageal reflux	Use preventive medications

space and results in alveolar hypoventilation. Ventilation-perfusion mismatch in areas of atelectasis contributes to hypoxia.

In the early stages of a severe exacerbation, compensatory hyperventilation may cause a fall in P_{aCO_2} and even a respiratory alkalosis. More severe obstruction and inadequate alveolar ventilation ultimately result in marked CO_2 retention, respiratory acidosis, and respiratory failure. *Pseudonormalization* of P_{aCO_2} is therefore ominous: The apparently "normal" P_{aCO_2} of 40 mm Hg coupled with altered mental status is a clear sign of respiratory failure. The acidosis that results from hypoxia and hypercapnea leads to pulmonary vasoconstriction, pulmonary hypertension, and right-sided heart strain.

PEDIATRIC ANATOMIC DIFFERENCES The child with asthma is at higher risk of respiratory failure than an adult due to these anatomic differences:

1. Increased compliance of the infant rib cage and immature diaphragm results in paradoxical respiration, and inward displacement of the ribs during inspiration contributes to increased work of breathing and respiratory muscle fatigue.
2. Young lung tissue lacks elastic recoil and is more prone to atelectasis, resulting in ventilation-perfusion mismatch.
3. Airway walls are relatively thicker and result in greater narrowing with bronchoconstriction.

Thus, if expiration is hampered by obstruction, complete collapse of alveoli and lung segments may occur.

Evaluation

To avoid delays in treatment, a brief physical examination should be performed before a detailed history is obtained. Treatment with inhaled (β_2 -agonists should not be withheld while the initial evaluation is in progress, even if the patient is in the triage area owing to lack of availability of a treatment room. Examination of vital signs should include respiratory rate, pulse, blood pressure, temperature, and pulse oximetry (SpO_2). A room-air oxygen saturation of <90-93 percent in an infant or child should prompt supplementary oxygen administration, and concern for need for admission (see Chap. 123). Supplemental oxygen should be administered immediately to a child in respiratory distress, without delay, to obtain pulse oximetry on room air. Oximetry may be inaccurate in states of poor perfusion.

After initial stabilization, perform a complete examination. The child's chest must be visible for complete examination. Inspection and auscultation should be performed to assess ventilation, accessory muscle use, and work of breathing. The severity of disease may be underes-

timated in the "silent" or "quiet wheezer," in whom the expiratory phase usually is prolonged and wheezing is absent due to extreme air trapping.

The tripod position is a significant indicator of distress: The child sits forward, hands over knees, on the edge of the bed. The nostrils should be inspected for presence or absence of nasal flaring, foreign bodies, and concurrent sinusitis. Hallmark "musical" polyphonic inspiratory and expiratory wheezes may not always be present on lung examination and are not prognostic of severity of disease. Extremities should be inspected to assess cyanosis and clubbing. Insensible fluid losses may result in delayed capillary refill and poor skin turgor. Pulsus paradoxus in severe exacerbation is usually 20 to 40 mm Hg and may be reflected by significant jugular venous distention, which is otherwise difficult to appreciate in the pediatric examination.

A thorough series of questions can aid the physician in assessing risk factors and comorbidities and in formulating an educational and discharge plan. A history of asthma may be denied because pediatricians who are reluctant to give the diagnosis of asthma use *reactive airway disease* as alternative nomenclature. History of precipitating factors (see Table 124-1), medications and home care, previous hospitalizations, intubation, and tracheostomy should be determined, and medical records should be reviewed. History of prematurity, bronchopulmonary dysplasia (BPD), supplemental oxygen requirement, and neonatal intensive care unit admissions should be determined.

Often such information is not volunteered. In adolescents, inquire about the use of inhalants, tobacco, drugs of abuse, and over-the-counter purchases of bronchodilators that their parents may not be aware they have been using. History of aspiration or choking, as well as possible ingestion, should be included for all ages. Family history of asthma and allergy also can give a sense of whether or not the parent or caretaker will be able to continue treatment once the ED visit terminates.

The NIH-EPR-2 (Table 124-2) is a consensus document for assessing severity of an acute asthma episode. Table 124-3 provides guidelines for assessing the general severity of the condition.

Peak expiratory flow rate (PEFR) should be determined to monitor response to acute treatment and also for the ongoing assessment and management of asthma.¹ Forced expiratory volume in 1 s (FEV₁) is estimated by measuring PEFR and correlates with the degree of airway obstruction; PEFR is already decreased by 25 percent once wheezing is detected by stethoscope (Table 124-4). PEFR values in liters per minute are based on the child's height. A PEFR of less than 50 percent indicates severe obstruction, and less than 25 percent indicates possible hypercarbia. In the ED, PEFR is an excellent tool to evaluate mild asthma or for reevaluating patients after treatment, especially those who know their "personal best" score. Pre- and posttreatment values should be obtained when possible.

TABLE 124-2 Classifying Severity of Asthma Exacerbations

	Mild	Moderate	Severe	Respiratory Arrest Imminent										
Symptoms														
Breathless	While walking	While talking (infant—softer, shorter cry; difficulty feeding)	While at rest (infant—stops feeding)											
	Can lie down	Prefers sitting	Sits upright											
Talks in	Sentences	Phrases	Words											
Alertness	May be agitated	Usually agitated	Usually agitated	Drowsy or confused										
Signs														
Respiratory rate	Increased	Increased	Often >30/mn

TABLE 124-3 Classification of Asthma Severity: Clinical Features Before Treatment

	Days with Symptoms	Nights with Symptoms	PEFR or FEV ₁ *	PEFR Variability
Step 4 Severe Persistent	Continual	Frequent	<60%	>30%
Step 3 Moderate Persistent	Daily	≥5/month	>60%–<80%	>30%
Step 2 Mild Persistent	3–6/week	3–1/month	≥80%	20–30%
Step 1 Mild Intermittent	≤2/week	≤2/month	>80%	<20%

♦Percent predicted values for forced expiratory volume in 1 second (FEV₁) and percent of personal best for peak expiratory flow rate (PEFR) (relevant for children 6 years old or older who can use these devices).

Notes: Patients should be assigned to the most severe step in which *any* feature occurs. Clinical features for individual patients may overlap across steps. An individual's classification may change over time.

Patients at any level of severity of chronic asthma can have mild, moderate, or severe exacerbations of asthma. Some patients with intermittent asthma experience severe and life-threatening exacerbations separated by long periods of normal lung function and no symptoms.

Patients with two or more asthma exacerbations per week (i.e., progressively worsening symptoms that may last hours or days) tend to have moderate-to-severe persistent asthma. *Source:* NIH Guidelines.¹

The use of PEFR meters in children younger than age 5 is limited by patient cooperation. In older children, the ability to perform deep inspiration and forced expiration may not be feasible during an acute exacerbation.

Arterial blood gas analysis should be obtained to determine PaCO₂ in children with impending respiratory failure, if the patient is hypoventilating, if PEFR is less than 30 percent of predicted, or if the patient is not responding as expected to treatment. It also may be helpful in differentiating intensive care unit from regular floor admission.

TABLE 124-4 Predicted Average Peak Expiratory Flow for Normal Children and Adolescents, Male and Female

Height, in.	L/min	Height, in.	L/min

Complete blood count and chemistries are usually unnecessary unless there is a concurrent febrile illness or coexisting disease. Chronic steroid use can cause leukocytosis and elevated band count. Chronic use or abuse of albuterol can cause hypokalemia. If the child is taking theophylline, a level should be obtained.

Chest x-ray is not recommended routinely but should be performed in new-onset asthma, for severe episodes requiring admission, or if pneumonia, pneumothorax, foreign body, or pneumomediastinum are in the differential diagnosis. Findings typical of asthma are hyperinflation, flattened diaphragm, increased anteroposterior diameter, peribronchial cuffing, and atelectasis.

Differential Diagnosis

NEW-ONSET ASTHMA In the new-onset "wheezier," upper and lower respiratory and nonrespiratory causes must be differentiated (Table 124-5).

INFECTION Fever and focal wheezing implicate infectious etiologies such as pneumonia or bronchiolitis. Nocturnal wheezing, nocturnal cough, and poor exercise tolerance may be clues of more chronic illness. Sinusitis can exacerbate asthma symptoms; a history of nasal congestion and nocturnal cough or snoring should be treated with at least a 2-week course of antibiotics and nasal steroids. Recurrent attacks, failure to thrive, and a history of sinusitis and chronic ear infections should raise suspicion of cystic fibrosis as an etiology.

CARDIAC LESIONS: CONGENITAL AND ACQUIRED Infants with a history of bronchopulmonary dysplasia (BPD) may present with mild illness with rapid deterioration. Prolonged mechanical ventilation in the neonatal period causes smooth muscle hypertrophy and pulmonary hypertension, leading to cardiac disease. It may be necessary to distinguish pulmonary edema as a cause of wheezing; usually a history of diuretic use will aid in the diagnosis. Congenital heart lesions causing congestive heart failure, often exacerbated by concurrent viral infections, also can present with wheezing that can be mistaken for asthma. Chap. 120 presents a detailed discussion of pediatric heart disease.

TABLE 124-5 Differential Diagnosis of Asthma

Bronchopulmonary dysplasia (BPD)
Cystic fibrosis
Bronchiectasis
Pneumonia

Cardiovascular disorders
Congestive heart failure
Tricuspid atresia and transposition
Vascular ring
Miscellaneous
Foreign-body aspiration
Anaphylaxis
Hyperventilation syndrome
Salicylate ingestion [3-blocker ingestion]

UPPER AIRWAY OBSTRUCTION/FOREIGN-BODY ASPIRATION Wheezing from croup, tracheomalacia, epiglottitis, retropharyngeal abscess, upper airway foreign body, or vocal cord dysfunction can be misdiagnosed as asthma. In these situations, wheezing is loudest over the trachea, and wheezes heard in the lungs are transmitted from the upper airway. Chap. 133 presents a detailed review of upper respiratory emergencies.

GASTROESOPHAGEAL REFLUX DISEASE (GERD) A history of postprandial wheezing or coughing is indicative of GERD with microaspiration of liquid into the tracheobronchial tree. Severe GERD has been implicated in apnea and sudden infant death syndrome. Recurrent microaspiration can result in wheezing, fever, and pneumonia. Suspicion of GERD as a cause for wheezing requires further evaluation (see Chap. 117) and specific treatment.

Treatment

P₂-RECEPTOR AGONISTS p₂-Receptors are widely distributed on bronchial smooth muscle and airway epithelial cells. β₂-Receptor agonists activate adenylate cyclase, increase cyclic adenosine monophosphate (cAMP) levels, cause bronchial smooth muscle relaxation due to increased binding of intracellular calcium to the endoplasmic reticulum, and decrease myoplasmic calcium.

Albuterol (Canadian name, salbutamol; do not confuse with the long-acting salmeterol, which is contraindicated in an acute episode) is the treatment of choice. Dosage is listed in Table 124-6. Continuous aerosolized therapy with albuterol is a safe,⁹ fast, and effective way to deliver medication directly to the lung capillary beds and may be associated with a reduction in hospital admission.¹⁰ Continuous cardiac monitoring is employed with continuous albuterol infusions.

Tachycardia and jitteriness are common side effects (more so with oral medication than with inhaled medication), and rarely, dysrhythmias have been reported. During an acute attack, use of a β₂-receptor agonist may cause transient drops in P_{O₂} due to pulmonary vasodilatation and ventilation-perfusion mismatch.¹¹

Levalbuterol (Xopenex), the R-isomer of albuterol, results in less tachycardia than racemic albuterol. It is not currently used for acute exacerbations but is used as home nebulization therapy for asthma, although there are limited data demonstrating that its benefits outweigh standard albuterol treatment. It is more expensive than albuterol.

Salmeterol (Serevent), a long-acting p₂-agonist that reduces the need for prn albuterol dosing, is not indicated for use in acute exacerbations. It is also available in combination with fluticasone (Advair) as maintenance therapy.

Tachyphylaxis has been documented with chronic and improper use of p₂-agonists¹² and appears to be related to saturation of p₂-receptors from frequent dosing intervals and/or decreased downregulation of the number of p₂-receptors on leukocytes of asthmatic pa-

tients. When this occurs, increasing doses of p₂-agonists prove to be ineffective. Efficacy is preserved as long as the medication is used as needed and not overused or abused. Overuse of such medications as aerosolized epinephrine (available over the counter as Primatene Mist) has been implicated in the deaths of asthmatics from tachyphylaxis and cardiac dysrhythmias. Such over-the-counter preparations have no place in asthma management, even in mild asthma.

METERED-DOSE INHALER (MDI) Although the literature has stated that MDI therapy is just as effective as nebulizer treatment in children older than 6 years of age, patient cooperation limits its effectiveness in the emergency setting. Failure to improve with home MDI use occurs in children due to tachypnea, inability to take a breath and hold it, and inability to form a seal around the chamber mouthpiece, at which point nebulized medication becomes a necessity.

SUBCUTANEOUS EPINEPHRINE If a patient is unresponsive to the preceding therapy or respiratory distress increases, subcutaneous epinephrine should be administered while intravenous line placement is attempted. Give 0.01 mL/kg aqueous epinephrine 1:1000 to a maximum of 0.3 mL. This may be repeated every 20 to 30 min for a total of three doses.

TERBUTALINE More p₂-specific than epinephrine, terbutaline can be given SC in place of epinephrine as 0.01 mL/kg of a 1 mg/mL solution up to 0.25 mL. Nebulized terbutaline has no advantage over albuterol.

Terbutaline is the only intravenous p₂-agonist available in the United States (intravenous albuterol is available in Europe and Canada). Its use could be considered in older children who have not responded to conventional therapy. Adverse effects include myocardial ischemia and tachyarrhythmias, so continuous cardiac monitoring and intensive care admission are needed when the drug is given. Intravenously, terbutaline is given as 0.05 to 0.1 fig/kg per min.

CORTICOSTEROIDS Glucocorticoids inhibit the secretion of inflammatory leukotrienes and prostaglandins and prevent and reverse the increase in vascular permeability that leads to airway edema. They also cause an increase in density of p₂-receptors on leukocyte cell membranes and reverse tolerance to p₂-agonists.

Early administration during the course of an acute exacerbation is recommended for all patients unless (1) the PEF is greater than 50 percent *and* there is an immediate response to the first treatment or (2) when exercise-induced attacks occur in a previously well child. If the parent has already administered a dose at home, the dose can be repeated in the ED. Orally, prednisone or prednisolone is administered as 2 mg/kg. Prednisolone formulations are as follows: Pediapred 5 mg/5 mL, Prelone 15 mg/5 mL, and Orapred 15 mg/5 mL, the latter of which is reportedly more palatable. Intravenous methylprednisolone is available as Solumedrol, given as a single 2 mg/kg dose.

There is no real advantage to the administration of intravenous over oral glucocorticoids in the acute setting.¹³ If a child has vomited oral medicines or is already intubated, then intravenous administration is preferred. Intramuscular administration is also an option.

While the early administration of steroids in the ED may not actually change the need for admission,^{14,22} we believe that steroids treat inflammation and reduce relapse attacks and therefore should be administered as early as possible in the acute attack to prevent prolonged hospitalization.

INTRAVENOUS FLUIDS Most children presenting in status asthmaticus will be dehydrated because of increased insensible losses. Administer a bolus of fluid [20 mL/kg of NS] to aid in thinning secretions and repleting lost volume, especially in patients for whom admission seems inevitable.

ANTICHOLINERGIC THERAPY Anticholinergics are thought to prevent bronchoconstriction induced by cyclic guanosine monophosphate. Nebulized ipratropium bromide (Atrovent) may provide an

TABLE 124-6 Albuterol Dosage Guidelines

Dosage for adolescents: 2.5–5.0 mg q20min X 3 doses or 10–15 mg per h by continuous nebulization with at least 25% oxygen

Dosage for children: 2.5–5.0 mg q20min X 3 doses

or

0.5 mg/kg per h by continuous nebulization with at least 25% oxygen

Dosage for infants/neonates: 0.05–0.15 mg/kg per dose, q20min X 3 doses

2.5 mg albuterol is prepared as 0.5 mL of 0.5% albuterol diluted with NS to a final volume of 3 mL or 2.5 mg albuterol is contained in 3 mL of commercially available 0.083% albuterol solution

Source: Clinical Pharmacology 2000 <http://cpip.gsm.com> (July 2002 update).

additive benefit when used with albuterol,^{23,24} for acute asthma. It can be mixed with albuterol solution for combined administration by nebulizer. Ipratropium is a safe drug with few side effects and may be given to patients of all ages. An MDI in combination with albuterol (Combivent) is at this time indicated for adult use only.

The dosage of nebulized ipratropium bromide is as follows:

Adolescents >14 years of age: 500 μ g in an initial nebulization
 Children up to 14 years of age: 125-250 μ g in an initial nebulization
 Neonates: 25 μ g/kg in an initial nebulization

MAGNESIUM SULFATE The exact mechanism of action of magnesium is unknown but may resemble the tocolytic effects of magnesium sulfate on uterine smooth muscle. Patients who receive intravenous magnesium show improvement in short-term pulmonary function without adverse effects, such as low blood pressure.^{25,26} Magnesium sulfate may be given as 25 to 50 mg/kg IV over 20 min; this may be repeated once to a serum magnesium level of 4 mg/dL. The maximum dose for children is 2 g. Nebulized administration is not recommended.

HELIOX Heliox is generally available as 80:20 or 60:40 mixtures of helium and oxygen. The 60:40 mixture should be used in order to administer supplemental oxygen. If available, it may be initiated in the ED. It is recommended for the asthmatic who does not improve with conventional treatment but in whom intubation is not imminent.²⁷ The lower density and high diffusivity of the gas allow easier passage through turbulent obstructed airways. The peak flow rate increases, while airway resistance and work of breathing decrease. It is possible to continue to administer β -agonists during Heliox treatment.

OTHER THERAPIES Theophylline is a competitive phosphodiesterase inhibitor that was thought to aid bronchodilation by increasing cAMP. It is no longer used routinely because it has no benefits over (β_2 -agonists for treatment, has an extremely narrow therapeutic-toxic ratio, has adverse central nervous system and cardiac side effects, and has multiple drug interactions. It is reserved for patients who clearly respond to it or for those who remain refractory to other modes of treatment. Aminophylline 6 mg/kg (85 percent theophylline) is given in 25 to 50 mL of NaCl IV over 20 min. If the patient is already taking theophylline but the level is subtherapeutic, a loading dose can be given [$\text{mg} = (\text{desired level} - \text{measured level})/2 \times \text{kg}$].

Agents for Adjunctive Ambulatory Treatment

Inhaled glucocorticoids improve long-term control of asthma, minimize the use of rescue medication, and have minimal side effects compared with systemic glucocorticoids. Table 124-7 lists doses of commonly used agents.

Cromolyn sodium has long been used to inhibit mast-cell degranulation and histamine release. It is not recommended in acute attacks.

Nedocromil (Tilade) works similarly; however, it may be effective only if strict compliance is maintained. A primary feature is that it reduces the cough component of asthma; it is also considered to be "steroid sparing."

Leukotriene receptor inhibitors (LTRIs) are increasingly popular agents for use in the outpatient prophylactic management of asthma. These medications do not supersede steroid use in acute attacks. They are classified as 5-lipoxygenase inhibitors or 5-lipoxygenase-activating protein inhibitors, of which montelukast is approved for pediatric use; zafirlukast may be used in children aged 12 years and older. Currently, only limited data are available, but the initial response is encouraging and suggests less need for medication and chronic steroid use. Although initial studies have revealed a relatively good safety profile, zafirlukast has been linked to several adult cases of Churg-Strauss syndrome²⁸ (granulomatous necrotizing vasculitis).

TABLE 124-7 Discharge Treatment Dosage Guidelines

Sympathomimetic agents: adrenergic agonists

Short-acting (β_2 -agonists *Albuterol* (= salbutamol) Nebulizer solution (5 mg/mL) 0.05 mg/kg (min 1.25, max 2.5 mg) in 2 to 3 mL of NS q4-6h Or premixed 2.5 mg/3 mL of NS q4-6h MDI (*Proventil UFA*, *Ventolin*, generic) 90 μ g per puff
 1-2 puffs q3-4h
 Suspension 2 mg/5 mL, 0.1 mg/kg per dose, q6-8h
 Long-acting (β_2 -agonists
Albuterol extended-release tablets (Repetabs, Volmax) 0.1-0.2 mg/kg q12h
Salmeterol (*Serevent*) 21 μ g per puff q12h

Anticholinergic agents

Ipratropium bromide (*Atroveni*) Nebulizer (0.25 mg/mL) 0.25-0.5 mg q6h MDI (18 μ g per puff) 1-2 puffs q6h

Treatment of inflammation Glucocorticoids

Prednisone (5-, 10-, and 20-mg tablets) 1-2 mg/kg PO qd
 Prednisolone (*Prelone*, *Pediapred*) (5 mg/5 mL, 15 mg/5 mL) 1-2 mg/kg PO qd "Burst dose" max 60 mg per d X 3-10 days Inhaled steroid preparations Beclomethasone
Vanceril DS (84 μ g per puff) 2 puffs bid *Beclovent* (42 μ g per puff) 4 puffs bid Triamcinolone (*Azmacort*) (100 μ g/puff) 2 puffs bid Flunisolide (*Aerobid*) (250 μ g per puff) 2 puffs bid Budesonide (*Pulmicort Turbuhaler*) (100, 200, and 400 μ g per puff) 200-400 μ g bid

Unclassified anti-inflammatory agents Cromolyn sodium (*Intal*)

MDI (800 μ g per puff) 2-4 puffs bid Neb (10 mg/mL) 20 mL qid Nedocromil (*Tilade*) MDI (1.75 mg per puff) 2 puffs qid
 Leukotriene receptor inhibitors 5-Lipoxygenase inhibitors
Zileuton (*Zyflo*) 600 mg qid (not for children age 12 and under) 5-Lipoxygenase-activating protein inhibitors Zafirlukast (*Accolate*) 20 mg bid (children age 12 and up) Montelukast (*Singulair*) 5 mg qd (children age 6 and up) 10 mg qd (ages 12 and up)

Interleukin 4-receptor medications are not currently approved for pediatric use.

Complications of Moderate and Severe Asthma Exacerbation

Respiratory failure may occur even if treatment is in progress, mainly from muscle fatigue. Atelectasis is common and may be responsible for the overdiagnosis of pneumonia in pediatric asthmatic patients. While pneumomediastinum is rare, children may present with vague chest pains for which a radiograph can reveal the diagnosis. Most can be managed on an outpatient basis, provided that they can be seen again within 24 h or can return to the ED quickly if respiratory distress develops. Generally, mediastinal air will resorb over 2 to 3 days. A large pneumomediastinum and/or pneumothorax requiring chest tube thoracostomy will require admission for close monitoring and observation.

Reassessment and Disposition

Treatment algorithms greatly simplify the decision of whether or not a child should be admitted. Disposition can be made after 2 to 4 h of

therapy for patients who remain stable (Table 124-8). A child who does not respond after 2 h of continuous treatment whose Paco_2 is greater than 40 mm Hg should be admitted to an intensive care unit for continuous therapy. Children with oxygen requirements, refractory asthma, and/or dyspnea on exertion may be admitted to the floor. If parents of children with newly diagnosed asthma do not feel comfortable taking care of their children even with adequate teaching, admission may be warranted (this also applies to patients with mild attacks requiring nebulization but with limited resources and inability to obtain nebulizers on weekends and at night).

An intubated patient or patient requiring continuous nebulization should be transported to a facility with pediatric intensivist capability by advanced life support (ALS) providers with pediatric airway experience.

Discharge Instructions and Ambulatory Treatment

Children responding well to conventional therapy may be discharged after 2 to 4 h of treatment. A short ED observation period is recommended for patients with an incomplete response but acceptable PEFR. Detailed discharge instructions should outline medication administration, inhaler use, and follow-up (see Table 124-7). No child should be discharged without an MDI and spacer, and prescriptions for oral glucocorticoids are generally recommended unless the attack was extremely mild (resolved with minimal treatment) or exercise-induced. A tapered dose generally is not needed for "burst dose" (3- to 10-day) therapy²⁹ because the side effect of adrenal suppression with prolonged use is unlikely to occur. Of the two most common forms of methylprednisolone, Pediapred is reported to taste better than Prelone; however, its lower concentration requires that three times the volume of Prelone be given for the same dose. Orapred may be prescribed instead of Prelone but is not widely available.

A courtesy call to the private pediatrician of the child who has been treated for asthma in the ED should be made because it facilitates continuity of care for the child and ensures follow-up. All children should be referred to their pediatrician for follow-up within 24 h.

BRONCHIOLITIS

Bronchiolitis, or inflammation of the bronchioles, is the term applied to the clinical syndrome of wheezing, chest retractions, and tachypnea in children younger than age 2 years; it causes more significant illness in infants younger than 6 months of age.

Epidemiology

Peak prevalence is from late October to May. The peak age of incidence in urban populations is 2 months and results in hospitalizations lasting 5 to 7 days. Disease in older children is usually milder.

Pathophysiology

Respiratory syncytial virus (RSV) causes 50 to 70 percent of clinically significant bronchiolitis. Non-RSV bronchiolitis is caused by influen-

zavirus, parainfluenzavirus, echovirus, and rhinovirus. *Mycoplasma pneumoniae* and *Chlamydia trachomatis* also produce symptoms. Adenovirus causes a particularly destructive form, bronchiolitis obliterans, observed in native Canadian Eskimo populations.

The highly infectious RSV is transmitted by direct contact with large droplets of secretions and self-inoculation by contaminated hands via the eyes and nose. No significant transmission occurs by small-particle aerosol. RSV-infected secretions remain infectious on countertops for more than 6 h. Strict attention to hand washing and use of masks and gloves can prevent transmission. RSV is shed from the respiratory tract of symptomatic and asymptomatic patients for up to 9 days. Immunocompromised patients may continue to shed for up to 6 weeks. Immunity to the virus is variable owing to antigenic diversity, so reinfection does occur. No vaccine has yet been developed.

Mucous plugging results from necrosis of the respiratory epithelium and destruction of ciliated epithelial cells. This and submucosal edema lead to peripheral airway narrowing and variable obstruction, with areas of patchy atelectasis or overdistention in lung segments. Progressive disease causes severe pneumonia, with extensive destruction of respiratory epithelium, parenchymal necrosis, and formation of hyaline membranes. Bronchiolar regeneration occurs within 3 to 4 days; however, cilia may take as long as 15 days to regenerate.

Increased airway resistance and decreased compliance result in increased work of breathing. Like the infant with lower airway obstruction, the infant with bronchiolitis breathes at higher lung volumes due to uneven resistance within the lung. Alteration of gas exchange results from the patchy atelectasis and airway obstruction.

Clinical Features

Symptoms can vary from minimal rhinorrhea to bronchiolitis or pneumonia and respiratory failure. Severe illness and apnea are more likely to occur in children with a history of prematurity, cystic fibrosis, congenital heart disease, or immunocompromise.

Infection begins with nasal discharge, pharyngitis, and cough. Fever accompanies the first few days of illness, with temperatures as high as 40°C (104°F). The parent brings the child to the ED because of wheezing, increased respiratory symptoms, nasal congestion, and difficulty feeding. Symptoms reach a peak at 3 to 5 days, generally resolving in 2 weeks with normalization of pulmonary function. Resulting wheezing can persist for weeks to months.

Physical findings include tachypnea greater than 50 to 60 breaths/min, tachycardia, mild conjunctivitis, chest retractions, prolonged expiration with hyperresonant chest, wheezes throughout, and hypoxemia. The most reliable clinical finding that correlates with hypoxemia is tachypnea, which signifies serious impairment of gas exchange. The hypoxemic child with bronchiolitis may not show cyanosis. The severity of wheezing or intercostal retractions also will not correlate with the severity of hypoxemia. Respiratory rate must be followed, but this may be difficult because variation occurs with fever and crying. Abnormal pulse oximetry is a predictor of severe disease, and most children with saturations of < 90-93 percent will need admission.

YOUNG INFANTS AND APNEA The mechanism inducing RSV-related apnea in young infants is not completely understood but may be related to hypoxemia and upper airway obstruction.³⁰ Infants at highest risk are younger than 6 weeks old and have a history of prematurity, apnea of prematurity, and low O_2 saturation on admission. It is difficult to predict apneic events. The severity of wheezing and retractions does not correlate with frequency of apnea, and most infants younger than 1 month of age will have atypical disease and may present without wheezing and retractions. Apneic infants may require intubation during the course of the illness, sometimes requiring mechanical ventilation for up to a week or more. After extubation, these infants are not at higher risk of apnea and may be discharged without apnea monitors.

TABLE 124-8 Admission Criteria

Respiratory failure requiring intubation
Status asthmaticus: Persistent retractions, tachypnea
Oxygen requirement after 2 h of therapy
Return ED visit within 24 h
Limited home resources
Pneumothorax
Complete lobar atelectasis
Large pneumomediastinum
Underlying cardiopulmonary disease

Children with underlying diseases such as bronchopulmonary dysplasia, cystic fibrosis, immunodeficiency, or congenital heart defects are at increased risk of severe RSV infection. Care must be taken in treating infants with a history of BPD because many will have a tendency toward chronic CO₂ retention. Since hypoxemia remains the major respiratory stimulus in this population, supplemental oxygen may cause further CO₂ retention; therefore, saturations of 94 to 95 percent are acceptable standards in such patients.

Numerous retrospective analyses and observations note that children with bronchiolitis as infants frequently develop asthma later on.³¹

Diagnosis

The diagnosis of bronchiolitis is suggested by clinical presentation, patient age, and history of RSV exposure or community epidemic. Immunofluorescence assays currently available are extremely sensitive but not necessary for all patients. We feel that a confirmatory test for RSV is unnecessary unless admission is being considered and then only for bed-placement purposes as deemed by individual hospitals. Since the prevalence of RSV during an epidemic is so high, routine testing is costly and is best reserved for children with predisposing medical conditions or complicated disease courses.

Complete blood counts and chemistries may not be helpful in diagnosis. The white blood cell count can be normal or elevated with a left shift. An elevated band count may be present. Chemistries should be obtained if there is poor feeding or evidence of dehydration. Chest radiography to rule out pneumonia is indicated for children with concurrent cardiopulmonary illness or those who are ill-appearing and hypoxemic and may reveal patchy atelectasis, segmental atelectasis, hyperinflation, and peribronchial thickening. The history should include questioning about possible ingestion; salicylate ingestion may present with respiratory distress and mixed metabolic acidosis and respiratory alkalosis, and (3-blocker ingestions can exacerbate wheezing.

Emergency Department Management

GENERAL CARE During RSV epidemics, the emergency physician will be exposed to a broad spectrum of patients at varying stages of disease and must be able to identify those who need admission and those who are at risk for apnea. Most cases of bronchiolitis are treated on an outpatient basis, for which follow-up in 24 h with a private pediatrician is essential. Infants in respiratory failure will require emergent intubation and admission to the intensive care unit.

Children with suspected respiratory compromise should be monitored carefully, including continuous pulse oximetry and cardiac monitor. Treatment is mainly supportive, the most important therapy being supplemental humidified oxygen. At concentrations of 28 to 40 percent, arterial hypoxemia is improved in most infants.

Increased insensible fluid loss occurs from increased work of breathing and can cause significant dehydration that warrants a 20 mL/kg NS bolus. Patients with poor fluid intake due to congestion also may require intravenous hydration and admission (especially if parents are unable to feed the child owing to uncontrollable secretions). Beyond initial resuscitation, fluid replacement should not exceed maintenance due to the potential for the development of pulmonary edema in some of these children.

Fever should be controlled with acetaminophen or ibuprofen. A 9-year prospective study of 565 children with documented RSV infection showed that the risk of secondary bacterial infection was low; subsequent secondary bacterial infections were seen more frequently in the group treated with antibiotics. Studies have failed to show any utility in obtaining blood cultures in children with fever attributable to RSV. Infants with high temperatures and documented RSV therefore are unlikely to require workup for occult bacteremia *unless they ap-*

pear septic. A complete blood count should be drawn from children *who appear toxic* and have a temperature above 38.5°C (101.3°F) to rule out intercurrent infections. Antibiotics should be reserved for concurrent otitis media or other identifiable bacterial infections.

RACEMIC EPINEPHRINE Racemic epinephrine is an effective treatment for the wheezing of bronchiolitis. Nebulized racemic epinephrine has been compared with albuterol and found to reduce hospitalizations in children with bronchiolitis,³² improving symptom scores of respiratory rate, wheezing, and retractions at 15 min compared with nebulized saline.³³ The exact mechanism of its action in bronchiolitis is unknown. It can be used safely in hospitalized children up to every 2 h as a 0.1% solution (0.5 mL in 3.5 mL of NS). If used in the ED, we recommend an observation period of 4 h before a disposition decision is made. Generally, infants and children showing minimal response or deterioration after a single treatment will require hospitalization.

ALBUTEROL AND IPRATROPIUM Unless there is a history of asthma, there is a limited role for bronchodilator therapy in the treatment of bronchiolitis. A trial of bronchodilator therapy, however, is an optional and reasonable treatment and can be aborted if the child fails to show a response. Many studies of oral and nebulized albuterol alone show that it fails to improve oxygen saturation or to reduce the length of hospitalizations,^{34,36} leading some authors to question the benefit of such therapy. Ipratropium also does not affect the natural course of the disease,³⁷ although anecdotes suggest that it may have a role in drying up secretions.

HELIOX Heliox may be considered for children with severe obstructive symptoms and works for the same reasons as in asthma. A recent study³⁸ showed that its use increased SaO₂ in children when compared with oxygen alone. Its can be a useful bridge in reducing the need for intubation in certain populations of infected children.

Other Treatment Modalities

GLUCOCORTICOIDS Controlled studies have failed to demonstrate any proven benefit to the use of glucocorticoids, including studies on oral prednisolone and dexamethasone.³⁹ We do not recommend the use of glucocorticoids unless there is a history of asthma; however, these drugs have been helpful in infants with a history of BPD. Initial reports on budesonide, a smaller molecule that has been studied widely in Europe and Australia, suggest a benefit. In a Finnish study⁴⁰ of 100 patients, budesonide was seen to reduce the number of hospital admissions and subsequent wheezing episodes as compared with controls. A more recent study on nebulized budesonide⁴¹ stated that its effects in preventing postbronchiolitic wheezing were unremarkable. It is currently being introduced in the United States in a MDI form, and more studies need to be performed before it can be recommended routinely.

RIBAVIRIN Ribavirin is a guanosine-resembling synthetic nucleoside analogue generally used as inpatient therapy. When delivered as a small-particle aerosol, it has produced improvement in oxygenation. It is thought to work by decreasing viral protein synthesis. Candidates for such treatment are those with immunodeficiency, cystic fibrosis, congenital heart disease, and severe illnesses of infancy. Since the introduction of intravenous immunoglobulin, the use of ribavirin appears to be less frequent.

RESPIGAM RSV IMMUNE GLOBULIN INTRAVENOUS (HUMAN) RespiGam has been in use for the past few years as outpatient passive immunization for infants at risk for severe RSV disease. The treatment involves monthly intravenous infusions of immunoglobulin during

RSV season. It is recommended for infants with documented BPD and for those with a gestational age of less than 35 weeks (at the discretion of the physician). The PREVENT study⁴² demonstrated a reduction in the incidence and duration of RSV hospitalization and severity of illness.

PALIVIZUMAB (SYNAGIS) Palivizumab is the first monoclonal antibody that can be given by intramuscular injection to provide protection against infection (protein binding neutralizes the virus). Like RespiGam, it is administered monthly to patients at highest risk and is desirable for children in whom vascular access is a challenge. The Impact-RSV trial showed a 55 percent reduction in hospitalizations in a group of 1500 patients, with few adverse effects.

Disposition

Parents should be educated on the natural course of RSV infection and how to identify markers of respiratory distress. Infants with visible moderate to severe respiratory distress, hypoxia, apneic spells, or dehydration should be admitted to the intensive care unit. Infants without wheezing but with sustained tachypnea (RR >60 breaths/min) also should be admitted, preferably to a step-down unit. Hospitalization should be considered in all infants with a history of BPD, congenital heart disease, and immunocompromise. Infants and children with resting oxygen saturations of less than 93 percent should be evaluated carefully for possible admission.

Those with mild disease who are taking fluids well and whose parents are capable of taking care of them may be released with good follow-up instructions. Home health visits and nebulizers may be instituted if deemed necessary. Parents should be instructed on how to perform aggressive nasal suctioning and evaluate respiratory distress. Albuterol in syrup form also may be initiated, but only for children who respond to nebulized albuterol in the ED. Use of vapor solutions available over the counter should be discouraged, and parents who smoke cigarettes should be cautioned that tobacco smoke worsens the illness. Decongestants and antihistamines are of questionable benefit; their use in infants younger than 6 months of age is not recommended.

SEIZURES AND STATUS EPILEPTICUS IN CHILDREN

Michael A. Nigro

In children aged 0 to 9 years, the prevalence of seizures is 4.4 cases per 1000, and in those 10 to 19 years, the prevalence is 6.6 cases per 1000. Simple febrile convulsions constitute a separate category, with an incidence of 3 to 4 percent in children.

These numbers alone do not reveal the most important features of the seizure phenomenon: the increased morbidity and mortality rates that are a direct result of seizures, their cause, or their treatment. The overall mortality rate is two to three times higher in epileptic than in nonepileptic patients. The earlier the onset of seizures and the more deprived the social environment, the higher the morbidity and mortality rates are.

This chapter reviews pediatric seizures in the following clinical categories:

1. The first seizure
2. Breakthrough seizures in a known epileptic
3. Febrile seizures
4. Neonatal seizures
5. Infantile spasms
6. Seizures associated with head trauma
7. Status epilepticus

Emergency care should include (1) safely stopping the seizure, (2) identifying and immediately correcting treatable or reversible causes, and (3) initiating appropriate diagnostic studies and determining whether admission is needed or whether outpatient follow-up is appropriate. The differences in the treatment of children are distinctive enough so that, unless the physician is experienced in pediatric management or able to readily obtain pediatric or neurologic consultation, the child should be transferred to a pediatric facility.

ETIOLOGY

A *seizure* is an episodic alteration in motor activity, behavior, sensation, or autonomic function. It represents an abrupt change in brain function. The term *epilepsy* indicates recurring seizures without a simple discernible and reversible cause.

Physiologically, a seizure is an abnormal, sudden, and excessive electrical discharge of neurons (gray matter) that propagates down the neuronal processes (white matter) to affect end organs in a clinically measurable fashion. The International Classification of Epileptic Seizures is still accepted as the contemporary standard¹ (Table 125-1).

Seizures are also categorized by presumed cause: *primary*, *idiopathic*, or *secondary*; due to prior neurologic insult; or some underlying metabolic, structural, inflammatory, or systemic disorder. Diagnosis, treatment, and disposition strategies depend on the clinical status of the patient and the underlying cause.

Idiopathic seizures account for about 25 to 50 percent of children seen with seizures, depending on the study cited. Secondary seizures occur for a wide variety of reasons (e.g., inflammatory, structural, metabolic, or secondary to general illness). In such cases, correction of the primary problem is necessary. Thus, the primary goal of seizure evaluation is to uncover disorders that are readily identifiable and reversible.

Correcting the metabolic abnormality treats seizures due to hypoglycemia, hypocalcemia, and electrolyte imbalance. Seizures can be a complication of disorders such as systemic lupus erythematosus, sickle cell anemia, leukemia, arteriovenous malformations, or neoplasms. Seizures have been reported in children after topical application of A¹, A¹-diethyl-m-toluamide, and lindane (Kwell). Toxic ingestions of substances such as camphor, theophylline, isoniazid, tricyclic antidepressants, oral and parenteral meperidine, cyclosporine,

TABLE 125-1 International Classification of Epileptic Seizures

Partial seizures (seizures beginning focally)
Partial seizures with elementary symptomatology (generally without impairment of consciousness)
With motor symptoms (includes Jacksonian seizures)
With special sensory or somatosensory symptoms
With autonomic symptoms
Compound forms Partial seizures with complex symptomatology (generally with impairment of consciousness)
With impairment of consciousness only
With cognitive symptomatology
With affective symptomatology
With "psychosensory" symptomatology
With "psychomotor" symptomatology
Compound forms
Partial seizures secondary generalized
Generalized seizures (bilaterally symmetric without localized onset)
Absences (petit mal) Bilateral massive epileptic myoclonus
Infantile spasms Clonic seizures Tonic seizures
Tonic-clonic seizures (grand mal)
Atonic seizures Akinetic seizures
Unclassified epileptic seizures

Source: Reprinted with permission from Gestaut H: Clinical and electroencephalographic classification of epileptic seizures. *Epilepsia* 11:102, 1970.

methylphenidate, lead, and mercury can cause seizures. Viral and bacterial meningitis, viral encephalitis, brain abscess, and more uncommon problems such as cat-scratch fever and mycoplasma-related encephalopathy may present with seizures. In a child with a ventriculoperitoneal shunt, seizures can arise from associated cerebral abnormalities or shunt malfunction. Unfortunately, one must always be alert to nonaccidental trauma (shaken baby syndrome) as a cause of new onset seizures.

ELECTROENCEPHALOGRAPHY

Electroencephalographic (EEG) recording on an emergent basis is important to diagnose nonconvulsive status epilepticus. In this condition, the patient seems to be seizure free but is unresponsive. The EEG demonstrates subclinical status epilepticus. In a child who unexpectedly remains comatose or in a neonate in whom clinical seizures may be difficult to detect, immediate and continuous EEG monitoring may more effectively direct aggressive antiepileptic drug (AED) treatment.

NEUROIMAGING IN EPILEPSY

The choice of central nervous system (CNS) imaging depends in part on the circumstances and the age of the patient:

1. For neonates and young infants, cerebral ultrasound is a quick and relatively reliable method to identify intraventricular and parenchymal hemorrhage, periventricular leukomalacia, major malformations, cerebral edema, and hydrocephalus.
2. Computed tomography (CT) is needed to evaluate seizures associated with head trauma or mass lesions.
3. Magnetic resonance imaging (MRI) is preferred for evaluating migrational defects, mesial temporal sclerosis, acute parainfectious disseminated encephalomyelitis, stroke, and neoplasm.
4. Magnetic resonance angiography is best for defining vascular abnormalities, stroke, and stroke-like events.
5. Transcranial Doppler sonography can be helpful in determining impending cerebrovascular occlusive disease of sickle cell anemia.

NEWER ANTIEPILEPTIC DRUGS

Newer AEDs are generally indicated in the management of seizures as add-on drugs, although there are currently numerous studies determining their value for initial and monotherapy.

Gabapentin

Gabapentin (Neurontin) is a novel AED with ill-defined mechanism of action, although it appears to increase the effect of 7-aminobutyric acid (GABA), the major cerebral inhibitor. It has no drug interactions, is not metabolized, and is not protein bound. It is excreted solely by the kidneys. The short half-life of 5 to 6 h and the limited intestinal absorption capability require frequent dosing of three to four times a day. Dosage is 20 to 60 mg/kg per d, and maximal dosage can be reached in several days. Side effects are mild, self-limiting, and usually consist of vertigo, lightheadedness, and infrequently, behavioral changes. Rarely, myoclonic seizures have been provoked soon after initiating the drug. Antiepileptic drug levels are not useful in determining therapeutic and toxic effects.

Lamotrigine

Lamotrigine (Lamictal) probably acts on voltage-sensitive sodium channels and excitatory amino acid neurotransmitters. **Two very important features of lamotrigine include the adverse effect of rash, which can progress to Stevens-Johnson syndrome, and drug interactions.** The incidence of serious rash has been reduced by lower dosing regimens. The half-life of lamotrigine is reduced by 50 percent when administered with enzyme inducers, such as phenytoin, carbamazepine, and phenobarbital, and is doubled when used in conjunction with valproate. The combination with valproate has been associated with most adverse reactions.

Lamotrigine is indicated in the treatment of partial and generalized epilepsy, including absence, drop, and myoclonic seizures. When administered with enzyme inducers, the dose begins at 2 mg/kg per d and is increased over 8 to 12 weeks to a maximum of 15 mg/kg per d. When used with valproate (Depakote), it should be started at 0.2 mg/kg every other day, increased by 0.2 mg/kg per d to 1 mg/kg per d, and over the next 8 to 12 weeks increased to a maximum of 5 mg/kg per d. When changes are made in reducing or introducing co-medication, the lamotrigine dose will have to be modified in most instances. Given as monotherapy, the half-life is 25 to 30 h. It has minimal protein binding. Blood levels do not reflect toxic or therapeutic effects. There is no reported significant hepatic or hematologic side effect.

Topiramate

Topiramate (Topamax) became available in 1997. It acts on the GABAergic system, sodium channels, and glutamate receptors by preventing the propagation of the seizure from its focus. The half-life is 19 to 23 h, so the drug can be given twice a day. Eighty-five percent of the drug is eliminated unchanged through the kidneys, and 15 percent is metabolized by the hepatic P-450 system. It is indicated in the treatment of partial seizures and is being evaluated as monotherapy. In children, the drug is begun slowly at 1 mg/kg per d and over 8 to 12 weeks is gradually increased to a maximum of 10 mg/kg per d or 400 mg/d, if necessary. In infants the dose is increased to 20 mg/kg per d in view of greater drug clearance. The major side effect limiting dosage and rate of increasing dosage is the effect on memory and name recall.

Tiagabine

Tiagabine (Gabitril) is a GABA reuptake inhibitor, which inhibits epileptic excitatory activity. With a relatively short half-life of 5 to 8 h, the drug can be administered three times a day. Absorption is slower and the drug more easily tolerated when given with meals.

Metabolism is via the P-450 mechanism and, as a result, the half-life is significantly reduced by co-administration with enzyme inducers, such as carbamazepine, phenytoin, and phenobarbital. The maximum effective dose in children at this time is estimated to be 1 mg/kg per d. This dose should be started at 0.1 mg/kg per d and gradually increased over the next 6 to 10 weeks. Because of high protein binding, free levels of co-administered AEDs should be monitored (phenytoin, carbamazepine, and valproate). Most common side effects are sedation, behavioral changes, and activation of myoclonic seizures.

Oxcarbazepine

Oxcarbazepine (Trileptal) is a 10-keto analogue of carbamazepine. Its active metabolite is a monohydroxy derivative that has a half-life of 10 h, allowing for a twice-daily dosing. It is begun at 10 mg/kg per d and increased to a maximum of 60 mg/kg per d or to tolerance and seizure control. It is approved for use as adjunctive treatment of partial epilepsies. It can be used in combination with any of the existing AEDs, including carbamazepine. Unlike carbamazepine, it has no epoxide metabolites and is not affected by erythromycin. It does interact with anovulatory agents in a manner similar to that of carbamazepine by decreasing their effect at low doses, and hence warrants a caution to sexually active teens.

Depacon is the intravenous preparation of valproate. It is usually administered intravenously when the oral maintenance dose cannot be tolerated. Dosage is the usual maintenance dose administered IV over 15 min. The loading dose is 10 to 30 mg/kg IV over 15 min.

Extended-Release Agents

Carbatrol and Tegretol XR are extended-release forms of carbamazepine that permit bid dosing.

Fosphenytoin

Fosphenytoin (Cerebyx) is a prodrug of phenytoin that contains a disodium phosphate ester that is cleaved during hydrolysis, yielding a molecule of phenytoin. Phosphatases are ubiquitous and present in newborns, so fosphenytoin can be used at any age. It is water soluble and can be given intravenously and intramuscularly without soft tissue injury. A 1 mg phenytoin equivalent (PE) is the therapeutic equivalent of 1 mg of phenytoin. Fosphenytoin can be infused at 3 mg PE/kg per min, with therapeutic free phenytoin levels achieved by 7 to 8 min after infusion and 30 min after intramuscular use. Rapid infusion in alert patients may produce perineal pruritus.

Zonisamide

Zonisamide (Zonegran) is a sulfonamide indicated as adjunctive therapy for partial seizures in adults. Studies are currently underway in the United States to determine the safety and effectiveness in children, but zonisamide is used extensively in Japan in the pediatric population. Oligohydrosis and hyperthermia have been described in children as a complication of the drug. It is also contraindicated in patients with hypersensitivity to sulfonamides. Zonisamide has a long half-life of 60 to 80 h, and enzyme-inducing drugs (i.e., carbamazepine, phenytoin, and phenobarbital) increase drug clearance. Dosage begins at 1 mg/kg per d and is increased every 2 weeks at a rate of 1 to 2 mg/kg per d until seizure cessation, or a maximum of 12 mg/kg per d.

Levetiracetam

Levetiracetam (Keppra) is a novel AED indicated for adjunctive therapy for the treatment of partial seizures in adults, and studies are currently

investigating the safety and effectiveness in children. Levetiracetam is not protein bound, and there have been no significant drug interactions reported with other AEDs. In adults the plasma half-life is 6 to 8 h, and 66 percent of the dose is renally excreted unchanged. In children the clearance is 40 percent higher than in adults. Dosage is initiated at 10 mg/kg per d and increased by 10 to 20 mg/kg per d every 2 weeks to a target dose of 40 to 60 mg/kg per d.

ADDITIONAL ADVANCES IN EPILEPSY TREATMENT

Vagus Nerve Stimulation

The Cyberonics vagus nerve stimulator (NeuroCybernetic Prosthesis System) is programmed to deliver a stimulus at a specific intensity and frequency for a specific interval (e.g., 15 s every 3 min). Although the mechanism of action is uncertain, electrical stimulus of the left vagus nerve can significantly reduce seizure frequency. Common side effects include hoarseness and difficulty swallowing during stimulation. Problems with instrumentation are unlikely to warrant an ED visit. If a patient is experiencing significant discomfort upon activation of the vagus nerve stimulator, the stimulator can be temporarily turned off by taping a magnet over the subcutaneous pacemaker.

Ketogenic Diet

Ketones are an alternative energy source for cerebral metabolism. By severely restricting glucose and increasing fat intake, ketosis can be maintained and seizure control improved. There are several concerns about an ED visit that warrant mention. **It is necessary to maintain ketosis; as a result, glucose infusions should be avoided, if possible, and prescriptions given should have no measurable carbohydrate content. Renal calculi and pancreatitis are two complications of the ketogenic diet.**

THE FIRST SEIZURE

Immediate anticonvulsant treatment is not needed unless the child is in status epilepticus or seizures recur in the ED² (Tables 125-2 to 125-4). Instead, the emergency physician can concentrate on defining the cause and determining the appropriate disposition.

History

For a first seizure, the history should be directed to the identification of risk factors for underlying neurologic or metabolic abnormality and risk factors for neurologic morbidity from seizure. **Risk factors include a family or sibling history of seizures, presence of underlying neurologic abnormality, and a history of trauma, focal seizure, or seizure lasting longer than 2 min.**

Examination and Evaluation

On physical examination, vital signs and careful physical and neurologic examinations are needed. Physical examination should assess for underlying metabolic or neurologic abnormalities, including evidence of trauma, abnormal head size, abnormal facies or body habitus suggestive of genetic abnormality, petechiae, cafe-au-lait spots, or adenoma sebaceum. Clinical evaluation for sources of infection, including ears, mastoids, soft tissue, chest, gastrointestinal tract, and urine, should be done. Neurologic examination must be thorough to detect any abnormality such as meningismus, distended fontanelle, cranial nerve abnormalities, or focal weakness.

Suggested laboratory studies are outlined in Table 125-2. Head CT scan is generally obtained and necessary in the ED if there are focal neurologic signs on examination, if the seizure was described as focal by the caregivers, or if there is suspicion of trauma or abuse. Fever and

TABLE 125-2 Evaluation for Neonatal Seizure, First Seizure, or Status Epilepticus (SE)

Clinical assessment
History
Physical examination
Neurologic examination
Laboratory tests/procedures Stat
bedside glucose CBC
Na, K, Cl, CO ₂ , calcium, magnesium BUN, creatinine Urinalysis Consider depending on age and presentation:
Toxicology screen
Urine and serum amino acid screen
Serum ammonia
Liver function tests
Arterial blood gases for SE or persistent altered mental status
PCR for herpes, cytomegalovirus, and others
EEG if nonconvulsive status suspected
EEG for neonates
Lumbar puncture if meningitis suspected
Imaging studies
Head CT for trauma, altered mental status
MRI for suspected dysplastic disorders
Chest x-ray Skeletal survey if abuse suspected

Abbreviations: BUN = blood urea nitrogen; CBC = complete blood count; CT = computed tomography; EEG = electroencephalogram; MRI = magnetic resonance imaging; PCR = polymerase chain reaction.

suspicion of meningitis requires appropriate intravenous antibiotics (see Chap. 116) followed by CT (depending on clinical evaluation) and lumbar puncture. In the patient with trauma or persistent altered mental status after a first seizure, head CT should be obtained. If the child is fully recovered with no deficit, an MRI is preferred, because CNS dysplasias are not readily identifiable by CT.

Disposition

A child with a first focal seizure or any suspected or proven underlying neurologic or systemic abnormality should be admitted and neurologic consultation obtained. Children with a brief, non-focal first seizure, normal recovery, normal neurologic examination, and normal laboratory and radiologic results in the ED can be discharged after neurologic consultation and after arrangements have been made for follow-up.

In general, the EEG can be done on an outpatient basis. Antiepileptic drugs may or may not be started in the ED, depending on the recommendation of the consultant.

BREAKTHROUGH SEIZURES IN KNOWN EPILEPTICS

When seizures recur in known epileptics, something has occurred to alter the balance of the excitation-inhibition complex, causing the seizure threshold to be lowered. Complete seizure control is not always possible. A child with mental retardation, cerebral palsy, and complex partial seizures with or without secondary generalization is most likely to have recurring seizures. Tonic-clonic (grand mal) seizures are the most dramatic and often lead to emergency treatment. The usual causes of seizure breakthrough are lowered anticonvulsant blood levels, change in habits, complicating factors of epilepsy management, and progression of the underlying cause. Superimposed head trauma also may precipitate seizures (see discussion on head trauma and seizures, below). An unprovoked episode of seizures may occur in a well child with adequate levels of anticonvulsants.

TABLE 125-3 Initial and Maintenance Doses in the First Seizure (Nonstatus Partial and Tonic, Clonic, and Tonic-Clonic Seizures of Childhood)

Drug	Route	Initial Dose, mg/kg per d	Maintenance Dose, mg/kg per d	Therapeutic Level		Half-Life, h
				Total	Free	
Phenytoin (Dilantin)*	PO/PR	8	4-8	10-22	1.0-2.2	24

*Higher free phenytoin levels when administered with valproate.

†With chronic use.

‡Requires 6 to 8 weeks to achieve maintenance dose. Coadministration with valproate requires very low dosage initially, whereas coadministration with an enzyme inducer requires higher initial dosage.

§Not recommended for routine use.

Abbreviations: NA = not applicable; PE = phenytoin equivalent.

Evaluation

LOWERED ANTICONVULSANT BLOOD LEVELS

Due to Noncompliance This is a common cause, most often in a pre-teen or teen who has been given the responsibility for self-medication. Noncompliance is seen more often with three times per d and daily dosing.

Related to Intercurrent Infection Anticonvulsant levels fall during acute infections (viral or bacterial), with or without fever. Quite often, a child's seizure recurrence is an indication of the infection before the acute problem is evident (e.g., varicella or otitis media).

Interaction of Different Drugs An example of this kind of interaction is the reduction of the phenytoin level by the induction of parahydroxylation when barbiturates are used concomitantly (see Problems of Anticonvulsant Use).

CHANGE IN HABITS

1. Altered sleep patterns because of trips, holidays, or parties.
2. A job, examinations, or an emotional stress may lead to seizures in active teens. If a pattern develops, knowledge of the pattern is quite helpful in defining treatment.
3. Alcohol use can lower the seizure threshold and increase noncompliance.
4. The use of illicit drugs or prescription drugs that lower the threshold. Examples are neuroleptic agents, lindane (Kwell), theophylline, phencyclidine, lysergic acid diethylamide, cyclosporine, isoniazid,

meperidine, tricyclic antidepressants, stimulants, and certain anesthetic agents (e.g., Ethrane).

COMPLICATING FACTORS OF EPILEPSY MANAGEMENT

1. Toxic levels of drugs. An example is phenytoin intoxication, which can increase seizure frequency. Carbamazepine and other AEDs in therapeutic dosage have been found to infrequently increase seizures. Tiagabine and gabapentin may increase myoclonic seizures.
2. The use of phenytoin in some myoclonic epilepsies.
3. Anticonvulsant-induced osteomalacia with hypocalcemia (rickets). This uncommon problem may increase the seizure frequency and typically occurs after 5 to 7 years of use.
4. Downregulation of benzodiazepine receptor sites with decreasing antiepileptic response (e.g., clonazepam and nitrazepam).
5. Carbamazepine and oxcarbazepine induced hyponatremia.

PROGRESSION OF THE UNDERLYING CAUSE Examples are subacute focal (Rasmussen) encephalitis, neoplasm, arteriovenous malformation, and degenerative disease (ceroid lipofuscinosis and Huttenlocher-Alpers). Blume and coworkers found that 16 of 38 children undergoing cerebral resection for intractable seizures unexpectedly had cerebral tumors.³

When a child known to have epilepsy presents with recurring seizures, several steps may minimize the treatment time and disclose the reason for the breakthrough. The physician should first assess the airway and obtain vital signs. If the patient is febrile, a source of infection should be sought. Next, if the patient is having seizures at the time, the physician should test for the levels of anticonvulsants

TABLE 125-4 Doses for Status Epilepticus in Children

Drug	Recommended Loading Dose	Route	Repeat	Rate	Maximum Dose
Diazepam intravenous	0.2 mg/kg	IV	3 times	1 mg per min	5 mg, 0–2 y 10 mg, ≥2 y
Diazepam IV preparation for rectal administration	0.5 mg/kg	Rectal	0.25 mg/kg in 10 min	Bolus	Switch agents if 2nd dose ineffective
Diazepam gel for rectal administration (Diastat)	0–5 y 0.5 mg/kg 6–11 y 0.3 mg/kg >12 y 0.2 mg/kg	Rectal	No	Bolus	One dose. Switch agents if one dose ineffective
Lorazepam	0.1 mg/kg	IV	4 times	>2 min	0.4 mg/kg
Midazolam	0.2 mg/kg	IV	1 time	>2 min	0.4 mg/kg
Midazolam infusion		IV	Continuous	0.04–0.05 mg/kg per h	Until seizure cessation
Phenobarbital	20.0 mg/kg	IV	0	1 mg/kg per min	400 mg
Fosphenytoin	20.0 mg PE/kg	IV	0	3 mg PE/kg per min	Until effective therapeutic level reached
Clonazepam	0.3 mg/kg	NG	1 time		10 mg
Depacon	10–30 mg/kg	IV	0	Over 15 min	IV preparation of valproate
Pentobarbital	5 mg/kg	IV	Continuous	0.5–3.0 mg/kg per h	Until 3–6 s burst suppression
Propofol	1 mg/kg	IV	Continuous	3–7 mg/kg per h	No better than phenobarbital
Lidocaine	2.0 mg/kg	IV	0	5–10 mg/kg per h	Rarely effective

Abbreviation: PE = phenytoin equivalent.

(phenobarbital, phenytoin, valproic acid, or carbamazepine), electrolytes, calcium, and glucose, obtain a complete blood cell count with a differential count, and establish an intravenous line.

Treatment

Once these procedures have been completed, anticonvulsant management is initiated. Assume the anticonvulsant levels are low and give a partial loading dose. If the patient is compliant, give the daily dose of phenobarbital or phenytoin PO, if the patient is able to swallow, or *IV*, if not. If the patient is known to be noncompliant or if the levels of the anticonvulsant are significantly below the therapeutic range, give double the daily dose (e.g., in a child on 60 mg of phenobarbital, give 120 mg initially and repeat the dose if the seizures recur despite levels in the low therapeutic range).

If the anticonvulsant levels are within a high therapeutic range and the child is well without an obvious source of infection or other cause of breakthrough, then one can decide whether another anticonvulsant is necessary. One may decide to wait and see whether there is a trend toward increased seizure frequency, which would warrant additional medication, or whether this is a solitary episode, which would warrant observation, monitoring of drug levels, and follow-up. If the levels are within the high therapeutic range and seizures recur, additional anticonvulsants are warranted in appropriate loading doses (see Table 125-3). **Neurologic consultation should be obtained before adding another medication.**

Recurring or frequent tonic, tonic and clonic, or clonic seizures warrant loading doses that produce therapeutic levels safely and rapidly. Phenobarbital or fosphenytoin can be administered IM and IV, and Depacon (valproate) can be given intravenously. Rectal administration of liquid preparations of valproate, phenobarbital, phenytoin, primidone, and carbamazepine can result in therapeutic levels within 4 h. Using large enough doses of primidone, carbamazepine, topiramate, and tiagabine most likely will result in significant CNS toxicity and a greater likelihood of sedation, ataxia, and confusion. Because of

the greater risk of serious rash, lamotrigine should not be given in an emergency situation for immediate seizure control. Rapid loading with levetiracetam and zonisamide has not been carefully evaluated.

Seizures that begin with focal features, partial or complex partial (temporal lobe, psychomotor), may appear less dramatic and typically warrant a slower modification of drug therapy unless the seizures are prolonged or postictal Todd paralysis occurs. If a patient requires additional drugs, phenobarbital, phenytoin, and valproate can be used interchangeably without producing uncomfortable side effects.

Patients with petit mal (generalized absence) epilepsy rarely are brought to the ED, because the seizures are not alarming to the parents. If some injury occurs because of the absence spells, or if the parent is unusually concerned and brings the child for emergency treatment, determining the blood levels of anticonvulsants is most useful. Addition of another anticonvulsant can be initiated, e.g., lamotrigine (Lamictal), ethosuximide (Zarontin), valproate (Depakote), clonazepam (Klonopin), or acetazolamide (Diamox).

Disposition

Most often, epileptic patients with breakthrough seizure can be sent home, and the pediatrician or neurologist can modify the drug regimen. After the initial evaluation, modification of drug therapy, and treatment for any superimposed problems, the emergency physician should (1) arrange for follow-up, (2) emphasize the need for compliance, and (3) provide treatment for infection or other precipitating factors.

FEBRILE SEIZURE

Febrile seizure is a unique and common form of seizure in childhood. Although various types occur (tonic, tonic and clonic, and clonic), the characteristics of a simple febrile seizure distinguish it from other symptomatic and idiopathic seizure disorders. **A febrile seizure is a**

seizure associated with fever, but without evidence of intracranial infection or defined cause, usually occurring between 6 months and 5 years of age.^{4,5} Typically, these seizures are generalized and last less than 15 min, and there is no postictal focal neurologic deficit. The EEG usually does not demonstrate paroxysmal (epileptic) activity, and there often is a family history of similar seizures. A rapid rise in temperature, usually above 38.8°C (101.8°F), occurs at the onset of the illness and, on occasion, recurs several times in the course of the illness. Three to four percent of young children experience febrile seizures; of these, 30 to 40 percent have recurrences, especially when the first seizure occurs when a child is younger than 1 year. The mortality from simple febrile seizures is extremely low.

Evaluation

The first febrile seizure warrants the most concern, because the benign nature of the illness has not yet been established. The initial evaluation is directed toward identifying the cause of fever and excluding serious causes, such as meningitis, encephalitis, bacterial sepsis, toxic exposure, or underlying neurologic abnormality. Any febrile illness, such as upper respiratory infection, gastroenteritis, or urinary tract infection, can be associated with a febrile seizure. Glucose test strip should be determined, but the need for other laboratory studies generally depends on the patient's clinical condition. Lumbar puncture is needed whenever intracranial infection appears likely. A child older than 18 months who is clinically nontoxic, has normal mental status, has not received prior antibiotics, and demonstrates no clinical concern for meningitis does not need lumbar puncture.

Treatment

Therapy for the cause of the fever is the main goal. Fever should be reduced with acetaminophen, 10 to 15 mg/kg PO or PR at 4-h intervals, to a total dose of 600 mg. The dose of ibuprofen is 10 mg/kg every 6 to 8 h, to a total dose of 40 mg/kg (see Chap. 115). Tepid sponging with water, never with alcohol, provides an additive response to antipyretics. A simple febrile seizure does not warrant treatment with AEDs, because of the good prognosis in untreated children and the high incidence of adverse drug effects.⁶

If a child exhibits repetitive seizures with this or prior febrile seizures, then phenobarbital can be administered with a loading dose of 15 mg/kg IV followed by 4 to 6 mg/kg per d to attain therapeutic levels of 15 to 50 fxg/mL. The drug is continued until the child improves.

Chronic AED prophylaxis with phenobarbital or valproate is limited to children with (1) complex febrile seizures (prolonged or focal), (2) a preexisting neurologic deficit (e.g., cerebral palsy), (3) onset before age 6 months, (4) repeated seizures in the same illness, (5) prior nonfebrile seizures, and (6) more than three febrile seizures within 6 months. PR or PO administered diazepam also has been used successfully to prevent seizures when given at the onset of a febrile illness.^{6,7} The dose of oral diazepam is 0.2 to 0.5 mg/kg given every 8 h during the febrile illness. However, about 40 percent experience side effects such as lethargy, ataxia, and irritability.

Disposition

Children with a simple febrile seizure do not need admission. Follow-up with the pediatrician or family physician should be arranged. Admit the ill child without an easily treatable problem, one in whom recurrent seizures have occurred within several hours or 1 day, or one with a complex febrile seizure.

NEONATAL SEIZURES

Seizures in neonates are difficult to identify. All neonates experiencing seizures should be considered to be at serious risk from the under-

lying disorder, the effect of unremitting seizures, and increased risk for epilepsy. Prompt, effective anticonvulsant therapy and other specific therapies lessen the impact of short-term detrimental effect on long-term neurologic functioning. In many instances, the seizure itself is less important for its immediate effects than for its indication of significant underlying disease (e.g., infection, metabolic disorder, or CNS malformation) that ultimately will have more effect on morbidity and mortality.

Multifocal or fragmentary seizures occur more commonly at this age, and clonic or tonic movements independently affect the limbs simultaneously or fleetingly. Autonomic dysfunction may be the only manifestation of neonatal seizures, with the infant exhibiting pupillary changes, apnea, and cardiac irregularity. The difference in seizure presentation is due to the lack of arborization of the immature brain, which prevents rapid propagation of electrical epileptic activity, and to the particular disorders to which newborns are subject (e.g., hypoxic ischemic encephalopathy, metabolic conditions such as inborn errors of urea cycle and amino acid metabolism, and dysplastic conditions). Unilateral (partial or focal) seizures may be associated with structural lesions, and permanent neurologic deficit may be associated with them.

Non-CNS causes of neonatal seizures include sepsis, cardiac disease, hypoxia or apnea, hypoglycemia, electrolyte abnormalities such as hypocalcemia, and complex hereditary metabolic disorders. Infectious CNS causes include viral or bacterial meningitis or encephalitis (such as *Listeria*, herpes, toxoplasmosis, cytomegalovirus, or rubella) and perinatal CNS hemorrhage. Examples of dysplastic CNS disorders are Cornelia de Lange syndrome, Sturge-Weber syndrome, and tuberous sclerosis.

Evaluation

While ensuring the airway, oxygenation, and circulation, obtain a history to identify perinatal risk factors for seizures. Verify gestational age of the infant and determine whether there was premature rupture of the membranes, delivery complications, and maternal perinatal infection. Determine feeding patterns, because urea cycle defects with hyperammonemia, maple syrup urine disease, and methylmalonic acidemia usually become evident days or weeks after feedings with protein are initiated. The infant with nonketotic hyperglycinemia may exhibit seizures immediately after birth. Table 125-2 lists laboratory studies needed for the evaluation of neonatal seizures.

Most will require lumbar puncture to detect viral or bacterial meningitis. Cerebral imaging is needed to identify cerebral hemorrhage and structural abnormalities. Ultrasound may be sufficient for diagnosis in some cases, but MRI is the best study for migrational defects of the CNS (e.g., lissencephaly, heterotopia, and agenesis of the corpus callosum).

Treatment

Treatment principles in the management of neonatal seizures are as follows:

1. Identify and correct treatable causes (hypocalcemia, hypoglycemia, and electrolyte imbalance).
2. Identify and treat associated problems such as sepsis, hyperbilirubinemia, and acidosis.
3. Initiate anticonvulsant therapy with appropriate loading doses and carefully observe blood levels to adjust the maintenance dosage (Table 125-5).

Ensure adequate ventilation and oxygenation. Obtain bedside glucose determination and administer glucose as 5 mL/kg of D10W if hypoglycemia is present (see Chap. 129). For active seizures, phenobarbital is the treatment of choice, and fosphenytoin is a good alternative. Pyridoxine is sometimes given empirically for refractory seizures.

TABLE 125-5 Drug Regimen for Neonatal Seizures

5 mL/kg D10W given to infants with proven hypoglycemia or when highly suspect because of circumstances Calcium gluconate (10%) 200-500 mg/kg per d divided in 4 doses (in proven hypocalcemic infants) Magnesium sulfate 25-50 mg/kg IV or IM. Repeat q4-6h for 3-4 doses if necessary to normalize magnesium
Phenobarbital 20 mg/kg at rate of 1 mg/kg per min, then 3-4 mg/kg per d Fosphenytoin 20 mg PE/kg at rate of 3 mg/kg per min, then 4-8 mg PE/kg per d in 2 divided doses IV or PO. Phenytoin maintenance 8-12 mg/kg per d in 2 divided doses to maintain a free level of 1.0—2.2 Lorazepam 0.10 mg/kg over 2 min. Repeat twice at 10-min intervals if necessary Midazolam 0.2 mg/kg over 2 min. Repeat once if necessary. If refractory seizures use midazolam continuous infusion at 0.04-0.5 mg/kg per h Pentobarbital as an alternative to continuous midazolam infusion. Initial pentobarbital dose is 5 mg/kg bolus followed by continuous infusion of 0.5—3.0 mg/kg per h to maintain electroencephalographic burst suppression at 3- to 6-s intervals

Abbreviations: D10W = 10% dextrose in water; PE = phenytoin equivalent.

Several factors influence drug treatment in neonates: (1) variations in the metabolic half-lives of drugs, (2) hypoxia, tissue acidosis, and renal or hepatic dysfunction increase anticonvulsant half-lives requiring lower dosing and less frequent administration, and (3) greater difficulty in identifying the end point of seizure control in neonates. Consequently, blood levels of seizure medications must be monitored during treatment.

PHENOBARBITAL The drug of choice is phenobarbital, 10 to 20 mg/kg *iv* administered at a rate of 1 mg/kg per min. Blood levels of phenobarbital of 16 to 40 μ g/mL are necessary to achieve seizure control in most cases. Levels of 40 to 80 μ g/mL have been maintained in resistant cases with inconsistent benefit. Dosages of 3 to 4 mg/kg per d maintain mid to high therapeutic levels and prevent toxicity. In infants younger than 7 days, the half-life of phenobarbital is 100 h; after 28 days of continuous therapy, the half-life is reduced to 60 to 70 h.

FOSPHENYTOIN Fosphenytoin is the second drug of choice and is well tolerated in neonates. The loading dose of fosphenytoin is 15 to 20 mg PE/kg administered at a rate of 3 mg PE/kg per min, with intravenous maintenance of 4 to 8 mg PE/kg per d. Free phenytoin levels up to 2.2 μ g/mL may be necessary for adequate seizure control.

PYRIDOXINE AND BIOTIN Pyridoxine (vitamin B₆), 100mgperd, is empirically used when no reasonable cause for seizures has been identified and the seizures remain uncontrolled. Seizure reduction rather than EEG improvement is the best indication of B₆ response. Biotin, 10 mg per d, is the long-term replacement therapy for biotinidase deficiency.

OTHER AGENTS In poorly responsive neonatal seizure, it is reasonable to consider newer agents (e.g., topiramate) given more quickly than usual, so that a full dose is achieved in 5 to 10 days.

In status epilepticus of neonates, diazepam or lorazepam must be used with caution, because its half-life may be prolonged, and respiratory depression superimposed on an immature and possibly compromised respiratory apparatus should be anticipated. Diazepam may exaggerate hyperbilirubinemia by uncoupling the bilirubin-albumin complex and should be used with caution in jaundiced babies.

INFANTILE SPASMS

Infantile spasms are a unique form of seizures. The onset is typically between 3 and 9 months of age but may begin as late as 18 months.

Concurrently, the child exhibits regression in development. The spasms are very brief, lasting a split second, often with flexion or extension of the head and trunk. They occur singly or repeatedly in bursts of 5 to 20 spasms at a time, usually several times per day and more often upon arousal from sleep or with sudden auditory or physical stimulation. The EEG is abnormal in virtually every case. Mental retardation in patients with this disorder is as high as 85 percent. Parents are often frustrated because medical professionals fail to recognize these spasms as seizures.

There are many causes of infantile spasm, including migrational defects, prior CNS trauma, hypoxia, neurocutaneous disorders, and infectious and metabolic disorders. The idiopathic type is the most alarming, because it affects children with no prior neurologic disorder and no etiology is identified. Differential diagnosis includes benign myoclonus, dyskinesia due to gastroesophageal reflux, and tics.

Evaluation

Once infantile spasms are recognized, prompt neurologic referral is recommended. Basic assessment includes electrolytes, calcium, glucose, complete blood count, creatinine, and lumbar puncture. The lumbar puncture is warranted to identify the rare syndrome of glucose transporter defect, which is a potentially treatable cause of infantile spasms. If the cerebrospinal fluid glucose is less than 60 percent of blood glucose, this disorder should be strongly suspected. Magnetic resonance imaging is the preferred neuroimaging study and can be done electively.

Treatment

Although adrenocorticotrophic hormone is still considered the most effective agent for infantile spasms, the frequency and severity of side effects warrant the use of newer, less toxic AEDs, especially topiramate, which can be increased much more rapidly in this situation, with dosages as high as 30 to 40 mg/kg, to achieve cessation of spasms. Clonazepam, valproate, and vigabatrin (in cases of tuberous sclerosis) are alternatives.⁷

HEAD TRAUMA AND SEIZURES

Head trauma can result in three types of seizures: immediate seizures, early posttraumatic seizures, and late posttraumatic seizures.

Immediate Posttraumatic Seizures

Immediate seizures result from impact and presumably are due to traumatic depolarization of neurons. The risk of recurring seizures in these patients is minimal unless there are more serious prognostic factors such as prolonged coma and penetrating head injury. Emergency treatment is the identification and correction of depressed skull fracture, intracerebral hemorrhage, or hematoma; and the reduction of cerebral edema, oxygenation, ventilation, and correction of shock, and the careful administration of anticonvulsants. Fosphenytoin is the drug of choice, given at 20 mg/kg PE at a rate of 3 mg per min (see Table 125-4). It is helpful for the neurosurgeon or neurologist to avoid the use of sedative anticonvulsants (barbiturates or diazepam), if possible. Long-term management of immediate posttraumatic seizures remains controversial. In a patient who recovers rapidly, chronic anticonvulsant use usually is not indicated. An exception would be a patient with a seizure history or a family history of epilepsy.

Early Posttraumatic Seizures

Early posttraumatic seizures occur within the first week after trauma, and epilepsy results in 20 to 25 percent of these patients. These seizures are presumed to result from the focal effects of contusions or

lacerations and associated hypoperfusion, which causes ischemia and related metabolic changes. Evaluation includes assessment for intracerebral hemorrhage or hematoma, or associated metabolic abnormalities such as hyponatremia. Treatment of choice is intravenous loading of fosphenytoin (see Table 125-4) and referral to neurosurgery or neurology, as clinically appropriate. Long-term anticonvulsant therapy is generally recommended.

Late Posttraumatic Seizures

Late posttraumatic seizures occur after 1 week and may be seen as late as 10 years after the trauma. Structural changes, such as atrophy with gliosis and permanent local vascular changes, altered dendrite branching, and presumably modified neurotransmitter function, account for the development and permanence of these seizures. Of these seizures, 40 percent are focal or partial seizures and 50 percent are temporal lobe seizures, indicating the predilection for traumatic injury and known epileptogenic properties of this structure. The risk of recurring seizures in this group is reported to be as high as 70 percent, and long-term anticonvulsant therapy is necessary. Patients at greater risk for chronic posttraumatic seizures include those with depressed skull fractures, posttraumatic amnesia more than 24 h after the trauma, dural penetration, acute intracranial hemorrhage, early posttraumatic epilepsy, and a foreign body in a cerebral wound. The more severe the seizure and the later the onset, the less likely remission will occur.

Emergency management of late posttraumatic seizures consists of airway and circulation stabilization, administration of anticonvulsants, with intravenous fosphenytoin being the preferred agent (see Table 125-4), and imaging to identify neurosurgically correctable lesions. Long-term anticonvulsant therapy is needed.

STATUS EPILEPTICUS

Status epilepticus (SE) is a state of continuous seizures lasting at least 30 min. As a practical measure, seizures are usually treated as SE if they persist longer than 10 min. Classification of status seizures is listed in Table 125-6. In absence (petitmal) SE, the child appears dazed and may exhibit repetitive eye blinking.

Epilepsia partialis continua is a serious neurologic condition, although it does not appear life threatening at first. The patient exhibits repeated continuous or minimally interrupted clonic jerking of one side of the body and usually one part of an extremity for days, weeks, or months. It is typically due to encephalitis or cerebrovascular accident or associated with heterotopias and indicates a relatively poor prognosis. Initial management is similar to that of SE.

About 5 to 10 percent of children with epilepsy experience one bout of SE. The longer it persists, the greater the morbidity and the mortality rates and the more difficult it is to control the seizures. In patients

with no neurologic sequelae, the mean duration of SE is 1 h 30 min. The mean duration of status grand mal in patients who die is 13 h.

Experimental models in animals have demonstrated permanent cell damage in the hippocampus, amygdala, cerebellum, thalamus, and middle cerebral cortical layers after 60 min of seizure activity. Even with artificial ventilation and correction of existing metabolic derangements, most changes still occur. Cell death results from the increased metabolic demands and the exhaustion of the continuously firing neurons. In addition, secondary effects exaggerate the adverse effects. The cerebral partial pressure of oxygen and amounts of cytochrome A and cytochrome A3 reductase decrease enhance the risk of cell damage. Increases in calcium, arachidonic acid, arachidonic diglycerol, prostaglandin, and leukotriene levels in the neurons exaggerate or cause cerebral edema or cell death. Increased levels of cyclic adenosine monophosphate and increased release of prolactin, growth hormone, adrenocorticotrophic hormone, cortisol, insulin, glycogen, epinephrine, and norepinephrine may contribute to the progression of cell damage, with loss of physiologic responsiveness.

Later secondary effects include lactic acidosis, elevated cerebrospinal fluid pressure, hyperglycemia followed later by hypoglycemia, dysautonomia with hyperthermia, diaphoresis, dehydration, hypertension followed by hypotension, and eventually shock. In addition, excessive muscle activity leads to rhabdomyolysis, myoglobinuria, and renal failure. Neuropathologic studies have indicated that nucleovacuolation and ischemic nerve cell damage lead to neuronal dissolution.

Evaluation and Treatment

To obtain the most effective and rapid cessation of SE, the following evaluation and therapeutic goals must be reached^{8,9}:

1. Specific delineation of the type and subtype of SE so that appropriate treatment can be chosen. For example, tonic-clonic generalized SE is very responsive to diazepam or phenytoin; noncontinuous clonic or tonic-clonic seizures may be refractory to diazepam.
2. Identification and treatment of the reversible precipitating cause of SE (e.g., cerebral infection, trauma, electrolyte disturbance, brain abscess, hypoglycemia, or sickle cell crisis).
3. Rapid cessation of SE to prevent secondary effects that prolong the seizures and cause irreversible neuronal damage.
4. Full support of medical systems to prevent complications of the seizures or the treatment (e.g., respiratory depression, dysrhythmia, aspiration pneumonia, shock, and myoglobinuria).

The end point of therapy is cessation of the clinical seizures, with return of normal function. When a patient fails to arouse, the possibility of nonconvulsive status must be entertained, and then the end point is improvement in the EEG abnormality.

BENZODIAZEPINES Lorazepam, a rapid acting benzodiazepine, is the drug of choice in SE.¹⁰ Benzodiazepines are effective in SE via several mechanisms: (1) agonist binding at the benzodiazepine receptor increases GABA for its receptor and GABA acts as a receptor for a longer period, and (2) benzodiazepines block sustained high-frequency discharges of epileptic neurons. Benzodiazepines are effective, because they have high lipophilicity, rapid brain penetration, and brain receptor binding. Benzodiazepines are effective for prehospital control of seizures.^{11,12}

Lorazepam is preferred over other benzodiazepines, because it has a longer duration of action, although it has a slightly longer onset of action than diazepam. The dose of lorazepam is 0.1 mg/kg IV given over 2 min and repeated for a maximum of 8 mg.

To maintain the seizure-free state, a long-term AED is started simultaneously with phenobarbital 20 mg/kg, at 1 mg/kg per min. Alternatively, fosphenytoin 20 mg/kg at 3 mg/kg per min, can be used.

Diazepam was the benzodiazepine used initially in the modern era of epilepsy management and can be used in addition to or instead of

Tonic status
Simple partial status
Partial motor status including epilepsia partialis continua
Partial sensory status
Partial status with vegetative or autonomic symptoms
Partial status with cognitive symptoms
Partial status with affective symptoms
Complex partial status Absence (petit mal) status

SECTION 12 • PEDIATRICS

lorazepam. The dose of diazepam is 0.2 to 0.5 mg/kg IV, given at a rate of 1 mg per min and repeated as needed, to a maximum of 2.6 mg/kg. Most patients stop seizing with one or two bolus doses.

Midazolam is a very rapid-acting benzodiazepine and is rapidly absorbed intramuscularly. When given intramuscularly, seizure control occurs within 2 to 3 min of injection. It has been used by intravenous, intramuscular, nasal, and rectal routes in the treatment of SE.^{13,17} Midazolam has a distribution half-life of 1.5 to 3.5 h. The initial dosage is a 0.2 mg/kg bolus, which can be repeated in 15 min. Because of its short half-life, it is used as a continuous infusion at 0.05 to 0.4 mg/kg per h to treat continuous unresponsive seizures. In one study,¹⁷ more rapid cessation of seizures occurred with midazolam (7.8 to 4.1 vs. 11.2 to 3.6 min) than with intravenous diazepam. This result was attributed to the ease of administration of the intramuscular midazolam as compared with the time needed for intravenous site acquisition with the diazepam.

The following steps should be followed when treating continuous tonic-clonic SE (see Table 125-4):

1. Assess basic functions immediately and maintain blood pressure, airway, and pulse.
2. Obtain blood to be tested for levels of anticonvulsants, electrolytes, serum urea nitrogen, calcium, and glucose and for a complete blood cell count with differential while inserting an intravenous catheter for fluid administration.
3. If hypoglycemia is present, administer 5 mL/kg of D10W.
4. Administer lorazepam, 0.1 mg/kg IV, and repeat up to a total dose of 8 mg or early signs of respiratory depression; or administer diazepam, 0.2 mg/kg IV over 2 min, and repeat in 15 and 30 min, if necessary, to a total dose of 2.6 mg/kg.
5. Administer fosphenytoin, 20 mg PE/kg IV at 3 mg/kg per min, as the benzodiazepine is being infused.
6. Administer phenobarbital, 20 mg/kg IV at 1 mg/kg per min, if fosphenytoin is ineffective.
7. If seizures persist, give additional phenobarbital 10 mg/kg, to reach levels of 60 [xg/mL.
8. If seizures continue, administer pentobarbital, under intensive care monitoring, 2 mg/kg bolus, followed by maintenance of 1 to 2 mg/kg per h, to effect 3 to 6 s of EEG burst suppression.
9. In noncontinuous SE, administer continuous midazolam at a dose of 0.04 to 0.05 mg/kg per h despite step 8.

LIDOCAINE Lidocaine also may be useful in the management of seizures in children in whom other drugs have failed.¹⁸ The loading dose is a 2 mg/kg IV bolus followed by an intravenous infusion of 5 to 10 mg/kg per h.

PROPOFOL Propofol may be useful for seizures not responding to benzodiazepines or fosphenytoin,^{15,16,19,20} but further study is needed before it can be recommended as a standard agent for SE in children. The meta-analyses by Classen and associates reported an average loading dose of 1 mg/kg and infusion rates of 2.94 mg/kg per h (± 2.00) minimum to 6.98 mg/kg per h (± 5.34) maximum.¹⁶ There was no apparent superiority of propofol to pentobarbital in the studies they reviewed for the meta-analyses. The use of propofol has been advocated in adults with refractory SE,¹⁰ but its prolonged use in children with refractory SE was associated with progressive severe metabolic acidosis and rhabdomyolysis, which the authors concluded was due to propofol.¹⁹

Noncontinuous SE can be more difficult to treat, because the end point is more elusive. Rapidly acting drugs such as diazepam and lorazepam are less effective, and a more sustained effect is necessary. Noncontinuous SE often is not responsive to appropriate therapeutic levels of phenytoin and phenobarbital. Midazolam can be given as a continuous infusion of 0.04 to 0.05 mg/kg per h. Alternatively, large doses (0.2 to 0.6 mg/kg) of clonazepam via nasogastric tube may be used to produce

the desired effect of cessation of noncontinuous seizures, and the anti-convulsant effect can be maintained by additional drugs (phenytoin or phenobarbital) and clonazepam (0.1 to 0.3 mg/kg per d).

DIFFERENTIAL DIAGNOSIS OF SEIZURES

The differential diagnosis of seizures must consider many disorders that can produce loss of consciousness, unusual movements, impaired awareness, or bizarre behavior. Many of these disorders are age specific.

In newborns, jitteriness or hyperexcitability appears as high-amplitude tremulousness easily brought about by passive movement of the extremities or jarring of the crib. Drug-withdrawn infants are irritable and tremulous and may have diaphoresis, vomiting, and diarrhea, but they may also have seizures. Sepsis, hypoglycemia, and hypocalcemia may produce nonepileptic paroxysmal activity in addition to seizures. Hyperekplexia, or startle disease, mimics tonic and clonic seizures, is very responsive to clonazepam, and if left untreated has a significant risk for sudden neonatal or infant death. Seizures are part of the differential diagnosis of near-miss sudden infant death syndrome (see Chap. 119). In older infants, cyanotic and pallid breath-holding spells can occur after an abrupt trauma (a fall or a minor spanking) or a verbal reprimand. Bradycardia and a brief tonic nonepileptic seizure often occur. The prolonged QT syndrome and neurocardiogenic syncope may cause nonepileptic seizures or syncopal episodes (Chap. 131). Drug intoxication manifested by hyperkinesis, impaired awareness, or altered behavior (hallucinations) is usually accidental at this age. In adolescence, phencyclidine intoxication mimics complex partial seizures and may result in seizures with more severe overdoses.

Congenital heart disease can produce paroxysmal events at all ages. Abrupt mental status changes may occur in patients with disorders such as pulmonary hypertension, acquired cardiomyopathy, aortic stenosis, or tetralogy of Fallot (see Chap. 131).

Hyperkinetic movement disorders can be difficult to differentiate from complex partial seizures. Sydenham chorea is now rare, and drug-induced chorea (ethosuximide, carbamazepine, or diphenhydramine hydrochloride) and lupus-induced chorea are likewise very uncommon. Tourette syndrome is seen more frequently, but rarely does the child appear acutely ill. Kinesogenic chorea is a movement disorder brought on by action and mimics simple motor partial seizures. Intermittent focal dystonia can affect one limb and last from seconds to hours.

Pseudoseizures represent a particular problem because the "seizures" appear to represent a significant threat to the patient's safety, and vigorous anticonvulsant therapy is often initiated. Unfortunately, pseudoseizures often occur in patients with documented epilepsy. Secondary gain should become evident in these cases. The "seizures" are atypical in that the patient may waken fully in the interictal phase and require repeated large doses of anticonvulsants even to the point of protracted drug-induced depression. Another form of pseudoseizures consists of those described by the parent and never observed by other witnesses (Munchausen by proxy). In this case, the parent receives much attention, and psychiatric, psychological, and social services inputs are essential.

Neurologic referral, or even hospitalization, is needed to treat pseudoseizure, prevent recurrences, provide family education, and avoid inappropriate treatment.

PROBLEMS OF ANTICONVULSANT USE

Unwanted features of anticonvulsants may be seen soon after the drug is initiated or may develop weeks, months, or years later. These problems may turn up during evaluation for other illnesses (e.g., macrocytic anemia) or be the basis for emergency treatment.

Immediate side effects often subside in time. Lethargy is usually dose related and subsides with chronic use and can occur with the old-

est AED (phenobarbital) and the newest AEDs (topiramate and tiagabine). Irritability and changes in cognition can persist and be significant but are unrelated to drug levels (all drugs). Rashes may occur within days or weeks of initiation of therapy but must be differentiated from concurrent viral exanthem. Pruritic and/or morbilliform rashes usually require cessation of medication. Stevens-Johnson syndrome, with bullous skin lesions affecting mucous membranes, is a serious potential reaction. There is a risk of serious sequelae: blindness, esophageal stenosis, or loss of life.

With valproic acid use, hepatic failure may occur within days or up to 2 years after first use. The drug reaction results in behavior alteration, increasing lethargy, and vomiting. Levels of liver enzymes may be minimally to markedly elevated, and hyperammonemia with or without symptoms of hepatic failure may be found. Immediate cessation of valproate, hospitalization, and observation are necessary when symptomatic hepatic reaction is evident. In asymptomatic patients with enzyme level elevations, a reduction of the dosage and careful observation are warranted. Gastrointestinal side effects are common with initial use of valproic acid and may be so severe that more serious hepatic problems are considered. These side effects can be avoided by taking the drug with meals, by avoiding carbonated beverages and citric juices, and by using the enteric-coated form or sprinkles. Pancreatitis secondary to valproate use may occur with initial and chronic use and has been associated with fatalities.

Toxicity due to overdosage at any time can produce some readily identifiable symptoms and signs. Phenytoin toxicity occurs when serum levels exceed 25 $\mu\text{g/mL}$ in most patients ($>20 \mu\text{g/mL}$ in some patients). Nausea, dysarthria, diplopia, and ataxia are seen early, with progression to impaired levels of consciousness and decerebrate posturing. Virtually all anticonvulsants produce ataxia and lethargy with significant overdosage. Cardiopulmonary monitoring during high-dose drug use in SE should be employed, because cardiac dysrhythmia, hypotension, or respiratory depression can occur. The use of fosphenytoin has eliminated the problem of venous and subcutaneous extravasation-related phenytoin side effects. Chronic phenytoin use can result in folate deficiency with macrocytic anemia, acquired osteomalacia (increased vitamin D turnover), neutropenia (often transient), peripheral neuropathy, lupus-like syndromes, and myasthenic weakness.

Valproate-induced thrombocytopenia is a significant side effect warranting lowering or discontinuation of the drug, if platelet levels are significantly lowered or bleeding is evident. Lower carnitine levels due to valproate metabolism may be a contributing factor of valproate hepatotoxicity.

Drug interactions may be quite dramatic. Valproate and aspirin use can result in a bleeding diathesis. Antihistamines used in conjunction with barbiturates can be very sedating, warranting smaller doses of the antihistamine. When erythromycin is used, particular care must be exercised, because the carbamazepine levels may rise to toxic levels rapidly. Toxicity is greater when carbamazepine and lithium are used together, even though blood levels may be in the therapeutic range. Total phenytoin levels are typically reduced when valproic acid and tiagabine are also used, but free phenytoin usually remains therapeutic, and it is essential to measure free phenytoin. When barbiturates are used concomitantly with phenytoin, increased parahydroxylation can enhance metabolism of phenytoin, so that therapeutic levels fall, resulting in seizure breakthrough. Hyperbilirubinemia and hypoalbuminemia can affect anticonvulsant binding and blood levels.

Movement disorder (e.g., chorea) can result after several weeks or months of use of ethosuximide and carbamazepine. The movements may be profound and usually respond to the reduction or discontinuation of the drug and, if necessary, the use of diphenhydramine (Benadryl), 12.5 to 25 mg IV. Clonazepam and diazepam can cause acute bladder dysfunction with urinary retention.

Zonisamide has the unique complication of anhidrosis, and therefore a child may present with heat stroke. Topiramate and felbamate

are associated with weight loss, and topiramate is also associated with renal calculi.

Many problems of dose-related toxicity can be avoided by maintaining therapeutic blood levels. This is applicable for valproic acid, phenytoin, phenobarbital, and carbamazepine but has not been substantiated in new AEDs. Blood level determinations should be done randomly to determine compliance at times of increased seizure frequency or when signs of toxicity develop. In some patients, side effects develop at therapeutic levels. Idiosyncratic effects cannot be predicted, but families must be made aware that significant side effects can develop with little warning, and evaluation by a physician is recommended before a drug is dismissed. Obtaining the patient's history, consulting with the primary physician or consultant, and reviewing readily available drug information in the package insert or pharmacology databases make emergency evaluation and treatment of anticonvulsant drug reactions simpler.

ERRORS IN EMERGENCY MANAGEMENT OF SEIZURES

After a patient arrives for treatment, the initial assessment may be incomplete, resulting in inappropriate or inadequate therapy. Not identifying treatable infections, electrolyte imbalance, child abuse, and accidental trauma can lead to rapidly progressive deterioration and demise or may make seizure control difficult. By not ascertaining anticonvulsant levels in a patient with epilepsy, the physician loses an opportunity to determine whether the anticonvulsant is ineffective or simply at too low a level.

If the emergency physician communicates with the primary physician, unnecessary studies and drugs that were ineffective or produced some side effects can be avoided. In addition, it is important to consult with the patient's physician when prescribing non-anticonvulsants that might interfere with anticonvulsants or produce unwanted side effects.

In the aggressive treatment of seizures (SE and recurring breakthrough seizures), inadequate loading doses or improper drug selection may prolong the seizure and worsen the prognosis. Excessive dosage can result in respiratory depression or hypotension and, in rare instances, can exacerbate the seizures. If nonepileptic paroxysmal disorders are not recognized, the patient is put at the additional risk of unnecessary medication and inadequate treatment of the real disorder.

Emergency physicians cannot deal with all the problems facing patients with epilepsy. Follow-up care by the primary physicians or appropriate consultants ensures better compliance and, one hopes, lessens emergency situations in the future.

ered. This includes poisoning due to anticholinesterase insecticides, organophosphates, and carbamates. These liquids may look like milk to a child if they are placed in inappropriate containers such as plastic milk jugs. Diarrhea due to these agents is accompanied by profuse sweating, lacrimation, hypersalivation, and abdominal cramps. Vomiting and diarrhea may also be a nonspecific presentation for other infectious diseases such as otitis media, urinary tract infection, or more serious conditions including intussusception, malrotation, increased intracranial pressure, and metabolic acidosis.

EPIDEMIOLOGY

In the United States, children younger than 3 years of age have 1.3 to 2.3 episodes of diarrhea each year. The prevalence is higher in children attending day-care centers. Up to one-fifth of all acute care outpatient visits to hospitals are by families with infants or children affected by acute gastroenteritis, and 9 percent of all hospitalizations of children younger than 5 years of age are for diarrhea.¹ Most enteric infections are self-limited, but excessive loss of water and electrolytes resulting in clinical dehydration may occur in 10 percent and is life-threatening in 1 percent.² Pathogenic viruses, bacteria, or parasites may be isolated from nearly 50 percent of children with diarrhea. Viral infection is the most common cause of acute diarrhea. Bacterial pathogens may be isolated in only 1 to 4 percent of cases. Specific pathogens, diagnostic aids, and treatment are outlined in Table 126-2. While identifying the specific viral or bacterial agent may be a challenging academic exercise, it is often not practical or necessary in the ED.

PATHOPHYSIOLOGY

Diarrhea can be caused by a variety of mechanisms including tissue invasion or toxin production (see Table 126-2). Destruction of intestinal villi results in decreased absorption of water, nutrients and electrolytes, resulting in watery diarrhea or dysentery. Enteric infections with *E. coli* may be used to illustrate the different mechanisms of diarrhea. Enteroinvasive *E. coli* (EIEC) directly invades the gut epithelium causing inflammation, which results in leukocyte infiltration and

126 VOMITING AND DIARRHEA IN CHILDREN

Christopher M. Holmes Summer
A. Smith

Emergency physicians frequently see children who present with vomiting and/or diarrhea as their chief complaint. A careful history and physical examination will usually sort out those children with life-threatening manifestations of their illness from those who are less urgently ill. The most common cause of vomiting, diarrhea, and dehydration is acute viral gastroenteritis. This chapter will primarily address the differential diagnosis, etiology, diagnosis, and management of acute viral gastroenteritis.

VOMITING AND DIARRHEA

Vomiting is a coordinated reflex process that results in the forceful evacuation of stomach contents. The most common cause of acute vomiting is usually a self-limited viral illness. However, more serious and potentially life-threatening illnesses may present primarily with vomiting, and are presented in Table 126-1. The management of these illnesses is beyond the intent and scope of this chapter.

Diarrhea is best defined as an excessive loss of electrolytes and fluid in the stool. Generally, young infants produce about 5 g/kg of stool a day with the amount increasing to 200 g per d by adulthood. The small bowel absorbs the vast majority of water in the gastrointestinal tract. Illnesses that interfere with absorption of water in the small intestine or secretion of water tend to produce voluminous diarrhea. In contrast, colonic processes such as dysentery produce frequent small-volume bloody stools.

Causes of diarrhea are legion, but the most common etiology of diarrhea in children is infectious. Noninflammatory infectious diarrhea is caused by viruses and parasites that localize to the proximal small bowel, or by toxin-producing bacteria. Infectious diarrhea is typically profuse and watery and commonly associated with nausea and vomiting. Fever is less likely. Clinicians frequently use the name gastroenteritis, but the stomach is generally not involved.

Other causes of acute diarrhea are uncommon, but must be consid-

TABLE 126-2 Clinical Features, Diagnostic Aids, and Treatment of Diarrhea

Agent	Clinical Features/Historical Clues	Diagnostic Aids	Treatment
Viral			
Rotavirus	Watery diarrhea, winter, most common agent	Enzyme immunoassay available but of little help in acute management	Rehydration
Enteric adenovirus	Watery diarrhea, ± concurrent respiratory symptoms		
Norwalk	Watery diarrhea, epidemic gastroenteritis, with associated fever, headache, myalgias		
Bacterial			
<i>Campylobacter jejuni</i>	Fever, abdominal pain, watery or bloody diarrhea, may mimic appendicitis, animal reservoir	Fecal WBC, stool culture	Rehydration plus Erythromycin ethylsuccinate (EES) 50 mg/kg per d divided qid
<i>Shigella</i>	Fever, abdominal pain, headache, mucoid diarrhea, possible seizure, toxic megacolon, small inoculum, very contagious	Fecal WBC, stool culture, swab culture	TMP-SMX (Bactrim) 8/40 mg/kg per d divided bid or Ampicillin 50–100 mg/kg per d divided qid
<i>Salmonella</i>	Fever, dysentery, animal reservoir, large inoculum	Fecal WBC, stool culture	Antibiotics prolong carrier state and indicated only if complicated (septic, hemoglobinopathy); TMP-SMX 8/40 mg/kg per d divided bid* or ceftriaxone or cefotaxime
<i>Escherichia coli</i>			
Enterotoxigenic (ETEC)	Watery diarrhea, cholera-like enterotoxin	Stool culture, ELISA	TMP-SMX 8/40 mg/kg per d divided bid
Enterohemorrhagic (EHEC)	Dysentery, serotype O157:H7 associated with HUS	Fecal WBC, stool culture, PCR, serotype with HUS, check CBC, BUN, creatinine	Supportive care, no antibiotics
Enteroinvasive (EIEC)	Dysentery, <i>Shigella</i> -like	Fecal WBC, stool culture	TMP-SMX 8/40 mg/kg per d divided bid
<i>Vibrio cholerae</i>	Rice-water diarrhea, enterotoxin		TMP-SMX 8/40 mg/kg per d divided bid
<i>Yersinia enterocolitica</i>	Fever, vomiting, diarrhea, abdominal pain, may mimic appendicitis, animal reservoir	Stool culture, serology	Ceftriaxone (Rocephin) 50 mg/kg per d (controversial)
<i>Clostridium difficile</i>	Recent antibiotic use	Fecal WBC, stool culture, toxin assay	Metronidazole (Flagyl) 15–40 mg/kg per d divided tid, discontinue other antibiotics
<i>Staphylococcus aureus</i>	Food poisoning, toxin mediated	History	No antibiotics
Parasitic			
<i>Giardia lamblia</i>	Diarrhea, flatulence, mountain streams, day care	Stool ova and parasite	Rehydration plus Metronidazole 15–40 mg/kg per d divided tid
<i>Entamoeba histolytica</i>	Bloody mucoid stools, hepatic abscess	Serologic test	Metronidazole 15–40 mg/kg per d divided tid

*Increasing resistance.

fecal leukocytes on stool examination. Alternatively, diarrhea may be a result of toxin production. Enterotoxins alter cell function without causing cell death. Enterotoxigenic *E. coli* (ETEC) adheres to mucosal epithelium and elaborates an enterotoxin. The heat labile toxin, which is similar to the toxin produced by *V. cholerae*, increases cyclic adenosine monophosphate, which in turn promotes secretion of electrolytes and fluids into the intestinal lumen.

Enterohemorrhagic *E. coli* (EHEC) produces shiga-like cytotoxin, which differs from enterotoxin, and inhibits protein synthesis, ultimately causing cell death. Infection with enteropathogenic *E. coli* (EPEC) differs from the other forms of *E. coli* infection. It does not produce traditional *E. coli* enterotoxins, nor is it invasive. The organism attaches to the mucosa and destroys microvilli, interrupting absorption. Viruses and parasites cause diarrhea by a variety of mechanisms similar to those discussed above.

CLINICAL FEATURES

A careful assessment of the child's state of hydration is essential, although clinical assessment of dehydration is difficult. The most accurate and objective method is to compare the child's weight when well versus the weight while ill. The value of a history is somewhat limited

by the lack of objectiveness on the part of the caregiver, but can be helpful by providing information on what fluids and foods have been offered. A history of last urine output should be obtained, but this may not be obvious in infants and toddlers who are having frequent watery stools. Dehydration may be assessed on the basis of the physical examination, along with the vital signs. Combinations of physical signs, including ill general appearance, vital signs, capillary refill >2 s, dry mucous membranes, and absent tears, are good objective predictors of the degree of dehydration (Table 126-3). The presence of two or more signs predicts 5 percent dehydration, whereas three or more signs predicts 10 percent dehydration.³ Severe dehydration accompanied by lethargy, hypotension, and delayed capillary refill requires immediate ad-

ministration of parenteral fluids. Capillary refill may be affected by conditions other than dehydration, but is generally an excellent indicator of dehydration until proven otherwise.⁴ Guidelines for assessing dehydration are listed in Chap. 132.

DIAGNOSIS

The approach to the child with vomiting and/or diarrhea has two main functions. First, the clinician must seek out those conditions that are life-threatening, and swiftly intervene. Anticipation and aggressive fluid resuscitation may be necessary to prevent shock or further deterioration. Historical and clinical information may be incomplete while interventions are occurring. The second purpose of the assessment is to determine the degree of dehydration and proceed with appropriate rehydration.

The less acutely ill child should have a careful history and physical examination performed with selective laboratory and radiologic evaluation. Various cultures and immunoassays of stool for the presence of enteric pathogens are now well established in most hospital laboratories. Routine stool culture for bacterial pathogens now includes *C. jejuni*, *Y. enterocolitica*, and *Aeromonas* in addition to *Salmonella* and *Shigella*. Subculturing for *E. coli* serotypes or stool assays for *C. difficile* toxin activity are readily available. Enzyme immunoassays are also available to test stool for the presence of rotavirus, enteric adenovirus, and astrovirus.

Most children present with a nonspecific gastroenteritis and not dysentery. The clinician must assess the likelihood of defining a treatable etiology, and as a consequence, the indication for doing a stool culture. The presence of fecal leukocytes and/or positive guaiac testing has been used as a screening tool to identify children at increased risk for invasive bacterial enteric infection. Fecal leukocyte testing has poor sensitivity and guaiac testing has poor specificity.⁵ The most prudent approach is that of combining these tests with the clinical findings. If the child is febrile, has abrupt onset of diarrhea occurring more than four times a day, or blood in the stool, the illness is more likely to be caused by a bacterial pathogen and stool cultures are indicated.⁵ The likelihood of identifying bacterial pathogens is increased if the patient's stool or accompanying exudates contains polymorphonuclear leukocytes.

Anaerobic stool cultures and assay of stool for *C. difficile* toxin activity should be obtained in children who have been receiving antibiotics and develop bloody diarrhea. A history of hiking or camping should prompt examination for ova and parasites. In addition, a swab of mucus or bloody exudates from the stool should be placed in transport medium and sent to the laboratory for culture of *Shigella* species. *Shigella* is a fastidious pathogen and is more likely to be recovered from a swab than from a fresh stool specimen. In cases of persistent or recurrent diarrhea, especially with weight loss or day care center exposure or in immunocompromised children, stool samples should be collected in fixative and examined for *G. lamblia*, *E. histolytica*, and *Cryptosporidium*. Depending on geographic location or travel history, serologic testing for *E. histolytica* infection may be indicated.

MEASUREMENT OF ELECTROLYTES AND BLOOD GLUCOSE

Dehydration caused by diarrhea is usually isotonic and measurement of serum electrolytes is not always necessary. However, it is most important to be aware of the physical findings of hypernatremic dehydration such as hyperirritability, sunken eyeballs and fontanelle, parched mucous membranes, and thickened, doughy skin. If hypernatremia is suspected, or if dehydration is moderate to severe, measurement of electrolytes is mandatory. Infants and children who have hypernatremic dehydration have special requirements for rehydration after initial fluid resuscitation and require hospitalization.

Children receiving IV therapy are generally ill enough that electrolytes and blood glucose levels should be checked initially. Pro-

tracted vomiting and/or diarrhea associated with concomitant fasting may increase the risk of hypoglycemia. Younger infants, those born small for gestational age, and children with underlying metabolic disease are at higher risk of developing hypoglycemia. Bedside measurement of blood glucose may help in managing these infants. However, several studies have shown that other laboratory findings are generally neither helpful in acute management, nor predictive of ultimate disposition and should be used selectively.⁷ Laboratory testing should not replace clinical reassessment.

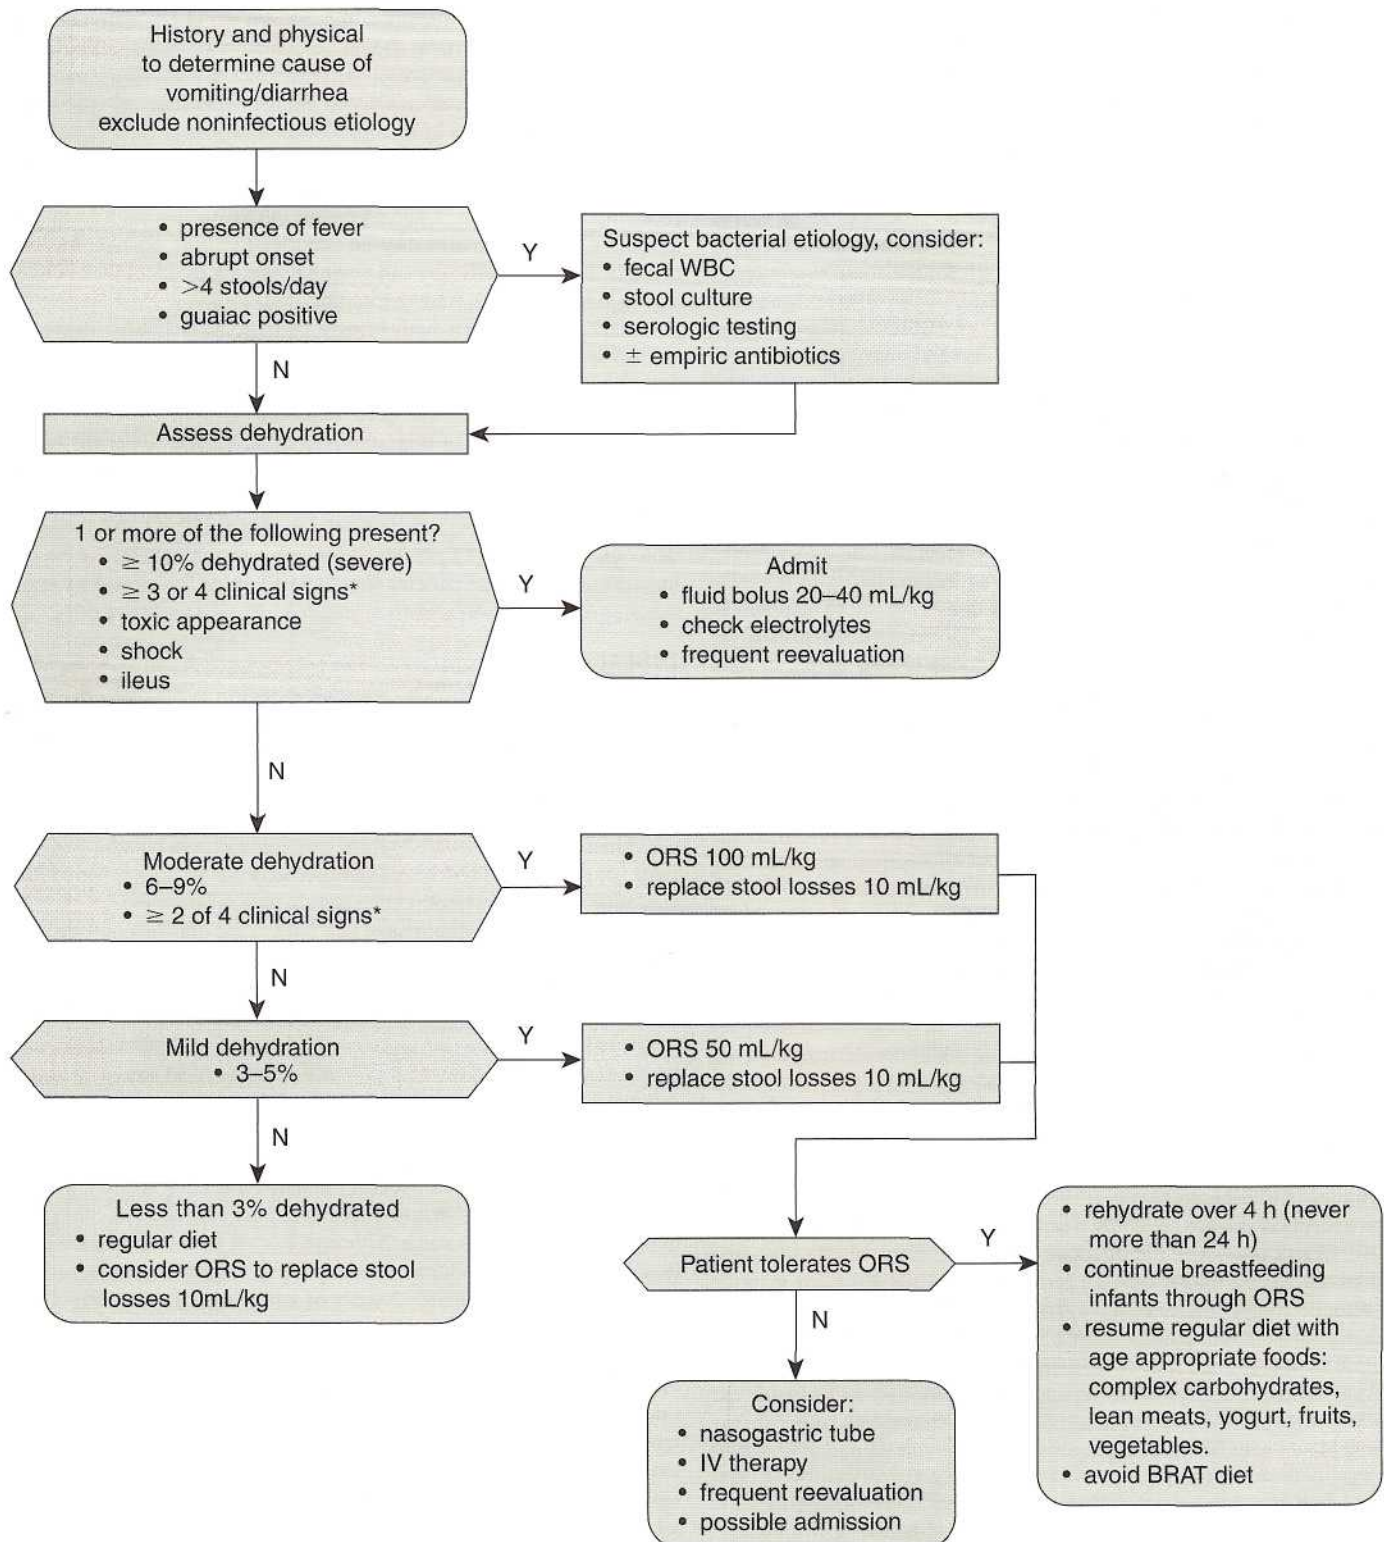

EMERGENCY DEPARTMENT TREATMENT

After other life-threatening diseases have been ruled out, the management of acute gastroenteritis is then directed at preventing or treating the underlying dehydration. The American Academy of Pediatrics (AAP) has published guidelines (summarized in Figure 126-1) for management of acute diarrhea and vomiting in children aged 1 month to 5 years. The AAP practice guidelines evolved in part from the recognition that practitioners in the United States often do not use oral rehydration therapy (ORT) even though there are several oral rehydration solutions (ORS) available in the United States.⁸ ORT is less expensive than intravenous fluid therapy, is generally readily accepted by dehydrated children, and generally rehydrates more than 90 percent of dehydrated children with lower complication rates.⁹

ORT capitalizes on the fact that glucose-coupled sodium and water absorption remains sufficiently intact during most infections, despite significant impairment of NaCl uptake. Glucose-electrolyte solutions such as Pedialyte are readily available in the United States. The glucose concentration of these solutions does not exceed the sodium concentration in millimolar units by more than 2:1. The ideal composition of ORS is a matter of controversy and heated debate. The World Health Organization solution developed almost 30 years ago has an osmolality of about 310 mOsm/L. Newer hypoosmolar solutions such as Pedialyte, with an osmolality of about 250 mOsm/L, have proven to be equally safe, and may result in lower stool volumes and reduced duration of diarrhea.^{9,10} In contrast, other clear fluids often used as replacements, such as soft drinks, juices, sports drinks, and jello water, are largely carbohydrate based. These fluids are typically deficient in NaCl, and have osmolalities ranging from 510 to 1225 mOsm/L. The use of these highly osmolar sugar-based solutions to treat acute diarrhea will predictably amplify net small intestinal fluid secretion and increase diarrhea.

Vomiting is not a contraindication to continuing ORT, although parents sometimes may not be willing to continue their efforts in the face of continued emesis. The key to success in a vomiting child is to give small volumes of ORS, often starting with 5 mL at a time given every 2 or 3 min. ORS may also be given in frozen form as a popsicle. ORT is labor-intensive, and parents may be unavailable or unwilling to give this a try.

If rehydration measures are successful, reinstatement of food should begin as soon as possible. The once common management of diarrhea and vomiting by starvation is never appropriate. Recent studies have shown that the introduction of full-strength formula or unrestricted diet immediately following rehydration is associated with decreased duration of diarrhea, positive nitrogen balance, and increased weight gain. Breast-feeding should be routinely continued in infants with acute gastroenteritis. Infants who have been receiving formula feedings and who are not dehydrated may rapidly return to their feeding. There is no need to give dilute formula. The bananas, rice, applesauce, toast (BRAT) diet widely recommended by practitioners does not provide adequate energy, fat, or protein. Instead, consumption of complex carbohydrates, lean meats, yogurt, fruits, and vegetables should be encouraged. Fatty foods and foods high in simple sugars like juices and soft drinks should be avoided. Finally, there is little evidence to support a lactose-free diet.¹¹

*Clinical signs of dehydration see Table 126-3. BRAT = bananas, rice, applesauce, toast; ORS = oral rehydration solution like Pedialyte; WBC = white blood cell.

FIG. 126-1. Guidelines for management of vomiting and diarrhea in children. (Adapted with permission from American Academy of Pediatrics, Provisional Committee on Quality Improvement, Subcommittee on Acute Gastroenteritis Practice Parameter: The management of acute gastroenteritis in young children. *Pediatrics* 97:424, 1996.)

Specific Therapy

REHYDRATION The treatment of a child with diarrhea is directed by the degree of dehydration. If there is no dehydration, continued age-appropriate feedings are encouraged. ORT may be given in 10 mL/kg amounts to replace ongoing stool losses. Mild dehydration (3 to 5 percent) should be corrected by giving 50 mL/kg ORT plus replacement of continuing losses during a 4-h period. The continuing losses from stool and emesis are replaced by giving an additional 10 mL/kg for each stool. Age-appropriate feeding should continue after the dehydration is corrected, and as the child so desires. Moderate dehydration (6 to 9 percent) is corrected by giving 100 mL/kg ORT plus replacement over a 4-h period. Ongoing losses are corrected as above. Reassessment should occur hourly, and thus may be best accomplished in a supervised setting such as the ED or physician's office. If oral therapy fails, and intravenous access is difficult, placement of a nasogastric tube to provide ORS may be successful.

Clinical studies strongly support the use of ORT, yet the clinician must know how and when to use intravenous fluid therapy. A severely dehydrated infant or child presents with a medical emergency. Intravenous fluids should be given in 20 mL/kg increments, with immediate reassessment for continued fluids. Children in shock should receive at least 60 mL/kg in the first hour with frequent reassessments. Electrolytes and blood glucose determinations should be performed, and plans for hospitalization implemented.

Parents may request medications to treat the symptoms of diarrhea and vomiting, but their use is controversial and mostly not recommended. As a general rule, pharmacologic agents such as antiemetics, anticholinergics, opiates, and adsorbents are not suggested for use because of the self-limited nature of the vomiting and its tendency to improve as the dehydration is corrected. Side effects may be augmented in infants and children in the presence of diarrheal disease.¹² Additionally, most are not approved for use in children less than 2 years of age. The European Society for Paediatric Gastroenterology, Hepatology and Nutrition issued nine pillars of good treatment of acute gastroenteritis listed in Table 126-4.¹³

DYSENTERY Antibiotic therapy does not affect the clinical outcome in most cases of acute diarrhea and may be contraindicated in some infections. Patients with uncomplicated *Salmonella* gastroenteritis should not be given antibiotics unless they appear septic or are bacteremic, have a hemoglobinopathy, or have an underlying chronic gastrointestinal disorder. However, infants less than 6 months of age are an exception and are generally treated with antibiotics because of their overall risk of bacteremia or suppurative disease. If the child has had diarrhea lasting longer than 10 to 14 days, has a significant fever or systemic complaints, and has inflammatory cells or blood in the stool, then empiric antimicrobial treatment may be indicated after sending a stool sample for bacterial culture. Empiric therapy should provide coverage for the usual dysenteric agents such as *Shigella*, *Salmonella*, and *Campylobacter*. Ampicillin or trimethoprim-sulfamethoxazole is a reasonable choice. Debilitated patients, children with an underlying gas-

trointestinal disorder, immunocompromised children, and children with severe bloody diarrhea should be treated with oral antibiotics.¹⁴

Children who have been receiving antibiotics and develop bloody diarrhea may have antibiotic-associated colitis. Most cases of antibiotic-associated colitis caused by *C. difficile* resolve spontaneously when antibiotics are discontinued. Infants and children with protracted diarrhea that has not improved after discontinuing antibiotics may benefit from receiving metronidazole. Cholestyramine, an anion exchange resin that adsorbs *C. difficile* toxins, may be beneficial in mild disease, but because of its limited efficacy and potential binding of antibiotics, it may not be indicated in the emergent setting.

Infants and children with bloody diarrhea may have a gastrointestinal infection due to *E. coli* O157:H7 and are at risk of developing hemolytic uremic syndrome (HUS).¹⁵ The source most frequently identified in outbreaks has been exposure to undercooked ground meat or poultry, eggs, or unpasteurized milk. Person-to-person transmission, especially in child day care centers, is also a well-recognized risk factor for childhood HUS. The risk is highest for children under 5 years of age who are infected with *E. coli* O157:H7 and the incidence may approach 13 percent. Although antibiotic therapy may not impact outcome, these patients should be admitted for supportive care.

DISPOSITION

All infants and children who appear toxic should be admitted. Patients with 10 percent dehydration, intractable vomiting, or altered consciousness should be given an infusion of NS or LR, regardless of the serum osmolality, and admitted. Any child who presents with acute bloody diarrhea and laboratory evidence of hemolytic anemia, thrombocytopenia, and/or elevated serum creatinine should be admitted. Infants who are less ill but whose families may not be able to follow the guidelines for administering ORS should also be admitted.

Infants who are malnourished and have acute diarrhea require special attention. They more often need to be admitted to the hospital as they may develop metabolic acidosis accompanied by an increase in the anion gap and renal dysfunction. This is in contrast to most well-nourished infants, who develop hyperchloremic acidosis due to fecal losses of bicarbonate. The latter group of infants can be expected to improve with oral therapy.

Infants under 1 year of age pose a more difficult problem because of the risk of rapid dehydration and hypoglycemia. Signs of sepsis in this age group may be nonspecific. The threshold for hospital admission should be lowered in any infant who fails to make eye contact or to respond to a parent's voice. Although bilious vomiting may develop in older infants and children who acquire viral gastroenteritis, bilious vomiting in an infant under 2 years of age is a sign of intestinal obstruction until proven otherwise.

Most cases of acute gastroenteritis do not require consultation. In cases of suspected intestinal obstruction, appendicitis, or intussusception, surgical consultation is indicated. Many surgeons prefer consultation prior to radiologic confirmation of intussusception. Ingestion of toxins often requires consultation with a poison control center or toxicologist. In cases in which abuse or neglect is suspected, social service and the primary care physician should be involved. Chronic diarrhea or chronic vomiting should be discussed with the child's primary care provider to determine whether consultation is indicated.

DISCHARGE INSTRUCTIONS

Infants and children who are not dehydrated or who have responded well to oral or intravenous hydration may be discharged with instructions to take ORS and age-appropriate feedings. The family should be instructed to return to the ED or to their own physician if the child becomes unable or unwilling to drink the ORS, begins to vomit, has increased emesis, develops bilious emesis, or shows signs of

TABLE 126-4 Nine Pillars of Treatment of Acute Gastroenteritis

Use of ORS for dehydration
Hypotonic solution
Fast oral rehydration over 3-4 h
Rapid realimentation with normal feeding (including solids) thereafter
Use of special formula is unjustified
Use of diluted formula is unjustified
Continuation of breast-feeding at all times
Supplementation with ORS for ongoing losses
No unnecessary medication

dehydration, such as decreasing urine output or decreased tearing, or if there is a decrease in the child's level of activity or state of alertness. Infants and small children should be reevaluated within 24 h, especially if they continue to have diarrhea. The family should be instructed to telephone their primary care provider and he or she should decide if a visit is necessary. If the family does not have a primary care physician, then the family should contact the ED.

The child's age influences the presenting signs and symptoms significantly. The spectrum of pathologic gastrointestinal (GI) conditions of a 2-day-old infant is vastly different from that of a 2-week-old, and both are quite different from that of a 2-year-old.

HISTORY

An infant or young child cannot give a complete history, but if the child is verbal, try to get the historical information from the child; then obtain the history from the parent or caregiver. Find out the accurate chronology of events, whether fever has been a part of the illness, the quality and location of pain, feeding and bowel habits, and the quality and quantity of vomiting and bowel losses. Inquire whether blood has been present in vomitus or stools. Ask about weight changes. A history of prematurity, necrotizing enterocolitis, congenital anomalies, inborn errors of metabolism, cystic fibrosis, intussusception, or sickle cell anemia are all associated with abdominal complications.

Unfortunately, because some children are either too young or too frightened to speak for themselves or have not been under continuous observation, one may miss trauma as a cause of an abdominal emergency. Such trauma may be accidental or secondary to abuse. Always keep trauma in the differential diagnosis when evaluating pediatric patients presenting with what appears to be an abdominal emergency.

EVALUATION

Children vary greatly in their ability to cooperate with a physical examination. Take a few moments to gain the confidence of the child before any painful examination or procedures are performed. Allowing the child to rest or be on the caregiver's lap may help. Remove clothing to avoid missing an incarcerated hernia, petechiae, visible masses, or peristalsis. Look first and then feel. Consider some non-touch maneuvers and observations such as the child's responses during coughing, walking, climbing onto the table, or jumping up and down.

The child can be invited to self-palpate or palpate with the physician. Start in the least painful areas. Also, evaluate extraabdominal areas such as the pharynx, mucous membranes, neck, lung fields, inguinal regions, femoral triangles, testes, and scrotum. Failure to do so may result in delayed or missed diagnoses. The rectal examination and guaiac test may provide important clues to the diagnosis. The diagnosis of Hirschsprung disease, volvulus, or intussusception may be missed without them.

The more important studies include a urinalysis, a complete blood count and differential, and a test of the stool for occult blood. Other tests, ultrasound, and x-ray evaluation should be guided by history, physical examination, how ill the child appears, and the differential diagnoses. Electrolyte and lipase determination, a pregnancy test, and chest and abdominal x-rays may be useful in certain cases. Computed tomography and ultrasonography are also helpful in the evaluation of stable patients with acute pain.¹

Once the history, physical examination, and laboratory studies are completed, one should develop a list of differential diagnoses. If a child is critically ill, resuscitation and evaluation must be simultaneous. Early surgical consultation is essential for a child with an acute abdomen. If the child is ill but stable and the findings are equivocal, admit the patient for observation and reassessment.

KEY SYMPTOMS

The important GI signs and symptoms are pain, vomiting, diarrhea, constipation, upper or lower GI bleeding, jaundice, and masses.

Pain

Abdominal pain can be a manifestation of a variety of disease states not necessarily related to the intestinal tract.^{2,3} The origin of the pain

Evaluation of abdominal emergencies in children can present a diagnostic challenge. Some diseases are common to both adults and children while others are age specific, such as congenital anomalies, volvulus, malrotation, and Hirschsprung disease. One must understand the differential diagnoses of the presenting symptoms, recognize the clinical manifestations of the more common and life-threatening diseases, and be sensitive in approaching infants and children. Chap. 117 also discusses abdominal pain in neonates.

One can classify abdominal disease processes in several ways. Is the child febrile or afebrile? Does the disease appear to be obstructive or nonobstructive, abdominal, or extraabdominal in nature? Is it due to a local or a systemic process? Does the child appear healthy and happy or sick and septic?

SECTION 12 • PEDIATRICS

may be extraabdominal, such as one might see in a 3- to 6-year-old with tonsillitis or pneumonia. Therefore a careful general physical examination is necessary. One should distinguish between two types of pain: peritoneal and obstructive:

1. Peritoneal pain tends to be exacerbated by motion and thus keeps patients relatively immobile, for example as in appendicitis.
2. Obstructive pain is usually spasmodic and associated with restlessness and motion, for example as with intussusception.

In the very young (up to 2 years of age), pain is usually described by the caregiver in general terms, such as fussiness, irritability, and inconsolableness. With severe peritoneal pain, the caregiver may state that the child is very irritable or lethargic or seems to be grunting as if in pain. Peritonitis or pain from intussusception may present as lethargy or an altered level of consciousness.

Between 2 and 6 years of age, pain of GI origin is usually referred to the periumbilical region, and diagnosis requires correlation of the patient's observations and the physician's visual and tactile evaluation. Youngsters with pain of peritoneal origin walk with obvious discomfort and prefer to lie still. In contrast, youngsters with obstructive pain may be unable to remain still on the examining table. The etiologies of pain vary significantly with age (Table 127-1). Every emergency physician must be familiar with and recognize the life-threatening causes of pain (Table 127-2). The clinician must provide appropriate supportive therapy while completing the diagnostic evaluation and/or consultation.

TABLE 127-1 Etiology of Pain

Under 2 years	6-11 Years
Appendicitis	Appendicitis
Colic (first 4 months)	Diabetic ketoacidosis
Congenital anomalies	Functional pain
Gastroenteritis	Gastroenteritis
Incarcerated hernia	Henoch-Schölein purpura
Intussusception	Incarcerated hernia
Malabsorption (gaseous distention)	Inflammatory bowel disease
Malrotation	Obstruction
Obstruction	Peptic ulcer disease
Sickle cell pain crises	Pneumonia
Toxins (lead, arsenic)	Renal stones
Trauma	Sickle cell syndrome
Urinary tract infection	Streptococcal pharyngitis
Volvulus	Torsion of ovary or testicle
	Toxins (lead, arsenic)
	Trauma
	Urinary tract infection
2-5 Years	Over 11 Years
Appendicitis	Appendicitis
Diabetic ketoacidosis	Cholecystitis
Gastroenteritis	Diabetic ketoacidosis
Hemolytic uremic syndrome	Dysmenorrhea
Henoch-Schönlein purpura	Ectopic pregnancy
Incarcerated hernia	Functional pain
Intussusception	Gastroenteritis
Malabsorption (gaseous distension)	Incarcerated hernia
Obstruction	Inflammatory bowel disease
Pneumonia	Obstruction
Sickle cell pain crises	Pancreatitis
Toxins (lead, arsenic)	Peptic ulcer disease
Trauma	Pneumonia
Urinary tract infection	Pregnancy
Volvulus	Renal stones
	Sickle cell syndrome
	Torsion of ovary or testicle
	Toxins (lead, arsenic)
	Trauma
	Urinary tract infection

TABLE 127-2 Life-Threatening Causes of Pain

Appendicitis	Peptic ulcer disease: complications
Congenital anomalies (malrotation, intestinal atresia or stenosis, imperforate anus, intra-abdominal bands, etc.)	Pneumonia
Diabetic ketoacidosis	Sepsis
Ectopic pregnancy	Toxins (lead, arsenic, mushrooms, spider bite)
Hemolytic uremic syndrome	Trauma
Incarcerated hernia	Volvulus
Intussusception	
Newborn (0-2 Months)	Infant (2 Months to 2 Years)
	Appendicitis
	Congenital adrenal hyperplasia
	Diabetic ketoacidosis

Vomiting

Vomiting is a common childhood problem and may be a specific or nonspecific manifestation of a benign process or a serious, life-threatening illness or injury. Vomiting or regurgitation may be a manifestation of a relatively minor problem (e.g., a nervous parent, poor feeding habits, or gastroesophageal reflux), or it may be a sign of a more serious illness. Bilious vomiting is always a serious manifestation in an infant or child. Vomiting may be a sign of obstructive or nonobstructive GI diseases, or of infections or metabolic disorders (Table 127-3).

Vomiting (bilious or not) is a classic symptom of mechanical intestinal obstruction in children. In the early phases of illness, before a child has developed electrolyte abnormalities (e.g., in a child with pyloric stenosis) or before a child has gangrenous bowel (e.g., intestinal volvulus), the child's general condition may appear to be good. The child may be hungry immediately after vomiting and even eat vigorously. One must not ignore the possibility of a serious underlying in-

Congenital adrenal hyperplasia

Foreign body

TABLE 127-3 Causes of Vomiting

Congenital anomalies	Gastroenteritis
Food poisoning	Head trauma
Gastroenteritis	Hirschsprung disease
Gastroesophageal reflux	Hydrocephalus

Incarcerated hernia	Toxins
Meningitis	Trauma
Metabolic acidosis	Urinary tract infection

traabdominal pathologic condition merely because a vomiting child appears to be systemically well.

Evaluate the child's circulatory and volume status and administer boluses of NS at 20 mL/kg for any child in shock or dehydrated. A one-time dose of an antiemetic may be given safely to children over 6 months of age. Children with shock or severe dehydration will need consultation. For young children who appear systemically well, 30 mL of clear liquids or infant rehydration solution can be provided at 15- to 30-min intervals.

Diarrhea

Diarrhea is an increased number of watery stools over a defined period of time. An infant may have a formed or semi-formed stool after each feeding and this could be normal. Several mechanisms can cause diarrhea in the child, including osmotic, secretory, and transit disorders. Viral and bacterial pathogens cause the majority of episodes of diarrhea. Some tumors, such as neuroblastomas, secrete hormones that can increase stool water content.

When the presenting symptom is diarrhea, one must quantify the number and volume of stools, consistency, and the presence of blood. Ascertain the norm for the child, since there is great individual variability in frequency and type of stools. Associated symptoms or the presence of diarrheal illness in other members of the family may help in establishing the diagnosis. Assess for and treat dehydration and electrolyte imbalance. Diarrhea may represent fluid expelled around an anatomic obstructive mass, such as an impaction, or functional obstruction, as in Hirschsprung disease (absence of parasympathetic ganglia cells in the muscle layers of the colon). Bloody diarrhea may be infectious or a manifestation of a systemic disease (e.g., hemolytic uremic syndrome; Table 127-4).

Treatment of diarrhea will vary depending on the cause. A suspicion of Hirschsprung or Crohn disease warrants surgical consultation. Malabsorption, hemolytic uremic syndrome, cystic fibrosis, or persistent diarrhea with weight loss and failure to thrive warrants pediatric consultation. Other causes may only require rehydration solution for 24 h and avoiding fatty or high-carbohydrate foods for a couple of days. Stool cultures are warranted in children with bloody diarrhea, diarrhea for more than 5 days, or toxic appearance, or to track an epidemic form of illness.

Constipation

Constipation is infrequent, dry, hard stools that may result from defects in filling or emptying the rectum and may be a sign of either a pathologic or functional process (Table 127-5). Eventually, watery stool works its way around the impaction and causes diarrhea. **Thus the rectal examination is very important in the evaluation of both constipation and diarrhea.**

Causes of constipation are quite different in infants and older children. In infancy, one must consider causes such as maternal drugs, congenital GI anomalies, cystic fibrosis, Hirschsprung disease, poor intake, and anal fissure. Note the abdominal shape and girth, the presence of bowel sounds and masses, and check the anal area. Check rectal tone, examine for an anal fissure, and check the stool for occult blood. If a bowel obstruction is suspected, surgical consultation is nec-

TABLE 127-5 Acute and Chronic Constipation

Infectious	Cerebral palsy
Infantile botulism	Myotonic dystrophy
	Spina bifida
	Spinal cord disease or injury
	Tumor

essary. If no systemic cause or serious illness is suspected, dark thick molasses or corn syrup can be added to the diet. Finally, if the child is listless or hypotonic, one should consider infantile botulism.

In older children, one should not automatically think that the cause is functional. Constipation is seen in children who are anorexic or who have cerebral palsy, neuromuscular disease, dehydration, hypercalcemia, hypokalemia, hypothyroidism, or depression, or who have ingested drugs such as diuretics, antihistamines, anticholinergics, or narcotics. A thorough history and physical examination, including a rectal exam, are necessary. An empty rectal vault does not rule out constipation. If there are signs of bowel obstruction, tumor, or serious illness, one should consult an appropriate specialist.

Acute constipation is treated by increased oral fluids and possibly a stool softener or milk of magnesia. Chronic constipation is treated in three separate steps, and follow-up with a primary care specialist is important. The steps are clean-out, maintenance, and behavior modification.

Upper and Lower Gastrointestinal Bleeding

There are many causes of upper and lower GI bleeding, and the type of disorder is somewhat age dependent (Table 127-6). It is frequently difficult to determine the cause of minimal to moderate GI bleeding. Repeated episodes of bleeding require GI studies, endoscopic evaluation, and Meckel isotope scanning.

Bleeding in the neonate may be a sign of necrotizing enterocolitis, GI duplication, infection, milk allergy, or sepsis, or it may be nothing more than an anal fissure. GI bleeding in the healthy appearing newborn, either vomited or per rectum, may be the result of swallowed maternal blood (see Chap. 117). Small amounts of fresh blood in the diaper may result from an anal fissure. Milk allergy is an IgE-mediated disorder characterized by diffuse mucosal hyperemia. Bleeding can be mild or severe. Coagulopathies can cause GI bleeding in the newborn. The presence of small to moderate amounts of blood in the stool of an infant, particularly if associated with vomiting, should lead to consideration of malrotation of the midgut.

If the infant or child has bloody diarrhea, considerations include infectious colitis or inflammatory bowel disease.⁴ If the child has colicky abdominal pain, consider intussusception. If bleeding is painless, Meckel diverticulum should be suspected. Major painless upper GI bleeding in infants or children is most commonly the result of bleeding

TABLE 127-4 Causes of Diarrhea

Anatomic: Hirschsprung disease
Dietary: allergy, malabsorption, overfeeding
Infectious: bacterial, parasitic, toxic, viral
Inflammatory: Crohn disease, hemolytic uremic syndrome, ulcerative colitis
Malabsorption: cystic fibrosis, enzyme deficiencies, celiac disease
Systemic: endocrinopathy, immunodeficiencies
Obstructive: fecal impaction

	Polyps; benign, familial	

varices secondary to portal hypertension, which can be due to hepatitis, or congenital diseases such as cystic fibrosis, α_1 antitrypsin deficiency, glycogen storage disease, or Wilson disease. If rectal examination identifies a severe, large fissure or rectal tear, one should consider possible abuse. Treatment for fissures includes stool softeners and sitz bath.

In the older child, consider GI polyps, internal hemorrhoids, severe gastroenteritis, Henoch-Schönlein purpura, hemolytic uremic syndrome, or an anal fissure. In adolescents, one must consider stress ulceration, peptic ulcer disease, and inflammatory bowel disease.

Treatment

The child with upper or lower gastrointestinal hemorrhage must have a rapid assessment of hemodynamic status and receive aggressive treatment of hypovolemia with intravenous fluids and/or packed red blood cells. Signs of hemodynamic instability in the child include tachycardia, tachypnea, unstable vital signs, pallor, poor capillary refill, altered mental status or ongoing blood loss. Fluid should be administered until the child is hemodynamically stable and packed red blood cells should be given to children with significant hemorrhage. Fresh frozen plasma may be needed if the child also has liver disease. Both gastrointestinal and nongastrointestinal sources of bleeding should be considered. The oropharynx should be evaluated for signs of bleeding. A nasogastric tube should be placed in all patients with a significant history of hematemesis or if the examination reveals melena. If the aspirate reveals active bleeding, then gastric lavage should be started with room temperature normal saline. A pediatric surgeon, gastroenterologist, or pediatrician should be consulted.

Jsamdiee

Jaundice can be an ominous sign, since it represents hepatic dysfunction. It might represent sepsis, congenital infection [TORCHS (toxoplasmosis, rubella, cytomegalovirus, herpes simplex, syphilis)], or postnatal viral hepatitis. It might represent a minor or a major ABO or Rh factor incompatibility, with the possibility of kernicterus or death. It may represent the first signs of cystic fibrosis, galactosemia, or

other hepatic enzyme deficiencies, or it could be the harbinger of an anatomic problem such as biliary atresia, a choledochal cyst, or even pyloric stenosis. All icteric patients should be evaluated promptly and consultation strongly considered (Table 127-7).

Masses

The presence of a mass could be the first sign of a congenital anomaly or a tumor (e.g., Wilms tumor or neuroblastoma). It could be a pyloric "olive" or an intussusception mass if associated with vomiting or a guaiac-positive stool. If a child has an acute surgical abdomen or intestinal obstruction, resuscitation and prompt surgical consultation is necessary. Otherwise, emergency evaluation should be followed by pediatric consultation and admission (Table 127-8).

DIAGNOSIS AND MANAGEMENT OF SELECTED DISORDERS

Gastrointestinal Emergencies in Infants in the First Year

MALROTATION WITH AND WITHOUT VOLVULUS Volvulus is a major life-threatening complication of malrotation.⁵ The complications of malrotation occur most commonly in the first year of life, although malrotation can give rise to symptoms at any time in a person's life. The vast majority of cases occur within the first month of life. It is the most urgent of GI emergencies in infants and children because of consequent gangrene of the entire midgut. The time interval from the first symptom to the development of total midgut gangrene may be only a few hours.

Pathophysiology During gestation, at approximately 6 weeks of age, the elongating intestines prolapse into the yolk sac. Upon reentry at 10 weeks, the midgut undergoes a 270° counterclockwise turn around the superior mesenteric artery. Usually the duodenum and the cecum become fixed by peritoneal bands, and the small intestine has a broad mesenteric attachment along its base. Abnormal rotation and inadequate fixation can occur during gestation. Incomplete rotation or malrotation can leave the cecum high in the abdomen, with its peritoneal attachments crossing the duodenum in an obstructing manner. The mesentery fails to fan out, and the midgut is suspended and its entire vascular supply travels along a narrow pedicle.

Clinical Features The presenting symptoms are usually vomiting, ultimately becoming bilious, with or without abdominal distention, and streaks of blood may be seen in the stool. Infants with symptoms

TABLE 127-7 Causes of Jaundice

Unconjugated	Conjugated
ABO or Rh incompatibility	Anatomic defect: biliary, hepatic
Autoimmune hemolytic anemia	Hemolytic uremic syndrome
Hepatic: Crigler-Najjar syndrome, Gilbert disease	Hepatic abscess
Hypothyroidism	Hepatitis: congenital, acquired
Sepsis	Hepatitis: TORCHS
Sickle cell anemia	Inflammatory bowel disease
G6PD deficiency	Metabolic: cystic fibrosis, galactosemia, etc.
	Sepsis

of obstruction or bilious vomiting must receive prompt surgical consultation and active resuscitation. The most dramatic presentation in newborns is the sudden onset of an acute abdomen and shock, with a rigid and discolored abdomen associated with bilious or bloody vomiting and bloody stools, indicating the presence of gangrenous bowel. On physical examination, such infants may appear pale, have grunting respirations, and approximately one-third of such infants may appear jaundiced.

In older children, the pain is usually constant, not colicky. This symptom complex usually occurs in previously healthy children. However, there may have been minor episodes of vomiting or abdominal discomfort in the past. A child suspected of harboring a malrotation with possible midgut volvulus should have flat and upright abdominal x-rays. The presence of a loop of bowel overriding the liver is suggestive of the diagnosis. Occasionally, an upper GI examination may reveal an abnormal location of the ligament of Treitz.

Intussusception, duodenal stenosis, or atresia can produce a clinical picture similar to midgut volvulus.

Treatment An infant with symptoms of obstruction or bilious vomiting must receive prompt surgical consultation, active resuscitation, and hospital admission. Start intravenous fluid immediately, and place a nasogastric tube. Send blood for type and cross-match. An elevation of the white blood cell count may suggest early gut necrosis. Electrolytes and venous blood gases may identify sodium or potassium abnormalities or ongoing acidosis. Any child with vomiting or bloody stools who is identified as having an incompletely rotated bowel requires urgent laparotomy to prevent the development of midgut volvulus and total midgut gangrene.

INCARCERATED HERNIA

Clinical Features An incarcerated hernia will not be detected unless the infant or child is totally undressed at the time of examination. The symptoms can include irritability, poor feeding, vomiting, and an inguinal or scrotal mass. The differential diagnosis of an inguinal or scrotal mass most frequently includes hydrocele of the cord or the scrotum, undescended testicle, torsion of the testicle, torsion of the appendix testis, inguinal lymphadenopathy, inguinal node abscess, orchitis, and inguinal or scrotal trauma. The incidence of incarceration of inguinal hernias is highest in the first year of life. In both boys and girls, the incarcerated sac may contain small or large bowel. In girls, an ovary may be present in the sac.

Treatment In most instances, it is possible to achieve manual reduction of the incarcerated hernia without the use of sedation if it has been present for only a short time. The infant should be placed in Trendelenburg position and, once the child is quiet, a gentle milking of the hernia contents toward the inguinal rings should be attempted. One may provide sedation with a short-acting agent such as midazolam or fentanyl (see Chap. 134). The few patients who do not respond to these maneuvers must undergo surgical reduction. Once the hernia is reduced, follow-up should be arranged with the pediatric surgeon within

24 to 48 h for surgical repair on an elective basis. If it was a difficult reduction, the child may need admission on the recommendation of the pediatric surgeon.

INTESTINAL OBSTRUCTION

Clinical Features Intestinal obstruction presents in infants and young children in the classic manner, with symptoms of pain (manifested by irritability), vomiting, abdominal distention, and later, absence or diminution of bowel movements. The differential diagnosis of intestinal obstruction in newborns and infants includes intestinal atresia or stenosis, meconium ileus (newborns only), incarcerated inguinal hernia, intussusception, malrotation, malrotation with volvulus, volvulus around a congenital intraabdominal band, duplication cysts of the intestinal tract, imperforate anus, and Hirschsprung disease.

Diagnosis and Treatment Flat and upright films of the abdomen show dilated loops of bowel with air-fluid levels (Figure 127-1). Such

FIG. 127-1. Mechanical intestinal obstruction. A. Upright film. B. Flat film.

an appearance on the plain x-ray film warrants a barium enema examination with a Hirschsprung catheter, which helps to differentiate between Hirschsprung disease, malrotation, and colonic stenosis, and separates lower large bowel obstruction from upper small bowel obstruction.

Once intestinal obstruction is diagnosed, prepare the patient for surgical intervention by having an intravenous line started and a nasogastric tube placed; the child should be admitted.

PYLORIC STENOSIS Consider pyloric stenosis in the infant with a history of nonbilious projectile vomiting. The disorder affects approximately 1 in 150 male and 1 in 750 female patients. It occurs more frequently in first-born males, and a familial incidence is noted in approximately 50 percent of patients. It is caused by diffuse hypertrophy and hypoplasia of the smooth muscle that narrows the antrum of the stomach to a small channel that can be easily obstructed.

Clinical Features Onset is rare before the age of 1 week, and the disorder usually begins in the second or third week of life. It seldom develops after the third month of life. Initially, the infant may only regurgitate small amounts of milk, making it difficult to distinguish the cause of vomiting from simple regurgitation, gastric reflux, or milk intolerance. Vomiting usually becomes projectile within a week of onset of symptoms, and the vomitus is never bile stained, although it may occasionally have streaks of blood. Vomiting occurs just after or near the end of feeding, and afterward the infant will refeed hungrily unless the child has become malnourished or dehydrated.

Vomiting eventually becomes projectile. Constipation may be noted because the infant is not retaining enough formula and becomes dehydrated.

Physical examination usually demonstrates a hungry infant who has failed to gain weight over the past several weeks or has lost weight. Jaundice occurs in 1 to 2 percent of cases. If one undresses and then feeds the infant, peristaltic waves can sometimes be seen passing from left to right across the upper abdomen, just prior to an episode of vomiting. Palpation of a pyloric tumor—the "olive"—is pathognomonic. The olive usually is felt near the lateral margin of the right rectus muscle just below the liver edge. Palpation of the olive is very dependent on the amount of hypertrophy of the pylorus and the skill of the clinician.

In advanced cases, the physical examination will reveal dehydration and lethargy. The child may appear moribund, with sunken eyes, decreased elasticity of the skin, and loss of subcutaneous tissue.

Diagnosis If the olive is palpated, further studies are not necessary. If no olive is palpated, abdominal ultrasonography is recommended. Accuracy depends on the use of a high-resolution machine and an experienced sonographer. Although false positives are rare, false negatives can occur in up to 20 percent of cases, often due to bowel gas interference. If the diagnosis is strongly suspected and the findings on ultrasonography are normal, an upper GI series can be performed. This usually demonstrates delayed gastric emptying and indentation of the antrum by the pyloric olive. The pyloric channel is narrowed and appears stringlike. If pyloric stenosis is not noted, the radiographer can evaluate the infant for gastroesophageal reflux. The major risk from the upper GI series is the potential for aspiration.

Treatment Once the diagnosis of pyloric stenosis is confirmed or is strongly suspected, surgical consultation should be obtained. Surgery is the treatment of choice, and the procedure is very safe. Oral intake should be restricted and an intravenous line started. Dehydration and electrolyte abnormalities must be corrected before surgery. Much of the reduced morbidity and mortality from surgery for this disease can be attributed to improved preoperative status. Extensive and protracted vomiting in pyloric stenosis may lead to hypokalemia, hyponatremia, and hypochloremic metabolic alkalosis. Fluid and electrolyte replacement is discussed in Chap. 132.

INTUSSUSCEPTION Intussusception occurs when a portion of the alimentary tract is telescoped into another segment. It is the most common cause of intestinal obstruction between 3 months and 6 years of age and is rare under 3 months of age. The male:female ratio is 4:1.

Pathophysiology The cause of most intussusception remains unknown. A seasonal incidence seems to follow peak viral illness seasons. In some patients, recognizable causes for intussusception are found, such as Meckel diverticulum, intestinal polyp, duplication, lymphosarcoma, or as a complication of Henoch-Schonlein purpura, but these are rarely found in infants under 2 years of age. Rarely, tumors or foreign bodies may cause intussusception. Prior to 2000, the rotavirus vaccine was associated with an increased incidence of intussusception and was withdrawn from the market. Ileocolic intussusception is the most common type. The upper portion of the bowel invaginates into the lower portion, bringing the mesentery with it. Constriction of the mesentery obstructs venous return with engorgement of the intussusceptum. With edema and bleeding, there may be bloody stools, with mucus giving rise to the characteristic "currant jelly" stool.

Clinical Features The classic patient is a robust, 6- to 18-month-old infant without prior difficulty. Suddenly, the child appears to be in pain. The youngster may be playing quietly in the playpen and suddenly stop playing, begin to cry, and even roll around in discomfort. Just as suddenly, the pain ceases, and the child appears to be as happy and content as before the onset of pain. Episodes of the painful attacks may recur at intervals that become shorter and shorter and with increasing duration. Some children become very still, listless, and pale, and appear to be in a shocklike state due to the visceral pain. Vomiting is rare in the first few hours, but usually develops after 6 to 12 h. The classic "currant jelly" stool associated with intussusception is a late manifestation of the disease complex and is present even then in only 50 percent of cases.⁶ Its absence should not delay evaluation for intussusception in the patient. However, a positive stool guaiac test is present in almost every case.

Fever can occur and even rise to 41°C (106°F). Respirations may be shallow and grunting in nature.

Apathy or lethargy may be the only presenting sign of intussusception in up to 10 percent of cases. Because of this, some infants will receive a lumbar puncture and other diagnostic studies, thus delaying the diagnosis and management of the child's illness.^{7,8,9}

Examination between attacks may reveal the often-described sausage-shaped tumor mass of intussuscepted bowel in the right side of the abdomen. If this mass is felt in the epigastrium, the long axis is usually horizontal. At least one-third of patients do not have a palpable mass, but the absence of a mass must not delay further investigation. An ileoileal intussusception may have a less typical presentation, with symptoms and signs suggestive of intestinal obstruction.

Diagnosis and Treatment The presumptive diagnosis of intussusception is made based on the history. The apparent well being of a child in the absence of clinical findings should not mislead the physician. An x-ray examination of the abdomen may show a mass or filling defect in the right upper quadrant of the abdomen (Figure 127-2), but can be normal in 30 percent. An air contrast enema is diagnostic and is frequently curative.⁷ Air insufflation is preferred over barium enema because it enables better control over colonic pressure used for the reduction,¹⁰ and if perforation should inadvertently occur, there is no spillage of barium into the peritoneum. The pediatric surgeon should be consulted before diagnostic procedures, so that prompt surgery can be done if reduction is unsuccessful or if there is a complication.

After successful reduction, the child is generally admitted for observation for complications of reduction and because of a 5 to 10 percent recurrence rate, usually within the first 24 to 48 h following re-

FIG. 127-2. Intussusception. Plain film with loss of bowel pattern in the right upper quadrant.

duction. A second attempt at air reduction can then be considered and is usually successful. If another episode of intussusception occurs, then surgical reduction is necessary.

Gastrointestinal Emergencies in Children 2 Years and Older

APPENDICITIS

Clinical Features Appendicitis can occur in children younger than age two, but the presentation is usually one of peritonitis or sepsis because of the delay in diagnosis.¹¹ The most common symptoms in children under two are vomiting, pain, diarrhea, and fever. Other clinical features that might confuse the diagnosis include irritability, grunting respiration, cough, and hip pain.¹² The child under two usually has a fever and diffuse abdominal tenderness, with localized right lower quadrant tenderness noted in less than 50 percent. One-third to one-half of the patients may have abdominal distention or abdominal rigidity. Due to the difficulty of making the diagnosis of appendicitis in children under 2 years of age, the appendix is often perforated by the time of surgery.

Over age two, appendicitis becomes a more important part of the differential diagnosis of abdominal pain. The symptoms of appendicitis may not progress in the classic fashion in young children. The usual progression involves early anorexia followed by the development of mild to moderate periumbilical pain, then vomiting and migration of the pain to the right lower quadrant of the abdomen. While adult studies indicate that pain usually precedes vomiting, the sequence may not be followed in young children. Vomiting may be the first symptom noted by the parents.¹² The typical sequence is absent in approximately one-third of children with appendicitis. Physical examination findings also vary based on the time course of the disease and the time of patient presentation.

On physical examination, tenderness may be localized to the right lower quadrant or may involve the entire abdomen. Bowel sounds are unreliable in determining the presence or absence of appendicitis. Walking, climbing onto the stretcher, or jumping up and down all cause pain. Guarding or rebound tenderness may be unreliable early in the time course of appendicitis. These signs are present more frequently in cases of a perforated appendix.¹² The following signs and symptoms make the diagnosis of acute appendicitis more difficult:

1. The temperature may be normal.
2. The white blood cell count may be normal.
3. The child may not be anorexic and may actually request food.
4. The heavily built child may manifest minimal right lower quadrant tenderness.
5. Appendicitis can follow an episode of gastroenteritis. Intensification of pain in the presence of a history of gastroenteritis should suggest an acutely inflamed appendix secondary to gastroenteritis.¹³
6. Appendicitis has been identified in children younger than 2 years of age. Incidence of perforation in this age group is much higher because of the difficulty of making a diagnosis and the confusion with gastroenteritis.

The white blood cell count has insufficient sensitivity or specificity to confirm or eliminate the consideration of appendicitis. A urinalysis may help evaluate whether the child is suffering from pyelonephritis. However, if the urine has a few white cells, the child may still have appendicitis rather than a UTI.

Ultrasonography (US) is a subject of interest in identifying patients with appendicitis. It is, however, operator dependent and has missed not only inflamed but also ruptured appendices. Increased experience with the use of ultrasound to evaluate children with abdominal pain has improved sensitivity from 76 to 93 percent and specificity from 88 to 98 percent. Non-visualization of the appendix on abdominal ultrasonography is strongly associated with false-negative ultrasound studies.¹²⁻¹⁴⁻¹⁵

Computed tomography (CT) has better sensitivity and specificity than ultrasonography in most studies in children, whether contrast is used PO or PR. CT can also identify other causes of pain. Sensitivities are reported from 95 to 97 percent and specificities from 87 to 100 percent. These two modalities are useful in the indeterminate or atypical case.¹⁶⁻¹⁹ CT scans using oral and colonic contrast with small 5-mm cuts starting just above the cecum and extending distally had the highest sensitivity.¹² There is some concern that CT scans may be less accurate in younger children due to a relative lack of body fat, that make it difficult to differentiate an inflamed appendix from surrounding tissue or bowel.²⁰

Treatment Once the diagnosis of appendicitis is strongly considered or confirmed, surgical consultation should be obtained and the child should be admitted to the hospital. The child should receive any appropriate supportive therapy. If the child is febrile, rectal acetaminophen may be given. The child should not receive any oral fluids or food. Start an intravenous line and administer fluid boluses, particularly if the child shows signs of sepsis or shock. Closely monitor the child's vital signs and give pain medication parenterally as appropriate.

If the diagnosis is possible but not probable, surgical consultation should be considered and the child reexamined until either resolution of the illness or a need for laparotomy is determined.

If a perforated appendix is suspected or the child appears septic, resuscitate the patient in the usual fashion by providing oxygen, ensuring adequate ventilation, and treating hypovolemia and shock. Administer broad-spectrum antibiotics such as ampicillin/sulbactam, piperacillin/tazobactam, cefoxitin, or cefotetan.

With the high potential for misdiagnosis and the difficulty of diagnosing appendicitis in children, one must rely on the history, physical exam, and clinical suspicion. No single test or combination of clinical and laboratory features is 100 percent reliable. Ultrasonography and

contrast CT may reduce the rates of misdiagnosis. Understanding the spectrum of the clinical illness and the variation of signs and symptoms in children of different ages will enhance the physician's ability to manage children with acute abdominal pain.

MECKEL DIVERTICULUM A Meckel diverticulum can cause a variety of signs and symptoms, such as bleeding, peritonitis, intussusception, and intestinal obstruction. The presence of gastric mucosa in the diverticulum may give rise to an ulcer in the adjacent ileum, which may cause symptoms such as painless rectal bleeding. Bleeding is brisk and usually bright red. The ulcer may perforate and cause peritonitis. Isotope scanning reveals the presence of a Meckel diverticulum containing gastric mucosa in up to 50 percent of cases. A scan with normal findings does not eliminate the diagnosis.

Acute inflammation in a Meckel diverticulum may simulate acute appendicitis or may initiate intussusception. Finally, the vitello-intestinal remnant attaching the apex of a Meckel diverticulum to the intraabdominal umbilical region may be the focus around which volvulus of the small bowel or an internal hernia develops, each of these giving rise to intestinal obstruction. Surgical consultation is necessary.

HENOCH-SCHONLEIN PURPURA AND HEMOLYTIC UREMIC SYNDROME Henoch-Schonlein purpura (HSP) and hemolytic uremic syndrome (HUS) can cause abdominal pain and GI bleeding.

In HSP, some children may present with joint pain, abdominal pain, or seizure. Usually there is a petechial or purpuric rash on the buttocks and lower extremities. Many children have guaiac-positive stools, but rarely present with hematochezia unless there is associated intussusception. Treatment is usually symptomatic and on an outpatient basis unless the child appears ill or has a complication of the disease, such as renal failure, intestinal perforation, or a rare complication, testicular torsion.

In HUS, there is usually a history of a gastroenteritis with or without bloody diarrhea, up to 2 weeks before onset of illness. Toxigenic strains of *Escherichia coli* have been implicated as a possible link to HUS. Low-grade fever, pallor, hematuria, and hematochezia occur. The central nervous system can be involved. Hypertension occurs in up to 50 percent and seizures in up to 40 percent of cases. Acute bowel perforation, toxic megacolon, intussusception, renal failure, and pancreatitis can occur.

COLON POLYPS Single polyps or multiple or classic familial polyposis may give rise to painless hematochezia. Single polyps are usually benign (juvenile), with no propensity for malignant degeneration. Frequently, the parent describes what is obviously a prolapsed polyp, easily palpated on rectal examination. It is rare for bleeding originating from a polyp to be life-threatening. Familial polyposis is rare and is a premalignant syndrome. The child should be referred to a pediatric surgeon.

PANCREATITIS Pancreatitis is not common in childhood. The most common cause is abdominal trauma. It can also occur as an idiopathic or postviral process (after mumps, influenza, coxsackie, etc.) or be due to drugs or toxins. Systemic diseases such as cystic fibrosis, systemic lupus erythematosus, and α_1 antitrypsin deficiency can cause pancreatitis.²¹

Clinical findings include central abdominal pain, vomiting, and sometimes fever. The abdomen may be distended and is tender to palpation. Patients should receive fluids to correct dehydration and any hypovolemia and receive appropriate pain management. Most will need admission for intravenous hydration, pain management, and diagnostic studies.

Intraabdominal Masses

Every child should have a careful abdominal examination because intraabdominal masses grow silently at first until they cause obstruction,

bleeding, or hemorrhage into the tumor or until a parent sees a mass protruding in the abdomen. The child should be supine with his or her head turned toward the parent, and one should carefully palpate all quadrants of the abdomen. If a mass is palpated, the child should be referred to a pediatric surgeon and diagnostic imaging studies obtained. A careful rectal examination, especially if the child has constipation or a gait abnormality, must be done to check for a presacral teratoma and for ovarian masses. Both of these tumors can show calcifications on plain film x-rays in approximately 50 percent of cases.

Neuroblastomas can arise from adrenal glands or along the sympathetic chain. They often cross to the midline, and the best cure rate is obtained in children under 1 year of age. Computed tomography is the best way to evaluate this tumor. Wilms tumor is an intrarenal tumor initially and should be considered in children with hematuria. US and CT help define this tumor. Bone scan is also needed. Rhabdomyosarcoma occurs in the pelvis or anywhere there is striated muscle, and it is highly malignant.

In girls over the age of menarche, one must consider pregnancy, and if there is lower quadrant pain, one must consider ectopic pregnancy. One should obtain a serum pregnancy test and consider the use of ultrasonography.

Portal Hypertension

Portal hypertension is rare in children in the United States, but is one of the common causes of major upper GI hemorrhage. Extrahepatic portal thrombosis, parenchymal liver disease associated with fibrocystic disease, and biliary cirrhosis in youngsters with congenital biliary atresia surviving as a result of portal enterostomy are examples of conditions that can result in portal hypertension and esophagogastric varices. Other causes include a history of hepatitis, congenital diseases such as α_1 antitrypsin deficiency, glycogen storage diseases, and Wilson disease.

Massive hematemesis is the usual initial manifestation, along with hematochezia in children, whereas ascites is more common as the presenting sign in infants. A nasogastric tube can be placed to empty the stomach and to monitor for continued bleeding, and blood transfusions given as indicated. Correct any coagulation abnormalities. Emergency consultation with a surgeon, pediatric surgeon, or a pediatric gastroenterologist is necessary.

DIABETIC KETOACIDOSIS

Frederick Place
Thom Mayer

EPIDEMIOLOGY

Diabetes can be subclassified into several different forms. Of the two major categories, type I or juvenile-onset diabetes, characterized by an abrupt and frequently complete decline in insulin production, most commonly begins in childhood. Type II or adult-onset diabetes, marked by increasing insulin resistance and most commonly found in obese adults, is being seen with increasing frequency in overweight adolescents with a strong genetic tendency. Type I diabetes (no longer called insulin-deficient diabetes mellitus) is the most common pediatric endocrine disorder with an estimated prevalence of 1 in 400. As many as 27 percent to 40 percent of new-onset diabetics present in diabetic ketoacidosis (DKA).^{1,2} In known diabetics, DKA is much less common and tends to be clustered in a small subset of patients, with 5 percent of diabetic children accounting for nearly 60 percent of DKA episodes.³ DKA is the leading cause of mortality in diabetics younger than age 24 years and cerebral edema is the leading cause of mortality in DKA.⁴

PATHOPHYSIOLOGY

The fundamental cause of DKA is an absolute or relative insulin deficiency resulting in the inability of cells to take up and utilize glucose. Counterregulatory hormones (catecholamines, cortisol, growth hormone, glucagon) are elevated, driving many of the physiologic disturbances. These hormones increase glucose production by promoting glycogenolysis, gluconeogenesis, lipolysis, ketogenesis, and further decrease glucose utilization by antagonizing insulin.

As the serum glucose exceeds the renal absorption threshold, an obligatory osmotic diuresis ensues resulting in the classic symptoms of polyuria and polydipsia. If not recognized early, this can lead to profound dehydration and electrolyte disturbances. Acidosis stems from the complex metabolic derangements induced by insulin deficiency and unopposed glucagon. The cellular milieu of the body is essentially in a state of functional starvation, unable to utilize the excess glucose. Decreased lipid uptake by adipose tissue and increased lipolysis re-

sults in an overabundance of circulating free fatty acids, which are converted by the liver into the ketoacids acetoacetate and (3-hydroxybutyrate).

Despite this profound shift in substrate production, ketoacid utilization and renal elimination are both impaired, resulting in a high anion gap metabolic acidosis. In certain patients, the acid base status may be more complex. Persistent vomiting and severe volume depletion may result in a superimposed metabolic alkalosis and may mask the severity of the acidosis with a relatively normal pH. Severe dehydration and poor perfusion causing a lactic acidosis will result in a superimposed nonanion gap acidosis. Alternatively, a patient who remains relatively well hydrated will lose sodium with ketoanions in the urine while retaining chloride and demonstrate a significant nonanion gap acidosis.

CLINICAL FEATURES

Polyuria, polydipsia, and polyphagia constitute the classic triad leading to the diagnosis of diabetes. Other common insidious symptoms include weight loss, secondary enuresis, anorexia, vague abdominal discomfort, visual changes, and genital candidiasis in the toilet-trained child. The diagnosis is established by demonstrating hyperglycemia and glucosuria in the absence of other causes such as steroid therapy, Cushing syndrome, pheochromocytoma, hyperthyroidism, or other rare disorders.

Uncontrolled diabetes will present to the emergency physician along an entire spectrum from simple hyperglycemia without ketonuria to diabetic ketosis (hyperglycemia with ketonuria) to full-blown DKA. DKA is generally defined as a metabolic acidosis (pH <7.25 to 7.30 or serum bicarbonate <15 mEq/L) with hyperglycemia (serum glucose >300 mg/dL) and ketonemia >1:2 serum dilution.^{5,6} A vigorous search for precipitants should be undertaken. The most common cause of DKA in known diabetic children and adolescents is poor compliance. Other precipitants include intercurrent viral illness and focal infections such as urinary tract infection or gastroenteritis. Type I diabetics experience DKA much more commonly than do type II diabetics, but it is not uncommon for the latter to develop DKA under moderately severe physiologic stressors.

In the known diabetic, the diagnosis of DKA is relatively straightforward. Patients complain of polydipsia and polyuria (if not dehydrated), diffuse nonfocal abdominal pain often associated with vomiting, and generalized malaise, in addition to any focal complaints related to a precipitating trigger.

Physical findings in DKA are related to dehydration and the concomitant acidosis. Patients appear dehydrated, tachycardic, and hypotensive. Respiratory compensation for the acidosis is noted in the deep Kussmaul respirations and should not be misinterpreted as hyperventilation, even when associated paresthesias are present. Acetoacetate is converted to acetone and is responsible for the classic breath odor of nail polish. The level of consciousness may range from alert to somnolent to comatose. In a child with DKA and a depressed level of consciousness, cerebral edema should be strongly considered.

Abdominal pain and vomiting often accompany DKA. Care should be taken to distinguish nonspecific abdominal pain or gastroenteritis from more serious intra-abdominal disorders such as acute appendicitis. Focal abdominal tenderness, failure of pain to resolve with fluid therapy, or associated fever suggest an underlying intra-abdominal process.

An elevated glucose in the presence of ketonemia/ketonuria and acidosis almost always indicates DKA. However, other rare conditions possess similar clinical characteristics. Any condition resulting in prolonged vomiting or excessive fasting can result in ketoacidosis, but the glucose is not elevated. In the adolescent patient without known diabetes, toxic ingestions of ethylene glycol, isopropyl alcohol, or salicylates should be considered.

CEREBRAL EDEMA

Cerebral edema is the most dreaded complication of pediatric DKA. Mortality rates have been reported from 40 to 90 percent and only 14 to 57 percent of children who develop the disorder are left neurologically normal.^{4,7} Cerebral edema more commonly develops in children younger than 5 years and is rare in persons older than 20 years.⁷ It is likely that all patients in severe DKA have some degree of subclinical cerebral edema,⁸ but the specific risk factors associated with overt, life-threatening cerebral edema are young age, severe hyperosmolality, hyponatremia, and severe acidosis.^{5,7} Failure of the serum sodium to rise commensurately with the fall in glucose during therapy may be an important contributor.⁹ Newer studies refute the belief that overaggressive fluid resuscitation per se is a significant risk factor.¹⁵ Nevertheless, caution and restraint is prudent, particularly in the extremely hyperosmolar patient (i.e., greater than 340 mOsm/L). Recently, it has been proposed that cerebral edema is caused not by rapid changes in osmolality but rather by cerebral ischemia induced by the combination of severe dehydration and hypocarbia.⁵

While rarely noted at presentation, cerebral edema typically manifests itself 6 to 12 h after the onset of therapy (Figure 128-1). Interestingly, many patients appear to be improving clinically and biochemically prior to deterioration from cerebral edema. Premonitory symptoms occur in as few as 50 percent of individuals and include severe headache, declining mental status, seizures, and papillary edema. Unfortunately, respiratory arrest may be the first sign of cerebral edema. Early aggressive intervention based on the clinical evaluation, often before confirmatory CT findings, is vital to prevent respiratory arrest, herniation, and death.^{7,10} Once respiratory arrest has occurred, meaningful recovery is unlikely to occur.⁷

Standard treatment for cerebral edema is mannitol (1mg/kg intravenous bolus) and definitive airway management if necessary. Fluid administration should be kept to the minimum possible to retain a functioning intravenous catheter. Alternately, a "heparin lock" alone can be placed in the established catheter allowing immediate intravenous access for administration of medications and other therapeutic interventions as they become necessary. If the patient appears more clinically stable and is still in the ED, half of normal maintenance fluids can be given until the child reaches the pediatric intensive care unit (Table 128-1). Hyperventilation reduces cerebral blood flow and may worsen cerebral ischemia. Dexamethasone is likewise ineffective. In the patient with clinically apparent cerebral edema that is not well supported by CT findings, consideration should be given to cerebral venous sinus thrombosis, a finding often missed on plain noncontrast head CT, and which requires contrast CT or MRJ.

INITIAL LABORATORY EVALUATION

Routine blood studies should include a complete blood count (CBC); serum glucose; electrolyte panel including calcium and phosphate; venous blood gas (VBG), serum phosphate, and urinalysis (Table 128-2). Hyperglycemia, metabolic acidosis, and ketones on urinalysis confirm the diagnosis of DKA. Other laboratory studies, such as serum ketones, blood cultures, hepatic enzymes, magnesium, serum osmolality, and lipase are at the clinician's discretion. A venous blood gas (VBG) should replace the arterial sample for assessing the degree of acidosis and hypocarbia, avoiding an additional painful procedure (or procedures). The pH from a VBG is only 0.03 less than that from an arterial blood gas (ABG) and is an accurate reflection of the acid-base status.¹¹

Care should be taken in interpreting laboratory results as several factitious abnormalities may be seen in DKA. An increased white blood count is often seen in DKA and should be interpreted in context with physical findings and diagnostic studies for infection. Elevated salivary amylase in DKA confounds the diagnosis of pancreatitis and lipase is a more accurate test. Depending upon the type of laboratory analysis for creatinine, serum ketones may result in a factitious elevation in the serum creatinine.

The serum glucose is usually above 350 mg/dL, but a glucose less than 300 mg/dL is still consistent with DKA. Euglycemic DKA may occur in the young, well-hydrated diabetic who is compliant with the insulin regimen, but has relative insulin deficiency caused by an intercurrent illness. However, even in the absence of hyperglycemia, insulin is needed.

Change in the serum potassium is the most critical electrolyte disturbance in DKA. Potassium depletion may be both profound and not reflected in initial laboratory values. The average potassium deficit is 3 to 5 mEq/kg (150 to 250 mEq potassium deficit in a 50-kg adolescent) and the initial serum level is often normal or high. Potassium depletion is a result of insulin deficiency (which normally drives potassium into cells), acidemia (which causes the redistribution of potassium out of the cells in exchange for hydrogen), volume contraction, and tissue catabolism. These processes all provide increased potassium available for urinary excretion. Within this context, initial hypokalemia signifies a severe deficit and a potentially dangerous situation.

The bicarbonate concentration is invariably low. A high anion gap acidosis from the ketonemia is usually noted. In simple DKA, the bicarbonate should fall to the extent that the anion gap rises. A fall in the bicarbonate level *less* than expected for a given rise in the anion gap in the vomiting patient indicates the presence of an accompanying metabolic alkalosis. Conversely, a fall in the bicarbonate level *greater*

FIG. 128-1. Time between the initiation of therapy and neurologic deterioration in children with diabetic ketoacidosis and cerebral edema.

than expected for the rise in the anion indicates a concomitant nonanion gap acidosis. This is frequently seen in well-hydrated patients who are still able to excrete the ketoanions while retaining chloride or in severely dehydrated patients with accompanying lactic acidosis.

The serum osmolality is increased in DKA and its rise correlates with the decrease in the level of consciousness at presentation. Osmolality greater than 340 mOsm/L often results in a stuporous or comatose patient while a serum osmolality of less than 300 mOsm/L should prompt reconsideration of the cause of the decreased arousal. It is generally believed that the development of cerebral edema is correlated with the rate of decline in the serum osmolality, and it is critical that patients with high serum osmolality have their fluid deficits corrected less rapidly.

Sodium deficits average 5 to 10 mEq/kg, but the serum sodium may be normal because of excessive free water loss. More typically, it is factitiously low because of hyperglycemia and a corrected value may be arrived at by using the formula *corrected sodium* = $1.6 \times (\text{serum glucose} - 100)/100 + \text{measured serum sodium}$.

(3-Hydroxybutyrate (3-HB) is the major ketoacid produced. But unlike acetoacetate, it does not react with the nitroprusside used in urine and serum ketone assays, so measured ketone levels may appear low for the degree of acidosis and do not reflect the true extent of ketonemia. This fact also explains the paradoxical rise in measured ketones with therapy: 3-HB is converted to acetoacetate, which reacts more strongly with the assay. Using bedside ketone testing to monitor recovery is further complicated by the persistence of urine ketones after clearance of serum ketones.¹²

TREATMENT

Intensive monitoring and meticulous care of the DKA patient improves outcome, but management varies greatly between specialties. Emergency physicians more aggressively hydrate and bolus with insulin than do pediatric intensivists and endocrinologists, despite emerging data suggesting increased risk of complications.¹³

TABLE 128-2 Laboratory Evaluation in DKA

Attention should be directed toward three related but independently addressed problems: perfusion status, electrolyte disturbances, and hyperglycemia and ketonemia (Table 128-3). The initial focus should always be on volume status and vital signs. Next, electrolyte disturbances should be addressed and insulin therapy begun. Other problems such as associated infections should obviously be addressed concurrently.

Fluid Resuscitation

The immediate priority is to stabilize hemodynamics and begin volume resuscitation. The average fluid deficit is 10 percent of body weight, but is often greater. An initial 20 mL/kg bolus of NS should be given to the patient clearly in shock and repeated if needed. Once vital signs have stabilized, it is important to resist the desire to correct the fluid deficit too rapidly, especially if there is a high calculated osmolality (i.e., >340 mOsm/L). The fluid deficit should be corrected slowly as in other severe dehydration states, especially in the context of a high osmolar state. Traditionally, this has meant a 50 percent deficit replacement in the first 8 h with the rest over the next 16 to 24 h. However, many institutions are now even less aggressive, replacing the deficit evenly over 24 to 48 h. This moderated approach helps avoid overhydration, pulmonary complications, and possibly cerebral edema.

Electrolyte Replacement

SODIUM Sodium depletion from vomiting and urinary losses rarely causes a problem by itself and is most often related to the extent of dehydration. The main concern with sodium lies in its correction. It has been fairly convincingly demonstrated that the failure of serum sodium to rise in the treatment of DKA is associated with the development of cerebral edema. Typical protocols recommend 0.45 percent sodium chloride correction at 1.5 times maintenance for empiric replacement therapy, but in an attempt to decrease the risk of cerebral edema, some newer protocols have advocated sodium concentrations of 0.66 to 0.8 percent sodium chloride (e.g., 125 mEqNa⁺/L) and calculated fluid replacements to tighten control over biochemical parameters.^{1,10} This approach is effective in ensuring a steady rise in the sodium concentration.⁹

POTASSIUM Potassium should be withheld until hyperkalemia (i.e., potassium >6.0 mEq/L) is excluded and the patient is urinating. Because the electrocardiogram may be normal in the face of hyperkalemia it can be falsely reassuring, thus the serum potassium level must be monitored. Potassium deficits are often large, and both initial

TABLE 128-3 Management of DKA in Children

- 10-20 mL/kg NS bolus until hemodynamically stable*
- Then begin 0.45% NS at 1.5 times maintenance in the EDf
- If K⁺ is <5.5 mEq/L and patient is urinating, add 30 mEq potassium per liter (half as KCL and half as Kphosphate). If initial K⁺ is 2.5-3.5 mEq/L, add 40 mEq K⁺/L; consider adding more if the K⁺ is <2.5 mEq/L.
- Begin regular insulin at 0.1 units/kg per h after intravenous fluid bolus (if done) is complete. Adjust dose to maintain glucose decline at 50-100 mg/dL per h. Do not decrease insulin infusion to less than 0.05 units/kg per h.
- Add dextrose to intravenous fluids when BS is <200-250 mg/dL.
- Follow serum electrolytes every 2 h; follow serum glucose every hour.

*Bolus therapy is not done to correct dehydration but only to restore hemodynamic stability.

f Alternatively, one can calculate fluid deficit and correct 50% over the first 12-16 h. Some authorities recommend a higher calculated sodium concentration of between 0.45% and 0.9% NS.

Abbreviations: BS = blood sugar; K = potassium; KCL = potassium chloride; NS = normal saline.

rehydration and insulin therapy can cause a precipitous decline in potassium levels due to redistribution.

Initial hypokalemia (i.e., <3.0 mEq/L) indicates a profound deficit and therapy should be aggressive. The recommended rates of potassium replacement vary widely but in general, maintenance fluids should contain between 30 and 40 mEq K^+ /L. Consider higher doses for children with demonstrated hypokalemia. Serum potassium should be monitored at minimum every 2 h.

OTHER ELECTROLYTES Phosphate depletion is well described in DKA but the value of intravenous replacement has never been proven. Many authorities recommend half of the potassium replacement in the form of potassium phosphate. In the absence of replacement, one should monitor for symptomatic hypophosphatemia (serum phosphate <1 mmol/L, muscular weakness, rhabdomyolysis, respiratory depression). The same rule applies to magnesium replacement. Hypocalcemia, when present, is likely secondary to overaggressive phosphate replacement.

Hyperglycemia and Insulin Therapy

Fluid resuscitation will reduce serum glucose levels somewhat. After the patient is hemodynamically stable, a low-dose insulin infusion should be started. The goal of insulin therapy is to evenly reverse the ketonemia and acidosis. High dose insulin therapy does not improve the rate of recovery, but it does place the patient at greater risk of hypoglycemia and hypokalemia, and a loading bolus of 0.1 units/kg, once common, is no longer considered beneficial.

The insulin infusion dose is 0.1 units regular insulin/kg per h. As a rule of thumb, serum glucose should decrease approximately 50 to 100 mg/dL per h in a slow, controlled fashion to prevent intracerebral osmole shifts. If improvement of the pH is too slow (<0.03 pH units per h), the rate can be doubled.¹⁰ Generally, glucose corrects faster than the ketoacidosis and dextrose will need to be added to the intravenous fluids when the blood glucose dips below 250 mg/dL, with the goal of maintaining a serum glucose of 150 to 300 mg/dL until resolution of the ketoacidosis. The patient with euglycemic DKA will need the addition of glucose at the initiation of therapy. If the blood sugar continues to decline, additional glucose should be added before considering adjustment of the insulin drip. If the child is at the maximum glucose concentration available (or maximum tolerable concentration if peripheral access only), then the administration of insulin can be temporarily held for 10 to 15 min before restarting the insulin drip at a lower rate. In general, this should not be below 0.05 units/kg per h. The short half-life of intravenous insulin (5 to 10 min) along with the continued administration of glucose will correct transient hypoglycemia. Continued insulin administration is the mainstay of therapy and should be continued, allowing for reversal of the ketoacidosis. Serum potassium should be meticulously monitored, as insulin will begin driving potassium back into the cells.

The insulin infusion should not be transitioned to subcutaneous administration until a pH >7.30 and a bicarbonate >16 mEq/L has been reached and serum ketones have disappeared. At that point, subcutaneous insulin may be administered and the infusion stopped 30 to 60 min later.¹⁰

INSULIN PUMP Rarely, a child with an insulin pump will present in DKA. As the majority of cases of DKA are related to inadequate insulin delivery, this would imply a malfunctioning pump. Alternatively, the pump may be functioning correctly but the child is suffering from an intercurrent illness with increased and unmet insulin needs. Either way, the pump should be shut off and the child should be treated like any other insulin dependent diabetic in DKA.

Acidosis and Bicarbonate Therapy

The routine use of bicarbonate in the treatment of DKA is not recommended because it has never been shown to improve outcome, and it has been associated with a fourfold increase in the development of cerebral

edema.⁵ In addition, the use of bicarbonate therapy can lead to volume overload, accelerated hypokalemia, hypernatremia, and paradoxical central nervous system acidosis.¹⁴ Bicarbonate administration should be limited to critically ill patients with a pH <7.0 and hemodynamic compromise (unresponsive to fluid resuscitation) from depressed cardiac contractility and poor perfusion. If necessary, depending on the pH and the patient's clinical condition, bicarbonate may be administered slowly at 0.5 to 2.0 mEq/kg over 1 to 2 h. Correction should never exceed a pH of 7.1 or a serum bicarbonate of 10 mEq/L.

Disposition of Children in DKA

Most patients in DKA require admission to the intensive care unit, even when stable, because of intensive monitoring needs. Furthermore, many hospitals restrict the use of insulin infusions to intensive care settings. Known diabetics with a pH above 7.35 and a bicarbonate above 20 mEq/L with a known and resolving precipitant for DKA, a good clinical appearance, a solid social situation, and close follow-up with their primary physician may be discharged home.¹⁵ As many as 69 percent of patients with a starting pH >7.20 or a serum bicarbonate greater than 10 mEq/L will correct their acidosis within 6 h.⁶

HYPERGLYCEMIA WITHOUT KETOACIDOSIS

New-Onset Hyperglycemia

Many children with new-onset diabetes present with classic symptoms of diabetes such as polydipsia, polyuria, and malaise, and they are identified before significant ketoacidosis develops. They are frequently sent from the outpatient physician's office for management and admission. ED management is less intensive and should be done in coordination with the child's endocrinologist. In general, children with hyperglycemia but no DKA are only mildly dehydrated, may or may not have urinary ketones, and the serum pH is over 7.3. The speed at which such children will descend toward actual DKA is largely a function of hydration status and age. Infants and very young children will progress more rapidly because of their inability to independently access fluids and their increased metabolic rate. With appropriate attention paid to hydration status and timely insulin administration, DKA is very unlikely to develop in the hospital in the absence of serious underlying illness.

ED management should be restricted to drawing baseline laboratory studies, providing fluids PO or IV depending on the need, and possibly administering the first dose of insulin. An acceptable initial dose is 0.1 units/kg of subcutaneous regular insulin. Whether or not new-onset diabetic children are particularly sensitive to insulin is a matter of debate. Still, serum glucose should be monitored closely, every hour after insulin is administered. Children should be admitted in order to provide education about their disease and to establish their daily insulin requirements. The latter are generally in the range of 0.5 to 1.0 units/kg per day in divided doses: two-thirds in the morning and one-third in the evening.

Known Diabetics with Hyperglycemia

For the known diabetic who presents with hyperglycemia with or without an intercurrent illness or injury, management should focus on the primary reason for the ED visit. An additional dose of 10 percent of the child's normal daily insulin dose can be administered as subcutaneous regular insulin for simple hyperglycemia.

If the child has an intercurrent illness, more specific management guidelines may vary between endocrinologists and also depend on whether or not urinary ketones are present. An acceptable approach if the child has an intercurrent illness and no urinary ketones is to administer an additional 5 percent of the daily insulin dose every 4 to 6 h until the condition resolves. If the child has urinary ketones, one should administer 10 percent of the daily dose every 4 to 6 h until the ketonuria resolves, and then decrease to 5 percent, as noted above.

Glargine Insulin (Lantus)

Occasionally, a child will present with hyperglycemia without DKA after missing one or more doses of insulin glargine. Glargine is a long-lasting once-daily insulin preparation that has no peak effect. Generally, glargine is given at approximately 50 percent of the daily insulin requirement, the rest as a short-acting preparation, so that missing a single dose of glargine is not equivalent to missing all insulin doses for the day.

If the child is off schedule for insulin glargine and does not have DKA, a single injection of neutral protamine Hagedorn (NPH) insulin can be given, followed by resumption of the regular dosing schedule.

If the child is off schedule for insulin glargine and is in DKA, treatment is no different from treating DKA as described above.

HYPOGLYCEMIA

Randolph Cordle

Emergency physicians must recognize the sometimes subtle and other times stunning effects that hypoglycemia can cause, because prompt diagnosis and treatment may spare an otherwise normal child severe brain damage or even death. This is especially true in the first year of life when the diagnosis is difficult to make based on clinical findings alone (Table 129-1).

DEMOGRAPHICS

Most agree that a blood glucose lower than 40 mg/dL is abnormal at any age. Normally the whole blood concentration of glucose is 10 to

15 percent less than that found in the serum or plasma. This is due to dilution effects caused by the red blood cells in whole blood that contain little glucose. Therefore, acceptable serum or plasma glucose levels would be greater than 45 mg/dL. Values slightly above this level may still be a concern in symptomatic patients.

Pediatric hypoglycemia is relatively rare with a reported prevalence of only 6.54 in 100,000 children presenting to a pediatric ED.¹ Of these, 58 percent had a diagnosis of idiopathic ketotic hypoglycemia (IKH), and 10 percent were found to have insulin-dependent diabetes mellitus.

PATHOPHYSIOLOGY

Normally a highly sophisticated regulatory system maintains glucose concentrations within a very narrow range. This is a steady-state system, not an equilibrium, so the rate of production does not equal the rate of use at any given moment. Relative to body weight, glucose production and use are much higher in children than in adults. This difference is due to children's higher basal metabolic rate, use of glucose for growth and development, and greater activity.

All tissues can use glucose for energy metabolism. Tissues such as the heart, other muscles, and the kidneys can use other substrates quite efficiently; however, the brain, red blood cells, lymphocytes, and platelets are nearly totally dependent on glucose for their metabolism. In the fasted adult model, up to 80 percent of the glucose produced by glycogenolysis and gluconeogenesis is used for brain metabolism.² Nearly all the rest is used by the formed elements of blood. An adequate quantity of glucose for the brain's metabolism depends on its degree of use and the plasma glucose level.

The brain is a proportionately much larger organ in children than in adults. More than 80 percent of the fasted child's glucose use occurs by the brain. In fact, glucose use correlates better with brain weight than with body weight. In the postabsorptive state, the glucose requirement of small children is up to two and half times that of the adult, or about 5 to 7 mg/kg per min. After fasting, this requirement drops to 4 mg/kg per min, a value still much higher than that in the fasted adult. In children younger than 2 years, during the fasting state, nearly all the endogenously produced glucose is required and used by the brain. When inadequate quantities of glucose are available, development and growth stop, so that all sources of endogenous energy can be used strictly for the maintenance of brain metabolism.

During periods of inadequate glucose supply to the brain, alternative sources of energy such as ketones and Krebs cycle intermediates will be used. In adults, up to two-thirds of the brain's energy requirements, for short periods, can be supplied with these substances. However, ketones are not immediately available when acute changes in blood glucose occur, because their production occurs slowly over hours. Neonates and children with free fatty acid abnormalities, carnitine deficiency, and ketone-production-limiting hyperinsulinemias are at particular risk for devastating neuroglycopenia, because they lack the ability to effectively produce or use ketones as an alternative energy source.

Carrier-mediated transport is responsible, not only for shuttling glucose through the blood-brain barrier but also for moving it from the cerebrospinal fluid (CSF) into the extracellular space, where it can be used by the individual cells of the brain. A limiting factor in the movement of glucose from the plasma to the brain is the turnover rate of this carrier system. When the plasma glucose concentration and brain glucose use are normal, this carrier-mediated system maintains a three-fold surplus of glucose in the brain. This buffer allows for normal fluctuations of plasma glucose over time. The CSF glucose concentration is maintained at about 65 percent of that found in the blood, whereas that of the brain's extracellular fluid is maintained at about one-third the CSF glucose concentration. In general, CSF and brain extracellular glucose concentrations remain nearly constant. When the plasma glucose level drops to about 30 mg/dL, the supply to the brain cells becomes dangerously low. If not rapidly corrected, the extracellular glucose concentration may approach zero and neuronal metabolism will fail. Fortunately, acute changes in the plasma glucose concentration do not immediately affect that of the CSF and brain. Changes here lag behind those in the plasma by a few hours. As the plasma glucose concentration decreases, systemic changes occur, usually leading to a re-

supply of exogenously or endogenously produced glucose. If not, neuroglycopenia will occur. Peak CSF glucose levels do not occur until 2 h after intravenous dextrose is given. Equilibrium of glucose across the CSF, brain extracellular space, and plasma is typically not achieved for about 4 h. Assuming ongoing carbohydrate provision, plasma equilibrium occurs more quickly. Hence, when neuroglycopenic patients are given exogenous glucose, it often takes a few hours for their mental status to return to normal.

Although alternative fuel sources may temporarily maintain cerebral metabolism, the rapid return to glucose use is necessary for multiple reasons. Glucose is necessary for brain growth and development, the production of membrane lipids and structural proteins, and myelination. Prolonged or repetitive hypoglycemia may cause seizures, permanent neurologic deficits, mental retardation, or death.

Intermediary Metabolism

An elevated glucose concentration causes the release of insulin and suppression of glucagon and glucocorticoid secretion. The elevated insulin level also leads to the suppression of ketogenesis, gluconeogenesis, lipolysis, and glycogenolysis. Simultaneously, it induces glycogen production in the liver and muscle from glucose, protein production from amino acids, and fat production from lipids. Fats are also produced from endogenous lipids formed from surplus amino acids and glucose in the liver. Standard texts in endocrinology and metabolism should be reviewed for a complete discussion of intermediate metabolism. A brief discussion is provided in this chapter.

Glycogenolysis, Ketogenesis, and Gluconeogenesis

In the early fasting state, the remaining free glucose is used rapidly for energy. Thereafter, insulin levels drop as glucagon and epinephrine levels increase, thereby inducing glycogenolysis. Assuming that normal glycogen stores are present, children may be able to maintain a normal plasma glucose concentration for 4 to 6 h, only half the time seen in adults. This occurs because children produce and use more glucose per kilogram of body weight than adults, and they have smaller glycogen stores.

In the late fasting state, children become dependent on gluconeogenesis and ketogenesis. Low levels of insulin and elevated levels of growth hormone, cortisol, epinephrine, and glucagon stimulate lipolysis to provide glycerol for gluconeogenesis and free fatty acids for ketogenesis.

Gluconeogenesis is an energy consumptive reversal of glycolysis. It provides a mechanism for the production of glycogen in most organs of the body and glucose in the liver from pyruvate. During times of starvation, the majority of glucose formed in the liver enters the blood stream to meet the energy demands of glucose-dependent tissues of the blood, renal medulla, testes, and brain. In general, amino acids from skeletal muscle make up the substrates of gluconeogenesis. These substrates lose their ammonia group and donate their carbon backbone to the production of pyruvate. Eighteen of our 20 amino acids can be used as carbon donors in this process, although alanine plays a leading role due to its predominance in skeletal muscle. A quantitative deficiency in the mobilization of these precursors is thought to be the cause of IKH.

Alcohol leads to hypoglycemia by blocking gluconeogenesis in two important ways. Ethanol metabolism by alcohol dehydrogenase consumes oxidized nicotinamide adenine dinucleotide and produces reduced nicotinamide adenine dinucleotide and hydrogen ions. Elevated levels of reduced nicotinamide adenine dinucleotide push the pyruvate \rightarrow lactate and oxaloacetate \rightarrow malate reactions toward the consumption of pyruvate and oxaloacetate, thus depriving gluconeogenesis of two very important substrates.

Ketogenesis may play a vital role in providing glucose to the brain during the fasted state. By providing for the energy needs of the heart,

kidneys, muscles, and other tissues, ketogenesis allows a higher percentage of endogenously produced glucose to be used by the brain.

Triglyceride metabolism is another source of ketones, but ketone production depends on the presence of fatty acetyl coenzyme A (CoA) and carnitine in hepatocytes. Therefore, defects in fatty acetyl-CoA or in carnitine cause non-ketotic hypoglycemia and the accumulation of abnormal fatty acid metabolites in the liver. Clinical examples of such non-ketotic hypoglycemic disorders include carnitine deficiency and Jamaican vomiting illness. In the past, treatment for non-ketotic hypoglycemic disorders included frequent feedings to prevent development of the fasting state. Carnitine deficiency may be treated by adding carnitine to the diet. Jamaican vomiting illness is caused by the toxin hy-poglycin, found in the unripe akee fruit. Hypoglycin metabolites lead to esterification of carnitine and coenzyme A, preventing ketone production. Hypoglycin also suppresses gluconeogenesis.

Counter-regulatory chemicals also play a role in this system. When the glucose concentration approaches 70 mg/dL, glucagon and epinephrine levels begin to rise. By the time the glucose level reaches 55 mg/dL, an intense counter-regulatory chemical response is apparent. In children with insulin-dependent diabetes or chronic hyperinsulinemia, the epinephrine response may be blunted and may not occur until the glucose concentration is about 35 mg/dL. Under conditions of even normal glucose use, there may not be time for endogenous mechanisms to prevent severe hypoglycemia. P-Blockers often blunt the counter-regulatory catecholamine response to hypoglycemia, resulting in hypoglycemia without the classic catecholamine-induced clinical signs and symptoms. Instead, patients may develop predominantly neuroglycopenic symptoms and signs, such as seizure, "stroke," or coma. The release of glucagon is normally stimulated by hypoglycemia and elevated levels of growth hormone, epinephrine, and cortisol. However, calcium-channel blockers, P-antagonists, and anti-cholinergic drugs suppress its release. Therefore, these drugs may predispose individuals to hypoglycemia (Table 129-2).

CLINICAL FEATURES

Classically, hypoglycemic patients present with neuroglycopenic or excessive adrenergic signs and symptoms (Table 129-3). In general, the more rapid the decrease in glucose concentration, the more adrenergic-type symptoms will be noted. Variability and crossover in symptoms is the rule, however, and not the exception. Neonates and young children may present with poor feeding, jitteriness, emesis, ravenous hunger, lethargy, altered personality, repetitive colic-like symptoms, hypotonia, or hypothermia. In other cases, they unfortunately present after an apparent life-threatening event, seizure, or cardiac arrest. As children grow older, they begin to present more like adults, with signs of adrenergic excess followed by neuroglycopenia. If treatment is not forthcoming, the adrenergic symptoms may abate, leaving only the neuroglycopenic ones. In some cases, as with type I glycogen storage disease, patients may have no obvious symptoms despite an incredibly low blood glucose concentration. Children with unexplained catastrophic presentations such as coma, severe hypothermia, and car-diorespiratory arrest should have bedside glucose testing performed immediately, and, if clinically indicated, a specimen should be sent for

formal laboratory evaluation. Empirically treating patients after cardiac arrest with glucose may worsen neurologic outcomes, because hy-perglycemia is detrimental in cases of cerebral edema and anoxia. Therefore, whenever possible, bedside testing and historical data surrounding the event should guide therapy in this population. Hypoglycemia should be suspected in all moderately to severely injured or ill children. The underlying disease process often will mask the symptoms of hypoglycemia. Children with increased physiologic stress require periodic reevaluation for hypoglycemia, because they are often unable to maintain sufficient glucose influx to meet their increased needs. This is especially true in patients whose illness, injury, or treatment prevents them from being able to express their needs.

Idiopathic Ketotic Hypoglycemia

The most common cause of hypoglycemia in non-insulin-dependent children older than 1 year is IKH. It is more a physiologic aberration than a true pathologic syndrome.^{1,3} It usually presents in children younger than 18 months after a period of fasting. Often this is seen on holidays and weekends, when parents sleep late, thereby inadvertently extending the child's usual nighttime fasting period. It is also more common during illnesses preventing normal food intake. These children return to normal after a glucose load and have no suspicious findings in their history or physical examinations.' Historically, IKH was thought to occur because affected children were small for their age, but that idea has been called into question by more recent findings.^{1,3} Currently, alanine, by far the most important amino acid in gluconeogenesis, is thought to play a major role in this disorder.^{2,4} Haymond and colleagues found lower serum alanine concentrations in these patients than in age-matched control groups during fasting.³ Giving gluconeogenic precursors during periods of fasting prevents hypoglycemia, lending further support to the theory outlined above. Children with IKH present with expected ketonemia and ketonuria. If not tested for early, the ketones may be missed, because they dissipate rapidly with correction of the hypoglycemia. If assayed, insulin normally will be suppressed to no more than 5 to 10 n units/mL, and cortisol and growth hormone normally will be elevated during the hypoglycemic period. Abnormally elevated insulin levels should call the diagnosis into question.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of hypoglycemia differs in different age groups. Some disorders are seen only transiently in neonates, whereas others may start in the neonatal period but extend throughout childhood. Still others are not usually seen until after the neonatal period. For example, some inborn errors of metabolism always present in early infancy, whereas others may not be clinically apparent until the

child is a few years old. Table 129-1 lists some causes of hypoglycemia in childhood. A full discussion of each cause is beyond the scope of this chapter. Suspicion of many of these disorders should prompt a discussion with and referral to an expert in metabolic diseases.

Many drugs (see Table 129-2) may predispose children to hypoglycemia. Some have more supporting evidence and occur more frequently than others. Aside from insulin and possibly sulfonylurea-type medications, ethanol is by far the most common cause of drug-induced hypoglycemia in children. Ethanol inhibits gluconeogenesis. Hypoglycemia after the ingestion of alcohol may occur in adults but is far more likely in children, because of their higher relative glucose use and much lower relative quantities of glycogen. Children become more quickly dependent on gluconeogenesis than do adults. This effect on liver metabolism is often seen at alcohol levels too low to cause clinical intoxication. Therefore, any child with a history of alcohol ingestion should be closely monitored for hypoglycemia and given glucose orally or parenterally. In nonintoxicated patients, this may be accomplished by feeding. Intoxicated-appearing patients should always be evaluated for hypoglycemia at presentation and every few hours thereafter, if they are unable to eat. In young children who will not be able to eat for more than 4 h, maintenance fluids containing dextrose should be given.

Rapid bedside glucometers have evolved over the years. Qualitative reagent strips, based on nonspecific reduction reactions or enzymatic reactions, were replaced by more quantitative systems. Spectrophotometers used to read subtle enzymatic induced color-indicator changes proportional to the concentration of a more specific substrate, glucose, then took over the market. These systems are still in use but require more expertise and training to avoid user error. Therefore, in most institutions, they have been replaced by more user-friendly and possibly more precise amperometric systems. Enzymatic reactions with glucose lead to loss of electrons that are quantified and correlated with a priori set normal parameters to give a glucose concentration. These systems are calibrated for use on whole blood only. Their algorithms calculate results based on relatively normal whole-blood constituent concentrations. For example, patients who have very high hematocrits may have erroneously low results. Conversely, low hematocrits may produce spuriously high results. Spuriously low results also may be found in capillary samples from patients in shock or with decreased peripheral perfusion. False low results also may be found in patients with hyperglycemic and hyperosmolar conditions or severe dehydration. The correlation between one popular (Precision PCX) monitor using electrochemical detection and laboratory instrumentation was better in adults than in neonates (correlation coefficient, 0.984 vs. 0.889). The definitive diagnosis and workup should be based on the chemical analysis and not just on the bedside screening in all age groups, especially neonates. In symptomatic patients, treatment should begin based on the bedside test result. Treatment can be altered, if necessary, upon return of the chemical analysis.

EVALUATION

Evaluation is quite complex in some cases and controversial in others. In all cases, a detailed history should be obtained and a meticulous physical examination should be performed. Inquiry regarding prior episodes of hypoglycemia should occur. Detailed data regarding family, birth, development, and past medical history are needed. History of childhood death from an unknown cause in a first- or second-degree relative should be sought. Potential access to insulin, sulfonylureas, 3-blockers, salicylates, or other toxins should be determined. Physical examination should include a head-to-toe survey for signs of other serious illness and findings more specifically related to hypoglycemia. Hypopituitarism may be associated with midline defects such as abnormal incisors, palatal defects, cleft-lip defects, midface abnormalities, or abnormal palpebral fissures. Hyperpigmentation, undescended testes, severe dehydration, and micropenis may be associated with ab-

normalities arising from the adrenal or pituitary glands. Children with short stature or less than expected recent growth should be evaluated for growth hormone abnormalities.¹³ Height, weight, and head circumference should be plotted on a standardized growth chart. Tanner stage should be determined. The fundi should be evaluated for signs of optic nerve hypoplasia associated with hypopituitarism. Each patient should have a thorough examination of the abdomen. Large masses such as those from neuroblastoma and, more importantly, hepatomegaly associated with most hypoglycemia causing glycogen storage, fatty acid oxidation, and other metabolic abnormalities should be sought.

The goal is to diagnose hypoglycemia and any other clinically important associated disease processes. Physicians should then institute appropriate therapy. Concurrently, they must differentiate between ketotic and nonketotic hypoglycemia and, based on this information, make decisions regarding the potential need for further studies. In questionable cases, it is practical to collect an extra set of blood tubes and an additional urine specimen for later use, if deemed necessary. Many study results are valuable only if they are based on samples obtained when the child is hypoglycemic. This being said, children should not be allowed to remain hypoglycemic for any significant period before treatment. Overzealous or time-consuming attempts at laboratory collection should be avoided.

Prehospital protocols for hypoglycemic children should include the collection of appropriate blood specimens before treatment whenever possible. Prehospital laboratory specimens should not be discarded except at the discretion of the consultant or admitting physician. They should be placed on ice to prevent ongoing metabolism.

Most children who present to the ED, however, probably do not need extensive laboratory evaluation. Infants and especially neonates should be evaluated thoroughly on first presentation unless the cause of hypoglycemia is clear. Developmentally normal children older than 1 year who have normal head circumference and growth, make a complete recovery after receiving glucose, have normal electrolytes, and present with findings consistent with IKH do not usually need a detailed investigation. Patients with hepatomegaly, other signs of illness, significant acidemia, hyperpigmentation, or other clinically significant physical findings require a complete evaluation at presentation. In patients for whom a full workup is deferred, appropriate tubes of blood and a urine specimen may be collected and held by the laboratory. Close follow-up should be arranged, and the patient's primary care physician should be made aware of the child's visit and findings. Should hypoglycemia recur or the child's clinical situation change, the held specimens may be extremely valuable. See Figure 129-1 for a general approach to the laboratory evaluation of these patients. Variance from this approach is not only acceptable but expected based on the specifics of the individual clinical situation.

SPECIAL ISSUES AFFECTING DIAGNOSIS

Mentally challenged children can be especially difficult to evaluate. Often they have dysautonomia and feeding difficulties. A low threshold for blood glucose evaluation is appropriate in these patients, especially if the caretakers note a change in baseline behavior or mental status.

Most children who present with self-harming thoughts, suicidal threats, or true suicide attempts should have their glucose checked as part of their medical clearance. This is especially true of diabetic children and those with access to a relative's oral hypoglycemic agents. Inpatient monitoring of glucose may be necessary if overdose of an oral hypoglycemic agent is suspected. Management of such overdoses is often complex and is beyond the scope of this chapter.

In patients thought to have a factitiously depressed glucose associated with an elevated insulin level, the C-peptide level should be determined. If exogenous insulin is the cause, the C-peptide level will be inappropriately suppressed, and typically the insulin level in these

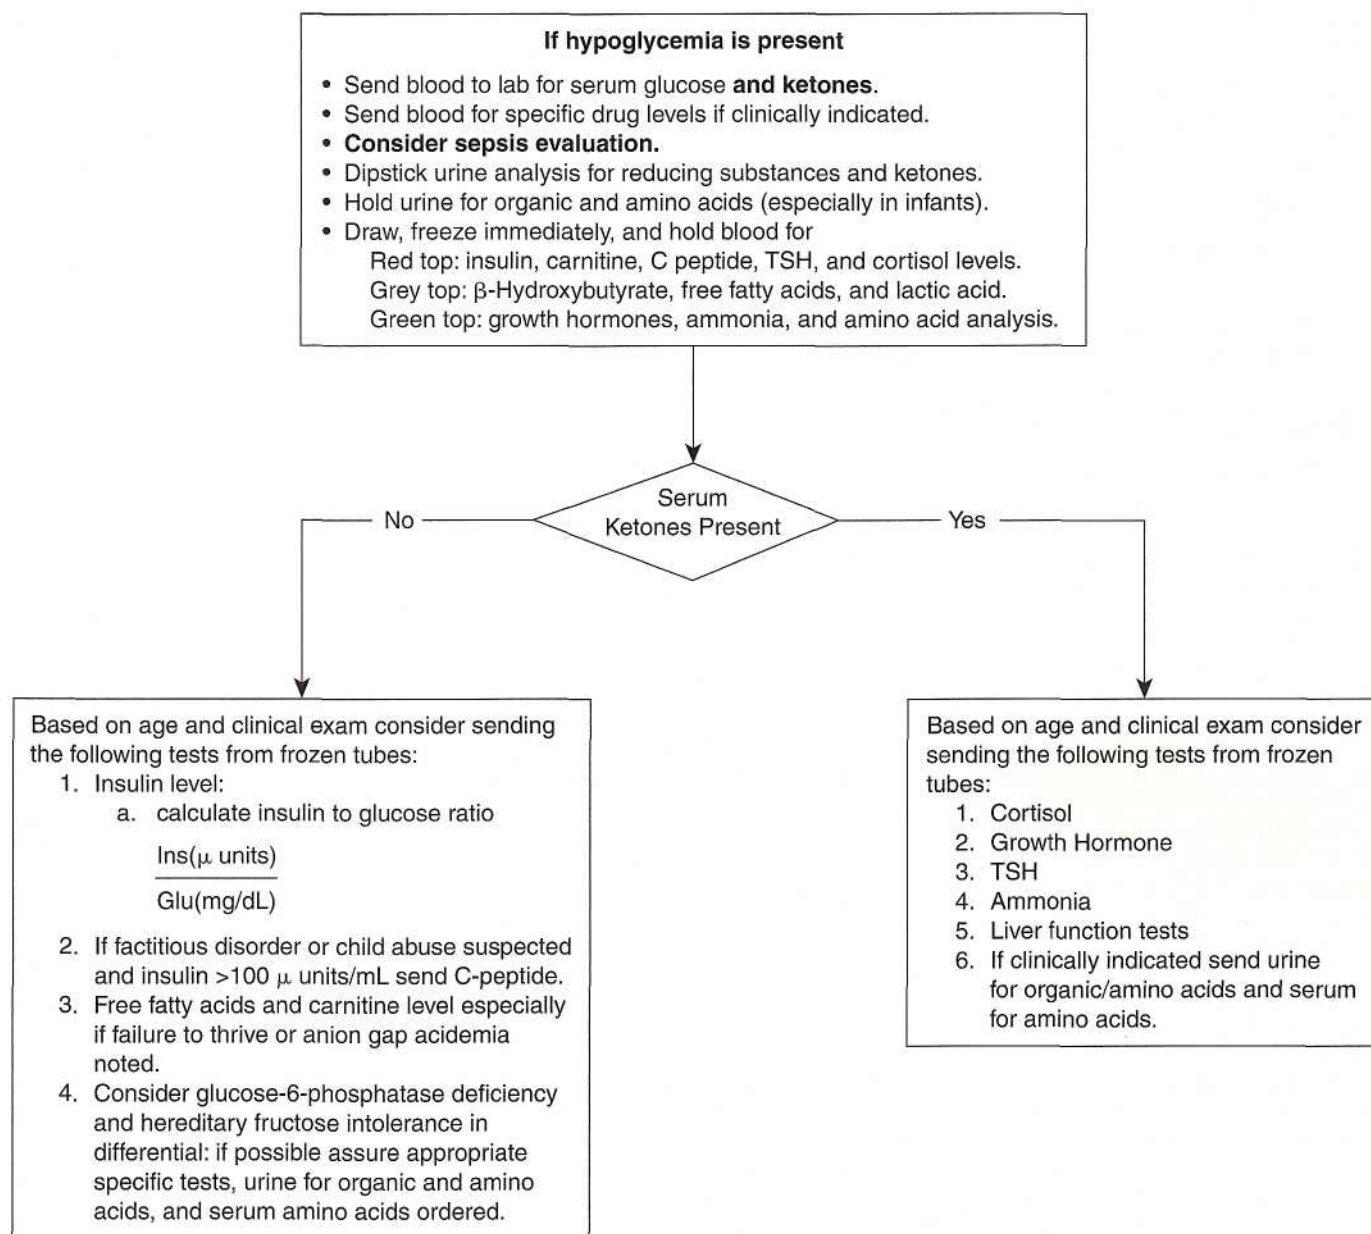

FIG. 129-1. General approach to the laboratory evaluation of hypoglycemia. TSH = thyroid-stimulating hormone.

cases will be very high. Normally C-peptide is produced in equimolar quantities during the processing of proinsulin to insulin; therefore, its levels should follow those of insulin itself. In cases of insulinoma, for example, insulin and C-peptide levels will be high.^{5,6}

Patients found to have hypoglycemia and non-glucose-reducing substances in their urine should have galactosemia ruled out. The dipstick urine test will be negative for glucose, but the laboratory evaluation for reducing substances will be positive in this case. This disease usually presents during infancy with failure to thrive, vomiting, hepatomegaly, and jaundice.

TREATMENT

Whenever possible, if the clinical condition allows, children should be treated with oral glucose loading. Clearly this should not occur in children unable to protect their airway. Common methods include orange juice with 2 tsp of sugar added per glass, maple syrup, honey (in older children), and, in mild cases, non-diet soda. Sucrose and fructose should not be given to any child suspected of having hereditary fruc-

tose intolerance. Lactose should not be given to children suspected of having galactosemia.

Once the glucose concentration is back to the normal range, children should be given a meal containing complex carbohydrates, proteins, and fats, with the presumption that inborn errors of metabolism have been ruled out. Children thought to have an inborn error should have consultation with a metabolic disease expert before feeding a normal diet to potentially prevent the additional buildup of substrate, due to an enzymatic defect and/or abnormally produced products of metabolism. Dextrose should be given until clarification of these issues is obtained through further testing and/or consultation.

When oral treatment is not an option, the intravenous route should be used (Table 129-4). If an intravenous line cannot be obtained, an intraosseous line should be considered. Glucose given through a nasogastric tube also can be lifesaving.

Intravenous boluses of 0.5 g/kg are most commonly used. This is equivalent to 5 mL/kg D10W, 2 mL/kg D25W, or 1 mL/kg D50W. If no clinical response is seen within 5 min, this dosing should be repeated and a bedside glucose checked. If the glucose remains below

TABLE 129-4 Treatment of Hypoglycemia

Oral (preferred); consider NG tube if IV access is poor in child unable to swallow

fD25 = 250 mg dextrose/mL NaCl.

JSee text. Abbreviation: NG = nasogastric.

50 mg/dL and three boluses have been given, the clinician should consider using one of the alternative agents listed below. The proper choice should be based on the clinical and historical findings.

Boluses in neonates should be given with D10W. Infants should receive D10W whenever possible, although D25W is acceptable. In older children, D25W may be used. D25W and especially D50W are very hyperosmolar and may cause phlebitis or tissue necrosis, if they extravasate. Even without extravasation, patients commonly complain of pain at the injection site for 1 to 2 weeks. The risk of extravasation is increased when smaller veins, such as those found in infants, are used. In addition, hyperosmolar loading in premature neonates is associated with an increased risk of intracranial germinal matrix hemorrhage and subsequent periventricular leukomalacia. The use of D25W and D50W also may lead to an increased incidence of rebound hypoglycemia due to endogenous insulin release. When time allows, diluting 50 or 25 to D10W with NS or half NS will decrease the risk of pain, phlebitis, and necrosis at the injection site by decreasing the osmolarity. This practice also prevents the administration of large volumes of free water when multiple boluses are required, as would occur if sterile water were used as the diluent. Because many of these patients are also dehydrated, this amount of electrolyte-containing solution is certainly not excessive and probably somewhat therapeutic.

Once the patient's glucose is brought into the normal range, maintenance fluids should be started. The amount of glucose required for maintenance of euglycemia varies with age, underlying glucose use, and the patient's insulin level. Neonates typically require D10 whereas older infants and children usually only require D5 in their maintenance fluids. Nonelectrolyte-containing dextrose solutions should never be used for multiple boluses or maintenance fluids. This practice can cause water intoxication, hyponatremia, intractable seizures, and death. Typically, DIONS or D10/45NS (77 mEq/L Na⁺) will be appropriate. Changes can be made once the serum sodium is known.

Likewise, potassium may be added once urine output is established and the current serum concentration is known. Knowing the current serum potassium concentration before adding it to maintenance fluids is especially important in patients with potential mineralocorticoid deficiency, such as those with 21-hydroxylase deficiency.

Patients who are hyperinsulinemic often require dextrose maintenance rates of 10 to 12 mg/kg per min. In some cases, 25 mg/kg dextrose per min will be needed. The clinician will need to use more con-

centrated dextrose-containing electrolyte solutions in these cases. A central line should be considered if greater than D12.5 containing maintenance fluid is required.

Glucagon is an effective treatment for hypoglycemia only if the patient has intact glycogen stores.³ Its use should be considered, especially in the prehospital arena, when an intravenous line cannot be placed. Controversy surrounds the use of glucagon in cases of sulfonyleurea overdose and hyperinsulinemia. Glucagon stimulates insulin release; therefore, at least theoretically, giving it to these patients could worsen hypoglycemia. Typical glucagon dosing is 1 mg in adults, 30 |xg/kg in children, and 50 f^g/kg in infants. The maximum single dose is 1 mg for hypoglycemia, although higher doses are used for other indications. It may be given SC, IM, or IV. If no intravenous line is available, the intramuscular route is probably best. One exception is in small neonates who may not have adequate muscle mass. The new recombinant form of glucagon is packaged with a diluent containing glycerin, sterile water, and hydrochloric acid. In contrast to the phenol-containing diluent found in older forms of glucagon, the recombinant glucagon diluent may be used in all age groups. If a 50 percent rise in serum glucose concentration is not seen within 30 min, the clinician should suspect previous depletion of glycogen stores, an abnormality in fatty acid oxidation, or type I glycogen storage disease. Less commonly, glycogen storage disease types III, VI, and IX can present in this fashion.

In refractory cases, especially those associated with adrenal insufficiency, steroids may be useful. Hydrocortisone succinate is a good choice owing to its effective glucocorticoid and additional mineralocorticoid effects. Most adrenally suppressed patients also will have associated mineralocorticoid depression. In these cases, a steroid such as hydrocortisone must be used instead of one such as dexamethasone, which has almost no mineralocorticoid activity. The dose of hydrocortisone succinate is 1 to 2 mg/kg IV every 6 h. The minimum dose is 25 mg and the maximum dose is 100 mg.

Hyperinsulinemic patients also may be given diazoxide to inhibit insulin release and activity.⁴ Octreotide may be a better choice; it is not associated with the rare hypotensive effects of diazoxide. Octreotide dosing for this potential indication is controversial. Diazoxide is given IV at 3 to 5 mg/kg for neonates and 1 to 3 mg/kg for children every 8 h. Diazoxide should be given over at least 30 min to prevent severe hypotension. In children who are able to eat, feedings every 3 to 4 h often will suffice. If given only simple carbohydrates, hyperinsulinemic children will develop postprandial hyperglycemia with subsequent rebound hypoglycemia secondary to stimulation of insulin secretion. Therefore, their diets should consist of complex carbohydrates, proteins, and fats. Raw cornstarch feedings at night usually maintain safe glucose levels and are not typically associated with the rebound phenomenon discussed above. Starches are absorbed slowly, leading to a lower but more continuous supply of glucose.⁷ Children with endogenous hyperinsulinemia due to insulinomas often require nearly total pancreatectomy.

Idiopathic ketotic hypoglycemia is best treated by prevention. Prevention efforts should include avoidance of prolonged fasts, provision of frequent high-carbohydrate and high-protein meals, and monitoring for urine ketones during periods of decreased oral intake, such as illness.^{3,7} If ketones are detected, the patient should be given additional carbohydrate- and protein-containing foods and/or be brought to medical attention at once.

ALTERED MENTAL STATUS AND HEADACHE IN CHILDREN Nancy Pook Natalie Cullen Jonathan I. Singer

ALTERED MENTAL STATUS

Altered mental status (AMS) in a child is the failure to respond to the external environment in a manner appropriate to the child's developmental level, despite verbal or physical stimulation.¹ Alteration in mental status consists of impairment of awareness and arousal, the two components of consciousness. Patients with AMS require simultaneous stabilization, diagnosis, and treatment. The objectives of treatment are to sustain life and prevent irreversible central nervous system damage. Once the patient is resuscitated, the next objective is to establish the cause of AMS and stop disease progression.

Pathophysiology

There is a spectrum of alterations of mental status, ranging from confusion or delirium (disorders in perception) to lethargy, stupor, and coma (states of decreased awareness). A lethargic child has decreased awareness of self and the environment. In an emergency setting, this translates to decreased eye contact with family members and nursing and physician personnel. A stuporous child has decreased eye contact, decreased motor activity, and unintelligible vocalization. Stuporous patients can be aroused with vigorous noxious stimulation. Comatose patients are unresponsive and cannot be aroused by verbal or physical stimulation, such as phlebotomy, arterial catheterization, or lumbar puncture.^{2,3}

Irrespective of the cause, AMS is indicative of depression of the cerebral cortex or localized abnormalities of the ascending reticular activating system. Both cerebral cortices must be affected to cause AMS. Classic causes of bilateral cortical impairment are toxic and metabolic states that deprive the brain of normal substrates. Altered mental status also can be produced through dysfunction of the reticular activating system that is housed in the brainstem and midbrain. This system connects cranial nerve nuclei and extends from the brainstem to the thalamus. It governs respirations, cardiovascular functions, many aspects of homeostasis, and daily wake and sleep cycles. Any abrupt interruption or selective destruction of the reticular activating system may result in AMS.¹

The pathologic conditions that affect awareness and arousal can be described by three broad pathologic categories: supratentorial mass lesion, subtentorial mass lesion, and metabolic encephalopathy.⁴

Supratentorial mass lesions cause AMS by compressing the brainstem and/or diencephalon. Signs and symptoms of this type of lesion include focal motor abnormalities that are often present from the onset of the altered level of consciousness. The progression of neurologic dysfunction is from rostral to caudal, with sequential failure of midbrain, pontine, and medullary functions. Compromise by supratentorial lesions causes slow nystagmus toward and fast nystagmus from a cold stimulus during caloric testing.

Subtentorial mass lesions lead to reticular activating system dysfunction, in which prompt loss of consciousness is generally the rule. There is a discrete level of dysfunction. Cranial nerve abnormalities are frequently found due to the highly packed neurologically eloquent anatomy. Abnormal respiratory patterns such as Cheyne-Stokes respiration, neurogenic hyperventilation, and ataxic breathing are common. With brainstem injury, asymmetric and/or fixed pupils are found. No eye movements occur despite cold stimuli to both auditory canals.

Metabolic encephalopathy usually causes depressed consciousness before depressed motor signs, which, when present, are typically symmetric. Respiratory function is involved relatively early, and abnormalities are often secondary to acid-base imbalance. Pupillary reflexes are generally preserved. Pupils may be sluggish, but the movement is intact and symmetric. Exceptions occur with profound anoxia and the influence of cholinergics, anticholinergics, opiates, and barbiturates.

Clinical Features

One individual should act as historian to perform a methodical and comprehensive interview. The key questions that must be explored concern prodromal events leading to the change in consciousness, recent illnesses, the likelihood of an infectious exposure or exposure to intoxicants, and the likelihood of trauma, including abuse.⁵ The historian should make inquiries regarding antecedent fever, headache, head tilt, abdominal pain, vomiting, diarrhea, gait disturbance, seizures, drug ingestion, palpitations, weakness, hematuria, weight loss, and rash. For infants and young children with AMS, developmental milestones should be pursued. The medical, immunization, and family histories are important in children of all ages. The clinician should be alert for any inappropriate responses or inconsistencies and delays in seeking care that may arouse the suspicion of child abuse.

One should proceed with a general examination only after cardiac and cerebral resuscitation. The objectives of the examination are to identify occult infection, trauma, toxicity, or metabolic disease.^{3,4} The neurologic examination should document the child's response to sensory input, motor activity, pupillary reactivity, oculovestibular reflexes, and respiratory pattern. Although several coma scales have been published, the most simplified and functional in an emergency setting is the AVPU scale. This is a descriptive tool in which *A* means "alert," *V* means "responsive to verbal stimuli," *P* means "responsive to painful stimuli," and *U* means "unresponsive."

After a targeted history and a focused examination, the treating physician should anticipate and observe changes in the patient's status that may indicate improvement or deterioration. An additional task of the physician who attends the patient is to make an operational, if not specific, diagnosis of AMS.

Diagnosis

The differential diagnosis for AMS in children is diverse and differs slightly from that for adult patients.^{1,3} The familiar mnemonic AEIOU TIPS (alcohol, encephalopathy, insulin, opiates, uremia, trauma, infection, poisoning, and seizure) remains a useful tool for organizing the diagnostic possibilities (Table 130-1).

ALCOHOL In younger pediatric patients, alcohol ingestion is typically accidental; intentional ingestion is more likely in adolescents. Altered mental status may occur with serum levels below 100 mg/dL. Hypoglycemia may occur concurrently.

ACID-BASE AND METABOLIC DISORDERS Children with diabetes may present in ketoacidosis. The classic presentation includes weight loss, polyuria, polydipsia, polyphagia, weakness, vomiting, abdominal discomfort, Kussmaul respirations, a fruity acetone breath, and AMS. Patients with diabetic ketoacidosis and many other pediatric disease states associated with a loss of circulating volume may develop inadequate

TABLE 130-1 AEIOU TIPS: A Mnemonic for Pediatric Altered Mental Status

Alcohol	0	Opiates
Acid-base and metabolic disorders	U	Uremia

perfusion. Patients with hypotonic or hypertonic dehydration may develop AMS with and without seizures. Poorly perfused patients or patients with inadequate air exchange have insufficient oxygen delivery to the brain and exhibit insomnia, somnolence, and confusion. Patients who develop hypercapnia as a result of primary lung disease or neurologic dysfunction also may present with AMS. Those with hepatic failure present with nausea, fatigue, and behavioral alterations and may rapidly become obtunded. Patients with inborn errors of metabolism typically present early in life with poor feeding, recurrent vomiting, seizures, metabolic acidosis, lethargy, stupor, and AMS.

ARRHYTHMIA AND OTHER CARDIOGENIC CAUSES Ventricular fibrillation causes unconsciousness by diminished oxygen delivery to the brain. In a Stokes-Adams attack, heart block leads to loss of consciousness. Critical aortic stenosis leads to unconsciousness through decreased cardiac output.

ENCEPHALOPATHY Hypertensive encephalopathy may occur in pediatric patients at diastolic pressures of 100 to 110 mm Hg. Reye syndrome follows a viral illness, such as influenza or varicella. Patients are afebrile and anicteric and develop pernicious vomiting. Con-

fusion and delirium may lead to increasing obtundation. Hemorrhagic shock and encephalopathy syndrome is a symptom complex of unknown cause that affects previously healthy infants. The common features include a mild prodromal, nonspecific illness of several days' duration followed by the onset of profuse, watery diarrhea that becomes bloody, and seizures. Patients present poorly perfused, with profound metabolic acidosis and evidence of disseminated intravascular coagulation. Laboratory evidence of hepatic, renal, pancreatic, and myocardial dysfunction is common.

ENDOCRINOPATHY Altered mental status is a rare presentation of these disorders. Patients with Addison disease present with nausea, vomiting, abdominal pain, weakness, malaise, hypotension, and mental status changes, including psychosis. Presumptive evidence is provided by finding hyperpigmentation, depressed sodium and blood sugar levels, an elevated potassium level, and a variably increased calcium level. Infants with congenital adrenal hyperplasia may present in an acute salt-losing, volume-depleted hypotensive crisis or with virilization, characterized by ambiguous genitalia and cortisol insufficiency also manifested as hypoglycemia. Thyrotoxic infants may present with ventricular dysrhythmia. Patients also may exhibit symptoms similar to those of adults, including goiter, irritability, exophthalmos, hyperthermia, high-output congestive heart failure, mania, delirium, psychosis, and, later, apathy and decreasing levels of consciousness. Patients with pheochromocytoma may present with hypertensive encephalopathy.

ELECTROLYTES Hyponatremic children become symptomatic with plasma levels around 120 mEq/L. Manifestations include anorexia, headache, nausea, vomiting, irritability, weakness, cramps, disorientation, seizures, and AMS. Hypernatremic individuals develop muscle weakness, irritability, seizures, and AMS. Disorders of calcium, magnesium, and phosphorus present with neuromuscular signs, including weakness, tetany, seizures, and apathy.

INSULIN Hypoglycemia may be an end product of an endocrinopathy (e.g., adrenal insufficiency, hyperthyroidism, or hypopituitarism) or the result of an exogenous substance, such as ethanol, salicylate, oral hypoglycemics, or insulin. Hypoglycemia may result from a common stress pathway of decreased gluconeogenesis, as seen during sepsis or Reye syndrome. Adrenergic signs of palpitations, hunger, and sweating are seen at levels below 60 mg/dL. Irritability, confusion, seizures, and coma occur at levels of 40 mg/dL or lower. Infants and children are prone to develop ketotic hypoglycemia with fasting, especially with infections in early infancy. Altered mental status from hyperglycemia is rare in children. The most common cause of hyperosmolar central nervous system dysfunction is diabetic ketoacidosis.

INTUSSUSCEPTION Intussusception is readily diagnosed in the small percentage of younger children who present with a classic constellation of abdominal pain, vomiting, abdominal mass, and rectal bleeding. Altered mental status may be the initial symptom and dominant concern of the physician and the parent caring for a child with intussusception. Altered mental status remains until the bowel obstruction is reduced.⁶

OPIATES Children who have ingested opiates may present with miosis, absent bowel sounds, and lethargy. Common opiates that may be present in the household include dextromethorphan, diphenoxylate and atropine (Lomotil), and loperamide (Imodium). Ingestion of clonidine also may cause signs and symptoms similar to opiate intoxication. Abuse and neglect should always be suspected in children with opiate intoxication.

UREMIA In children with chronic renal failure, neurologic dysfunction may develop secondary to stroke, hypertension, or metabolic de-

rangements. Encephalopathy occurs in over one-third of patients with chronic renal failure and is manifested by headache, irritability, cognitive derangement, and seizures. Hemolytic uremic syndrome is the most common cause of acute renal failure in childhood. It is characterized by oliguria, microangiopathic hemolytic anemia, and thrombocytopenia with purpura. Diverse etiologies may precipitate the disorder. The most common include a prodromal *Escherichia coli* enteritis or an invasive *Streptococcus pneumoniae* infection.

TRAUMA Trauma may occur at the cellular or global level. In the context of multisystem trauma, a hypovolemic state may create insufficient cerebral perfusion. Such hypovolemic states may be created by other "traumatic" insults, such as primary peritonitis or ruptured appendicitis with hypovolemia. Children may have transient loss of consciousness after closed-head injury. Occasionally, a seizure may occur immediately after closed-head injury, resulting in AMS from the postictal state. The signs and symptoms of acute epidural hematoma are typically posttraumatic loss of consciousness followed by a lucid interval and then rapid progression of AMS. Acute epidural hematoma also can present with a gradual loss of consciousness associated with ipsilateral pupillary dilatation. As in adults, subdural hematomas may be acute, subacute, or chronic. Most children with subdural hematomas have external signs of trauma. The exceptions are abused infants, typically younger than 6 months who may present without external signs of injury. Abused children who are shaken typically present with a history of vomiting, seizures, and changes in respiratory pattern associated with AMS. Retinal hemorrhages or a tense fontanel may suggest the diagnosis. Children with blunt head trauma are more inclined than adults to develop diffuse cerebral swelling, increased intracranial pressure, and AMS without extracerebral or intracerebral collections of blood.

TUMOR Primary brain tumor, or metastatic or meningeal leukemic infiltration, may alter the metabolism of the brain. Intracerebral tumors commonly produce focal neurologic dysfunction, whereas posterior fossa tumors typically block the ventricular system and create signs and symptoms suggestive of hydrocephalus. Supratentorial and infratentorial tumors may present abruptly with AMS, fever, or meningismus after an intratumor hemorrhage.⁷

THERMAL Extremes of body temperature also may lead to central nervous system dysfunction. Progressive hypothermia leads to insidious AMS. Patients who develop body-core temperatures higher than 41°C (105.8°F) develop headache, weakness, and dizziness followed by confusion, euphoria, combativeness, and AMS. Posturing, seizures, hemiparesis, and pupillary changes may be present.⁸

INFECTION Infection is more common as a cause of AMS in children than in adults. The incidence of bacterial meningitis and septicemia is highest in early infancy and considerably higher throughout childhood than in adulthood. Bacterial meningitis should be high on the differential diagnostic list in a pediatric patient with AMS. Unless there are contraindications to lumbar puncture, examination of cerebrospinal fluid (CSF) should be considered in lethargic, febrile pediatric patients (Table 130-2). Patients with encephalitis have fever and headache and may have signs of meningeal irritation or neurologic deficits. Herpes viruses, arbovirus, rotavirus, and Epstein-Barr virus are among the most common viral agents associated with encephalitis. Encephalitis may occur in the course of mycoplasmal illness, shigellosis, Lyme disease, or cat-scratch disease. Visceral larva migrans may produce encephalopathy in the young.

A brain abscess may create signs and symptoms suggestive of encephalitis. Patients with a brain abscess present with fever and

TABLE 130-2 Procedure: Lumbar Puncture

Relevant anatomy: CSF is produced by the choroid plexus and circulates around the brain and spinal cord within the subarachnoid space. A spinal needle traverses the skin, subcutaneous tissue, supraspinal ligament, interspinal ligament, ligamentum flavum, dura, and arachnoid before entering the subarachnoid space surrounding nerve roots that form the cauda equina in the lumbar region. **Indications:** The primary indication for emergent lumbar puncture is the possibility of central nervous system infection. It is also indicated for suspected

spontaneous subarachnoid hemorrhage. **Contraindications:** Absolute contraindications include the presence of infection in tissues near the puncture site and increased intracranial pressure secondary

to a space-occupying lesion. The presence of coagulopathy or lumbosacral deformity is a relative contraindication.

Possible complications: Common complications include localized back pain, residual paraspinous muscle spasm, and headache. Rare but debilitating events include subarachnoid bleeding, subdural bleeding, entrapped nerve through dural tear, paresis, pyogenic spondylitis, vertebral infection, meningitis, implantation of epidermal tissue with delayed epidural tumor. The most serious complication is cardiorespiratory arrest, which can result from a vasovagal phenomenon, malpositioning of the child's neck in flexion, or cerebral herniation.

Equipment needed: Necessary equipment consists of a lumbar puncture kit with spinal needle. A 22-gauge 1¹/₂-in. needle is used for children <6 y. A 22-gauge 2¹/₂-in. needle is required for children 6-12 y, and a 21-gauge 3y-in. needle is used in children > 12 y. A manometer with a three-way stopcock is used to measure CSF pressure. Consider use of a cardiorespiratory monitor and oxygen saturation measuring device.

Patient positioning: An assistant is generally required to ensure proper positioning of the patient. The classic posture for lumbar puncture is lateral recumbent with spine flexed and knees drawn upward to the chest, with shoulders and back perpendicular to the table. An alternative for a small infant is sitting with the thighs flexed toward the abdomen. It is critical to avoid flexion of the neck. **Steps of procedure:**

To prevent oxygen desaturation in the young, consider delivering 5 L oxygen/min through a tight-fitting face mask for several minutes before needle insertion.

The back may be cleaned with povidone-iodine surgical scrub, or povidone-iodine solution may be allowed to air dry on the skin. Sterile draping is optional in infants and best avoided to maximize landmark exposure and proper positioning. Local anesthesia with 1% xylocaine should be administered to all children, irrespective of age. The intersection of a line joining the superior portion of the iliac crest and the spine meets at the spinous process of L4. Optimal insertion is at the L3-L4

interspace but may be performed one space above or below. The spinal needle is inserted into the chosen site with the stylet in place through the epidermis and dermis. Then the stylet may optionally be removed for the

remainder of the procedure. The clinician may not feel an increasing resistance and "pop" into the subarachnoid space in younger children. Manometry may be performed as indicated in cooperative children who have lumbar puncture performed in the lateral decubitus position. Classic, relaxed

pressure is 5-15 cm H₂O, but normal values may range as high as 20-28 cm H₂O. If the tap is bloody, one may replace the stylet and leave the needle in place. Insert a second spinal needle one interspace cephalad and collect fluid for

analysis. Finally, withdraw both needles. This process minimizes red blood cell contamination in the collected fluid.

Place a bandage over the insertion site.

Analysis: Necessary CSF studies include bacterial culture and gram stain from tube 1, protein and glucose from tube 2, and cell count and differential from tube 3. Tube 4 may be sent for viral or fungal cultures or for latex agglutination in specific circumstances.

Abbreviation: CSF = cerebrospinal fluid.

headache that precede changes in presentation and consciousness. Affected patients also may present with generalized or focal seizure activity. Patients at risk for brain abscess include those with sinusitis, cyanotic congenital heart disease, immunodeficiency, and intravenous drug abuse.

Any systemic infection associated with vasculitis or vasodepressant toxins with shock may lead to AMS secondary to cerebral hypoperfusion.

INTRACEREBRAL VASCULAR DISORDERS Cerebrovascular events are uncommon in children, but subarachnoid hemorrhage from arteriovenous malformations or a ruptured berry aneurysm may cause focal neurologic deficits followed by status epilepticus and coma. Nuchal rigidity is an inconstant finding. Venous thrombosis may follow severe dehydration or a pyogenic infection of the paranasal sinuses, mastoid, or middle ear. Periorbital edema with cranial nerve abnormalities is a clue. Arterial thrombosis is uncommon in children, except in those with homocystinuria. Children with homocystinuria have a marfanoid appearance, dislocated lenses, and mental retardation. Intracerebral and intraventricular hemorrhages may follow birth asphyxia or trauma in neonates, but in older children they may signify a congenital or acquired coagulopathy. Signs of subacute bacterial endocarditis include splinter hemorrhages, splenomegaly, microscopic hematuria, and AMS caused by cerebral emboli. Acute infantile hemiplegia presents with an acute seizure followed by hemiparesis and coma. Acute confusional migraine may be associated with profound alterations in consciousness. Children with sickle cell anemia can develop cerebral thrombosis, status epilepticus, and coma.

POISONING Drugs may be transferred to a fetus transplacentally. Infants and children may receive drugs through neglect, abuse, or accident. Drugs may be used as a suicide gesture in adolescents. Altered mental status may be caused by exogenous intoxicants, such as ethanol, ethylene glycol, methyl alcohol, paraldehyde, salicylates, and anticholinergics, including antihistamines, cholinergics, opiates, carbamazepine, clonidine, sedative-hypnotics, amphetamines, cocaine, cannabis, nicotine, carbon monoxide, hydrocarbons, and multiple psychotropics within the categories of selective serotonin reuptake inhibitors, mood stabilizers, and antipsychotics.⁹ Ingestion of household and beauty products also may cause AMS.

PSYCHOGENIC Psychogenic unresponsiveness is rare in children. It is characterized by decreased responsiveness but otherwise normal findings on neurologic examination, including normal oculovestibular reflexes. Psychogenic unresponsiveness may occur as a conversion reaction, an adjustment reaction, a panic state, or a manifestation of malingering.

SEIZURE Generalized tonic-clonic major motor seizures and absence status epilepsy are associated with prolonged unresponsiveness in pediatric patients.¹⁰ A prolonged post-ictal phase in a febrile child with seizure suggests intracranial infection.

Diagnostic Adjuncts

Ancillary procedures for diagnosis of AMS include analysis of blood, gastric fluid, urine, and CSF (see Table 130-2); electrocardiography; roentgenography; ultrasonography; and computed tomography (CT).¹¹ Diagnostic tests should be guided by the clinical situation. Rapid estimation of the blood glucose level with a glucose oxidase strip is a universally accepted evaluation in pediatric patients with AMS. Confirmation by laboratory analysis of venous blood is recommended. Electrolyte determinations, liver function studies, and renal function studies may provide additional information regarding the state of hydration, suspected endocrine and metabolic derangements, and liver and kidney function. If the history is consistent with a toxic ingestion

or a toxidrome is identified, serum or urine toxicology screening is in order. The white blood cell count and differential blood cell count as independent evaluations are rarely helpful, except perhaps in management decisions regarding highly febrile children younger than 2 years. A blood culture should be obtained whenever serious bacterial infection is suspected.

An arterial blood gas or capillary blood gas analysis with pulse oximetric analysis may provide useful information in cases of trauma, respiratory distress, or suspected acid-base imbalance.

Shock or hypotension and hypoxia should be corrected before lumbar puncture, and empiric antibiotics should be given before lumbar puncture if bacterial meningitis is suspected. Lumbar puncture with CSF examination is necessary as soon as the patient is stabilized (see Chap. 116).

A 12-lead electrocardiogram should be obtained if there are pathologic auscultatory findings or a rhythm disturbance is found while monitoring the patient. An electrocardiogram may further guide therapy in cases of tricyclic antidepressant overdose.

Radiologic evaluation should be directed by the clinical scenario. Cervical spine immobilization is the first step in management of the head or multiple system trauma patient. This is followed by cervical spine radiography and/or CT of the cervical spine and head. A chest x-ray may be used to confirm or clarify examination findings and to document endotracheal tube placement. Abdominal films are indicated for the acute ingestion of radiopaque material, if suspected, or if the patient exhibits signs and symptoms of an acute abdomen, including possible intussusception. Abdominal ultrasound studies may be useful to screen cases of intussusception with an atypical presentation. A CT scan of the head may be obtained for suspected increased intracranial pressure, vascular disorder, or mass lesion.

Other studies for specific instances are blood ammonia, serum osmolality, blood alcohol level, thyroid function tests, blood lead level, or skeletal survey for suspected abuse. A portable electroencephalogram may diagnose non-motor status epilepticus.

Treatment

The first priorities in AMS are stabilization and reversal of acutely life-threatening conditions before specific diagnostic maneuvers, such as lumbar puncture, are undertaken.⁵ Airway, breathing, and circulation must be assured. For suspected cervical injury, spinal immobilization is mandatory, and the airway is opened with the jaw-thrust maneuver.

Hypoxia must be corrected, and continuous pulse oximetric monitoring should be established. There is no contraindication to providing oxygen to pediatric patients. Oxygen is obviously indicated for patients with signs of hypoxemia or hypoperfusion, but hypercapnia must be avoided. Bag-valve-mask ventilation may reverse hypercapnia, but endotracheal intubation is necessary to protect the patient from aspiration.

Fluid resuscitation is necessary in hypotensive comatose patients, because cerebral perfusion depends on adequate mean arterial pressure. A fluid bolus of 20 mL/kg of isotonic crystalloid should be given quickly. Poorly perfused patients should be reassessed and boluses repeated up to a total of 60 mL/kg, as necessary. Thereafter, pressors should be used. In hemodynamically stable patients with suspected head injury, encephalitis, or meningitis, the intravenous fluids should be reduced to an hourly rate that provides two-thirds of the calculated maintenance volume. Empiric therapy may be initiated with 2 mL/kg of a solution of D25W IV if hypoglycemia is strongly suspected. Alternatively, the blood glucose level may be rapidly estimated by means of a glucose oxidase stick, and glucose-containing fluids may be given for hypoglycemia.

If there is clinical suspicion of opiate or clonidine overdose, a narcotic antagonist may be administered. The recommended dose for naloxone is 0.01 to 0.1 mg/kg IV every 2 min, until the desired effect is achieved, or a total dose of 2 mg. Any dose, if successful, may be

repeated as necessary to maintain narcotic reversal. Flumazenil (Mazicon), a benzodiazepine antagonist, may be used for pure benzodiazepine ingestion in an otherwise healthy child. The dose is 0.01 mg/kg IV, with cardiac monitoring established.

Seizures should be aborted, if present. Benzodiazepines are typically first-line drugs. The longer-acting anticonvulsants, such as phenytoin or phenobarbital, also may be needed.

Acid-base balance should be restored with hydration and compensatory ventilation. Sodium bicarbonate should be used sparingly and only in circumstances in which the arterial pH is 7.0 or lower.

Core body temperature should be controlled. Maintaining euthermia is critical to minimizing metabolic demands. A child's increased relative body surface area hastens radiant heat loss. Heat loss may be minimized with the use of a heating lamp during resuscitative procedures.

Septic-appearing patients and those suspected of having intracranial infection should receive empiric intravenous antibiotics as quickly as possible. Antibiotics may be given before lumbar puncture.

Disposition

All patients with AMS should receive continuing care in an area that can provide physiologic monitoring and repeated physical examination. In general, this requires admission to an intensive care unit or transfer to a tertiary care center with pediatric intensive care capabilities. Only those patients with transient, reversible causes of AMS may be treated, monitored in the ED, and discharged after observation. Patients who are discharged (e.g., those with a closed head injury or simple febrile seizure) should receive disease-specific discharge instructions. Patients who are evaluated for AMS and discharged home should have a repeat evaluation within 24 h of discharge.

HEADACHE

Headache refers to any head pain including pain in the face, neck, and ears but is generally used to describe pain perceived in the scalp and cranium. A headache may occur in childhood as an acute process over a finite period or may occur repeatedly over an extended time frame. Those who sustain repeat, chronic headaches may have altered school performance, behavioral disturbances, and disproportionate over-reporting of all types of pain.¹²

Up to 2 percent of visits to the ED are for the chief complaint of headache,¹³ but it is an associated symptom in a great proportion of visits.¹⁴ The vast majority of children who are evaluated in an emergency setting have a benign cause for headache. In one series of 696 children with headache, 6.6 percent had emergent or urgent conditions causing headache, 80 percent of which were due to viral meningitis.¹⁵ In another study of 150 children aged 2 to 18 years who presented to an ED with acute severe headache, the leading causes of headache were upper respiratory tract infection with fever in 57 percent, migraine in 18 percent, viral meningitis in 9 percent, and undetermined in 7 percent.¹⁶ Two qualities associated with serious underlying disease were occipital location of headache and inability of the child to describe the quality of head pain. All patients with neurosurgical conditions had clear and objective neurologic signs.¹⁶

Pathophysiology

The pathogenesis for headache is complicated and often unclear. The brain and most of the overlying meninges have no pain receptors and thus are not sensitive to pain.¹⁷ Also insensate is the cranium itself, dura, ependymal lining, and choroid plexus.^{15,16} Pain may be perceived from any structure between the epidermis of the scalp and the periosteum of the skull. Extracranial pain may arise from cervical nerve roots, cranial nerves, or extracranial arteries traversing muscles or skin. Intracranial pain may arise from venous sinuses, large veins,

dura around large veins, or dural arteries and arteries around the base of the brain. Irritation of cranial nerves may lead to pain at specific areas within the head and neck region. As an example, the ophthalmic branch of the trigeminal nerve innervates the supratentorial vessels, pia, arachnoid meninges, and the skull periosteum. Irritation may result in pain radiating to the forehead, eyes, and temples. The pain nociceptors in the posterior fossa (inferior to the tentorium, cranial nerve roots, and cranial nerves VII, IX, and X) refer pain to the occiput, ear, and retroauricular areas.¹⁸ The posterior fossa is also innervated by glossopharyngeal and vagus nerves and thus may refer pain to the throat.¹⁷

Clinical Features

There are several common classification schemes for headaches. The most frequent approach divides headaches into two general categories, primary and secondary. Primary headaches are physiologic or functional, and secondary headaches have an anatomic basis. Primary headaches are often recurrent and are accompanied by a normal physical examination. Examples include migraine headache, tension headache, chronic daily headache, and headache associated with depression or fatigue. Secondary headaches are due to anatomic problems, such as intracranial mass, vascular malformation, or meningeal inflammation; craniofacial problems such as sinusitis, dental abscess, or otitis; or systemic disorders such as lupus cerebritis. Secondary or anatomic causes of headache have the greatest potential for morbidity or mortality. The appropriate acquisition of historical information, physical examination, and laboratory or radiologic data is necessary to identify the serious causes for headache (Tables 130-3 and 130-4).

HISTORY The child, parents, and caretakers should be asked about the characteristic features of the headache, such as quality, precipitants, timing, duration, location, associated symptoms, and family and personal medical histories. A detailed history may uncover historical features suggesting secondary headache (see Table 130-3).

Age at Presentation The complex migraine syndromes (acute confusional, abdominal, or basilar artery) may have their onset before age 4 years. Classic or common migraine is unlikely before age 6 years.¹⁹ Incapacitating headache associated with vomiting in a child younger than 7 years should lead to consideration of an intracranial mass lesion. Other predictors for a space-occupying lesion in children younger than 7 years include absence of visual aura and absence of family history of migraine.²⁰

Quality of Headache Children may be able to express the quality of head pain. The inability of a child to describe the quality of head pain does not preclude a serious underlying process.²¹ Herpes zoster can cause stabbing pain or uncomfortable hyperesthesias. Boring pain may be seen with sinusitis. Aching pain occurs with tension headache, encephalitis, or

TABLE 130-3 Historical Features Suggesting Secondary

Headache	Acute onset
Worst ever	
Posttraumatic	
Awakens from sleep	
With fever	
Aggravated by: sneezing, coughing, Valsalva, lying down	
Morning vomiting	
Altered mental status	
Change in behavior	
Change in pattern	
Toxic exposure	
Positive family history for migraines or subarachnoid hemorrhage	

TABLE 130-4 Physical Findings Suggesting Secondary Headache

Altered mental status
Septic or toxic appearance
Fever >104°C in infants and children or >38°C in neonates
Hypertension or hypotension
Diaphoresis
Facial herpes zoster
Petechiae
Café-au-lait spots
Hydrocephalus
Ptoxis
Visual field defect
Retinal hemorrhage or optic disc distortion
Asymmetry of motor or sensory responses
Thyromegaly
Nuchal rigidity
Head tilt

meningitis. Throbbing headache is associated with migraine, hypertension, or intracerebral hemorrhage.

Headache Precipitants Fever is the most common precipitant of headache in children.¹⁶ The intensity of headache with fever is variable and not related to the severity of the fever. Acute, posttraumatic headache is a common pediatric event. Occasionally, a posttraumatic event may lead to chronic headaches precipitated by exertional activities. Classic adult precipitants for migraine also occur in children. Chocolate, aged cheeses, monosodium glutamate, menses, or emotional distress may precipitate migraine headaches.¹⁸ Hypoxemia associated with an underlying medical condition, such as asthma, or created by toxic exposure (such as carbon monoxide or drug-induced methemoglobinemia) may initiate headache. Medications, such as vitamin A, oral contraceptives, tetracycline, or steroids, may induce acute or chronic headaches. Bifrontal "ice cream" headache may be induced by cold food on the palate. Headache exacerbated by chewing or teeth clenching suggests temporomandibular joint dysfunction. Prolonged reading-induced headache suggests ocular imbalance or accommodative error.

Timing of Headache Patients with obstructive hydrocephalus, pseudotumor cerebri, or brain tumor will experience headaches after lying down. They may awaken at night from sleep or experience headache upon arising in the morning.

Onset and Duration of Headache The duration of headache is not a particularly specific or sensitive feature. However, an acute event associated with fever suggests infection or inflammation, often within the craniofacial region. When the tempo of headache is hyperacute and intense at onset, subarachnoid hemorrhage is suspected. Subacute tempos suggest cluster headache, tumor, neuralgias, or migraine.

Location of Headache Occipital location is often associated with a serious underlying condition.²¹ Adverse drug effect, hypertension, and basilar artery migraine tend to create occipital headaches. Pain at the vertex is seen with sphenoid sinusitis. Periauricular or temporal pain is seen with temporomandibular joint and dental pathology. Retroorbital pain is associated with meningitis, dural sinus thrombosis, ethmoid, and maxillary and frontal sinusitis. Migraine involves frontal or temporal hemicrania in adolescence but may be bifrontal or generalized in younger children. Tension headache has the greatest variance in location: headache may be generalized, frontal, occipital, or posterior cervical.

Manipulations and Avoidance During an acute headache, patients with migraine prefer the silence and darkness. They reduce their

speech and seek sleep as a means of relief. As they rest, migraine patients may be noted to rhythmically rub the maximal area of pain. Migraineurs' behaviors contrast most with cluster headache patients. The latter have increased activity, pacing, rocking, or head butting. Patients with increased intracranial pressure will avoid the Valsalva maneuver. Pain intensifies with defecation, coughing, or sneezing. Children with brain tumors avoid placing their heads in a position that increases intracranial pressure. This lends to intermittent, unexplained head tilt. The emotional turmoil and chronicity of tension headaches leads to the highest degree of school absenteeism.

Associated Symptoms Associated symptoms are valuable refinements for a preliminary diagnosis and may be necessary to attain a headache classification. As an example, classic migraine or complicated migraine headache must be associated with motor, sensory, or visual disturbances. Migraineurs may see flashing lights (photopsia), bright wavy lines (teichopsia), or shimmering zigzag (scintillating scotoma). With confusional migraine, there may be visual size distortion (metamorphopsia) and distortions of space or time with sensory hallucinations. Hemiplegic migraine may be associated with paresthesias, transient hemiparesis, or aphasia. Blindness for half the visual field (hemianopsia) or other restricted visual fields is transient with migraine headache. Visual field defects or dimming of vision that are permanent suggest pseudotumor cerebri. Personality change, altered school performance, and rapid fluctuations in consciousness suggest brain tumor. Effortless, nonprojectile vomiting not associated with nausea strongly suggests brain tumor. Vomiting may occur at any time of the day, although the episodes tend to cluster in the morning. In the case of brain tumor, vomiting without systemic complaints or abdominal pain may last from days to weeks, resolve spontaneously, and then recur weeks to months later.⁷ In contrast, vomiting associated with migraine headache is coupled with anorexia, nausea, and occasionally abdominal pain. A headache with seizure suggests subarachnoid hemorrhage or tumor. Neck rigidity or syncope may be associated symptoms with subarachnoid hemorrhage.

Family History Children with migraine headache have a positive family history of migraine in up to 90 percent of cases. About 7 percent of children with cluster headache have a family history of similar headaches. Children whose parents have sustained subarachnoid hemorrhage have a four times greater risk of subarachnoid hemorrhage than do the general population. A family history of hypertension, diabetes, or atherosclerotic heart disease may predispose the child to medical conditions that may be associated with headache. Depressive states are occasionally hereditary. However, psychological or psychiatric disorders in parents, when combined with a dysfunctional environment, may predispose to tension headaches in the children.

Medical History Without a history of headache, it may be difficult to provisionally diagnose migraine headache, even with a classic history. Conversely, patients previously diagnosed with migraine, tension headache, fatigue headache, or depressive headache are not excluded from a more ominous diagnosis. A change in the existing headache pattern is the key. A recent inadequately treated infection may lead to bacterial dissemination. Complicated sinusitis, brain abscess, or venous thrombosis of the lateral or cavernous sinus may result from an inadequately treated parameningeal focus. Intracranial infection is more likely in children with immune deficiency. If there is a medical history of meningitis, recurrence may result from an anatomic congenital defect or immunologic impairment. Shunt malfunction or infection may cause the headache. Coagulopathy, such as hemophilia, predisposes the child to spontaneous intracerebral hemorrhage.

PHYSICAL EXAMINATION The general appearance and affect of the pediatric patient and interaction of the patient with any accompanying adult should be assessed during the acquisition of the history of

present illness. The search for systemic disease, craniofacial problems, or intracranial pathology is facilitated by analysis of vital signs, a focused head and neck examination, and a detailed neurologic examination (see Table 130-4).

Vital Signs Hypertension or hypotension associated with headache is significant. Any child with encephalopathy or seizures and a diastolic pressure greater than 110 mm Hg suggests a hypertensive emergency. Hypertension as the primary cause of headache should be considered when a child's blood pressure is greater than the 99th percentile for any given age or greater than 15 mm Hg above the 95th percentile. Blood pressures two standard deviations below the mean, particularly if associated with clinical signs of poor perfusion, suggest systemic infection, profound metabolic derangement, or occult trauma. Increased respiratory rate suggests metabolic derangement, hypoxia, or, rarely, increased central neurogenic drive. Resting increased heart rate in the absence of fever may reflect sympathetic response to pain. Tachycardia may result from fever. Temperature elevation with headache suggests infection, which may be localized to the central nervous system. Subarachnoid hemorrhage also can cause fever.

Head and Neck Soft tissue swelling of the scalp may be noted after cranial trauma. Tender scalp muscles suggest a muscular contraction headache. The presence of a machine-like cranial bruit indicates arteriovenous malformation. Periorbital edema, if combined with sinus percussion tenderness, suggests sinusitis. Eyelid edema without palpable tenderness over the sinuses suggests cluster headache. Lacrimation, nasal congestion, and rhinorrhea may be seen with sinusitis or cluster headache. Ptosis, sixth nerve palsy, and mydriasis may be seen with ophthalmoplegic migraine. Papilledema reflects increased intracranial pressure. Retinal hemorrhages in a child without a hemorrhagic diathesis suggests abusive head injury. Meningeal irritation suggests subarachnoid hemorrhage or intracranial infection. Dental caries with gingival erythema, induration, or mass suggest apical abscess. Malocclusive bite, palpable tenderness, and mandibular crepitation suggest temporomandibular joint dysfunction.

NEUROLOGIC EXAMINATION Transient neurologic findings such as somnolence, visual aura, aphasia, or hemiparesis can be seen with various migraine syndromes. Fixed neurologic abnormalities such as AMS, visual field defect, or any focal finding suggest a space-occupying intracranial lesion. Patients with neurologic conditions will have clear and objective neurologic signs.²¹

Diagnostic Adjuncts

Diagnostic procedures of potential utility for headache patients include phlebotomy for complete blood cell count, erythrocyte sedimentation rate, blood sugar, basic metabolic panel, carboxyhemoglobin measurement, lead level, blood culture, and thyroid function testing. Lumbar puncture is of obvious diagnostic utility for suspected intracranial infection, subarachnoid hemorrhage, and pseudotumor cerebri. Useful imaging studies include noncontrast and contrast head CT and magnetic resonance imaging of the brain.

There are no evidence-based studies to guide the clinician in the selection of various diagnostic investigations for headache. However, **there are several scenarios with a high percentage of positive findings, including first headache; worst headache; change in pattern of a chronic headache; headache associated with seizure, fever, or meningeal signs; AMS; or focal neurologic abnormality.**^{20,23,25}

Treatment

Headache management includes treatment of the underlying condition, relief of pain, modification of precipitating factors, and insuring continuity of care.

Treatment of the underlying condition can range from welcomed reassurance to a wide variety of therapeutic agents (such as oxygen, antibiotics, etc.) or therapeutic procedures (such as lumbar puncture for pseudotumor cerebri). Narcotic or non-narcotic analgesics should be given that are appropriate for the disease process and the perceived degree of pain.

Treatment options for common and classic migraine in children have not been well studied. There are no straightforward regimens that are uniformly successful. Acetaminophen is rarely helpful. Naproxen or ketorolac can be effective. Promethazine, prochlorperazine, metoclopramide, hydroxyzine, and ondansetron may reduce nausea and vomiting and induce sedation. Dihydroergotamine can be used in children older than 6 years if all other drugs have failed to provide acute headache relief. Ergotamines should not be given to children with basilar or hemiplegic migraine, because it may further reduce blood flow to the ischemic areas of the brain.

Potential precipitating factors should be addressed. For example, education can be provided for dietary avoidance for migraine. Situation modifications can be suggested for relief of tension headache. Patients with posttraumatic headache may temporarily benefit from exercise restriction. Continuity of care with the primary care physician should be arranged to ensure effective therapy, including prophylactic regimens such as β -blockers, cyclic antidepressants, or anticonvulsants for migraine.

Disposition

All patients with emergent causes of headache, such as subarachnoid hemorrhage, acute bacterial meningitis, severe hypertension, or intracranial mass lesion from tumor, hematoma, or abscess, require admission for definitive care. Any patient with intractable pain should be considered for admission.

SYNCOPE AND SUDDEN DEATH

William E. Hauda II
Thom Mayer

Although syncope is usually benign, it may be a symptom of serious cardiac disease and can predispose individuals to sudden death. The sudden death of a child may be due to cardiac, neurologic, or respiratory illnesses or trauma. This chapter discusses syncope and sudden death due to cardiovascular causes, although the other causes of sudden death are mentioned briefly.

EPIDEMIOLOGY

Syncope

Syncope is very common in adolescence and less common in younger children. Between 20 and 50 percent of adolescents experience at least one episode of syncope.¹ Syncope is a presenting symptom of 0.05 percent of pediatric visits² and 6 percent of hospital admissions.¹ Only 25 percent of patients referred to a cardiology or neurology specialty clinic for the evaluation of syncope are eventually diagnosed with a serious illness.³ The most common cause of benign syncope is neurally mediated syncope.² Therefore, prior syncopal events are not always associated with an increased risk of future sudden death.⁴

Sudden Death

A distinction must be made between sudden unexpected death and sudden cardiac death, because the first includes many causes, such as a seizure, asthma, or toxic ingestion. Sudden cardiac death includes just those causes that directly relate to cardiovascular dysfunction. The rate of sudden unexpected death in children is 2.3 percent of all deaths, or 1.3 cases per 100,000 patient years.⁵ Sudden cardiac death encompasses approximately one-third of these deaths, or about 600 deaths per year in the United States. Excluding trauma, sudden cardiac death is the most common cause of sports-related death in young athletes.⁶ The sports most frequently associated with sudden death are basketball, football, and track events. The greatest risk for sudden cardiac death is among patients with congenital or acquired structural cardiac disease, including postoperative congenital heart disease. The most frequent causes of sudden cardiac death in children are acute myocarditis, cardiomyopathy, cyanotic and noncyanotic congenital heart disease, valvular heart disease, congenital complete heart block, Wolff-Parkinson-White syndrome, long QT syndrome (LQTS), Mar-

fan syndrome, coronary artery disease, and anomalous coronary arteries.⁷ Hypertrophic cardiomyopathy is the most common cause of sudden cardiac death in adolescents without known cardiac disease.⁷

PATHOPHYSIOLOGY

Syncope is the temporary loss of consciousness from reversible disruption of cerebral functioning and usually refers to inadequate cardiac output and cerebral hypoperfusion, resulting in a temporary loss of consciousness.

Vascular syncope occurs when a stimulus causes venous pooling in the legs, leading to a decrease in ventricular preload and a compensatory increase in heart rate and myocardial contractility. After fainting, return of consciousness occurs while lying on the floor, because gravity no longer contributes to venous pooling of blood. Neurally mediated syncope (NMS), or reflex syncope, occurs when receptors in the atria, ventricles, and pulmonary arteries sense a decrease in venous return, and an efferent brainstem response via the vagal nerve causes bradycardia, hypotension, or both. This reflex is also called the *Bezold-Jarisch reflex*. Because the pathophysiology of NMS is related to abnormal circulatory control, this form of syncope is often grouped with other forms of vascular syncope, such as orthostasis and hypovolemia.

Cardiac syncope occurs when there is an interruption of cardiac output from an intrinsic cardiac problem. These causes are divided into tachydysrhythmia, bradydysrhythmia, outflow obstruction, and myocardial dysfunction.

Any event that causes sufficient cerebral hypoperfusion can lead to sudden death. The most common causes are seizures, cardiac diseases, and metabolic diseases. Little is known about the most common dysrhythmias that cause sudden death in children, because such cardiopulmonary arrests often are not witnessed. In children, bradycardic or asystolic arrests are thought to be most common, especially in children younger than 1 year, but ventricular fibrillation is also seen in older children.⁸ Overall in children, however, the incidence of ventricular fibrillation as the presenting cardiac dysrhythmia is much lower than that in adults.⁸

CLINICAL FEATURES

Syncope is characterized by a sudden onset of falling with a brief episode of loss of consciousness. Other associated symptoms or signs are usually related to the etiology for the syncopal event. Two-thirds of children experience a prodrome of lightheadedness or dizziness before the event,³ whereas vertigo is much less common. Involuntary motor movements occur with all types of syncopal events but are more common with seizures.³ Stokes-Adams syndrome is defined as cardiac syncope associated with very brief tonic or clonic motor activity. This is different from the longer duration tonic and clonic motor movement characteristic of a generalized seizure. Factors related to more serious causes of syncope are outlined in Table 131-1. Events that may mimic syncope in children are listed in Table 131-2.

Sudden cardiac death is usually an unexpected, unwitnessed, terminal event. When resuscitation is rapidly started in patients who have a witnessed arrest, the likelihood of survival is much greater, approaching 25 percent. Witnesses may be able to describe prodromal symptoms to aid in determining the cause of the event.⁹

TABLE 131-1 Risk Factors for a Serious Cause of Syncope

Exertion preceding the event
History of cardiac disease in the patient
Family history of sudden death, deafness, or cardiac disease
Recurrent episodes
Recumbent episode
Prolonged loss of consciousness
Associated chest pain or palpitations
Medications that can alter cardiac conduction

TABLE 131-2 Events Easily Mistaken for Syncope

Condition	Distinguishing Characteristics
Basilar migraine	Headache, rare loss of consciousness, other neurologic symptoms
Seizure	Loss of consciousness simultaneous with motor event, prolonged postictal phase
Vertigo	Rotation or spinning sensation, no loss of consciousness
Hyperventilation	Inciting event, paresthesias or carpopedal spasm, tachypnea
Hysteria	No loss of consciousness, indifference to event
Hypoglycemia	Confusion progressing to loss of consciousness, requires glucose administration to terminate
Breath-holding spell	Crying before event, child 6-18 mo old

DIAGNOSIS

No clinical or historical features reliably distinguish vasovagal syncope from other causes.³ The patient's history of the event and observations of witnesses present during the event are crucial to identifying the likely causes for the syncopal event. Certain historical features and a careful history and physical examination will increase an emergency physician's suspicion of a potentially serious cause (see Table 131-1). Particular attention should be directed to the cardiovascular examination, including palpation of the cardiac impulse, auscultation of the heart, and evaluation of the peripheral pulses. Orthostatic measurements will identify volume depletion or autonomic dysfunction. The physical examination will often be completely normal. An electrocardiogram (ECG) should be obtained for almost all children and usually will be normal.³ Children who have an unmistakable episode of vasovagal syncope do not need an ECG. Other laboratory studies are directed by the nature of the history and physical examination but are not routinely helpful in identifying the cause of syncope.

Many of the diseases that cause syncope also cause sudden death in children. A syncopal event can be the presenting symptom of these more serious illnesses. Up to 25 percent of children who die suddenly have a history of at least one prior syncopal event.⁵ However, because syncope is a very common event, a syncopal event by itself is not associated with an increased risk of sudden death unless certain features are present (see Table 131-1).⁴ The two most common causes of sudden cardiac death among children who do not have known cardiac disease are hypertrophic cardiomyopathy and myocarditis.⁵ Primary rhythm disturbances undoubtedly are underrepresented due to the inherent difficulty in identifying these causes after death.

In contrast, among athletes who have died suddenly, only 10 percent had previously experienced at least one episode of syncope.⁹ Even with a standard sports screening evaluation, fewer than 5 percent of athletes who subsequently die are suspected of having cardiac disease.⁹ The two most common cardiac lesions associated with sudden death among athletes are hypertrophic cardiomyopathy and aberrant coronary arteries.⁹ Other coronary artery abnormalities, Marfan syndrome (ruptured aortic aneurysm), valvular heart disease, myocarditis, and dilated cardiomyopathy are less common.

History

The most crucial step in evaluating a child with a syncopal or near death event is a careful medical history. Interview any family members, friends, or witnesses who were with the child just before the event. The events leading up to the incident should be described in detail, as should any apparent change in the child's behavior or symp-

oms. Pay particular attention to details such as the intake of medications, drugs, fluids, and food. Note the position the child was in when syncope occurred, because recumbent positioning is less consistent with NMS or other forms of vascular syncope. **A history of syncope during exertion or exercise increases the likelihood of the more serious etiologies.** The prodromal symptoms often will aid in identifying the cause of the event. The sequence and timing of motor movements, level of consciousness, and postural positioning will help to differentiate primary seizures from NMS or other true causes of syncope. A history of previous syncopal events should be sought. Any known medical problems should be considered, especially known cardiac diseases, diabetes, seizures, medication or drug use, or psychiatric or psychological problems. Ask about a family history of structural cardiac disease, dysrhythmias, sudden death, migraines, or seizures. Statements by the witnesses that the patient appeared dead and required cardiopulmonary resuscitation must be evaluated carefully. The duration of pulselessness and the degree of intervention required should be carefully recounted by the witnesses. Anytime that cardiopulmonary resuscitation has been performed, even if by an inexperienced lay person, the event should be considered a resuscitated sudden death and evaluated comprehensively.

Physical Examination

Complete cardiovascular, neurologic, and pulmonary examinations are crucial, but the findings are normal in the vast majority of children with syncope, regardless of the seriousness of the etiology. Neurologic examination should include deep tendon reflex, gait, and coordination testing. The cardiovascular examination includes assessment of blood pressure, resting heart rate, oxygen saturation, and respiratory rate. Pulse quality should be assessed in all extremities. Blood pressure and heart rate also should be measured during positional changes (orthostatic vital signs). Auscultation should be performed to identify any murmurs, abnormalities in rhythm, and variations or abnormalities in heart sounds. Any abnormalities in the cardiovascular assessment require an in-depth cardiac evaluation.

Laboratory Assessment

An ECG is recommended for nearly every patient, except those with an unmistakable vasovagal episode.¹⁰ Abnormalities on the ECG may not correlate with the syncopal event, and some patients with an arrhythmic cause of syncope will have normal ECGs.³ Other laboratory tests should be guided by clinical suspicion (e.g., a hemoglobin measurement for a patient with possible anemia or a glucose measurement for a patient with diabetes). Routine laboratory studies are not needed in a child with a clear episode of vasovagal syncope. However, patients with an atypical presentation or worrisome associated symptoms should have a serum chemistry panel, hematocrit, thyroid function tests, chest radiograph, and ECG in the ED. Hyperthyroidism predisposes patients to supraventricular tachycardias (SVTs), so thyroid function tests must be obtained with any child in whom an SVT is considered. In adolescents, a serum alcohol level and urine drug screen should be considered due to the possibility of illicit drug use (most commonly cocaine and amphetamines).

An echocardiogram should be obtained for patients with known or suspected cardiac disease. A patient with abnormal heart sounds, cardiac murmurs, evidence of cardiac chamber enlargement or repolarization abnormalities on ECG, or other features that suggest myocardial dysfunction requires a prompt echocardiogram. If an echocardiogram cannot be obtained in the ED, then an inpatient evaluation must be performed.

The clinical utility of other tests, such as stress tests, tilt-table tests, electrophysiologic studies, and cardiac catheterization, usually is directed by the pediatric cardiologist and is beyond the scope of this chapter.

Patients resuscitated from sudden death must have a complete evaluation unless a clear cause for the arrest is apparent. The diagnostic possibilities are extensive, so laboratory and radiographic studies should be directed by clinical and historical information. All such patients should have a serum chemistry panel, myocardial band enzymes of creatine phosphokinase (CPK-MB), complete blood cell count, serum alcohol level, urine drug screen, thyroid function tests, chest radiograph, and ECG in the ED. Look for complications resulting from the arrest, such as hypothermia, acidosis, rhabdomyolysis, and cerebral edema or hypoxia. The inpatient evaluation can include an echocardiogram, cardiac catheterization, stress test, and electrophysiologic testing as directed by the pediatric cardiologist.

SPECIFIC CONDITIONS

Neurally Mediated Syncope

This category comprises vasovagal syncope, vasodepressor syncope, neurocardiogenic syncope, reflex syncope, and simple faint. Three clinical patterns of NMS occur: vasodepressor syncope (due to vasodilation), cardioinhibitory syncope (due to vagal stimulation), and mixed syncope (due to both). Any disorder that causes vasodilation, vagal stimulation, or both can result in syncope. Neurally mediated syncope is the most common cause of syncope in children² and usually is preceded by a sensation of warmth, nausea, lightheadedness, and a visual grayout or tunneling of vision.¹⁰ This type of syncope frequently lasts less than 1 min.³ Common precipitating factors include prolonged recumbence just before standing or prolonged standing, sight of blood or disfiguring injury (e.g., fractures or soft tissue injuries), emotional upset, mild physical trauma or pain, physical exertion, and hot or crowded conditions. Other contributing factors that are less common include hypovolemia, anemia, dehydration, and pregnancy. Neurally mediated syncope also can occur with swallowing, urination, defecation, and coughing; breath-holding spells are a variant of this form of syncope. Medications that alter vascular tone or heart rate may contribute to the development of syncope, including P-blockers, calcium-channel blockers, and diuretics. Surreptitious use of diuretics is common among athletes, such as wrestlers, who must maintain weight restrictions.

Identifying NMS as the cause of syncope can be difficult in an ED. Because NMS is related to a wide range of clinical states and physiologically is mediated by inadequate compensatory mechanisms to maintain blood pressure and cardiac output, the distinction between syncope, NMS, and other causes of orthostatic syncope is often blurred. However, NMS and other orthostatic causes of syncope are generally considered to be benign illnesses.

ORTHOSTATIC SYNCOPE Patients typically will complain of lightheadedness and weakness after standing for a period ranging from seconds to minutes. Factors that predispose children to orthostatic syncope include anemia, dehydration, and medications, especially calcium-channel blockers and angiotensin-converting enzyme inhibitors.² A drop of greater than 20 mm Hg in blood pressure with an increase in heart rate of more than 20 beats/min while checking vital signs with the child in the supine to standing position is often considered diagnostic of orthostatic hypotension.

SITUATIONS. SYNCOPE Urination, defecation, coughing, and swallowing have been described as causing syncope. The pathophysiology probably is related to an exaggerated Valsalva response causing cardioinhibitory syncope. Stretching, neck extension, external neck pressure, and hair grooming also have been described as causing syncope, presumably due to carotid sinus hypersensitivity or abnormal Valsalva responses.

FAMILIAL DYSAUTONOMIA Abnormalities in heart rate and blood pressure control can be inherited as a primary disorder, such as the Riley-Day syndrome. This disorder results from abnormal development of the sensory and autonomic ganglia, perhaps due to a lack of nerve growth factor during embryogenesis. Manifestations include failure to thrive, developmental delay, temperature instability, abnormal sweating, absent lacrimation, breath-holding spells, and seizures.

Cardiac Dysrhythmias

Outpatient continuous portable ECG monitoring (Holter monitoring) identifies the cause of syncope in only 3 percent of pediatric patients.³ A cardiac dysrhythmia should be suspected if the syncope is associated with an intense sympathetic stimulus, such as fright, anger, surprise, or physical exertion.¹¹ The event usually will start and end abruptly, in contrast to nonarrhythmogenic causes such as hypoglycemia or seizures, which are more gradual. Associated symptoms may include palpitations or irregularities of heartbeat.

LONG QT SYNDROME This disorder may be inherited or acquired and is characterized by a prolonged QT interval on the ECG. Although the incidence of inherited LQTS is rare (1 in 5000 births), LQTS is associated with hypertrophic cardiomyopathy and thus accounts for up to half of the cases of sudden cardiac death.¹² Classically, a patient with LQTS should have a corrected QT interval that is longer than 0.44 s on the ECG.¹¹ Other abnormalities on the ECG associated with LQTS include torsade de pointes, T-wave alternans, notched T waves in three leads, and prominent U waves. Patients with a LQTS may have a normal ECG in the ED.³ These patients may be diagnosed by a history of LQTS in a family member (familial LQTS), stress testing (exertional LQTS), or Holter monitoring (intermittent LQTS). The history also should include any recent use of medications that can prolong the QT interval (Table 131-3). The 10-year mortality rate can be reduced from 70 to 4 percent by appropriate treatment.¹² Genetic studies to date have identified four genetic loci associated with LQTS, all of which encode proteins involved in sodium and potassium transport. Two congenital syndromes not associated with structural heart disease are also recognized: Romano-Ward syndrome is an autosomal dominant heterozygous condition not associated with deafness, whereas Jervell-Lange-Nielsen syndrome is the homozygous disease associated with deafness.

WOLFF-PARKINSON-WHITE SYNDROME Wolff-Parkinson-White syndrome is characterized by antegrade conduction through an accessory pathway causing a reentrant SVT. Symptoms are manifested when conduction down the accessory pathway occurs at very rapid rates, leading to a reentrant SVT. An ECG may show the characteristic delta wave, but it may be normal. Although Wolff-Parkinson-White syndrome occurs in only 0.1 percent of the general population, it is more common in patients with Ebstein malformation, corrected transposition of the great arteries (levo-TGA), and hypertrophic cardiomyopathy. The risks of sudden death and syncope are greatest in patients who have atrial dysrhythmias such as atrial fibrillation and atrial flutter. Patients at greatest risk for death are those who conduct antegrade over the accessory pathway, allowing 1:1 conduction of an atrial dysrhythmia. Atrial fibrillation and atrial flutter are rare before adolescence.

ATRIOVENTRICULAR BLOCK This condition is most common in children with congenital heart disease but also occurs as a rare congenital disorder. Atrioventricular (AV) block is most common after heart surgery but also occurs with acquired heart disease, such as hypertrophic cardiomyopathy and myocarditis, and muscular dystrophy. Acquired AV block occurs in 87 percent of children with carditis associated with Lyme disease.¹³ Congenital AV block was first described

TABLE 131-3 Medications That Prolong the QT Interval

Macrolide antibiotics
Erythromycin (many trade names)
Clarithromycin (Biaxin)
Azithromycin (Zithromax)
Tricyclic antidepressants
Imipramine (Tofranil)
Amitriptyline (Elavil)
Amoxapine (Asenden)
Desipramine (Norpramin)
Nortriptyline (Pamelor)
Others
Phenothiazines
Thioridazine (Mellaril)
Pimozide (Orap)
Antifungals
Fluconazole (Diflucan)
Ketoconazole (Nizoral)
Gastrointestinal prokinetics
Cisapride (Propulsid)
Antihistamines
Astemizole (Hismanal)
Terfenadine (Seldane)
Diphenhydramine (Benadryl)
Epinephrine
Local anesthetics used by dentist or physician
Trimethoprim
Trimethoprim-sulfamethoxazole (Bactrim)
Antiarrhythmics
Class IA
Quinidine (many trade names)
Procainamide (Pronestyl)
Disopyramide (Norpace)
Class IC
Ecainide (Enkaid) Flecainide
(Tambocor) Anti-nausea
Dolasetron (Anzemet)
Appetite Suppressant
Phentermine (Adipex, Fastin)
Quinolone Antibiotics
Moxifloxacin (Avelox)

by Morquio in 1901, and although the risk of death is highest in infants, asymptomatic children may also die in adolescence.¹⁴ Congenital AV block is also associated with mothers who have connective tissue disease. Syncope from a high-degree AV block not related to positional changes or exertion is called a *Stokes-Adams attack*. Prophylactic pacemaker insertion is routinely performed in children with acquired or congenital AV block.

SICK SINUS SYNDROME Sick sinus syndrome is also known as *tachycardia-bradycardia syndrome*. Isolated sinus node dysfunction rarely causes syncope; a syncopal event is more likely to be due to a reentrant atrial tachycardia. Most commonly, these dysrhythmias are associated with prior heart surgery, especially the Mustard or Senning operation for transposition of the great vessels and the Fontan operation. Syncope and sudden death can occur after pacemaker placement, because the pacemaker will prevent bradycardia but not tachycardia.

SUPRAVENTRICULAR TACHYCARDIA Any cause of SVT can lead to syncope while recumbent if the heart rate is high enough to inhibit cardiac filling or if coincident vasomotor abnormalities occur.¹⁵ Wolff-Parkinson-White syndrome and atrial fibrillation are the most common causes, but primary SVT can also occur. Episodes of SVT are associated with congenital heart disease, including Ebstein anomaly and levo-TGA.

PACEMAKER MALFUNCTION Although pacemakers are not common in childhood, any child with a pacemaker who has syncope or presyncope should be presumed to have a pacemaker malfunction. Syncope can be caused in several ways: lack of pacemaker output (low battery, broken lead, or malfunction), noncapture of myocardium (exit block or lead fracture), retrograde AV conduction (reflex vasodilatation from enhanced jugular venous pulsations with a ventricular pacemaker), and pacemaker-mediated tachycardia (sensed atrial tachycardia or retrograde P waves with an atrial sensing pacemaker).

Structural Cardiac Disease

HYPERTROPHIC CARDIOMYOPATHY Also known as *idiopathic hypertrophic subaortic stenosis*, this disease is a dynamic and a fixed subvalvular obstruction. Exertional syncope is a common presentation, but infants may present with congestive heart failure and cyanosis. Any child with exertional related syncope must have this diagnosis considered. Onset of symptoms in early childhood is associated with a greater risk of mortality; the 10-year mortality rate is 50 percent for children diagnosed before 14 years of age.¹⁶ Syncopal events appear to be related to myocardial ischemia and/or ventricular tachycardia, probably as an LQTS. An echocardiogram is necessary to exclude or confirm this diagnosis and should be done in the ED or on the inpatient ward. Most investigators recommend implantable cardiac defibrillators in children with hypertrophic cardiomyopathy.

DILATED CARDIOMYOPATHY This disorder is unusual in children but can occur by three general mechanisms: idiopathic, with congenital heart disease, or after myocarditis. Syncope and death are thought to be caused by ventricular dysrhythmias or severe myocardial dysfunction.

ARRHYTHMOGENIC RIGHT VENTRICULAR DYSPLASIA This disorder is rare in the United States but is a common cause of adolescent death in Italy. Presentation is more common in older adolescents or adults. Patients usually present with congestive heart failure, cardiomegaly, and syncope or sudden death from an dysrhythmia. Electrocardiographic abnormalities include left bundle branch block and T-wave inversion, but some patients may have a normal ECG. Even the echocardiogram, cardiac catheterization, and myocardial biopsy can be nondiagnostic.

CONGENITAL CYANOTIC AND NONCYANOTIC HEART DISEASE Hypercyanotic spells may progress to syncope in tetralogy of Fallot, tricuspid atresia, TGA, and Eisenmenger syndrome. Children with structural heart disease are also prone to ventricular dysrhythmias and AV block.

VALVULAR DISEASES Several valvular lesions are associated with syncope and sudden death. In general, the degree of valve dysfunction correlates with the risk of sudden death. *Aortic stenosis* is usually due to a congenital defect, often associated with a bicuspid valve, although unicommissural or severely dysplastic valves also occur. Other associated cardiac anomalies, in particular coarctation of the aorta, also occur. Most patients are identified by the presence of a murmur. Exertional syncope is due to reduced cerebral blood flow and is commonly associated with chest pain, dyspnea on exertion, and poor exercise tolerance. *Mitral valve prolapse* (MVP) itself is probably not associated with an increased risk of sudden death.¹⁷ A child with MVP and syncope requires a more intensive diagnostic workup. Adults with MVP and significant mitral regurgitation have more frequent dysrhythmias, but this has not been shown in children. *Ebstein malformation of the tricuspid valve* is an uncommon disorder. Sudden death is thought to be due to the development of supraventricular or ventricular dysrhythmias.

PULMONARY HYPERTENSION Primary pulmonary hypertension (without structural heart disease) is uncommon but can present in adolescence. It is often associated with dyspnea on exertion, shortness of breath, exercise intolerance, and syncope. Eisenmenger syndrome is acquired pulmonary hypertension due to a cardiac shunt. High blood flow to the pulmonary circulation from a left-to-right shunt leads to a reactive increase in pulmonary resistance. After months to years, the development of pulmonary hypertension causes the shunt to reverse to a right-to-left shunt, and cyanosis becomes apparent. One-half of patients with pulmonary hypertension develops syncope. Physical findings include an increased ventricular impulse, a loud second heart sound, and cyanosis, which is particularly prominent in patients with Eisenmenger syndrome. Syncope and sudden death in these patients usually are related to a dysrhythmia.

CORONARY ARTERY ABNORMALITIES Many of these patients present with sudden death during exercise or have a history of exercise-induced syncope. Abnormalities of coronary artery origin include the left main artery arising from the right sinus of Valsalva or, less frequently, the right artery arising from the left sinus. In both cases, the aberrant artery often passes between the aorta and the pulmonary artery, thus placing it at risk for extrinsic compression, especially during physical exertion. Other abnormalities include myocardial overbridging, coronary artery fistulae, coronary artery spasm, coronary ostial stenosis, coronary artery aneurysms, and stenosis from Kawasaki disease.

Noncardiovascular Causes

SEIZURES Although not truly syncope, a seizure may appear to be a syncopal event even to the medical professional. Seizures often have little or no prodrome and are associated with a loss of consciousness. Seizures usually have a prolonged recovery phase (postictal phase), which most syncopal events lack. Other findings commonly associated with a seizure include onset while supine, convulsions immediately with loss of consciousness, and a warm, flushed, or cyanotic skin color. Many patients who are diagnosed with a syncopal event in the ED are later found to have a seizure disorder.² Adding to the confusion, up to 71 percent of syncopal events may have associated behavior that could be called a seizure. Unfortunately, electroencephalographic monitoring is frequently normal even in patients who have experienced a seizure.

BREATH HOLDING Breath-holding spells are probably related to NMS. Typically, the children are 6 to 18 months old and have an intense emotional trigger that causes crying and then a breath hold during expiration.¹⁸ The children then become cyanotic or pale and lose consciousness from the progressive cerebral hypoperfusion. Myoclonic activity or seizure activity may occur. The episode is usually short, requires no specific intervention, and rapidly resolves with gasping respirations and progressive loss of cyanosis or pallor. Up to 20 percent of children with breath-holding spells develop NMS in later life.¹⁸

ATYPICAL MIGRAINE Basilar artery migraines may be associated with syncope due to poor cerebral circulation during vasospasm. Most patients with this disorder also will have headache, a family history of migraines, symptoms referable to the posterior cerebral circulation (visual changes, dysarthria, tinnitus, vertigo, or ataxia), and a normal heart rate and blood pressure during the event.

HYPERVENTILATION Severe hypocapnia can cause syncope by intense cerebral vasospasm that leads to cerebral hypoperfusion. Typically, there is also a history of dyspnea, chest tightness, lightheadedness, tunnel vision, carpopedal spasm, or paresthesias.

HYSTERIA Hysterical syncope is an event that occurs without neurologic or cardiovascular changes but otherwise has the visual appearance of syncope. Often these events occur in front of an audience, are independent of posture, and rarely result in injury. Patients frequently will fall gracefully and without injury to the floor. The patient may even describe the event, often in an indifferent or unconcerned manner, clearly indicating that consciousness was not lost.

HYPOGLYCEMIA Syncope due to hypoglycemia is more commonly of a gradual onset and is associated with diaphoresis, tachycardia, hunger, and generalized weakness. Unconsciousness resolves with glucose administration but does not usually resolve with recumbency. A history of disorders of glucose production (enzyme or storage deficiencies) or glucose use (diabetes) is usually present.

TREATMENT

Syncope

Most children with syncope will be fully recovered by the time they arrive at the ED.²³ Continued altered level of consciousness should prompt an evaluation for causes other than syncope. Treatment should be tailored to current symptoms. Signs of compromised oxygenation, ventilation, or circulation should be addressed immediately. A cardiac monitor should be applied to the patient while gathering the history and physical findings to document any transient dysrhythmias. Vascular access and blood for laboratory studies should be obtained for all children except those in whom a simple vasovagal event explains the symptoms. Treatment is targeted to specific identified etiologies for the syncopal event. Ongoing cardiac dysrhythmias or seizures should be managed as appropriate. Most patients, however, will have no treatable dysrhythmias in the ED.

Sudden Death

A child who survives an out-of-hospital cardiac arrest must be rapidly stabilized, and any identified conditions must be quickly treated. In general, the principles of pediatric advanced life support are followed (see Chap. 14). Unstable ventricular or supraventricular rhythms should be treated immediately with a cardioverter using direct-current countershocks in a synchronized or unsynchronized fashion. Wide QRS-complex tachydysrhythmias should not be treated with class 1A agents such as procainamide and quinidine if LQTS is suspected, because these medications act by also prolonging the QT interval. Class IB drugs, such as phenytoin or amiodarone, should be used instead.

Treatment in the ED is directed at identifying the probable cause for the arrest so that future events can be prevented. The possible etiologies are extensive, so laboratory and radiographic studies are directed by clinical and historical information. All patients should have a serum chemistry panel, complete blood cell count, serum alcohol level, urine drug screen, thyroid function tests, chest radiograph, and ECG in the ED. The inpatient evaluation can include an echocardiogram, cardiac catheterization, stress test, and electrophysiologic testing.

DISPOSITION

Syncope

A child who had a syncopal event can present a challenging disposition decision. When the cause of syncope is not readily apparent from the ED evaluation, multiple additional tests are frequently performed but rarely provide further diagnostic information.¹⁹ Unfortunately, few studies have examined the most effective evaluation in the ED and the hospital. Obviously, any child with a dysrhythmia documented by prehospital providers or on the ECG in the ED must be admitted. Children who

have any of the risk factors listed in Table 131-1 also should be admitted in consultation with a pediatric cardiologist. Patients with a normal ECG but a history suspicious for dysrhythmia are candidates for outpatient ambulatory cardiac monitoring. Identified causes of syncope should be treated as appropriate in the ED, and admission to the hospital should be directed by the need for further evaluation or therapy. All children admitted for a syncope evaluation should be placed on a cardiorespiratory monitor in the hospital.

If, after appropriately thorough history, physical, and laboratory evaluations, a clear precipitating cause for the syncope cannot be identified in the ED, the child may be discharged to home with close follow-up by the child's primary physician or a cardiologist. Because NMS accounts for up to 50 percent of the cases of syncope in children, most pediatric patients without cardiac risk factors or exercise-induced symptoms may be safely evaluated as outpatients.¹⁹ Many of these children will have additional tests as outpatients, including portable rhythm monitoring, tilt-table testing, and stress testing, although the cost effectiveness of this approach remains in doubt.¹⁹

Sudden Death

After stabilization, children who have suffered a sudden cardiac arrest should be transferred to a pediatric intensive care unit that is capable of managing cardiac disorders. These children must be transferred with a crew capable of treating cardiac arrest from any dysrhythmia. In general, this should be done with a dedicated pediatric critical care transport team and consultation with the receiving pediatric intensivist.

FLUID AND ELECTROLYTE THERAPY

William Ahrens

INTRODUCTION

Fluid and electrolyte abnormalities are among the most common problems confronting physicians who care for children. This is primarily due to the high incidence of gastroenteritis in the pediatric population, and the vulnerability of children to the loss of water and solutes. In poor countries, diarrheal diseases are common causes of infant death. In the United States, they often result in prolonged ED stays and hospitalization. Electrolyte abnormalities are most commonly secondary to fluid imbalances.

FLUID REQUIREMENTS

The key to managing fluids in infants and children is the realization that there are vast differences in the maintenance requirement of water in the first 2 years versus the rest of life. This reflects a direct correlation between caloric expenditure, reflected by the basal metabolic rate, and the requirement for free water. Rapidly growing infants have an extremely high basal metabolic rate and require an enormous number of calories relative to their body weight. They therefore require a correspondingly enormous amount of water. The daily turnover of free water in infants is up to 3 to 4 times that of adults. This includes increased insensible losses from the skin and respiratory tract, which are usually electrolyte free. Urine accounts for approximately 50 percent of daily fluid requirements and is the predominant cause of sensible losses; because infants have a decreased ability to concentrate urine, they lose a relatively large amount of free water through their kidneys in order to excrete solutes. In addition, a larger percentage of young infants' total body water is contained in the extravascular space in comparison with older children and adults. This puts them at greater risk for cardiovascular compromise when confronted with sudden fluid losses.^{1,2}

Caloric expenditure and therefore fluid requirements can be estimated from body surface area, which is huge in infants in comparison to adults. However, in the ED, weight is a sufficiently accurate and more easily obtained method of calculating fluid requirements. The fundamental formula is:

For the first 10 kg: 100 mL/kg per d
For the second 10 kg: 50 mL/kg per d
For more than 20 kg: 20 mL/kg per d

For example,

1. A 10-kg baby requires 100 mL X 10 kg, or a total of 1000 mL per d.
2. A 20-kg baby requires 100 mL X 10 kg = 1000 mL + (50 mL X 10 kg) = 500 mL, for a total of 1500 mL per d.
3. A 40-kg baby requires 100 mL X 10 kg = 1000 mL + (50 mL X 10 kg) = 500 mL + (20 mL X 20 kg) = 400 mL, for a total of 1900 mL per d.

Hypermetabolic states increase the need for free water. The most common of these are fever (which increases the free water requirement by approximately 12 percent per degree of elevation in temperature centigrade above normal), and increased sweating.

Electrolyte requirements remain constant throughout childhood and can be estimated by body weight. All infant formulas contain sufficient electrolytes to satisfy these, as do Ricelyte and Pedialyte. The requirement for sodium is 2 to 3 mEq/kg per d and for potassium is 2 mEq/kg per d (Table 132-1).^{1,2}

ISOTONIC DEHYDRATION

Isotonic dehydration occurs when there is a proportionately equal loss of sodium and water; the serum sodium thus remains within the normal

TABLE 132-1 Maintenance Requirements for Fluid and Electrolytes, Based on Body Weight

Body weight	0-10 kg	10-20 kg	>20 kg
Total water volume	100 mL/kg	1000 mL + 50 mL/kg for each kg > 10 kg	1500 mL + 20 mL/kg for each kg >20 kg
Sodium	3 mEq/kg	3 mEq/kg	3 mEq/kg
Potassium	2 mEq/kg	2 mEq/kg	2 mEq/kg
Chloride	5 mEq/kg	5 mEq/kg	5 mEq/kg

range of 130 to 145 mEq/L. It most often results from diarrheal illness and is the most common fluid and electrolyte problem encountered in pediatrics. Fluid is initially lost from the extracellular space. Intracellular fluid then shifts into the vascular tree, which protects circulating blood volume at the expense of intracellular dehydration.

The clinical manifestations of isotonic dehydration depend on the absolute volume deficit, the rate at which fluid is lost, and the age of the patient. When fluid is lost over a relatively long period, a large deficit may be well tolerated and clinical manifestations can be rather subtle, even though up to 40 percent of intracellular fluid may be lost. This most commonly occurs in patients with protracted diarrheal illnesses. In contrast, sudden massive loss of fluid such as occurs in cholera-associated or rotavirus diarrhea can be fatal if not treated aggressively, because most of the volume is lost from the extracellular space and there is insufficient time for intracellular fluid to shift into the vascular tree. This is especially true in young infants, because a relatively large percentage of their total body water is contained in the extracellular space. Rapid fluid loss can result in cardiovascular collapse, whereas older children will remain well compensated.

EVALUATION

The most accurate way to estimate the degree of dehydration is calculating weight loss, which in acute situations amounts to free water deficit. However, this information is rarely available. In practice, estimating the degree of dehydration depends on integrating multiple factors. Patients usually have a history of vomiting and diarrhea. It is useful to quantitate the approximate number of stools and to determine whether the patient is able to tolerate any oral feedings without vomiting. Parents are asked what liquids the child has been given, since excess free water can cause hyponatremia, and homemade remedies may contain excess sodium. A history of decreased urine output implies significant fluid loss, but may be difficult to quantitate when associated with significant diarrhea.

Physical examination has been demonstrated to provide a reliable estimation of the degree of dehydration² (Table 132-2). Hypotension

indicates hypovolemic shock. The patient's mental status is important: normal mental status usually implies mild dehydration, whereas irritability signifies at least moderate fluid loss. Lethargy implies severe volume loss and/or an electrolyte abnormality, especially hypernatremia. Decreased skin turgor and sunken eyes and fontanel imply moderate to severe fluid loss and usually occur when intracellular fluid has had time to diffuse into the intravascular space. In these patients, vital signs may be only slightly abnormal and not indicative of the degree of dehydration.

It is important to realize that assessing the degree of dehydration in very young infants is notoriously difficult, and fluid losses are often underestimated.*³

LABORATORY FINDINGS

In isotonic dehydration, the sodium level is within the normal range. The potassium level is usually normal or slightly decreased. The serum bicarbonate level is often decreased: in mild dehydration it is usually in the range of 15 to 20 mEq/L, whereas in more severe cases it falls below 10 mEq/L. A low serum bicarbonate level reflects stool losses, the presence of ketones from "starvation," and in severe dehydration, lactic acidosis. The blood urea nitrogen level usually rises with increasingly severe fluid losses. Urine specific gravity also rises in significant dehydration and may reach 1.030. In young infants, a decreased ability to concentrate urine may result in a falsely low specific gravity. In infants and children with mild to moderate dehydration, it is usually unnecessary to evaluate serum electrolytes. In neonates and young infants it is prudent to evaluate serum electrolytes if there is a history of significant fluid losses.⁴

MANAGEMENT

The management of dehydrated children depends on the degree of fluid loss, as well as a patient's ability to tolerate oral liquids (Table 132-3). Mildly dehydrated patients (<5 percent) who tolerate oral fluids can usually be discharged home on clear liquids with close follow-

TABLE 132-2 of Dehydration

Extent of Dehydration	Mild	Moderate	Severe
Weight loss†	5%	10% 4-	15% 7-
Infants	3%	6%	9%
Adolescents			
Pulse	Normal	Slightly increased	Very increased
Blood pressure	Normal	Normal to orthostatic, >10 mm Hg change	Orthostatic to shock
Behavior	Normal	Irritable, more thirsty	Hyperirritable to lethargic
Thirst	Slight	Moderate	Intense
Mucous membranes*	Normal	Dry	Parched
Tears	Present	Decreased	Absent, sunken eyes
Anterior fontanelle	Normal	Normal to sunken	Sunken
External jugular vein	Visible when supine	Not visible except with supraclavicular pressure	Not visible even with supraclavicular pressure
Skin* (less useful in children >2 years of age)	Capillary refill <2 s	Slowed capillary refill, 2-4 s (decreased turgor)	Very delayed capillary refill (>4 s) and tenting; skin cool, acrocyanotic, or mottled*
Urine specific gravity	> 1.020	> 1.020; oliguria	Oliguria or anuria

*These signs are less prominent in patients who have hypernatremia.

†A 3-month-old has about 70% total body water; a 15-year-old has about 60%.

TABLE 132-3 Dehydration in Children

Dehydration that occurs gradually is much better tolerated in infants and children than a sudden large loss of fluid. Mental status is an important indicator of hydration status. In mild or moderate dehydration electrolytes are almost always normal. In moderately dehydrated infants and children it is safe to predicate therapy by calculating a deficit of 10%. In patients in whom intravenous access is difficult, it is reasonable to attempt hydration using a nasogastric tube.

up. A "next-day hydration check" is especially desirable in infants less than 4 to 5 months of age. Moderately dehydrated patients generally require intravenous therapy, although oral rehydration is an option. Severely dehydrated patients require aggressive resuscitation. Boluses of 20 mL/kg of NS or LR solution are given until improved mental status, vital signs, and peripheral perfusion indicate stable intravascular volume. In patients in shock this may require 60 to 80 mL/kg. Isotonic crystalloid is utilized because it will stay in the intravascular space. Fluid replacement then consists of replacing 50 percent of the estimated volume deficit in the first 8 h, and the remainder of the deficit in the next 16 h. It is important to remember that maintenance fluids must be added to the deficit replacement; failure to do so will result in inadequate replenishment of volume. Some patients may require additional fluids to replace ongoing losses, such as can occur with profound diarrhea. For practical purposes, it is safe to assume a 10 percent deficit in healthy infants and children who appear dehydrated.

For example, a 12-kg infant is estimated to be 10 percent dehydrated. After a 20-mL/kg bolus of NS, she is alert and perfusion is adequate. Fluid orders can then consist of:

1. Maintenance is 100 mL/kg \times 10 kg/24 h = 1000 mL + (50 mL/kg \times 2 kg/24 h) = 100 mL, for a total of 1100 mL/24 h or 46 mL per h.
2. Deficit = 10 percent of body weight (1.2 kg) = 1200 mL; replace 600 mL over the first 8 h or 75 mL per h; replace 600 mL over the next 16 h or 38 mL per h.

Thus, for the first 8 h, maintenance + deficit = 121 mL per h; for the next 16 h, maintenance + deficit = 84 mL per h.

Appropriate rehydrating solutions in infants are D5 .25NS or D5 .45NS. In infants, D5 .20NS is utilized for maintenance rehydration in isotonic dehydration. In children, D5 .45NS can be used for maintenance rehydration in isotonic dehydration. Glucose is added to the solution to minimize further catabolism. After the patient has urinated, potassium can be added at a maximum concentration of 40 mEq/L. Most patients will begin to tolerate oral feeding with clear liquids within 24 h. All severely dehydrated patients are admitted to the hospital.

Patients who are moderately dehydrated can be managed in a number of ways. Some patients can be aggressively rehydrated with NS over a period of 2 to 4 h in the ED and safely discharged. Resuscitation consists of 40 to 50 mL/kg. Rapid nasogastric rehydration in lieu of intravenous therapy has also been shown to be a viable option in dehydrated infants. This may be preferable to both clinicians and parents when confronted with an infant or child in whom intravenous access is difficult to obtain. It may also be considered in more severely dehydrated infants in whom intravenous access is difficult, but in whom an intraosseous line seems inappropriately invasive. A more detailed discussion of oral rehydration follows below.

The success of rapid rehydration may be correlated with an initial serum bicarbonate level of greater than 13 mEq/L, but further study is needed to clarify this. Extreme caution should be exercised in using rapid rehydration in neonates and young infants, since the underlying gastroenteritis is likely to continue and these patients are at relatively high risk of cardiovascular compromise. If they are discharged, follow-up must be expedient and absolutely certain. Patients with persistent profuse diarrhea and those with intractable vomiting are candidates for

admission. Fluid management is then the same as for severely dehydrated patients, with 50 percent of the deficit replaced in the first 8 h and the remaining 50 percent replaced over the next 16 h. Oral rehydration is also an option and is discussed further below.^{5,8}

HYPERNATREMIC DEHYDRATION

Hypernatremia is defined as a serum sodium greater than 150 mEq/L. Hypematremic dehydration occurs when there is a relatively greater loss of free water than sodium. It often occurs when patients with gastroenteritis are treated with salt-rich solutions. The predominant clinical problems related to hypematremic dehydration result from the increase in serum osmolarity. As sodium rises and osmolarity increases, fluid is drawn from the interstitial and intracellular spaces into the vascular tree. This protects circulating blood volume and peripheral perfusion and can result in deceptively normal vital signs, despite severe dehydration. Loss of intracellular fluid causes doughy, tenting skin. Faced with osmotic disequilibrium, brain cells create charged molecules in an effort to preserve intracellular volume and electrical neutrality. Despite this, mental status changes are common, including irritability, lethargy, and seizures.

The most essential aspect of managing hypematremic dehydration involves replacing lost free water in such a way that the serum sodium falls no more than 10 to 15 mEq/L per d. A more rapid decrease in serum osmolarity can result in the influx of water into brain cells, resulting in cerebral edema. In patients in whom perfusion is inadequate, a 10- to 20-mL/kg bolus of NS is administered. The management of hypematremic dehydration is predominantly based on clinical experience, and there is no universal agreement on the optimal subsequent hydrating solution to be used, but D5 .45NS will be adequate in the majority of cases and is probably less risky than the more hypotonic D5 .25NS. It is most important that rehydration be spread out over 48 to 72 h, rather than the 24 h used for isotonic dehydration. Frequent monitoring of serum sodium during the resuscitation is necessary. In cases of severe hypernatremia ($\text{Na}^+ > 165$ mEq/L), it is reasonable to consult a pediatric intensivist or nephrologist after the patient is stabilized. Even with optimal management, patients with severe hypernatremia are at risk for neurologic sequelae. The essence of resuscitation of hypematremic dehydration is a slow correction of serum sodium in order to minimize the possibility of sudden changes in brain cell osmolarity.

DIABETES INSIPIDUS

Diabetes insipidus, which is most commonly caused by a deficiency of the antidiuretic hormone (ADH) arginine vasopressin, usually occurs secondary to damage to the neurohypophyseal unit and commonly occurs after severe head trauma, central nervous system infections, and suprasellar tumors, especially craniopharyngiomas. An extremely rare form of diabetes insipidus is characterized by a failure of the renal tubules to respond to vasopressin and is referred to as *nephrogenic*; it is a congenital disorder.

Clinically, diabetes insipidus is characterized by polyuria that can be massive. Most patients also manifest polydipsia. The excessive loss of free water can result in hypernatremia. The patient's urine is usually extremely dilute, with a specific gravity of less than 1.005 and an osmolality of 50 to 200 mOsm/L. Diagnosis can be made by water deprivation testing or by serum assay of vasopressin.

Diabetes insipidus is treated with desmopressin (DDAVP), an analogue of vasopressin. The dose is individualized, and consultation with a pediatric endocrinologist is advisable.¹

HYPONATREMIC DEHYDRATION

Hyponatremia is defined as a serum sodium level of less than 130 mEq/L. There are many causes of hyponatremia, which are usually

categorized on the basis of whether total body water is increased, decreased, or normal. Hyponatremic dehydration most commonly occurs when a parent replaces acute fluid losses from vomiting and diarrhea with water. Much less common causes of hyponatremic dehydration include adrenal insufficiency states, third-space losses from ascites or pancreatitis, and diuretic use.

In severe cases of hyponatremic dehydration, shock can result. However, the most common clinical manifestations of symptomatic hyponatremia involve the central nervous system. Although a gradual reduction in serum sodium is usually well tolerated, a sudden decrease can result in irritability, lethargy, and seizures. Seizures are most common with a serum sodium level of less than 120 mEq/L, but are more dependent on the rate of fall than the absolute value of serum sodium. Hyponatremia should be considered in infants who have a first-time seizure not associated with a fever, especially if there is a history of vomiting and diarrhea.

The management of hyponatremic dehydration associated with cardiovascular instability consists of the infusion of NS in 20-mL/kg boluses until the patient is stable. Many patients with gastroenteritis who suffer hyponatremic-induced convulsions will stop seizing following the administration of a bolus of NS alone. Subsequent management is aimed at restoring both the volume and sodium deficits. The standard formula used in correcting serum sodium is:

$$(\text{Na desired} - \text{Na measured}) \times 0.6 \times \text{kg body weight}$$

in which 0.6 reflects the fractional distribution of sodium. To prevent overcorrection, the desired sodium level is usually 125 mEq/L, which corrects osmolality sufficiently to prevent further seizures. In stable patients with acute hyponatremia, volume resuscitation and sodium correction can be carried out over 24 h, as there is no physiologic advantage to raising the serum sodium rapidly. In patients with profound hyponatremia or persistent seizures, it may be necessary to infuse 3% saline at a dose up to 12 mEq/kg; in clinical practice this is rarely necessary. In patients with chronic severe hyponatremia, rapid correction of serum sodium has resulted in central pontine demyelination.⁹

HYPONATREMIA WITH INCREASED TOTAL BODY WATER

Causes of hyponatremia associated with increased total body water include acute water intoxication, the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), edema-forming states including nephrotic syndrome, cirrhosis, and congestive heart failure.

Acute water intoxication can result in a profound rapid decrease in serum sodium. It is often psychogenic, but can occur in young infants who are accidentally given large amounts of free water. If seizures occur, treatment with 3% saline may be necessary. In most cases, fluid restriction suffices to lower serum sodium.

In SIADH, antidiuretic hormone (ADH) is secreted without an appropriate physiologic reason, and this stimulates the resorption of free

water, causing a dilutional hyponatremia. SIADH occurs in a variety of disease states, including meningitis and following head trauma. In the ED a frequent cause of SIADH is meningitis. The most important laboratory finding in SIADH is a urine osmolality greater than serum osmolality. Hypouricemia is also usually present. The fundamental treatment is fluid restriction.

In nephrosis and cirrhosis, hyponatremia is usually mild and chronic. Even though total body water is increased, intravascular volume may be low due to third-spacing. Treatment usually consists of diuresis, with a combination of albumin followed by a diuretic. These patients are best managed in consultation with a pediatric nephrologist.

ORAL REHYDRATION

It has been repeatedly demonstrated that oral rehydration is as effective as intravenous therapy in treating infants with mild to moderate dehydration. It has had an enormous impact in developing countries, where prepackaged electrolyte solutions are available in lieu of infinitely more expensive intravenous solutions. Although time constraints may limit oral therapy in EDs in the United States, emergency physicians who do work in international medicine must be familiar with its use.

Water and electrolyte solutions created for treating dehydrated patients differ from maintenance solutes, primarily in their composition of electrolytes. Rehydration solutions contain 60 to 90 mEq/L sodium and 2 to 2.5 percent glucose, compared with maintenance solutions, which contain approximately 45 to 50 mEq/L sodium (Table 132-4). The higher sodium content is thought to facilitate the absorption of water in the small intestine. Some controversy exists regarding the propensity of the World Health Organization's rehydrating formula, containing 90 mEq/L sodium, to cause hypernatremia. In dehydrated patients, this appears to be rare, but reformulated oral rehydrating solutions containing 50 to 60 mEq/L sodium are preferred by some. Studies continue to investigate the optimum sodium content of oral rehydration solutions, as well as the optimum composition of sugars. Current evidence indicates that reduced osmolality formulas limit the duration of diarrhea. In practice, maintenance solutions can be effectively used if rehydrating solutions are unavailable.

Fluid replacement is accomplished by administering 50 mL/kg over 4 h to mildly dehydrated patients and 100 mL/kg to patients with moderate dehydration. Vomiting can be reduced by administering the fluid slowly. This can be done by using a teaspoon or eyedropper. Ongoing losses from continuing diarrhea are also replaced. Once adequate hydration is reestablished, supplemental feeding should be encouraged. This is especially important in malnourished infants.

Severe dehydration, persistent vomiting, continuing severe diarrhea, or significant hypernatremia may preclude the use of oral rehydration when intravenous therapy is available. However, if necessary, the vast majority of these patients can be salvaged by persistent administration of small quantities of oral fluids.^{10,11}

TABLE 132-4 Composition of Commercial Oral Hydration Solutions

	Na ⁺ (mEq/L)	K ⁺ (mEq/L)	Cl ⁻ (mEq/L)	Base (mEq/L)	Carbohydrate [% Weight for Volume]
Maintenance solutions					
Resol (Wyeth)*	50	20	50	Citrate, 34	2% Glucose
Ricelyte (Mead Johnson)	50	25	45	Citrate, 34	3% Rice syrup solids
Pedialyte (Ross)	45	20	35	Citrate, 30	2.5% Glucose
Rehydrate solutions					
Rehydralite (Ross)	75	20	65	Citrate, 30	2.5% Glucose
World Health Organization formulation (for use in cholera)	90	20	80	HOC ₃ , 30	2% Glucose

*Includes calcium, 4 mEq/L; magnesium, 4 mEq/L; phosphate, 5 mEq/L.

SPECIFIC SITUATIONS

Pyloric Stenosis

The protracted vomiting that characterizes pyloric stenosis can result in significant losses of hydrogen ion, chloride, potassium, and occasionally, sodium. This leads to the characteristic hypochloremic metabolic alkalosis. Fluid replacement must take into account potentially severe losses of chloride and potassium. Appropriate replacement can be accomplished with NS with 40 mEq/L potassium. Serum electrolytes should be monitored during therapy.¹

Adrenogenital Syndrome

The most common cause of adrenogenital syndrome in children is congenital adrenal hyperplasia secondary to deficiency of 21-hydroxylase. Defective steroidogenesis results in a deficiency of cortisol and an overproduction of intermediary metabolites. Affected infant boys appear normal, whereas infant girls have ambiguous genitalia. Adrenal insufficiency can also occur in patients who have been on long-term treatment with steroids.

Patients can present with vomiting, lethargy, and failure to thrive. Profound volume deficit can lead to shock. Glucocorticoid deficiency can result in hypoglycemia, and mineralocorticoid deficiency causes hyponatremia and hyperkalemia. Metabolic acidosis may be present.

Initial resuscitation is with NS until adequate perfusion is reestablished. Hypoglycemia is treated with intravenous glucose. In infants, D25 in a dose of 2 to 4 mL/kg is usually adequate. In older children and adolescents, D50 in a dose of 1 to 2 mL/kg is appropriate. Neonates are best treated with D10 at 1 to 2 mL/kg to avoid rapid shifts in osmolality. Treatment also consists of initiating glucocorticoid therapy with hydrocortisone at a dose of 50 mg/m² per dose IV every 6 h. Mineralocorticoid therapy is not necessary during the acute adrenal crisis.¹

Cystic Fibrosis

Patients with cystic fibrosis have an elevated concentration of sodium and chloride in sweat. During hot weather or strenuous exercise, affected children can suffer severe salt depletion and corresponding electrolyte abnormalities. Intercurrent pulmonary infection may be present. Profound chloride loss is compensated for by a rise in serum bicarbonate, resulting in a metabolic alkalosis. Hyponatremia is present, and serum potassium is decreased. Patients can present with lethargy and signs of hypoperfusion. Treatment is with NS, with supplemental potassium.¹

Hypokalemia

Potassium is the predominant intracellular cation. Hypokalemia occurs when the serum potassium falls below 3.4 mEq/L, and most commonly occurs secondary to profuse vomiting with or without diarrhea. Therapy with loop diuretics can also cause hypokalemia. In diabetic ketoacidosis, profound hypokalemia can result from osmotic diuresis, although in the face of the hydrogen-potassium shift that accompanies acidemia, serum levels may be normal or falsely elevated. Uncommon causes of hypokalemia are renal tubular acidosis and familial hypokalemia-induced paralysis.

Severe potassium depletion can result in skeletal muscle weakness, ileus, and cardiac conduction disturbances. A prominent electrocardiographic (ECG) manifestation is the U wave. Clinical manifestations generally reflect the rate of fall of serum potassium rather than the absolute level.

In most cases, hypokalemia occurs slowly, and it is difficult to determine whole body stores based on the serum level. In general, oral replacement over several days is adequate. Dehydration must be cor-

rected. If intravenous therapy is necessary, 0.2 to 0.3 mEq[K⁺]/kg per h is adequate. In extremely urgent situations, such as hypokalemia-induced respiratory insufficiency, 1 mEq[K⁺]/kg per h can be administered, with continuous ECG monitoring. This is usually done through a central line. In diabetic ketoacidosis, potassium repletion should begin early in the course of therapy, since diuresis-induced depletion can result in profound hypokalemia as acidosis is corrected and serum potassium shifts into cells.¹

Hyperkalemia

Hyperkalemia is defined as a serum potassium level greater than 5.5 mEq/L. In infants and children, hyperkalemia is most commonly due to hemolysis that occurs during blood drawing and does not reflect serum levels. Causes of true hyperkalemia include renal failure, rhabdomyolysis, the use of potassium-sparing diuretics, and adrenal corticoid insufficiency. Metabolic acidosis can result in hyperkalemia due to the hydrogen-potassium shift.

Cardiac conduction delay is the most common manifestation of hyperkalemia and is potentially life-threatening. Peaked T waves are the first manifestation, followed by prolonged PR interval and then widening of the QRS complex, an ominous finding that can precede ventricular dysrhythmias and asystole. Any patient with ECG changes requires emergent therapy to reverse cardiac conduction toxicity. Asymptomatic patients with normal ECGs usually do well with therapy to enhance potassium excretion. Most commonly, this occurs in patients with renal failure who have sustained a gradual rise in serum potassium.

Treatment of symptomatic hyperkalemia is directed at immediately antagonizing its deleterious effects on cardiac conduction and at enhancing potassium excretion (Table 132-5).

Sodium polystyrene sulfonate is a resin that exchanges sodium for potassium at a 1:1 ratio and therefore enhances potassium excretion. It can be administered orally or by enema. A dose of 1 g/kg will lower serum potassium by up to 1.2 mEq/L. When it is administered orally, it is usually given with a cathartic to enhance transit time through the gastrointestinal tract. Hypernatremia or volume overload are potential complications. In patients with hyperkalemia secondary to renal failure, dialysis is usually necessary. In patients with hyperkalemia secondary to metabolic acidosis, normalization of serum pH usually restores serum potassium to normal levels.¹

Disorders of Calcium

Normally, 99 percent of total body calcium is contained in bone. Normal serum levels are maintained by a complex interaction between dietary intake, absorption from the GI tract and resorption from bone, and renal excretion. Serum calcium is inversely proportional to serum phosphorus. The active form of vitamin D stimulates absorption of calcium and phosphorus from the GI tract; its formation depends on exposure to sunlight and healthy kidneys. Parathyroid hormone increases calcium resorption from bone in response to hypocalcemia and increases phosphorus excretion. Calcitonin decreases calcium resorption from bone in response to hypercalcemia.

TABLE 132-5 Treatment of Hyperkalemia

1. Calcium gluconate 10%* 100 mg/kg IV given at rate not to exceed 100 nigr per min; onset of action, minutes; duration, 60 min
2. Sodium bicarbonate 1-2 mEq/kg IV; onset of action, minutes; duration, hours
3. Regular insulin 0.1 units/kg iv with D25W, 0.5 g/kg IV over 30 min. Check glucose every 30 min. Onset, 30 min
4. Sodium polystyrene sulfonate 1-2 g/kg PO, NG, or PR
5. Albuterol inhalation, 0.5% solution; onset of action, minutes

*10% calcium gluconate contains 100 mg/mL.

In the serum, 45 to 50 percent of serum calcium exists in the ionized or free form; most of the remainder is bound to albumin. pH affects the proportion of calcium that is ionized and therefore bioavailable. Acidosis increases and alkalosis decreases the fraction of ionized calcium.

HYPOCALCEMIA This can result from hypoparathyroidism or end-organ resistance to parathyroid hormone. True hypoparathyroidism can be idiopathic, follow thyroid surgery, and can be associated with magnesium deficiency. End-organ resistance to parathyroid hormone is most commonly associated with vitamin D deficiency. The most common causes of this are dietary deficiency and chronic renal failure. Young infants fed cow's milk, which is high in phosphate, can develop significant hypocalcemia. A common cause of hypocalcemia is hyperventilation; the decreased P_{CO_2} results in an acute respiratory alkalosis that rapidly decreases ionized calcium.

Clinical manifestations of hypocalcemia include muscle weakness, vomiting, and irritability. Infants may simply appear "jittery." In severe cases, tetany, laryngospasm, carpopedal spasm, and seizures can occur. Carpopedal spasm is especially common in patients with hyperventilation syndrome. The most characteristic ECG abnormality is a prolonged QT interval.

Laboratory evaluation of hypocalcemia of unknown etiology includes total serum and ionized calcium, phosphate, total protein and albumin, measurement of parathyroid hormone, and blood urea nitrogen and creatinine.

Intravenous calcium is the treatment of choice for symptomatic hypocalcemia. Calcium gluconate 10% is administered in a dose of 100 mg/kg at a rate not to exceed 100 mg per min, with continuous ECG monitoring. Further management depends on determining the etiology of hypocalcemia.¹

HYPERCALCEMIA This exists when serum calcium exceeds 11 mg/dL and most often results from increased bone resorption. Probably the most common cause in children is malignancy involving the lymphoreticular system. Less common causes include vitamin D intoxication and hypervitaminosis A.

Clinical manifestations of hypercalcemia include fatigue, irritability, anorexia and vomiting, and constipation. Affected patients may be clinically dehydrated and complain of polyuria. An ECG may reveal bradycardia and a shortened QT interval.

The laboratory evaluation of hypercalcemia includes evaluation of total serum and ionized calcium levels, a complete blood count, and evaluation of total protein and albumin and alkaline phosphatase. An evaluation of the vitamin D level may also be indicated, depending on the patient's medical history.

The treatment of hypercalcemia depends on the etiology. In the acute scenario, patients with functioning kidneys can be treated by aggressive intravenous hydration followed by furosemide, which will enhance calcium excretion.¹

UPPER RESPIRATORY EMERGENCIES

Randolph Cordle

STRIDOR

The physical sign common to all causes of upper respiratory tract (URT) obstruction is stridor.

Stridor is due to Venturi effects created by somewhat linear airflow through a semicollapsible tube, the airway. During inhalation the relative pressure in the center of the airway becomes greater than that at its edges. This pressure differential leads to partial collapse of the airway walls. During expiration, the previously collapsed areas reopen due to the relative increase in air pressure. Forced expiration or expiration against a partially closed glottis may cause expiratory stridor even in patients with a normal airway. Physiologic airway support increases with caudal progression through the major airways. Therefore, less inspiratory collapse is found in the trachea compared with the supraglottic airway.

Both inspiratory and expiratory stridor are associated with obstruction at the supraglottic, glottic, and subglottic levels, as well as the trachea and primary bronchi. Supraglottic obstructions cause inspiratory stridor, with marked inspiratory and expiratory variation, while obstruction at the glottic and subglottic areas commonly cause both inspiratory and expiratory stridor of lesser magnitude. Finally, obstructions at the level of the trachea and primary bronchi may be associated with inspiratory or expiratory stridor, although usually of a much lesser degree. Although the posterior walls of the trachea and bronchi are somewhat collapsible, relatively good support is provided by the horseshoe-shaped cartilage within its walls. In premature infants and infants with tracheomalacia, these supports are not well formed and inspiratory and expiratory stridor may be impressive.

Expiratory stridor, or wheeze, is common in distal airways, since intrathoracic pressure may become much greater than atmospheric pressure during expiration. The pressure differential creates high flow through the semicollapsible bronchi, resulting in wheezes. This information can be clinically useful while evaluating a wheezing child. Commonly, gentle pressure over the chest wall or midabdomen during expiration will increase the intrathoracic pressure and exacerbate wheezing, thus making the patient's bronchoconstriction obvious. This maneuver may also assist in detecting inspiratory stridor because the child will follow this forced expiration with a much deeper inspiration than at rest. Patients with marked variation in the pattern of stridor should be considered to have a foreign body in the airway until proven otherwise. The quality of the pitch is not clinically useful for diagnosis. The age of the patient will narrow the differential diagnosis considerably (Table 133-1).

Stridor in Children below 6 Months of Age

An infant under 6 months of age with a long duration of symptoms (weeks to months) typically has a *congenital* cause of stridor, with the

TABLE 133-1 Common Causes of Stridor**Children <6 months of age**

Laryngotracheomalacia: chronic, resolves by age 2
 Vocal cord paresis or paralysis
 Arnold-Chiari malformation

Children >6 months of age: acute

Viral croup
 Epiglottitis
 Retropharyngeal abscess
 Foreign body aspiration

major causes being laryngomalacia, tracheomalacia, and vocal cord paresis or paralysis.

Laryngomalacia accounts for 60 percent of all neonatal laryngeal problems. It is due to a developmentally weak larynx. Collapse occurs with each inspiration at the epiglottis, aryepiglottic folds, and arytenoids. Generally, the stridor worsens with crying and agitation. It often improves with neck extension and when in the prone position. This is a self-limited disorder resolving by 2 years of age in over 90 percent of cases. Symptom exacerbations may occur with upper respiratory infections or increased work of breathing due to any cause. It only rarely is associated with respiratory distress, failure to thrive, apnea, or feeding problems. Definitive diagnosis is by fiberoptic laryngoscopy. Rarely, tracheotomy or epiglottoplasty may be needed. In many cases the tracheal support structures are similarly affected, leading to the diagnosis of laryngotracheomalacia. Less commonly, the larynx will be adequately supported while the trachea is not, leading to a diagnosis of tracheomalacia.

The next most common cause of neonatal stridor is vocal cord paralysis or paresis. Most infants will have a history of birth trauma, shoulder dystocia, macrosomia, forceps delivery, an abnormal cry, or other intrathoracic anomaly. Diagnosis is typically by flexible fiberoptic laryngoscopy with visualization of the cords during speech or crying. In emergent respiratory failure, endotracheal intubation can be quite difficult in a child with bilateral vocal cord paralysis. Placing the bevel of the endotracheal tube parallel to the small remaining glottic opening and rotating the endotracheal tube one-quarter turn while applying gentle pressure may assist in passing the tube. Force should not be used, as this may damage the laryngeal structures. Needle cricothyroidotomy and subsequent tracheotomy may be required to secure the airway. It is unlikely that the laryngeal mask airway (LMA) would be helpful in this case. Use of the LMA is contraindicated in abnormal or obstructed airways because the path of least resistance to flow will likely be around the mask and not into the airway. Retrograde intubation may be difficult as well, owing to the size of the structures and potential difficulty in passing the wire from the trachea into the hypopharynx.

Arnold-Chiari (Chiari II) malformation should be considered in children with trisomy 21, myelomeningocele, hydrocephalus, sacral dimple, sacral epidermal abnormality, or other neurologic abnormalities who present with stridor. Chiari II malformations are likely due to failure of the fetal neural folds to fully close. The developing ventricular system fails to fill with CSF and distend properly due to continual drainage through this opening in the developing spinal cord. The posterior fossa subsequently develops too small to contain the developing brainstem, cerebellum, and associated structures. As the brainstem and cerebellum develop, they partially herniate both towards the tentorium and through the enlarged foramen magnum into the spinal canal. Chiari II, but not Chiari I, malformations are usually associated with other CNS abnormalities. Compression of the cerebellar tonsils, pons, medulla, and upper cervical spinal cord can lead to difficulty swallowing, arm weakness, facial weakness, nystagmus, inability to look upward, apnea, and stridor. Recognizing this cause of stridor is important diagnostically and therapeutically, as inline stabilization must be maintained if intubation is required to prevent further com-

pression of vital CNS structures and death. Urgent neurosurgical consultation and likely decompression are also required.

Stridor in Children above 6 Months of Age

The patient above 6 months of age with a relatively short duration of symptoms (hours to days) characteristically has an acquired cause of stridor. Causes are either inflammatory, such as croup or epiglottitis, or noninflammatory, such as foreign-body aspiration. The remainder of the chapter discusses the most common acquired causes of stridor: epiglottitis, peritonsillar abscess, viral croup, foreign-body aspiration, retropharyngeal abscess, and bacterial tracheitis (Table 133-2).

EPIGLOTTITIS**Clinical Features**

Since the introduction of the *Haemophilus influenzae* vaccine, the incidence and demographics of this disease have changed remarkably. Currently *H. influenzae* is thought to be responsible for less than 25 percent of cases. Now, gram-positive organisms such as *Streptococcus pyogenes*, *Staphylococcus aureus*, and *Streptococcus pneumoniae* are responsible for most cases in immunized children. In immunocompromised children, herpes simplex, *Candida*, and varicella must also be considered.

Prior to the introduction of the *Haemophilus* vaccine, the median age of this disease was 3 years, with 25 percent occurring in children under age 2. Although epiglottitis can occur at any age, its median age of presentation has shifted to older children and adults.

The classic symptoms are an abrupt onset over several hours of high fever, sore throat, stridor, dysphagia, and drooling. Some cases may develop over 1 to 2 days. Physical examination reveals a toxic-appearing, apprehensive child with an ashen-gray color. The child often sits in a tripod position, or the "sniffing" position, with the neck slightly extended and the chin forward. As opposed to the child with croup, there is no cough. The voice may be muffled, but supraglottic foreign bodies, peritonsillar abscess, and retropharyngeal abscess may present similarly. If inflammatory changes extend beyond the epiglottis to include the vocal cords, voice pitch will be altered as well.

Older children and adults may have much more subtle presentations. In fact, some older children will complain of only a severe sore throat. Stridor may or may not be present. The diagnosis is suggested by severe sore throat, the finding of a relatively normal-appearing oropharynx, and striking tenderness with gentle movement of the hyoid.

Diagnosis

The ideal approach to the diagnosis of epiglottitis varies depending on the practice environment. Each institution should have a written "Suspected Epiglottitis Management Protocol." The steps necessary in all protocols include:

1. Immediate recognition and triage to a resuscitation area
2. Continuous monitoring by someone trained in the management of the difficult airway
3. Rapid consultation with appropriate colleagues
4. Consideration and risk-benefit analysis of patient transfer with appropriate personnel present during the transfer
5. Bedside radiology without disturbing patient or, if moved to the x-ray suite, constant monitoring by a physician with appropriate airway equipment and skills

Lateral neck radiographs are usually unnecessary in patients with the classic presentation for epiglottitis. When the diagnosis is uncertain, radiographs should be taken with the neck extended during inspiration using soft tissue technique. The child typically holds his or her head in the

TABLE 133-2 Common Acquired Causes of Stridor

	Viral Group	Bacterial Tracheitis	Epiglottitis	Peritonsillar Abscess	Retropharyngeal Abscess	Foreign-Body Aspiration
Etiology	Parainfluenza viruses Occasionally RSV Influenza	<i>Staphylococcus aureus</i> (most) <i>Streptococcus pneumoniae</i> <i>Haemophilus influenzae</i>	<i>Streptococcus pneumoniae</i> <i>Haemophilus influenzae</i>	<i>Streptococcus pyogenes</i> <i>Staphylococcus aureus</i>	Polymicrobial <i>Streptococcus pyogenes</i> <i>Staphylococcus aureus</i> Beta-lactamase producers Gram-negative rods Oral anaerobes	Variable Peanuts Sunflower seeds Balloons/other toys Hot dogs Raisins/grapes
Age	6 mo-3 y Peak 1-2 y	3 mo-13 y Majority <3 y	All ages Classically 1—7 Median now 7	10-18 y (most) 6 mo-5 y (rare)	6 mo-4 y Peak < 1 y Rare >4 y	Any 6 mo-5 y most common 80% <3 y About deaths
Onset	1-5 days	2—7 day viral upper respiratory infection Suddenly worse over 8-12 h	Rapid, hours	Antecedent pharyngitis	Insidious over 2—3 days after an upper respiratory infection or local trauma	Immediate or delayed possible
Position effect	None	None	Worse supine Prefer erect	Worse supine	Almost opisthotonic May improve in sniffing position	Usually none Location-dependent
Stridor	Inspiratory and expiratory	Inspiratory and expiratory	Inspiratory	Uncommon	Inspiratory when severe	Location-dependent
Cough	Seal-like bark	Usually Possible thick sputum	No	No	No	Often transient or positional
Voice change	Hoarse Not muffled	Usually normal Possibly raspy	Muffled "Hot potato"	Muffled "Hot potato"	Often muffled "Hot potato"	Location-dependent Primarily if at or above glottis
Drool	No	Rare	Yes	Often	Yes	Rare—often if esophageal
Dysphagia	No	No	Yes	Yes	Yes	Rare—typically if esophageal
Radiologic appearance	Subglottic narrowing "steeples" Distended hypopharynx	Subglottic narrowing Ragged tracheal air shadow Tracheal foreign bodies	Enlarged epiglottis Vallecular space loss Supraglottic ballooning	May see enlarged tonsillar soft tissue	Thickened bulging pretracheal soft tissue	Often normal Possible radiopaque density Ball-valve effect Segmented atelectasis Air contrast effect may be seen

sniffing position and has prolonged inspiration already, making it quite easy to obtain radiographs. Lateral neck radiographs are not required if the patient is already intubated, as often the typical findings for epiglottitis will not be seen in such cases. False-positive findings may occur if the radiograph is taken during expiration or with the head flexed. False-negative radiographic evaluations do occur, and if suspicion for the diagnosis still exists despite normal-appearing films, direct visualization of the epiglottis is necessary to exclude the diagnosis.

In evaluating lateral neck radiographs, the epiglottis, vallecula, hypopharynx, tracheal air column, arytenoids, and retropharyngeal or prevertebral space should be assessed. The epiglottis is normally tall and thin, projecting up into the hypopharynx (Figure 133-1). Normally there is a poorly delineated space between the epiglottis and the anterior aspect of the hypopharynx. In epiglottitis, the epiglottis is swollen and appears squat and flat, like a thumbprint at the base of the hypopharynx (Figure 133-2). Commonly, the vallecular airspace is obscured. Another common finding is ballooning of the hypopharynx just above the area of the larynx. This is illustrated by the different sizes of the hypopharynx in Figures 133-1 and 133-2. While not spe-

cific for epiglottitis, this distention does indicate significant obstruction of the upper respiratory tract. The retropharyngeal space is normally 3 to 4 mm wide. Commonly it is stated that it should be less than the width of the adjacent vertebral body. The tracheal air column should be of uniform width and smooth, without densities on its internal walls.

In some scenarios, gentle direct visualization can be attempted. Most proponents of this practice would agree that it should be performed only at sites where experts in pediatric airway management are present with appropriate equipment to maintain the airway by whatever means necessary. Typically this is done in the following stepwise manner. In his or her position of comfort, the child is asked to open their mouth wide. If the epiglottis is not seen, the child is asked to stick their tongue out, with a tongue blade used to depress the anterior aspect of the tongue in the hope of visualizing the epiglottis. Having the child inspire slowly the entire time the tongue blade is in their mouth will prevent gagging. If the epiglottis is still not seen, as is common, fiberoptic laryngoscopy by an operator skilled in the technique, and with the ability to intubate over the scope, is the safest next step.

FIG. 133-1. A normal lateral neck x-ray. Open arrow points to epiglottis.

Airway Management

Should the child develop respiratory fatigue or if airway obstruction or apnea occurs before the airway has been secured, bag-valve-mask ventilation can be effective. Securing the pop-off valve may be necessary to provide adequate inspiratory pressures.

Patients with epiglottitis who are initially seen in an office, clinic, or ED without pediatric or ear-nose-throat (ENT) subspecialty support should be transported to a referral center by ground or air, whichever is more appropriate, accompanied by personnel who can manage the airway. Oxygen should be given as needed. Nebulized racemic epinephrine should be considered to decrease airway edema. The child should be kept seated upright. Heliox can also be a temporizing measure until consultants arrive (see discussion of croup, below). The referral center should be alerted as soon as possible, so that decisions concerning intubation or tracheostomy can be made in concert with consultants, and so that support personnel can be mobilized as needed. Patients usually are intubated by the most skilled individual available as soon as the diagnosis is made. Sedation, paralytics, and vagolytics are used as indicated. In a child who is able to maintain an airway, the decision to administer paralytics must be accompanied by the absolute certainty that intubation will be successful. To reduce the incidence of postextubation stridor, a tube one size smaller than usual should be used. Tube sizes above and below this size should be immediately available. The correct tube size will have a slight leak on auscultation at end inspiration. Evaluation of returned volume, ETCO₂ monitoring,

FIG. 133-2. Lateral neck view of a child with epiglottitis.

and chest wall motion will provide far more valuable information on adequacy of ventilation than does the tidal volume set on the ventilator due to leakage of air around the tube, especially as the swelling dissipates. The tube should be secured immediately, with as little patient movement as possible afterward to minimize the likelihood of tube dislodgement.

Supportive Therapy

A second- or third-generation cephalosporin such as cefuroxime, cefotaxime, or ceftriaxone is generally administered to ensure adequate coverage of *H. influenzae*. With the increasing incidence of *S. pneumoniae* as a cause for epiglottitis and the marked increase in resistance of this organism to cephalosporins, one may empirically give vancomycin also. Some recommend adding nafcillin instead, based on the increasing incidence of gram-positive cocci, including *S. aureus*, as etiologic agents. Blood cultures are positive in 80 to 90 percent of patients. Cultures of the epiglottis itself are much less sensitive. Typically oral antibiotics are continued for 7 to 10 days after the patient is extubated.

VIRAL CROUP

Viral croup (laryngotracheitis or laryngotracheobronchitis) is responsible for most cases of stridor after the neonatal period. Children 6 months to 3 years of age are most commonly affected, with a peak incidence between 1 and 2 years of age. Croup is relatively uncommon after age 6. This is due to the much greater effect of a small amount of mucosal edema and inflammation in the airway of a small child versus that of an older child. As little as 1 mm of airway edema in an infant may cause a decrease in cross-sectional area of 50 to 60 percent. This leads to increased resistance and work of breathing. In the adult airway, 1 mm of edema is nearly inconsequential. The incidence of true croup is thought to be equal in males and females, but many authors believe that moderate to severe cases are twice as common in males. Most cases occur in the late fall or early winter.

Acute viral croup is thought to be on a continuum with spasmodic croup. Prospectively it is very difficult or impossible to differentiate them. Retrospectively, spasmodic croup is seen more commonly in atopic children, has no seasonal variation, usually has almost complete symptom resolution within 6 h, is not characteristically associated with fever, and is often recurrent. Both spasmodic croup and acute viral croup have characteristic nocturnal exacerbations.

Etiology

Practically all cases are viral. Parainfluenza virus types I, II, and III are most common, but sometimes indistinguishable syndromes can be caused by influenza A or B, respiratory syncytial virus (RSV), rhinoviruses, adenoviruses, and even measles virus. Cases caused by adenovirus may be associated with hemorrhagic cystitis and conjunctivitis. Measles pneumonitis should be considered in atypical cases and, if suspected, treated aggressively. In nonimmunized or immunosuppressed adults, measles pneumonitis may prove fatal. The incubation period for parainfluenza virus is 2 to 6 days, and virus is usually shed for about 2 weeks. In cases caused by RSV, the shedding may continue for a much longer period and symptoms may take months to clear completely. In children over the age of 5, *Mycoplasma pneumoniae* infection has also been associated with a croup-like syndrome.

Signs and Symptoms

There is typically a 1- to 5-day prodrome consisting of cough, coryza, and occasionally other upper respiratory infection-type symptoms. This is followed by a 3- to 4-day period of barking cough. The cough

is typically worse in the late evening and at night and may occur strictly during these times. Children may or may not have a low-grade fever during the illness. The typical duration of symptoms ranges from 3 to 7 days regardless of the treatment. Typically the third and fourth days are the worst, and then the child starts to improve. Children who do not follow this general course should be reevaluated.

Viral croup is classically associated with biphasic stridor, although often the inspiratory component is much greater than the expiratory component. Stridor is unaffected by position but increases with crying or agitation. Intercostal retractions and tachypnea are common signs. The voice is often hoarse but not muffled. If inflammation extends from the trachea to the more distal bronchi, wheezing or crackles may be present.

Diagnosis

Croup is a clinical diagnosis. Generally laboratory tests are unnecessary. The white count is typically normal or demonstrates a slight lymphocytosis. Blood cultures or nasopharyngeal washings are not clinically useful, since knowing the exact etiologic agent does not change management.

Radiographs are needed only if other causes of stridor are being considered, or in atypical or prolonged cases. A lateral neck film and posteroanterior (PA) chest radiograph should be obtained as appropriate. The aryepiglottic area is normal. The lateral neck radiograph may demonstrate slightly ill-defined tracheal air shadows, narrowing on inspiration greater than that on expiration, and slight distention of the hypopharynx. Typically, fixed subglottic obstructions—such as papillomas, foreign bodies, hemangiomas, and subglottic stenoses—cause narrowing of the airway that does not change with the phase of respiration. Many of the latter noncroup causes also cause asymmetry in appearance, whereas croup causes symmetrical changes in the air column. The PA chest x-ray is most useful to rule out radiopaque foreign body. In cases of croup, the normally squared shoulders of the subglottic tracheal air shadow will appear more like a steeple, pencil tip, nail, or hourglass.

General Treatment

Pulse oximetry should be measured and supplemental humidified oxygen given. Children with croup should not be sedated except in the course of a rapid-sequence intubation. Antibiotics are not indicated for patients with a confident diagnosis of croup. Antipyretics should be given for fever to decrease minute ventilation and work of breathing. The least invasive route possible should be used to provide hydration to replace insensible water losses from respiratory distress and fever. Urine output, or the number of wet diapers, should be monitored and intravenous hydration provided only if necessary.

Exposure to humidified air, either cold night air or moist air from a shower, has been reported useful by parents for years, but humidification in croup tents has been shown not to be effective. Mild humidification may calm and soothe the child while possibly causing some mucosal vasoconstriction. Croup tents should not be used. In addition to lack of efficacy, they lead to increased anxiety, separation from parents, decreased ability of staff to monitor the child, and difficulty in maintaining oxygen provision at adequate levels.

In general, calculating a croup score (Table 133-3)¹ is more useful as a research tool than as an adjunct to clinical practice. Its primary role is to provide a semiobjective scale by which to classify patients for comparative studies. Its usefulness as a tool for clinical decision making with individual patients is much less clear. The score, if calculated, should only be used as one piece of data in the decision-making process. For example, a child with severe retractions and markedly decreased air entry may have a score of only 5, but would be considered at high risk by most clinicians and treated aggressively. Generally, healthy-appearing children with stridor only when agitated do not re-

TABLE 133-3 Modified Westley Croup Score*

quire treatment with epinephrine. Children with stridor at rest or who appear in distress should receive epinephrine as discussed below. All children receiving catecholamines should receive steroids as well. The use of steroids, as discussed below, is generally agreed upon in moderate to severe episodes of croup. In mild croup, controversy exists regarding the absolute need of steroid treatment, but there is increasing evidence of efficacy in this population as well. The use of steroids in the mildest cases may vary between reasonable clinicians. Further research using clinically important endpoints should clarify their use in this population.

Epinephrine

Racemic epinephrine, a nearly equimolar mixture of the two isomers (D and L) of epinephrine, is a mainstay of moderate to severe croup treatment. The majority of its activity is due to the L-isomer. The D-isomer is only about 30 percent as active as the L-isomer. The drug is quite effective when nebulized. Positive effects can be seen in as little as 10 min, with maximal effects seen at about 1 h. In most cases its therapeutic effects are practically gone by 2 h. Nebulized epinephrine decreases airway edema by vasoconstriction of the boggy mucosal vessels. It does not alter the natural course of disease, but does improve ventilation. Use of racemic epinephrine decreases the number of children with croup requiring intubation, intensive care unit admission, and admission to the hospital in general.

L-epinephrine, a pure isomer, is used as an advanced cardiac life support (ACLS) drug in a 1:1000 concentration. It is at least as effective and safe as racemic epinephrine (Table 133-4). Although some forms contain sulfur dioxide, a known respiratory irritant, this has not caused significant problems in this patient group. Both racemic and

TABLE 133-4
Epinephrine**for Stridor**

Drug	Concentration	Accurate Dosing*	Quick Dosing
L-Epinephrine	1 : 1000 1 mL = 1 mg	0.5 mL/kg (max 5 mL)	2.5 mL <1 y 5 mL >1 y
Racemic epinephrine	2.25%	0.05 mL/kg (max 0.5 mL)	0.25 mL <6 mo 0.5 mL >6 mo

*Diluted if necessary with normal saline to make 3–5 mL total volume.

L-epinephrine are relatively contraindicated and may worsen the obstruction seen in patients with severe left ventricular outflow obstruction (idiopathic hypertrophic subaortic stenosis, subvalvular aortic stenosis, etc.). When the drug is used in these patients, very close monitoring is indicated.

Ledwith's group monitored patients for 3 h after epinephrine nebulization and found that 38 percent of the patients who had a recurrence requiring admission did so between the second and third hour.² Prendergast et al. also demonstrated that there was an upward trend in the croup score between the second and third hours in those patients ultimately requiring admission.³ The current recommendation for moderate to severe croup is to administer nebulized epinephrine with early steroids (see below) and monitor these patients in the ED for at least 3 h before considering discharge (Table 133-5).

Dexamethasone

Steroids should be given within 1 h of presentation, and early effects of steroid use may be seen at 1 to 2 h. Most likely this is due to vasoconstriction of the edematous mucosa. Steroid effects on immune modulation and protein synthesis occur later and may be responsible for their longer-term clinical benefits. Certainly any child receiving nebulized epinephrine should also receive steroids.

Dexamethasone, a fluorinated derivative of prednisolone, has anti-inflammatory effects about 25 times greater than those of hydrocortisone at equal doses. It has minimal to no mineralocorticoid effect. Its half-life is about 2 days (range 36 to 72 h). Peak effects are seen in 2 h with persistent effects over the next 1 to 2 weeks. Early studies used 0.6 mg/kg of dexamethasone IM. This was the standard to which alternative dosages and interventions were compared. It was then shown⁴ that doses greater than 0.3 mg/kg of dexamethasone IM were clearly beneficial, but doses less than this had marginal benefit. Subsequent studies demonstrated that oral dexamethasone was as effective as intramuscular dexamethasone at the same dosages. Studies, primarily from the adult asthma literature, have demonstrated near bioequivalence of intravenous and oral steroids. Giving steroids orally has become standard practice for asthma and croup.⁵ Geelhoed's group demonstrated that 0.15 mg/kg, 0.3 mg/kg, and 0.6 mg/kg of oral dexamethasone have essentially equivalent effectiveness.⁶ This author

personally uses 0.3 mg/kg of dexamethasone PO. Although 0.15 mg/kg is likely equivalent, giving the higher dose allows a buffer zone for a little bit of medicine being spit out. The greatest problem with giving oral steroids is vomiting and the bitter taste. Various steroid preparations are available (Table 133-6). Using crushed dexamethasone tablets or giving the medication in small aliquots over the first 30 min is said to reduce the number of children who vomit. This author typically gives the 10 mg/mL IV formulation PO. This makes the volume nearly inconsequential (20-kg child = 0.6 mL), the taste nearly irrelevant, and the incidence of vomiting near zero, a major benefit for our nursing colleagues.

More recent studies have investigated the use of nebulized steroids. If steroids could be selectively deposited at the area of inflammation, they could have a greater effect on the disease process with fewer side effects. Johnson's study using dexamethasone resulted in benefits that were not clinically significant, and two children in the study developed bacterial tracheitis with associated neutropenia.⁷ Nebulized dexamethasone is not recommended. Multiple other studies using budesonide have had more encouraging results. Limited data suggests nebulized budesonide may have efficacy similar to epinephrine in moderate cases. Some will try a nebulized dose of budesonide in these cases as it allows for earlier discharge when effective. Whether or not an oral dexamethasone dose should be given as well in these cases is controversial and open to further research. A few conclusions can be drawn. Nebulized budesonide is effective, but has lower efficacy in most studies than dexamethasone given orally or IM.⁸ Results are mixed regarding an additive effect of nebulized budesonide with oral dexamethasone. One of Klassen's studies demonstrated a number needed to treat (NNT) of four for nebulized budesonide in addition to oral dexamethasone. The outcome measure in this study was a two-point decrease in Westley croup score during a 4-h treatment period.^{8,9} Although still controversial, it may be reasonable to give a dose of nebulized budesonide in addition to oral dexamethasone in moderate to severe presentations of croup where this potential effect could be clinically useful.

A child with resting stridor, increased Pco₂, decreased Po₂, impaired mental status, cyanosis, age less than 1 year (some say 6 months), or a croup score above 8 (see Table 133-3) should be considered in early respiratory failure and managed aggressively to prevent progression to respiratory arrest.

Fortunately, if treated aggressively, less than 1 percent of admitted patients will need intubation. Intubation should be performed whenever clinically indicated by the most experienced operator available. Based loosely on the available literature and on personal experience, this author strongly considers elective intubation in the following situations.

1. A croup score above 8 without rapid improvement
2. Two catecholamine nebulizations required within 1 h and patient fatiguing or getting worse
3. Hourly nebulizations required beyond the second hour
4. Acute mental status changes associated with respiratory distress
5. Worsening respiratory failure despite ongoing treatment
6. Severe croup in a child with neonatal lung disease
7. Moderately severe to severe croup in a child who needs transfer (especially if by helicopter)

TABLE 133-5 Discharge Criteria for Croup

At least 3 h since last epinephrine
Nontoxic appearance
Able to take fluids well
Not clinically dehydrated (labs not necessary)
Room-air oxygen saturation greater than 90%
Age greater than 6-12 months*
Weather conditions allow rapid return to ED for worsening
Parents have a phone and no social issues for concern
Caretaker seems able to recognize change in child's clinical status
Relatively short transit time from home to hospital

*Controversial.

TABLE 133-6 Steroids for Croup

Steroid	Concentration	Dose	Route	Information
Dexamethasone	0.25, 0.5, 1, 1.5, 2, 4, 6 mg tablets	0.3 mg/kg	PO	Crush in juice, acetaminophen elixir, or applesauce Erratic GI absorption Minimize volume May contain 5% alcohol Taste varies by brand May contain 30% alcohol No need to dilute
	4, 10, 20, 24, mg/mL 8, 16 mg/mL	0.3 mg/kg	IV	
	0.5 mg/5 mL elixir	0.3 mg/kg	IM	
	0.1 or 1 mg/mL oral solution 10 mg/mL IV solution	0.3 mg/kg	PO	
		0.3 mg/kg	PO	
Budesonide	2 mg/4 mL	2mg	Nebulized	Not available in U.S.
Prednisolone	5 mg/5 mL syrup	1 mg/kg	PO	Pediapred 5% alcohol Prelone
	15 mg/5 mL syrup	1 mg/kg	PO	Orapred; great taste and less volume
	15 mg/5 mL	1 mg/kg	PO	
Prednisone	1, 2.5, 5, 10, 20, 50 mg tablets 1 or 5 mg/mL syrup	1 mg/kg	PO	Poor taste

In children with a less than 40 percent oxygen requirement, a trial of heliox should be given before intubation whenever feasible (see below).

The cricoid cartilage is normally the narrowest part of the young child's airway and will be especially narrow in croup owing to mucosal inflammation of the trachea. Subglottic stenosis after extubation can be minimized by using a tube that is 0.5 to 1.0 mm smaller than would typically be used. Never force a tube through the cricoid ring. Be sure a slight air leak is present after intubation.

Fiberoptic laryngoscopy should be considered in atypical or recurrent presentations of a croup-like syndrome. It may also be indicated in children who fail to respond to standard therapy and occasionally in the very young to rule out laryngomalacia and other congenital causes of stridor.

Heliox

Helium is much less dense than either oxygen or nitrogen. Replacing nitrogen with helium decreases airway resistance. Heliox will improve ventilation in patients with nearly all types of upper airway obstruction. In fact, Weber's group¹⁰ compared heliox to racemic epinephrine in a small number of patients with moderate to severe croup and demonstrated similar reductions in modified Taussig croup scores in the first and subsequent 3 h. Heliox may also restore laminar flow, improving ventilation and ventilation/perfusion matching. The work of breathing also decreases. Carbon dioxide diffuses much faster through a helium-oxygen mixture than it does through a nitrogen-oxygen mixture. This may make ventilation more effective. One easily forgotten point is that oxygen and helium gas cannot occupy the same space. Due to the rule of partial pressures, if the helium concentration is increased, the oxygen concentration must decrease. Helium has therapeutic effects only when its concentration makes up 60 to 80 percent of the inspired gas. Therefore an individual who requires greater than 35 to 40 percent oxygen cannot use this modality. The flow of oxygen and helium must be high enough to exceed the patient's minute ventilation to prevent entrainment of room air and increased dead-space ventilation.

The indications for the use of heliox are still somewhat controversial. Most would agree that children not requiring high-flow oxygen should be given a trial of heliox for poor ventilation secondary to partial upper airway obstruction. At a minimum this may serve as a temporizing measure and allow for a more controlled intubation. Following intubation, helium may be given through the ventilator circuit as a mixture with oxygen. Volume and flow readings from the ventilator will be inaccurate if helium is used, since ventilators are calibrated for use with a nitrogen-oxygen mixture.

BACTERIAL TRACHEITIS

Bacterial tracheitis, also known as membranous croup or membranous laryngotracheobronchitis, is rare. It is generally caused by bacterial superinfection of an antecedent viral upper respiratory infection. It is most commonly seen in children less than 3 years of age, with a median age of incidence of 4½ years. Nearly all reported cases have arisen in children between 3 months and 13 years of age. Typically, 2 to 7 days of a croup-like syndrome is followed by worsening symptoms and the development of a toxic appearance over a period of several hours. Children appear septic or similar in appearance to those with epiglottitis with a few important differences. As a rule, children with bacterial tracheitis have severe inspiratory and expiratory stridor, cough with occasional thick sputum production, a raspy or hoarse voice, and no dysphagia. They may also complain of a gnawing or burning substernal chest discomfort.

The history, physical exam, laboratory, and radiologic findings may help diagnose less obvious cases in well-appearing patients. Most patients will have a markedly elevated white count with an impressive left shift. Blood cultures are typically negative. Anteroposterior (AP) and lateral neck radiographs usually demonstrate subglottic narrowing of the trachea. Irregular densities may be seen within the trachea and its borders may appear ragged and indistinct.

Management is similar to that of epiglottitis. Ideally, these patients should go to the operating room for sedation, intubation, and bronchoscopy. Culture and Gram stain of the mucopurulent secretions should be obtained at this time. Gram-stain findings may help guide antibiotic therapy. In less severe cases without respiratory distress, bronchoscopy may be performed without immediate intubation. This is the exception to the rule, however, as greater than 85 percent of cases will require intubation.

Antibiotics effective against *S. aureus*, *S. pneumoniae*, and beta lactamase-producing gram-negative organisms such as *H. influenzae* and *Moraxella catarrhalis* should be given empirically. Vancomycin and a third-generation cephalosporin, such as cefotaxime or ceftriaxone, are commonly used.

FOREIGN-BODY ASPIRATION

Demographics

The peak incidence of foreign body aspiration is in the 1- to 3-year-old age group. At least 90 percent of cases are seen in children under age 4 and it has been reported in infants as young as 3 months. In children younger than 6 months, foreign-body aspiration is often secondary to a feeding given by a well-meaning sibling.

The most commonly aspirated foreign bodies fall into two groups: foods and toys. The most dangerous objects are those that are cylindrical or small, smooth, and round. Commonly aspirated foods include peanuts, sunflower seeds, raisins, grapes, hot dogs, and small sausages.

In 1979, the federal government instituted the Consumer Product Safety Act, which has decreased the incidence of toy aspiration. However, watchdog groups warn that most toys are not properly evaluated for safety prior to marketing. Anticipatory guidance should include recommendations that consumers directly inspect toys and follow all warning labels.

Although small, round metal objects typically do not cause tissue reactions, vegetable matter does. Aspirated vegetable matter commonly causes an intense pneumonitis and subsequent pneumonia and/or suppurative bronchitis. Aspirated vegetable matter is often difficult to remove if not found early. It swells with the absorption of moisture from the surrounding lung, and if left long enough, seeds may even sprout.

At presentation, many patients with foreign-body aspiration may be completely asymptomatic with a normal physical exam. Some data suggest that the majority will present with or will have previously had symptoms consistent with but not specific for foreign body aspiration. The study of Laks and Barzilay demonstrated fever in 36 percent, wheeze in 35 percent, crackles in 38 percent, and tachypnea in 45 percent of patients at presentation.¹¹ Although the location of the aspirated foreign body does play a role in determining the symptoms and signs seen on presentation, there is overlap between groups. Classic dogma is that laryngotracheal foreign bodies cause stridor, whereas bronchial foreign bodies cause wheezing. Studies have shown, however, that about 30 percent of laryngotracheal foreign bodies and up to 10 percent of bronchial foreign bodies will demonstrate wheezing and stridor, respectively. More importantly, a significant proportion will have no cough, wheeze, or stridor. It is true that the majority of patients presenting with severe immediate-onset stridor or cardiac arrest after aspiration will be found to have a laryngotracheal foreign body. Patients with alternating wheezing and stridor may have a mobile foreign body. Other signs and symptoms of foreign-body aspiration may include cough, history of a choking episode, history of persistent or recurrent pneumonia, apnea, pharyngeal pain, or persistent symptoms of croup or asthma remaining after adequate treatment for 5 to 7 days. Foreign-body aspiration should be considered in all children given a diagnosis of unilateral wheezing. Upper esophageal foreign bodies may impinge upon the posterior aspect of the trachea, leading to signs and symptoms of airway obstruction. Commonly the patient will present with stridor. Contrary to most cases of airway aspiration, patients with an esophageal foreign body typically will have dysphagia.

A high index of suspicion is required to diagnose this disorder. Foreign-body aspiration should always at least be considered in a young child with respiratory symptoms, regardless of the duration of symptoms, since many children may present more than 24 h after foreign body aspiration. If the clinical scenario clearly indicates the presence of a foreign body or airway obstruction, a protocol for obstructed airway should be implemented immediately (see Chap. 14). When the diagnosis is considered in a stable child, plain radiographs may be helpful if positive. Clinicians should never rule out foreign-body aspiration based only on plain radiographs, as they may be entirely normal in up to one-third of foreign-body aspiration cases. Most aspirated foreign bodies are not radiopaque.

Nonradiopaque foreign bodies at the laryngeal or tracheal locations may be identified by looking for telltale air contrast of the foreign body in relation to the surrounding normal soft tissues. Computed tomography (CT) may be helpful. In most cases, however, additional radiologic procedures are not ideal, and laryngoscopy and rigid bronchoscopy are indicated.

In cases of complete obstruction, segmental atelectasis may be seen on plain radiographs. In other cases, intermittent or partial obstruction occurs, creating a ball-valve effect (Figure 133-3). In these cases, additional radiographs or fluoroscopy may be helpful. Partial obstruction, most commonly of the right mainstem bronchus, may cause obstructive emphysema of the involved lung by allowing air past the obstruction on inhalation, but preventing its passage on exhalation. In cooperative, stable children, inspiratory and expiratory PA chest radiographs to search for hyperinflation of the involved lung with contralateral mediastinal shift and decreased excursion of the ipsilateral diaphragm may be indicated. Forced expiration by having a parent gently push on the child's lower abdomen during expiration may increase the sensitivity, but this has not been adequately studied. In young or uncooperative children, the ball-valve phenomenon may best be demonstrated by fluoroscopy. Bilateral decubitus PA chest radiographs may also be used, but are less sensitive than fluoroscopy. The obstructed side will remain fully inflated with the ipsilateral diaphragm inferiorly displaced when the involved side is down. When the unobstructed side is down, it will show the normal findings of diaphragmatic elevation, rib splinting, and decreased relative volume compared to the other side (Figures 133-4 and 133-5). Foreign-body aspiration is definitively diagnosed preoperatively in only about half of cases. Clinically suspected foreign-body aspiration should ultimately be ruled out by bronchoscopy.

Esophageal foreign bodies may sometimes cause stridor. Esophageal foreign bodies more commonly are radiopaque, and are therefore more easily seen on plain radiography. In general, narrow, flat foreign bodies such as coins will be oriented in the coronal plane if they are in the esophagus. The tracheal cartilages with the exception of the cricoid ring are incomplete and horseshoe-shaped, with the opening directed posterior. These anatomic characteristics cause most narrow, flat radiopaque tracheal foreign bodies to be sagittally oriented on radiography, but certainly exceptions to these generalities do occur. Radiolucent foreign bodies in the esophagus may be suspected in many cases due to an air-fluid level or soft tissue changes in the area just cephalad to the obstruction. Older children may complain of something stuck in the throat. Discussion of esophageal foreign-body management is found in Chap. 76.

Treatment

If a child who is presumed to have aspirated a foreign body has severe signs and symptoms but is maintaining the airway, and is alert and able to speak, the predetermined obstructed airway protocol should be instituted. If local personnel are not able to remove the foreign body, a transport team experienced in the management of the difficult pediatric airway should be summoned to the patient's location. Ideally, the transport team will have a physician member trained and experienced

FIG. 133-3. Inspiratory and expiratory films in foreign-body aspiration.

FIG. 133-4. Normal decubitus film with left side down.

in the removal of foreign bodies and in the management of the difficult pediatric airway. In general, the foreign body should be removed. If this is not possible, as in the case of a supralaryngeal foreign body, the child should be electively intubated prior to transport. Exceptions may occur based on clinical circumstances. Racemic epinephrine or heliox may be an alternative.

The outcome of patients with laryngotracheal foreign-body aspiration and sudden collapse or cardiopulmonary arrest primarily depends on appropriate bystander basic life support and emergency medical system response. Basic pediatric CPR and foreign-body removal are discussed in Chap. 14, and pediatric airway management is discussed in Chap. 15. The management of swallowed foreign bodies is discussed in Chap. 76.

FIG. 133-5. Decubitus film, right side down, with foreign-body aspiration on the right side.

PERITONSILLAR ABSCESS

Peritonsillar abscess in children most commonly presents in adolescents with an antecedent sore throat. Often there is a period of improvement prior to the onset of progressively worsening symptoms. Peritonsillar abscess may rarely occur in the younger child. Most commonly, patients appear acutely ill with fevers, chills, dysphagia, trismus, drooling, or a muffled or "hot potato" voice. When present, trismus is thought to be due to secondary inflammation of the neighboring pterygoid muscles. There may be ipsilateral ear pain and torticollis. Torticollis may represent an attempt to relax the ipsilateral sternocleidomastoid muscle so as to decrease pressure on the peritonsillar space.

The peritonsillar space includes the superior aspect of the tonsil and the area lateral to the adenoids to the area of the pyriform sinus. Once a tonsillar infection has escaped the boundary of the tonsillar capsule, purulent material may flow relatively freely throughout this area. These anatomic relationships are important to remember, as they help to explain the classic physical findings of this disease process.

Careful visualization of the oral cavity is a must to reliably rule out this infection. The majority of cases will involve the superior aspect of the peritonsillar space, which can lead to discovery with meticulous examination. This may be nearly impossible in the young child with trismus. Diagnosis in this case is more challenging. In this instance, some have recommended CT scanning of the oropharyngeal and cervical soft tissues, while others believe that this practice may be dangerous as the child could acutely obstruct the airway. One possible alternative is an ultrasound examination at the bedside.^{12,17} The literature on this topic is controversial and the reported accuracy likely dependent on the operator's experience, inclusion and exclusion criteria used in the study, and the pretest likelihood of abscess (or prevalence of disease in those included). Ultrasound may be useful for localization purposes when an abscess is seen.

Typically, however, bilateral tonsillar erythema and exudate will be noted on exam. The uvula and anterior pillar of the tonsil on the affected side may be displaced away from the involved tonsil. The involved tonsil is, as a rule, anteriorly and medially displaced. Cervical adenopathy is often present but does not differentiate this process from the much more common causes of pharyngitis.

When uvular deviation, marked soft palate displacement, severe trismus, airway compromise, or localized areas of fluctuance are noted, the diagnosis of peritonsillar abscess can be made with confidence and no imaging study is required. In less obvious cases with minimal or no trismus, no localized areas of fluctuance, and no displacement of pharyngeal structures, differentiating peritonsillar abscess from peritonsillar cellulitis is difficult. If a child appears toxic, the diagnosis should certainly be considered peritonsillar abscess until proven otherwise. In younger children, imaging may be required to help differentiate these processes (see above). In nontoxic-appearing adolescents with good follow-up, involved parents, and findings most consistent with peritonsillar cellulitis, a trial of antibiotics may be the best choice for initial treatment. Penicillin, a macrolide, or clindamycin are most commonly used.

The definitive treatment of peritonsillar abscess has changed significantly over the last decade. Previously, most cases were taken to the operating room for incision and drainage. Today, the majority of cases are treated as outpatients with needle aspiration, antibiotics, and pain control. Clearly, definitive follow-up is a must. The local protocol and individual physician comfort should dictate who performs the peritonsillar abscess aspiration. Very young and uncooperative children may be better served with formal incision and drainage in the operating room. Some have used ketamine successfully to accomplish this safely in the emergency department. The patient must be under control during needle aspiration to prevent injury to the jugular vein and carotid artery. In general, a single episode of peritonsillar abscess is not an indication for tonsillectomy.

RETROPHARYNGEAL ABSCESS

Demographics

Retropharyngeal abscess, although relatively rare, is the second most commonly seen deep neck space infection. The usual age range is 6 months to 4 years, with the peak incidence in infants. Retropharyngeal abscess is quite rare after age 4 because repeated upper respiratory-type infections have obliterated the retropharyngeal lymph nodes by this age in most children. Most cases of retropharyngeal abscess evolve insidiously over a few days following a relatively minor upper respiratory infection. Localized trauma to the posterior pharyngeal wall is another cause. This most commonly occurs in children who fall with a stick or similar object in their mouths.

Anatomic Relationships

Two major cervical lymph node chains enter the retropharyngeal space. They drain lymph not only from the nasopharynx but also the adenoids and the posterior paranasal sinuses. The retropharyngeal space is the potential space located between the posterior pharyngeal wall (more properly the buccopharyngeal fascia) and the prevertebral fascia. It extends from the base of the skull to the level of T1 or T2 in the area of the posterior mediastinum. It is the only deep neck space that extends the entire length of the neck. Anatomists believe that it may actually be in continuity with the prevertebral space, which extends to the level of the psoas muscle. For this reason or due to erosion through the prevertebral fascia, infections in the retropharyngeal space are known to have extended this entire length.

Signs and Symptoms

The symptoms most commonly found in patients with a retropharyngeal abscess are, individually, not specific, but, together, point toward the correct diagnosis. Although not commonly recognized in preverbal children, older children will complain of sore throat. Most have a history of high fever. Other symptoms include dysphagia, decreased oral intake, and stiff neck.

In general, children with retropharyngeal abscess appear quite ill. Signs of retropharyngeal abscess include muffled voice, persistently hyperextended neck, inspiratory stridor, meningismus, and, if partial airway obstruction is present, respiratory distress and tachypnea. Ipsilateral cervical adenopathy has also been described but is not specific. Often a unilateral or bilateral retropharyngeal mass can be visualized during examination of the oropharynx. Unilateral masses are typically easier to detect than bilateral ones. Although palpation will commonly demonstrate fluctuance, this practice is dangerous and unnecessary. Laboratory testing is neither sensitive nor specific for retropharyngeal abscess.

Classic teaching is that a lateral neck radiograph should be obtained when one suspects this infection. This radiograph should be taken during inspiration with the neck extended so as to limit false-positive results. Diagnostic criteria for this radiograph are controversial (Figure 133-6). Most would agree that the normal prevertebral soft tissue should be no wider at the second cervical vertebra than the diameter of the vertebral body at the same level. Radiographs showing slightly wider prevertebral soft tissues at this level without obvious bulging have a low specificity for retropharyngeal abscess. If the criterion for a positive test is considered two times the diameter of the vertebral body at the same level, the sensitivity is about 90 percent, but the specificity is still not very good unless air-fluid levels are seen within the retropharyngeal soft tissues. Still others have suggested using values of 7-mm prevertebral soft tissue width at C2 and 14-mm prevertebral soft tissue width at C6 as the criteria for the presence of a retropharyngeal abscess. The sensitivity and specificity of these criteria would seem to be quite dependent on the age and position of the

FIG. 133-6. Lateral neck view of a child with retropharyngeal abscess and widened retropharyngeal space.

patient. Others have found no correlation between the findings on lateral neck radiographs and CT scans in patients who clinically appear to have a retropharyngeal abscess. Therefore, definitive diagnosis should be based on CT scan results whenever possible. CT scan differentiates cellulitis from abscess and helps with surgical planning by demonstrating the degree of extension that has occurred. It can also be used to clarify equivocal x-ray findings. CT's sensitivity for retropharyngeal abscess is thought to be near 100 percent. Unstable patients should be intubated before going to the CT scan suite. A physician accustomed to managing the difficult pediatric airway and appropriate equipment should accompany stable patients. Risks and benefits of sedation must be seriously considered in non-intubated patients.

Treatment

After the airway has been stabilized, the patient should receive analgesia and in most cases be prepared for surgery. Retropharyngeal cellulitis and very small localized abscesses may do well with antibiotics alone. All other cases should undergo an incision and drainage procedure. These decisions should be made in consultation with an otolaryngologist.

Most retropharyngeal abscesses are found to contain mixed flora when cultured. Common organisms include *S. aureus*, *S. pyogenes*, *S. viridans*, and beta lactamase-producing gram-negative rods such as *Klebsiella*. Oral anaerobes such as *Peptostreptococcus* species, *Fusobacterium* species, and *Bacteroides* species are also frequently seen. Antibiotic choice is controversial. Single-agent therapy with ampicillin/sulbactam may be best. Others use clindamycin and/or nafcillin with a third-generation cephalosporin. Some believe that high-dose penicillin G is most appropriate. In patients who are not allergic to penicillin, ampicillin/sulbactam provides the broadest coverage of the potential etiologic agents. Penicillin-allergic patients who are not known to be allergic to cephalosporins may achieve the best results with clindamycin and a third-generation cephalosporin.

Most patients do quite well, but complications do occur. Airway obstruction from sudden rupture of the abscess cavity can be rapidly fatal. Aspiration pneumonia and empyema have been described. Abscess extension throughout the neck can cause airway obstruction and infection can extend into the mediastinum. Erosion into the carotid artery and internal jugular vein thrombosis have been reported. Extension to the retroperitoneum, involving the psoas muscle, has been reported.

We acknowledge the previous contributions of Nicholas Relich to this chapter.

PAIN ASSESSMENT

Because the ED is a common setting where children in a multitude of different scenarios experience pain, it is extremely important that physicians, nurses, and other health care professionals be familiar with the basic concepts and tools of pain assessment. One comprehensive general approach to pain assessment in children is QUESTT, which includes several assessment strategies providing both qualitative and quantitative information about pain (Table 134-1).²

Question the child for a description and location of the pain, using age- and culturally-appropriate and familiar language. A variety of familiar and age-appropriate words such as "owie," "boo boo," or "hurt" may be necessary to describe pain when questioning a child. Toddlers as well as some older children who have difficulty understanding pain scales can usually locate pain by pointing to the affected part.

Use a pain rating scale to provide a quantitative measure of pain intensity. Scales differ in their developmental appropriateness, i.e., the child's ability to grasp numeracy, abstract thought, and pictorial appreciation (Figures 134-1, 134-2, 134-3, and 134-4).

Evaluate behavior and physiologic responses to pain, such as facial expression. This is particularly useful in nonverbal children.

Secure parents' and caregivers' involvement. They know their child best. Parents should be encouraged to participate in their child's pain assessment and management.

Take the cause of pain into account. Because of the nature of emergency medicine, the emergency physician is perhaps most cognizant of the numerous and different types of pain that a child experiences. The nature of the pathology or type of procedure permits anticipation of the type, duration, and intensity of pain. For example, pain caused by a single venipuncture is short in duration as opposed to the persistent pain caused by a migraine headache.

Take action. Ensure that all appropriate modalities are enlisted to treat the specific disorder and the pain, with ongoing assessment and documentation of pain until it is resolved. A child who presents to the ED without a parent or guardian to consent should have severe pain managed without delay. Every institution should have policies that outline the procedures to follow in such cases.

Numerous measures and scales for assessing children's pain have been developed in the last 20 years, and these can be classified as physiologic, behavioral, or self-report, depending on the nature of the response that is measured.³ Tools specific to an age group or developmental stage should be selected. Children who are developmentally delayed, emotionally disturbed, or non-English speaking require special assessment. Pain severity in infants must be inferred from physiologic and behavioral responses, but for the toddler and older child, subjective measures can be included. Finally, pain measurement should be repeated and improvement assessed until pain has abated.

Objective or Nonself-Report Pain Assessment (Physiologic and Behavioral Scales)

Physiologic changes from pain include tachycardia, tachypnea, crying, sweating, blood pressure elevation, decreased oxygen saturation, pupil

134 ACUTE PAIN MANAGEMENT AND PROCEDURAL SEDATION IN CHILDREN Michael N. Johnston Erica L. Liebelt

Appropriate and safe treatment of pain and anxiety in children is an integral component of an ED's clinical practice. Children are reported to be less adequately treated for pain in the emergency department compared to adults. However, national mandates for hospitals to assess and treat pain adequately have brought about increasing awareness and education to health care providers about this important entity.¹ Indeed, some experts believe that this heightened awareness of pain should be deemed the "fifth vital sign." Furthermore, many of the myths and misperceptions that have contributed to inadequate pain management in children have disappeared in recent years due to the emergence of more scientific evidence, expertise, and education in this area.

Children presenting to the emergency department experience numerous types of acute pain—the most common being that resulting from illness, injury, or from necessary medical procedures. Pediatric pain experience, perception, and expression are determined by many factors, including the nature of the illness, injury, or procedure, developmental level, emotional and cognitive state, personal concerns, the meaning of pain, family attitudes, culture, and the environment. Anything that is painful for an adult is likely to be painful for a child, and it is the responsibility of the emergency medicine physician to recognize, assess, and treat all types of pain.

TABLE 134-1 QUESTT Approach for Pain Assessment in Children

Question the child.
Use pain rating scales.
Evaluate behavior and physiological changes.
Secure parents' involvement.
Take cause of pain into account.
Take action and evaluate results.

dilation, flushing or pallor, nausea, and muscle tension. No single physiologic change has been shown to correlate directly with a child's pain experience. These parameters can be muted in persistent pain and can be confounded by fear, anxiety, or fever.

The observation of children's physical behaviors when they experience pain is another method of assessing and measuring their pain. Specific behaviors associated with pain include withdrawal of the painful part, pulling ears, or refusing to use a body part. Facial expression has been demonstrated to be one of the most consistent behavioral indicators of pain. Description of the presence of a brow bulge, eye squeeze, nasolabial furrow, open lips, vertical stretch mouth, horizontal stretch mouth, lip purse, taut tongue, and chin quiver can provide an assessment of infant pain expression (see Figure 134-1).⁴

A number of objective numeric scores have been developed and validated for the assessment of pain intensity for infants and nonverbal toddlers. The CRIES scale was developed for the assessment of postoperative pain in neonates and infants at 32 to 60 weeks of gestation. This scale takes into account cry quality, need for oxygen, changes in heart rate and blood pressure, expression, and state of sleepiness.⁵ Another example is The Children's Hospital of Eastern Ontario Pain Scale (CHEOPS), which assesses pain by describing six behaviors—crying, facial expression, verbal expression, torso position, touch behavior, and leg position—on a 13-point scale that ranges from 4 (no pain) to 13 (worst pain).⁶ This scale is reliable in children under 5 years of age.

The primary limitation of behavioral scales is that they are indirect measures of children's pain. Children's distress behaviors are not necessarily

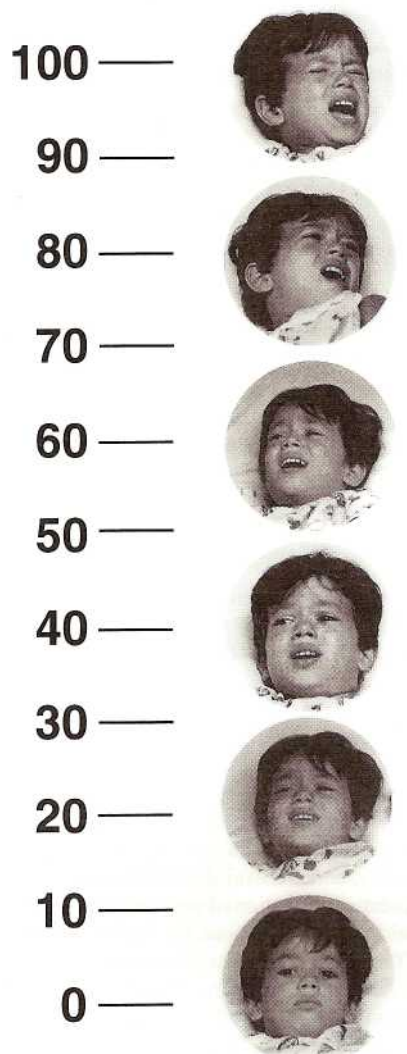

FIG. 134-3. Oucher pain scale. [The Hispanic version of the OUCHER was developed and copyrighted by Antonia M. Villarrael, PhD, RN (University of Pennsylvania) and Mary J. Denyes, PhD, RN (Wayne State University) in 1990. Reprinted with permission.]

essarily direct expressions of the intensity or quality of their pain experiences.

Subjective (Self-Report) Pain Assessment

Self-report pain measures are the gold standard for assessing children's pain. A child's self-report of pain provides direct information about many different aspects of the pain, including the sensory characteristics, the affective component, and other cognitive, behavioral, and emotional factors. Numerous creative and developmentally appropriate pain intensity rating scales have been developed and validated for children. Self-reports can be used reliably for developmentally normal children over the age of 4 years.

Facial expression scales are popular pain assessment tools because they are simple to use, and most children can readily identify with facial expressions of actual children or of cartoon drawings. The Wong-Baker FACES pain scale, which can be used for children age 3 years and up, demonstrates six cartoon facial expressions from "no hurt" to a tearful face representing "the worst hurt you could imagine" (see Figure 134-2).⁷ It is useful in the ED setting because the scale is compact and can be purchased in the form of a pin or badge that can be pinned to a coat, making it always available. The OUCHER pain scale

FIG. 134-4. A. Pain thermometer. B. Numeric rating scale. C. Visual analog scale.

is a photographic serial representation of children demonstrating the facial appearance of increasing intensity of pain along a vertical numeric scale ranging from 0 to 100 (see Figure 134-3).⁸ There are a number of versions of this assessment tool depicting different ethnic and racial groups.

Numeric scales can be used with children 5 years of age and older, provided that they can count and have a concept of the relative magnitude of numbers (see Figure 134-4). The pain thermometer or pain ladder are examples of such scales. They also have the advantage of not requiring special photographic images. Visual analogue scales (VAS) are simple, versatile, and well-validated scales that are probably best used for the sequential evaluation of pain. A VAS usually consists of a 10-cm horizontal line with endpoints marked as "no pain" and "worst pain possible." The child is asked to place a mark on the line that best describes his or her amount of pain. Then, the distance from the "no pain" end to the mark is recorded. Sequential measurements with a ruler may make this cumbersome for routine assessment in the ED. The colored analogue scale or CAS is similar to a mechanical VAS and was developed specifically for assessing pain in children.⁹ Children adjust the position of the slider, and the numbers corresponding to different slider positions are on the back of the scale. Unlike traditional VAS and numeric scales, the CAS varies in three dimensions—color, width, and length—so children can more easily understand that different scale positions reflect different values in pain intensity.

School-aged children and adolescents can use verbal numerical rating scales similar to those used by adults. Children are asked to rate the intensity of pain on a scale of 0 (no pain) to 10 (worst pain). This tool is simple to use, easy to record, and can easily be used for sequential evaluation of pain and response to pain relief interventions.

PAIN TREATMENT

Nonpharmacologic Modalities

Cognitive behavioral and physical techniques are useful nonpharmacologic adjuncts to pediatric acute pain management. Several simple age- and development-specific interventions can significantly decrease a child's anxiety and pain perception. Cognitive behavioral modalities include reassurance and explanation, relaxation, distraction, music, psychoprophylaxis, biofeedback, and guided imagery. Guided imagery can be used with children as young as 3 or 4 years, who have a rich fantasy world and can be encouraged to imagine their favorite place or activity. Environmental alterations such as dimmed lights, a quiet room, or stereo headphones may relieve anxiety. Distraction techniques such as storytelling, singing, and playing games

are effective. Hypnosis has also been shown to be helpful in relieving pain, but may not be practical in a busy emergency department. General strategies for nonpharmacologic pain relief techniques according to age and developmental stage are outlined in Table 134-2. Physical techniques include kinesthetic or tactile stimulation, application of heat and cold, and massage, as well as the more complex modalities of transcutaneous electrical nerve stimulation (TENS), acupuncture, acupressure, and electro-acupressure. Medical play demonstrating to the child what is going to happen is also useful for preschool and school-age children. Open and honest discussion with adolescents about procedures is imperative.

Pharmacologic Modalities

The choice of a pharmacologic agent for a pediatric patient's pain management should consider the nature of the procedure, the duration of the procedure, and the most appropriate route of administration. This choice should be made in conjunction with the use of nonpharmacologic techniques. Pharmacologic analgesic therapy can be categorized into systemic (opioid and nonopioid analgesics) or non-systemic (local anesthetic agents with topical, local, or regional administration). Avoidance of painful intramuscular and subcutaneous injections when possible is particularly important when treating children. Furthermore, absorption may be erratic and less predictable than with intravenous administration. The intravenous route is recommended for titration of opioid medications. Noninvasive topical or mucosal techniques for the delivery of systemic pharmacologic agents should be used where appropriate.

Suggested systemic medications, dosages, routes of administration, and comments for nonopioid analgesics are outlined in Tables 134-3 and 134-4 and for opioids in Table 134-5. Nonsystemic analgesic medications and techniques for administration, such as local anesthetics, topical anesthetics, and regional anesthetics are discussed in detail in Chap. 37.

Systemic Pharmacologic Agents

ACETAMINOPHEN Acetaminophen is a commonly-used analgesic and antipyretic that is useful for mild pain and as an adjunct for moderate pain in combination with some opioids. Its analgesic properties do not differ significantly from those of aspirin, but it has a safer profile in the pediatric population. Acetaminophen is a weak inhibitor of prostaglandin biosynthesis and thus possesses only very weak anti-inflammatory effects. Acetaminophen is rapidly absorbed from the gastrointestinal tract and onset of action is within 20 to 40 min with a

TABLE 134-2 Selected Nonpharmacologic Pain Management Techniques for Different Ages

Age	Techniques
Infant (0-12 months)	Tactile stimulation: rocking, swaddling, stroking Sucking a pacifier Distraction with bubbles, toys
Toddler (1—3 years)	Tactile stimulation: holding, patting, stroking Distraction with books, puppets, music, action rhymes Parental presence Medical play with a doll and/or equipment before procedure Guided imagery Comfort from blanket or toy from home
Preschooler (4—5 years)	Comfort from blanket or toy from home Medical play with a doll and/or equipment from procedure Guided imagery to remember and play out a superhero story or cartoon character Distraction with music, storytelling, singing a song, reciting nursery rhymes, remembering a movie Reward after procedure with discussion of this prior to procedure
School-age (6-12 years)	Procedural rehearsal and preparation Verbal reward along with toy or other incentive Guided imagery used prior to and during the procedure Breathing and muscle relaxation Thought stopping and positive self-talk during the procedure Parental presence Distraction by listening to music, watching television, or playing video game
Adolescent (>13 years)	Discuss openly issues involving pain Allow teen to choose useful techniques Guided imagery Distraction with music, TV, video games

peak effect in 2 h. The plasma half-life is 1.25 to 3 h, but may be increased by liver disease and following overdose. Acetaminophen is primarily metabolized by the liver through conjugation with a small amount metabolized by the cytochrome P450 enzyme system.

Recent reports about children developing fulminant hepatic liver failure from acetaminophen use emphasize the importance of educating caregivers about appropriate dosing, using the proper measuring device for each acetaminophen formulation, and the appropriate dosing intervals. Most of the reported cases of liver toxicity were due to inappropriate use of acetaminophen in supratherapeutic doses for ex-

tended periods of time, or in children who had underlying risk factors for developing toxicity. Thus it is also important to obtain a detailed history about other medical problems and other medications the child is consuming that may make the child more susceptible to the toxic effects of acetaminophen, even in therapeutic doses. Table 134-3 lists the doses and different formulations for acetaminophen.

TABLE 134-4 Pediatric Dosages for Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)

Drugs	Dose (mg/kg per dose)	Comments
Enteral NSAIDs		
Aspirin	Oral: 10-15 mg/kg q4h Rectal: As above	GI irritation Platelet dysfunction Reye syndrome in children Max dose: 4 g/d or 2.5 g/m ²
Ibuprofen	Oral: 7-10 mg/kg q6-8h	GI irritation, bleeding Renal insufficiency Max dose: 40 mg/kg per d or 2.4 g/d
Drops: 50mg/1.25mL Suspension: 100 mg/5 mL Chewables: 50 mg, 100 mg Tablets: 100 mg, 200 mg		
Naproxen	Oral: 5-7 mg/kg q8-12h	GI irritation Max dose: 1.5 l or 15 mg/kg
Suspension: 125 mg/5 mL Tablet: 200, 235, 375, 500 mg		
Parenteral NSAIDs		
Ketorolac	IV/IM: 0.5-1.0 mg/kg q6h	Max single dose: 30 mg iy 60 mg IM Max daily total dose: 120 mg/d

TABLE 134-3 Pediatric Dosing Units and Formulations of Acetaminophen

Dose	Max Dose
Oral: 10-15 mg/kg q4h Rectal: 25-40 mg/kg first dose, then 20 mg/kg q6h	75 mg/kg per d to a total of 4g/d
Formulation	Mg of Acetaminophen per Dosing Unit
Infant drops (solution, suspension)*	80 mg per 0.8 mL (1 dropperful)
Suspension liquid or elixir*	160 mg per 5 mL (1 teaspoon)
Chewable tablets	80 mg or 160 mg per tablet
Caplets	160, 325, 500, 650 mg per caplet
Tablets	160,325, 500 mg per tablet
Tablets (extended release)	625 mg per tablet
Suppositories	80, 120, 325, 650 mg per suppository

*The dosing devices that come with the product should be used with that product only.

TABLE 134-5 Pediatric Dosages for Opioid Analgesics

Drug	Dose		Duration of Action	Toxicity/Adverse Reactions
	Enterd	Parenteral		
Opioids				
Morphine	Oral: 0.3-0.5 mg/kg q4-6h Onset: 15-30 min	IV: 0.05-0.1 mg/kg Onset: 5-10 min IM/SC: 0.1-0.2 mg/kg Onset: 15-30 min	2-4 h	Respiratory depression (esp. with IV push) Hypotension Nausea, vomiting Pruritus
Codeine	Oral: 1-2 mg/kg q4h Onset: 30-60 min	IM: 0.5-1 mg/kg	4h	Nausea Use with caution in renal failure Not recommended for IV use Less pruritus than morphine
Hydromorphone	Oral: 0.03 mg/kg q4-6h Onset: 15-30 min	IV: 0.015 mg/kg Onset: 15 min	2-4 h	
Meperidine	NA*	IV/IM: 1-2 mg/kg Onset: IV 5-10 min IM 10-15 min	2-3 h	Respiratory depression (esp. with IV push) Hypotension Seizures Avoid with MAO inhibitors Less nauseating than codeine
Oxycodone	Oral: 0.1 mg/kg q4h Onset: 10-15 min	NA	3h	
Fentanyl	NA	IV: 1-3 xg/kg Onset: 1-2 min	30-60 min	Respiratory depression (esp. with IV push) Chest wall rigidity (see text for treatment) Use j dose in children <6 months old
Opioid Antagonist				
Naloxone	NA	IV/IM/IO/ETT: 0.001-0.01 mg/kg	30-40 min	Duration of action is shorter than agonists Potential for hypertension, pulmonary edema, and seizures, particularly in opioid-dependent patients

*Abbreviation: NA = not applicable.

ASPIRIN Aspirin is one of the oldest medications for treating minor pain, but it fell out of favor with the pediatric population with the emergence of acetaminophen in the 1970s. It has the advantage of possessing analgesic, anti-inflammatory, and antipyretic properties. Disadvantages include gastrointestinal irritation, nausea, and inhibition of platelets that can lead to bleeding. Moreover, it may induce bronchospasm in some asthmatic patients. There is a strong association between Reye syndrome and the use of aspirin in children with influenza and varicella. Thus the FDA advises that it not be used in children with these diseases. Dehydrated patients may be more susceptible to salicylate toxicity, even in therapeutic doses. For the management of acute pain, nonsteroidal anti-inflammatory drugs (NSAIDs) are a better choice because they are more potent than aspirin with fewer side effects.

NSAIDs Nonsteroidal anti-inflammatory drugs (NSAIDs) have become the most commonly used nonopioid medications for treating a wide variety of conditions associated with acute pain in the emergency department, including minor trauma, dysmenorrhea, and headache. Ibuprofen (Advil, Motrin) has anti-inflammatory, analgesic, and antipyretic properties. The analgesic effect is related to inhibition of prostaglandin synthesis through inhibition of cyclooxygenase. It can be used in children over 6 months of age as an alternative to acetaminophen. **NSAIDs should not be given to children with aspirin sensitivity and vice versa, because of cross-sensitivity of aspirin and NSAIDs.** The most frequent adverse effects involve gastrointestinal (GI) tract irritation and renal dysfunction. Renal failure has been reported. Dehydrated patients are at higher risk for renal failure. There is a rare association with aseptic meningitis and severe hepatic reactions. Safety and efficacy have been established for children over 6 months of age. Ibuprofen, like acetaminophen, comes in multiple formulations and caregivers should be instructed on the appropriate dose and time intervals (see Table 134-4). There is no evidence to support the practice of alternating acetaminophen and ibuprofen for superior analgesia. This practice may lead to confusion about dosing and inadvertent overdose.

Ketorolac (Toradol) is an anti-inflammatory, antipyretic, and potent analgesic agent with similar actions and side effect profile to other NSAIDs, with slightly less GI irritation when given intravenously or intramuscularly than oral NSAIDs. Overall, ketorolac has a lower incidence of side effects and longer duration of action than morphine. It acts peripherally, does not affect opiate receptors, and does not cause respiratory depression. Ketorolac is the only intravenous NSAID approved by the FDA. It may be used in combination with opioids, resulting in an opioid-sparing effect. Thus smaller opioid dosages may provide adequate pain relief. It should not be admixed in the same syringe as opiates or hydroxyzine due to incompatibilities. Ketorolac also has good oral bioavailability, but has not been shown to be more efficacious than less expensive NSAID oral preparations. There is limited data on its use in children less than 16 years of age. In addition to GI irritation and platelet effects, ketorolac has been reported to adversely affect renal function, particularly in the dehydrated patient. Additionally, an increased risk of renal failure in patients on diuretics has been reported. Because ketorolac is highly protein-bound, it should be used cautiously in the presence of other protein-bound drugs such as warfarin. Interactions with renal clearance of lithium resulting in increased lithium levels have been reported. There is potential for cumulative adverse effects if ketorolac is combined with aspirin or other NSAIDs. There have been reports of bronchospasm and anaphylactoid reactions in adults. Duration of ketorolac therapy should not exceed 5 days. The efficacy and safety of the new COX-2 inhibitors, celecoxib and rofecoxib, have not been evaluated in children less than 18 years of age.

OPIOIDS Opioid medications remain the mainstay of analgesic pharmacotherapy for severe pain. Opioids include the phenanthrene derivatives (e.g., morphine, codeine, hydrocodone, hydromorphone, oxycodone, and oxymorphone), the phenylpiperidine derivatives (e.g., meperidine and fentanyl) and the diphenylheptane derivatives (propoxyphene and methadone). **The three classes do not share allergic cross-sensitivity, so a patient with allergy to one class can be**

given an agent from another class. It is important to realize that there is a continuum between systemic analgesia and sedation with opioids. Close clinical and physiologic monitoring is essential with opioid use in the ED patient, as is an understanding of the relationship between level of pain, opioid dose, and conscious state. Opioids in general have analgesic effects at lower doses than those required for sedation.

Opioids are probably used too infrequently and in inadequate doses because of inexperience and unfounded fears of addiction. Most of the opioids can be given orally, intravenously, rectally, sublingually, subcutaneously, or intramuscularly (see Table 134-5). In the ED, the intravenous route is best for the rapid delivery and expeditious control of acute pain. Side effects with these drugs include respiratory depression, nausea, vomiting, pruritus, urticaria, and hypotension.

Adverse cardiorespiratory complications associated with opioid use may depend on the child's age and medical conditions. Infants <3 months of age, premature infants, history of apnea, airway compromise (large tonsils, abnormal airway anatomy), cardiorespiratory disease, hemodynamic instability, obtundation, neuromuscular disease, renal or liver disease, or intracranial hypertension are examples of medical conditions associated with an increased risk of cardiorespiratory complications following opioid administration. The presence of a risk factor does not preclude the use of an opioid analgesic. These children may be safely treated by titrating the medication to effect (which may entail reducing the standard dose by 50 percent) and continuous monitoring with high nursing surveillance.

Morphine remains the gold standard opioid for the management of moderate to severe acute pain. Its oral bioavailability is poor. Infants less than 3 months old are particularly sensitive to its respiratory depressant effects. Morphine induces histamine release and should not be used in children with asthma and in children who are hypovolemic.

Hydromorphone (Dilaudid) is a hydrogenated ketone of morphine and is five to seven times more potent. It is well absorbed following oral, rectal, or parenteral administration. It has a more rapid onset and a shorter duration of action than morphine when given orally. It may produce less sedation, pruritus, and nausea than morphine.

Meperidine (Demerol) is a synthetic derivative of morphine and is one-tenth as potent an analgesic per milligram of drug. Onset and duration of action are shorter than morphine, and meperidine has slightly better oral bioavailability. Normeperidine (6-/V-desmethylnormeperidine) is a toxic meperidine metabolite excreted by the kidney. Normeperidine is a cerebral irritant that can cause effects ranging from dysphoria and irritability to convulsions. Because of the unique toxic metabolite, meperidine is contraindicated in patients with impaired renal function. This metabolite will also accumulate in patients with normal renal function receiving prolonged therapy (e.g., sickle cell vasoocclusive crisis and burn patients). Dangerous drug-drug interactions contraindicate its use in patients on monoamine oxidase inhibitor (MAOI) drugs. Therefore meperidine should be reserved for otherwise healthy children who have demonstrated an unusual reaction or allergic response during treatment with other opioids, such as morphine or hydromorphone.

Fentanyl is a short-acting synthetic opioid, 80 to 100 times as potent as morphine. When administered intravenously it has a rapid onset of action of less than 1 min and a short duration of action (30 to 45 min) due to its high lipid solubility and rapid redistribution. The major ED role for fentanyl is as an analgesic component for short, painful procedures. In infants, it is less of a cardiovascular and respiratory depressant than morphine, and causes less histamine release, but the respiratory depressant effect may lag behind the analgesic effect. Fentanyl is associated with skeletal and thoracic muscle rigidity, especially following rapid intravenous administration. This may cause chest wall rigidity and laryngospasm (glottic rigidity), as well as generalized muscular rigidity. This effect is more likely to occur with high-bolus dosing (5 μ g/kg), but can occur with lower dosing (1 to 2 μ g/kg) given as a rapid bolus. Small infants, less than 6 months of age, are at greater risk. The management for chest wall rigidity includes: naloxone 0.001 to 0.01 mg/kg or neuromuscular blockade

(succinylcholine 2 mg/kg, or rocuronium 0.6 to 1.0 mg/kg, or pancuronium 0.1 mg/kg), and mechanical ventilation with 100 percent oxygen. Given the high potency of fentanyl, exercise caution to avoid inadvertently flushing a residual bolus of the drug remaining in the intravenous line.

Codeine is readily absorbed from the gastrointestinal tract, and a very useful agent in the ED for adjunct oral pain therapy with acetaminophen. Codeine is usually given orally because it maintains two-thirds of its effectiveness in oral form when compared to parenteral use. It is valuable for moderate pain associated with severe otitis media, dental abscess, or stomatitis. At therapeutic doses, the analgesic effect reaches a peak within 2 h and persists between 4 and 6 h. The plasma concentration does not correlate with brain concentration or relief of pain. Codeine crosses the blood-brain barrier, is found in fetal tissue and breast milk, but is not bound to plasma proteins. The plasma half-life is about 2.9 h. The elimination of codeine is primarily by the kidneys, and about 90 percent of an oral dose is excreted by the kidneys within 24 h of dosing. It can cause extreme nausea and many patients state they are "allergic" to codeine because of the nausea and vomiting.

Hydrocodone (Hycodan) is an oral analgesic that is more potent than codeine with less associated nausea and vomiting. Oxycodone (Roxicodone) is 10 times more potent than codeine and retains about 50 percent of its efficacy when given orally. It is often combined with aspirin (Percodan) or acetaminophen (Percocet, Tylox). Sustained-release oxycodone (Oxycontin) has become a popular drug of abuse/street drug. There is no indication for its routine use in the treatment of acute pain in children.

Documented clinical experience is insufficient to establish the safety and an appropriate dosing regimen for propoxyphene in children. Thus it is not recommended for use in pediatric patients.

Nonsystemic Pharmacologic Agents

Nonsystemic topical, local, and regional anesthetic techniques are of great value in the management of painful conditions or procedures in the pediatric ED patient and may minimize the need for opioids and sedatives. The amide and ester local anesthetic medications (lidocaine, bupivacaine, prilocaine, and procaine) and refrigerant agents are the most commonly used nonsystemic agents. Techniques range from topical applications such as lidocaine, epinephrine, and tetracaine (LET) and eutectic mixture of local anesthetics (EMLA), to ethyl chloride, local infiltration of local anesthetics, peripheral nerve block, hematoma block, and intravenous Bier block. The general discussion of these agents as well as specific comments regarding their use in children is found in Chap. 37.

PROCEDURAL SEDATION AND ANALGESIA

Terms and Definitions

Historically, "conscious sedation" was defined as a medically controlled state of depressed consciousness that allows protective reflexes to be maintained, retains the patient's ability to maintain a patent airway independently and continuously, and permits appropriate responses by the patient to physical stimulation or verbal command. Unfortunately, the term "conscious sedation" rapidly became a term that was universally applied to almost every sedation event in the outpatient setting, despite the fact that most sedation events in the ED do not meet this focused definition. The American College of Emergency Physicians in 1998 recommended the term "procedural sedation and analgesia" (PSA) be adopted and published a newer definition of sedation that more clearly reflected how sedation techniques are applied in the ED. This clinical policy defined PSA as "techniques of administering sedatives or dissociative agents with or without analgesia to induce a state that allows the patient to tolerate unpleasant procedures

while maintaining cardiorespiratory function. Procedural sedation and analgesia is intended to result in a depressed level of consciousness, but one that allows the patient to maintain airway control independently and, specifically, the drugs, doses, and techniques used are not likely to produce a loss of protective airway reflexes.¹⁰ The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) revised its standards for sedation practices in 2001, dropping the term "conscious sedation" and providing additional definitions for levels of sedation.¹¹ A universal set of terms and definitions for PSA has recently been proposed (Figure 134-5).¹²

Goals

The goals of pediatric PSA are to minimize pain, fear, and anxiety, maintain patient safety, control behavior, provide amnesia, and return the patient to a state safe for discharge. Factors involved in the selection of the sedation regimen include the specific procedure being performed, duration of the procedure, the developmental age and physical condition of the child, and physician experience with the agents. A checklist of requirements for procedural sedation in children is shown in Table 134-6. In the ED environment, PSA should only be performed by physicians appropriately skilled in airway and resuscitation management, and only for patients considered to be ASA class E, I, or II, or selected class III, after appropriate consultation (Table 134-7). The American Academy of Pediatrics (AAP) and the American Society of Anesthesiologists (ASA) have published guidelines for monitoring and management of pediatric patients during and after sedation for diagnostic and therapeutic procedures.^{13,14} Significant features of these documents are discussed below and should be incorporated into the ED's sedation policy.

Patient Evaluation

The first step is assessment of the patient for sedation in the emergency department. The history should identify any abnormalities of the major organ systems and airway, including current upper respiratory tract infection, fever, and dehydration; previous adverse experience with sedation, analgesia, or anesthesia; any neurologic disorder or impairment; medications and allergies; and time and nature of the patient's last oral intake. Focused physical examination should include baseline vital signs and oxygen saturation, and evaluation of cardiorespiratory status and the oropharynx and airway.

Appropriate candidates for sedation protocols in the ED are healthy patients or patients with mild systemic disease (see Table 134-7). Children with severe systemic disease (ASA III or IV); infants <3 months of age; premature infants <60 weeks postconceptual weeks of age; and children with underlying respiratory or airway disease, neurologic conditions, CNS injury, multiple trauma, or liver or kidney disease are at increased risk for sedation complications and require consultation with an anesthesiologist. For nonemergent sedation, fasting for 2 h from clear liquids and 8 h for solids and nonclear liquids is recommended. However, this length of fasting is often not possible in the busy ED environment. Children requiring urgent or emergent sedation despite recent oral intake should not receive deep sedation to avoid depression of protective airway reflexes that may result in aspiration. Procedures should be delayed, if possible, to facilitate gastric emptying that may decrease the risk of regurgitation and aspiration. Overall, noncompliance with AAP/ASA fasting guidelines for elective sedation is not a contraindication to PSA in the pediatric ED. The potential risk of aspiration appears to be low in most urgent and emergent sedations. However, physicians should always bear in mind the timing of the last oral intake and balance the risks of sedation with the urgency of the needed procedure and planned sedation depth. Routine use of agents such as ranitidine to raise gastric pH or metoclopramide to stimulate gastric emptying is not recommended or supported by current literature. Informed consent should be obtained from the child's

Procedural Sedation and Analgesia Definitions and Terminology*

General

PSA: A technique of administering sedatives, analgesics, and/or dissociative agents to induce a state that allows the patient to tolerate unpleasant procedures while maintaining cardiorespiratory function. PSA is intended to result in a depressed level of consciousness but one that allows the patient to maintain airway control independently and continuously. Specifically, the drugs, doses, and techniques used are not likely to produce a loss of protective airway reflexes.

Current Sedation State Terminology

Minimal sedation (anxiolysis): A drug-induced state during which patients respond normally to verbal commands. Although cognitive function and coordination may be impaired, ventilatory and cardiovascular functions are unaffected.

Moderate sedation (formerly "conscious sedation"): A drug-induced depression of consciousness during which patients respond purposefully to verbal commands, either alone or accompanied by light tactile stimulation. Reflex withdrawal from a painful stimulus is not considered a purposeful response. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is usually maintained.

Dissociative sedation: A trance-like cataleptic state induced by the dissociative agent ketamine and characterized by profound analgesia and amnesia, with retention of protective airway reflexes, spontaneous respirations, and cardiovascular stability.

Deep sedation: A drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully after repeated or painful stimulation. The ability to independently maintain ventilatory function may be impaired. Patients may require assistance in maintaining a patent airway and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained.

General anesthesia: A drug-induced loss of consciousness during which patients are not arousable, even by painful stimulation. The ability to independently maintain ventilatory function is often impaired. Patients often require assistance in maintaining a patent airway, and positive pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired.

parent or legal guardian with explanations about the procedure, sedation and analgesia plan, and associated risks. All information can be documented on a sedation assessment and monitoring record.

Equipment and Monitoring

The ED must be appropriately equipped for administering sedation to children of all ages and sizes. An oxygen source capable of delivering >90 percent oxygen and positive-pressure ventilation, appropriate size masks, and functioning suction apparatus with Yankauer-tip catheters must be at the child's bedside. Appropriately-sized laryngoscopes, endotracheal tubes, intravenous catheters, and emergency medications must be readily available. Airway management and breathing equipment must be checked before each sedation procedure. The child should be attached to a cardiac monitor and pulse oximeter. During the procedure, one person whose sole responsibility is monitoring the patient, a registered nurse with basic life support and pediatric advanced life support (PALS) training, or a physician who is not performing the procedure, must be present. Continuous quantita-

tive monitoring of oxygen saturation (pulse oximetry) and heart rate, and intermittent monitoring of respiratory rate and blood pressure should be recorded at 5- to 10-min intervals. Level of consciousness (response to verbal commands/tactile stimuli) and pulmonary ventilation (observing chest wall excursion and/or auscultation of breath sounds and/or capnography) should also be monitored. Limited studies on end-tidal CO₂ (ETCO₂) monitoring during procedural sedation have shown that significant increases in ETCO₂ may occur without clinical recognition of hypoventilation. Thus capnography may become an important component of the sedation monitoring armamentarium. All drugs and doses administered must be clearly documented, with special attention to calculation of single and cumulative doses in milligrams per kilogram. After the procedure the child must be observed and monitored in an area with suitable equipment and vital signs recorded every 15 min. Pulse oximetry should be maintained until the patient is fully alert. Observation should be continued until all discharge criteria are met (Table 134-8). Appropriate discharge instructions with follow-up should be conveyed to the child's caretaker.

SEDATION AGENTS AND TECHNIQUES

Indications for sedating infants and children in the emergency department include diagnostic imaging procedures (CT or MRI scans), as an adjunct to analgesia, and anesthesia for painful diagnostic and therapeutic procedures. Table 134-9 lists common pharmacologic options for sedation. Nonpharmacologic techniques should also be considered when preparing to sedate children and should not be forgotten in the midst of a busy emergency department. As previously discussed, parental involvement, verbal preparation, relaxation, tactile stimulation, guided imagery, and distraction techniques are all effective. Manual restraint (sheets or papoose boards) may be required as an adjunct to the nonpharmacologic and pharmacologic approach to procedures for infants and toddlers. Parents should not be asked to provide or be responsible for the restraint of the child, but rather should be encouraged to provide comfort.

An ideal pharmacologic agent for sedation is one that is effective, has rapid onset, is easily titratable with a predictable duration of action, is quickly eliminated or reversible, has no adverse effects, and is easy and painless to administer. Although no ideal agent exists, there are several good drugs and regimens that when administered appropriately can provide safe and adequate analgesia and/or anesthesia. Sedatives can be administered by a variety of routes including intravenous, intramuscular, oral, rectal, sublingual, transmucosal, and intranasal; each route has advantages and disadvantages. Intravenous administration allows the most precise titration of drug to the desired effect; intramuscular administration is usually painful and not titratable (ketamine being the exception). Oral and transmucosal routes are more readily accepted by children than nasal or rectal routes. Despite the options for administration routes, side effects can occur with any route of administration.

Specific Agents

BENZODIAZEPINES Benzodiazepines provide anxiolysis and amnesia but not anesthesia. They can be used alone as a sedative, or in

TABLE 134-7 American Society of Anesthesiologists Physical Status Classification System

I	Healthy, no underlying organic disease
II	Mild or moderate systemic disease that does not interfere with daily routines
III	Organic disease with definite functional impairment
IV	Severe disease that is life-threatening
V	Moribund
E (suffix)	A procedure undertaken as an emergency

TABLE 134-8 Recommended Discharge Criteria

Patient is alert and oriented; infants and those with initially abnormal mental status are at their baseline level of functioning
Vital signs are stable and within age-appropriate limits, including pain level
Protective reflexes are intact (gag, cough, swallow) Patient does not have protracted nausea and vomiting Patient is able to ambulate at the preprocedural level Patient is discharged in the company of a responsible adult Written instructions given for postsedation diet, medications, activities, and
contact phone number in case of emergency

TABLE 134-9 Sedative Drugs for the Pediatric Patient

Drug	Route/Dose	Duration of Action	Contraindication
Benzodiazepines			
Midazolam (Versed)	IV: 0.05-0.1 mg/kg (single max dose 2 mg) Subsequent incremental doses at 3-min intervals to desired effect or up to a total of 0.2 mg/kg IM: 0.3 mg/kg PO: 0.5-0.75 mg/kg (max dose 15 mg) Nasal: 0.3-0.5 mg/kg (max dose 5 mg) PR: 0.5 mg/kg (max dose 15 mg)	30-5 min	Uncontrolled pain CNS depression Shock Hypersensitivity to benzodiazepines
Diazepam (Valium)	IV: 0.1-0.2 mg/kg (max dose 10 mg) PO: 0.2-0.3 mg/kg PR: 0.5 mg/kg	2-6 h	
Barbiturate			
Pentobarbital (Nembutal)	IV/IM: 4-6 mg/kg (max dose 150 mg) PR: <4 y 3-6 mg/kg >4y 1.5-3.0 mg/kg		CNS depression Hypersensitivity to barbiturates Hepatic impairment Porphyrria
Nitrous oxide	50% N ₂ O/50% O ₂ via inhalation	3-5 min after ceasing inhalation	Previous narcotic/sedative within 4 h Impaired mental status Increased ICP or head trauma Intoxication Nausea/vomiting Pregnancy Pneumothorax Bowel obstruction
Ketamine (Ketalar)	IV: 1-2 mg/kg Administer atropine (0.01 mg/kg) concurrently, consider co-administration of midazolam 0.05 mg/kg (max 2 mg) IM: 4-5 mg/kg (combine atropine in the same syringe), consider coadministration of midazolam 0.05 mg/kg (max 2 mg) PO/PR: 10 mg/kg (administer with atropine 0.02 mg/kg) consider coadministration of midazolam 0.5 mg/kg (max 15 mg)	IV: 20-60 min IM: 30-90 min PO/PR: 60-120 min	Age \leq 3 months History of airway instability/tracheal stenosis URI/asthma exacerbation Cardiovascular disease/hypertension Increased ICP states (head trauma, hydrocephalus, brain tumor) Poorly controlled seizure disorder Glaucoma or acute globe injury Psychosis, porphyria, thyroid disorder
REVERSAL AGENTS			
Naloxone (Narcan)	IV/IM: 0.01-0.1 mg/kg per dose (max single dose 2 mg) Repeat to desired effect every 2 m	20-5 min	Use smaller doses 0.001 mg/kg in children dependent on opioids
Flumazenil (Romazicon)	IV/IM: 0.01 mg/kg per dose (max initial dose 0.2 mg) Repeat at 60-s intervals to desired effect or maximum of 0.05 mg/kg or 1.0 mg	20-5 min	Chronic benzodiazepine therapy for seizures Concomitant use of medications that have the potential to cause seizures (tricyclic antidepressants, theophylline, bupropion, isoniazid) Hypersensitivity to benzodiazepines

Abbreviations: ICP = intracranial pressure; URI = upper respiratory infection.

conjunction with a narcotic or local anesthetic for a painful procedure. Midazolam (Versed) is a short-acting benzodiazepine that has an onset of action within 5 min and a duration of action of 30 to 45 min. Midazolam is safe and effective for use in the ED in children undergoing laceration repair, fracture reduction, and other painful procedures. Adverse effects include respiratory depression and paradoxical insolubility. Anecdotally, this latter effect appears to happen with increased frequency in children with attention deficit hyperactivity disorder, and is reversible with flumazenil.

Diazepam (Valium) is a longer-acting benzodiazepine that has been used extensively as a sedative for children and has amnesic properties. Diazepam can be used for extended diagnostic procedures and for muscle relaxation for orthopedic reductions. It has been largely replaced by midazolam.

SEDATIVE/HYPNOTICS Chloral hydrate is a pure sedative/hypnotic with no analgesic properties that has been used primarily for sedation of infants and young children requiring painless diagnostic procedures.¹⁵ The time to sedation is relatively long (45 to 60 min) and its effects can last several hours because of its active metabolite, trichloroethanol, making it an impractical agent for use in the ED. Adverse effects include nausea, vomiting, and paradoxical delirium/excitement, which are not reversible. Serious adverse effects including airway obstruction and death have been reported with chloral hydrate use. It is not recommended for use in the busy ED environment.

The short-acting barbiturates can provide rapid onset of sedation for painless procedures such as computed tomography and magnetic resonance imaging studies in children with no preexisting central nervous system depression.¹⁶ Again, they have no analgesic or amnes-

tic properties. Intravenous pentobarbital has an onset of action within 30 s and children are usually appropriately sedated within 5 min. Its duration of action is 30 to 60 min, making it a better choice for children undergoing emergent procedures. Respiratory and central nervous system (CNS) depression can occur that can be exacerbated in the presence of other depressants such as opioids and benzodiazepines; patients must be closely monitored.

Methohexital is an ultra short-acting barbiturate similar to thiopental. It has been given rectally at doses of 20 to 25 mg/kg for induction of anesthesia in the past. More recently, intravenous use has been reported for sedation during painful procedures and radiologic imaging studies.^{16,17} The average intravenous dose is 1 mg/kg. Care must be taken as methohexital can cause myoclonus and may induce seizures in patients with temporal lobe epilepsy. Again, respiratory and CNS depression can occur, especially when given concurrently with other depressants such as opioids and benzodiazepines. More experience is needed before this agent can be recommended for routine use.

Etomidate is an ultra short-acting sedative hypnotic when given intravenously. It is routinely used in many EDs for rapid sequence intubation. As a newer agent for PSA, there are few published studies in children.^{18,19} It has minimal hemodynamic effects on patients; myocardial oxygen consumption is unchanged. Reported adverse effects are pain on injection, nausea, vomiting, myoclonus, and short-term adrenal suppression (more commonly seen with long-term use). It has no analgesic properties and therefore must be coadministered with an analgesic for painful procedures. Limited evidence suggests doses of 0.1 to 0.2 mg/kg given as an IV bolus. Again, respiratory and CNS depression can occur, especially when given concurrently with other depressants such as opioids and benzodiazepines. More experience is needed before this agent can be recommended for routine use in children.

NARCOTICS A discussion of individual narcotics is found in the preceding analgesia and pain management section. Narcotics can be administered intravenously in conjunction with an anxiolytic such as a benzodiazepine for sedation for painful procedures.

NITROUS OXIDE Limited studies in children have shown nitrous oxide (N_2O) to be an effective and safe sedative/analgesic either alone or in combination with a local anesthetic for laceration repair, orthopedic procedures, and other minor surgical procedures.^{20,21} It offers many advantages over other pharmacologic agents for use in the outpatient setting and ED. It provides analgesia, anxiolysis, and sedation without the need for intravenous line placement, has a low incidence of complications and adverse effects, and can result in shorter ED lengths of stay due to rapid recovery. Nitrous oxide interacts with the endogenous opioid system to confer analgesia and appears to blunt the patient's reaction to pain. It produces a sense of euphoria, relief from anxiety, and an almost detached attitude toward pain and the patient's surroundings.

In the outpatient setting, nitrous oxide should be delivered as a fixed-ratio mixture of nitrous oxide to oxygen, usually 50 percent N_2O to 50 percent oxygen (oxygen concentration must be a minimum of 30 percent) by a self-administered demand-valve apparatus with a scavenger device. This mode of administration protects against equipment failure and/or human error, which may result in too high a concentration of nitrous oxide. The gas is routinely delivered by an inspiratory effort of the patient, minimizing the risk of loss of consciousness and protective reflexes because the mask will fall off when the patient is sedated. The gas/oxygen mixture can be inhaled through a face mask, mouthpiece, or nasal hood in which a flavored lip balm lining or concentrated "child-friendly" scent can be applied to disguise the odor of the gas. For younger children unable to hold their own mask, the physician or parent can assist in the delivery of the mixture by placing the mask lightly on the child's face.

Nitrous oxide has a rapid onset of action of 3 to 5 min and a short duration of action on withdrawal of 3 to 5 min. The gas is not metabolized, and is eliminated by the lungs unchanged. Short-term use has no significant effects on other organs. The most commonly reported side effects are nausea and vomiting. Diffusional hypoxia is another potential concern since nitrous oxide rapidly diffuses out of the blood and into the alveoli, where it can displace oxygen and cause hypoxia. This theoretical concern has not been supported by clinical evidence. Nevertheless, supplemental oxygen should be administered throughout the recovery phase. Nitrous oxide use in the ED also has the potential for abuse, environmental contamination, and potential teratogenic effects, especially with chronic exposure. The use of nitrous oxide is contraindicated in patients with pneumothoraces, bowel obstruction, middle ear effusions, and patients undergoing procedures using balloon-tipped catheters because of its rapid diffusion into gas-collecting areas of the body, which could cause acute expansion, overdistension, and perforation. It also should be avoided in patients with head injuries, psychiatric diseases, or drug intoxication. Because of nitrous oxide's opioid agonist properties, it may result in deep sedation or general anesthesia if combined with a sedative or opioid. Thus extreme caution should be exercised when administering it to a patient with recent administration of either of these medications.

KETAMINE Ketamine is a unique sedative analgesic that has been studied extensively in children undergoing outpatient procedures.^{22,24} PSA using ketamine should be referred to as dissociative sedation, reflecting its unique properties.²⁵ A derivative of phencyclidine, ketamine produces a dissociative effect resulting in a trancelike cataleptic state, providing a combination of sedation, amnesia, and analgesia. Spontaneous respirations and pharyngeal muscular tone are maintained, as well as protective airway reflexes of coughing and swallowing. Ketamine has very few negative inotropic effects, making it a reasonable option for acutely ill patients. Its sympathomimetic actions may produce mild to moderate increases in heart rate, blood pressure, and cardiac output. However, in the catecholamine-depleted child, use of ketamine may result in hypotension due to unopposed direct vasodilatory effects. It also is a good option for the difficult-to-control child with mental retardation or behavioral disorder, in whom initial intravenous access can be difficult to obtain. Clinical effects from intravenous and intramuscular ketamine occur within several minutes and last about 30 min. It has also been shown to be effective when administered by the transmucosal, oral, and rectal routes. Because ketamine stimulates salivary and tracheobronchial secretions, it should be administered concurrently with an anticholinergic drug, either atropine or glycopyrrolate. Both agents may be combined in a single intramuscular injection. Hallucinatory emergence reactions have been reported with ketamine, although less frequently in children less than 10 years of age. Whether a benzodiazepine should always be given with ketamine is controversial. Recent studies suggest that the administration of midazolam with ketamine does not reduce the overall incidence of emergence reactions in children, but may decrease the incidence of vomiting in children less than 10 years old.^{26,27} This combination may prolong the patient's recovery time because benzodiazepines will inhibit ketamine's metabolism. Ketamine can also cause increased intracranial and intraocular pressure because of increased cerebral blood flow. Other adverse effects are nystagmus, random limb movement, ataxia (may last up to 24 h), and vomiting. Ketamine has the potential for causing laryngospasm and thus should not be used in patients with upper respiratory or pulmonary infections or who have increased salivary secretions. If laryngospasm occurs, the child should be ventilated with a bag-valve-mask. Paralysis and emergent intubation must be performed if this is unsuccessful. Contraindications to ketamine's use are age ≤ 3 months; history of airway instability or tracheal stenosis; procedures involving stimulation of the posterior pharynx; cardiovascular disease including congestive heart

failure and hypertension; head injury associated with loss of consciousness, altered mental status, central nervous system masses, abnormalities, or hydrocephalus; poorly controlled seizure disorder; glaucoma; acute globe injury; or psychosis.

Other Agents

Propofol is an ultra short-acting intravenous anesthetic marketed in the United States as Diprivan. It has been reported as a safe and effective nonanesthetic sedative for adults undergoing fracture reduction, reduction of joint dislocations, minor surgical procedures (incision and drainage of abscesses), cardioversion, and chest tube placement in the ED.²⁸ It has been used in the ICU setting in pediatric patients.²⁹ Propofol has been used in children in the ED for difficult fracture reduction, incarcerated inguinal hernia reductions, laceration repair, foreign body removal, and cardioversion.^{30,31} Propofol's onset of action occurs within seconds and its duration of action is extremely short, requiring continuous infusion for maintenance of clinical effects. After discontinuation of the drug in sedative doses, patients are usually awake and responsive within minutes. It does not possess any analgesic properties in sedative doses and must be used in conjunction with narcotics for painful procedures. Propofol has potent dose-related respiratory depressant effects, may quickly result in deep sedation, and may produce hypotension. More experience is needed before it can be recommended for routine use in children in the ED.

In the past, the "DPT cocktail," consisting of Demerol (meperidine), Phenergan (promethazine), and Thorazine (chlorpromazine), was a popular sedative/analgesic choice for children in the emergency department. Unfortunately, the intramuscular route does not allow for titration of effects and its onset of action is variable. The wide range of doses used and combination of three sedatives adds to confusion and potential for serious respiratory depression. In addition, the efficacy of this "cocktail" can be variable, while its duration of action can be several hours, making it a poor choice for sedation in the ED.³²

Reversal Agents

Naloxone is an opioid antagonist that should be readily available for reversal of respiratory depression, apnea, and severe hypotension. It can be administered in incremental doses of 0.01 to 0.1 mg/kg (maximum single dose 2 mg) to the desired reversal of life-threatening effects, because it would not be desirable to reverse all of the analgesia in a patient undergoing a painful procedure. Naloxone's duration of action is short (approximately 45 min); thus reversal of toxic effects of longer-acting opioids such as morphine, or large doses of short-acting opioids such as fentanyl, may require additional doses.

Flumazenil is a benzodiazepine antagonist that reverses the central nervous system depression, and to some degree the respiratory depression, secondary to inadvertent excess sedation. Incremental doses of 0.01 to 0.02 mg/kg (maximum single dose 0.2 mg) every 1 to 2 min can be titrated to the desired reversal effect. Respiratory depression and hypoventilation should be managed with standard airway management techniques and assisted ventilation if necessary. Flumazenil has also been shown to reverse the paradoxical delirium secondary to midazolam.³³ In the setting of a polypharmaceutical overdose, flumazenil should not be administered. It should not be used in patients on chronic benzodiazepine therapy or on tricyclic antidepressant medications because of the risk of seizures. Flumazenil's duration of action is about 40 to 60 min. Because the duration and degree of reversal depends on the plasma concentrations of benzodiazepine as well as the amount of flumazenil given, the sedative and respiratory depressive effects of the benzodiazepine may last longer than the antagonism produced by flumazenil. Both drugs should be readily available and appropriate doses calculated prior to initiation of the procedure.

PEDIATRIC EXANTHEMS

Michael S. Weinstock Alexander
M. Rosenau

Rashes represent skin signs that are useful in making the diagnosis of a variety of infectious and noninfectious illnesses. Rashes with diverse etiologies can look alike. An assessment of the signs and symptoms preceding or presenting along with the exanthem augment an accurate history in determining the diagnosis. Useful historical data includes prior immunizations, potential human or animal contacts, and recent environmental exposure.

Concerns for bioterrorism make it necessary for the emergency physician to recognize rare disorders such as cutaneous anthrax and variola, which are discussed below.

Another important concern for emergency medicine is the evaluation of rashes in large numbers of U.S. schoolchildren. Epidemics of nonspecific rashes in schoolchildren have been reported in 27 states and Canada since October 2001,¹ affecting up to 47 percent of children in some schools. The rashes are variously described as pruritic and erythematous, involving primarily the cheeks and arms, or as migratory urticaria. There are no associated systemic symptoms, and the rash is self-limited. Parvovirus B19 has been suspected as the cause in some cases, but the cause has not been determined in the vast majority of reported epidemics. The Centers for Disease Control and Prevention (CDC) recommends that epidemic-type rashes in schoolchildren be reported to the local health department. Information gathering should include (1) collect uniform information from patients so that rashes in schools can be differentiated from other types of rashes; (2) determine if family members or non-school contacts are affected; (3) provide follow-up to ensure that rashes have resolved; and (4) evaluate any associated systemic signs and symptoms.

The various etiologic agents and associated exanthems are noted in Tables 135-1, 135-2, and 135-3. Further discussion of cutaneous disorders is found in Section 21 and in general texts of dermatology.^{2,3}

BACTERIAL

Bullous Impetigo

Bullous impetigo, or staphylococcal impetigo, is a local skin infection caused by phage group II staphylococci. The staphylococci produce an epidermolytic toxin that acts locally to cause separation of the skin at the granular layer, giving rise to bullae. The infection occurs primarily in newborn infants and young children. The characteristic skin lesions of bullous impetigo are superficial, flaccid, thin-walled bullae that oc-

cur most often on the extremities but can occur anywhere. They range in size from 0.5 to 3 cm. They can arise from normal skin or may have a thin, red halo. The bullae are filled with a clear, pale-to-yellow fluid and rupture easily, leaving a moist, denuded base that dries rapidly with a shiny coating. Extensive areas of skin may be involved if left untreated.

The clinical appearance of the lesions usually makes diagnosis easy. However, single lesions or extensive involvement may not be as typical. Staphylococci cultured from the fluid of aspirated bullae will establish the diagnosis.

Systemic antistaphylococcal antibiotics, usually oral, along with local wound cleansing and topical antibiotics (such as Neosporin) are effective in eradicating the infection. Prognosis for complete recovery is

Impetigo Contagiosum

Impetigo is a superficial pyoderma caused by infection with staphylococci, although group A (3-hemolytic streptococci may also be cultured. It is a common skin infection, primarily affecting young children, especially in warm, humid conditions. Impetigo can arise at the site of insect bites or superficial cutaneous trauma; sometimes there is no apparent predisposing skin lesion. Fever and systemic signs are uncommon.

The skin lesions start as small erythematous macules and papules. These develop into discrete, thin-walled vesicles, which become pustular and quickly rupture (Figure 135-1). As the vesicles rupture, a yellow fluid forms an exudate, which dries to form a stratified golden yellow crust that accumulates. The crusts can be readily removed, leaving a smooth, red surface. The crusts can spread the infection to other parts of the body. Initially the lesions are discrete, but they may enlarge and become confluent. Local adenopathy may be present. The infection occurs most frequently on the face, neck, and extremities.

The diagnosis of impetigo can be readily made on the basis of the typical clinical appearance. Cultures are generally not necessary. Systemic antibiotic therapy must be combined with wound scrubbing and cleansing and application of Neosporin or mupirocin ointment for optimal results. Effective antibiotics include oral antibiotics such as

erythromycin, clindamycin, cephalosporins, amoxicillin-clavulanate and dicloxacillin.

Erysipelas

Erysipelas, or St. Anthony's fire, is cellulitis and lymphangitis of the skin caused by group A (3-hemolytic streptococci). It is frequently accompanied by fever, chills, malaise, headache, and vomiting.

The rash is characterized by local redness, heat, swelling, and a raised, indurated border. There is marked involvement of the superficial dermal lymphatics. The rash starts as an erythematous plaque that rapidly enlarges by peripheral extension. At first, it is scarlet, hot, brawny, swollen, and tender. The edge is raised and sharply demarcated. The rash can vary in appearance from a transient hyperemia to intense inflammation, vesiculation, and bulla formation. The face is the most frequent site. A skin wound, fissure, or ulcer may act as a portal of entry.

Diagnosis is made on clinical grounds, although aspiration of the leading edge of the lesion will frequently demonstrate streptococci. A brief course of parenteral penicillin is usually warranted because of the rapid advancement of the infection, the acutely toxic state of the patient, and the possibility of suppurative complications. Rapid clinical response is usually obtained. Macrolide antibiotics may be used in patients unable to take penicillin.

Mycoplasma Infections

Mycoplasma pneumoniae infections are a common cause of pneumonia, upper respiratory infections, and bronchitis in children between 5 and 19 years of age. The most frequent presenting clinical findings in children and adults are fever, cough, sore throat, malaise, headache, chills, and rash. An erythematous maculopapular rash, the most fre-

quent presentation, is located on the trunk and may be discrete or confluent. However, the most frequently reported exanthem is consistent with erythema multiforme and Stevens-Johnson syndrome, with lesions occurring primarily on the trunk, legs, and arms. The rash occurs most commonly during the febrile period. An enanthem of generalized ulcerative stomatitis or pharyngitis-tonsillitis associated with the exanthem is common. The diagnosis can be confirmed by the use of either serum cold agglutinins or several specific antibody tests.

Mycoplasma responds to several antimicrobials, including erythromycin, azithromycin, fluoroquinolones, and doxycycline. Infection with *M. pneumoniae* should be suspected in patients with pneumonia and a rash.

Scarlet Fever

Scarlet fever is an acute febrile illness, primarily affecting young children, caused by group A (3-hemolytic streptococci). Recently group C streptococci have been implicated as well. Clinical manifestations include acute onset with fever, sore throat, headache, vomiting, and abdominal pain followed by a distinctive exanthem in 1 to 2 days.

There are both an exanthem and an enanthem associated with scarlet fever. They are caused by an erythrogenic toxin elaborated by the streptococcal organism. The tonsils and pharynx are red and covered with exudate, although occasionally pharyngeal findings are minimal. The tongue has a white coating through which red and hypertrophied papillae project, creating the appearance of a "white strawberry tongue." The white coating disappears by day 4 or 5, and the tongue acquires a bright-red appearance, the "red strawberry tongue." Bright-red or hemorrhagic spots may be seen on the soft palate or anterior pillars of the tonsillar fossae.

The exanthem of scarlet fever begins 1 or 2 days after the onset of the illness. It starts on the neck, axillae, and groin, spreading to the trunk and extremities. The rash is red and finely punctate, consisting of 1- to 2-mm papules that give the rash a characteristic rough, sand-paper feel. It is sometimes easier to identify the rash by palpation. The rash blanches with pressure. Linear petechial eruptions, Pastia's lines, are often present in the antecubital and axillary folds. There is facial flushing with circumoral pallor. A brawny desquamation occurs at 2 weeks, yielding fine flakes of dry skin.

The diagnosis of scarlet fever is readily made on clinical grounds. Throat swabs usually culture group A (3-hemolytic streptococci, al-

though group C may be cultured as well. Treatment with antibiotics is necessary to reduce the incidence of rheumatic fever and nephritis, and will probably ameliorate the course of the disease. Penicillin is the antibiotic of choice, or use one of the macrolides for those who are penicillin-allergic.

RICKETTSIAL

Rocky Mountain Spotted Fever

Rocky Mountain spotted fever (RMSF) is an infectious disease caused by *Rickettsia rickettsii*, which is transmitted by ticks. The prominent clinical manifestations of RMSF can be directly related to the primary pathologic lesion in the endothelial cells lining small blood vessels where the organism multiplies. Rash, headache, mental confusion, terminal heart failure, and shock are manifestations of the generalized vasculitis.

The incubation period is from 2 to 12 days with either a sudden or gradual onset of symptoms. Peak severity usually occurs within 1 to 2 weeks. Headache, fever, toxicity, rash, and myalgia are the major clinical features. The rash (Figure 135-2), a pathognomonic feature of the disease, usually appears on the second or third day. The initial lesions first appear on the wrist and ankles, spreading rapidly to the extremities and trunk. These lesions also are found on the palms and soles of the patient. Initially lesions are small, erythematous macules that blanch on pressure. They rapidly become maculopapular and petechial.

Laboratory diagnostic confirmation is difficult during the early phase of the disease, frequently mandating treatment based on clinical criteria. Serologic tests are used to confirm the diagnosis of RMSF. Some laboratory data may be helpful in establishing the presumptive diagnosis early, such as hyponatremia, leukopenia, and thrombocytopenia.

Specific therapy consists of doxycycline or chloramphenicol. In seriously ill children over the age of 8, doxycycline is given at a dose of 2 to 4 mg/kg per d, divided in two doses. Chloramphenicol 100 mg/kg per d, in four divided doses, up to 3 g, is an alternative. Treatment can be terminated 2 or 3 days after fever returns to normal for 24 h. The mortality of RMSF in the United States has held steady for a decade at 3 to 6 percent of identified cases despite treatment.

VIRUSES

Enteroviruses

Enteroviruses are an exceedingly common cause of illness and exanthems in young children. Enteroviruses are small, single-stranded RNA viruses belonging to the picornavirus group and consist of polioviruses and nonpolioviruses (coxsackievirus and echovirus). There are many types of coxsackieviruses and echoviruses that have been associated with illnesses. They usually occur in epidemics and are most prevalent in the summer and early fall. Transmission usually occurs by the fecal-oral route and possibly by the respiratory route.

The clinical manifestations of infection with coxsackieviruses and echoviruses are extensive. The spectrum of disease includes nonspecific febrile illness, upper respiratory infection, parotitis, croup, bronchitis, pneumonia, bronchiolitis, vomiting, diarrhea, abdominal pain, hepatitis, pancreatitis, conjunctivitis, pericarditis, myocarditis, orchitis, nephritis, arthritis, meningitis, and encephalitis.

Similarly, the associated skin manifestations include an array of exanthems. Diffuse macular eruptions, morbilliform erythema, vesicular lesions, petechial and purpuric eruptions, rubelliform rash, roseola-like rash, and scarlatiniform eruptions have been reported.

Strict clinical-virologic associations have been difficult to demonstrate. A single clinical syndrome can be associated with many types

SECTION 12 • PEDIATRICS

of coxsackieviruses and echoviruses. On the other hand, some types of coxsackieviruses and echoviruses have been associated with multiple illnesses and exanthems.

Hand, foot, and mouth disease is an acute infectious illness, caused by enteroviruses, that primarily affects children. Initial manifestations include fever, anorexia, malaise, and sore mouth. Oral lesions appear 1 to 2 days later and cutaneous lesions shortly thereafter. The oral lesions begin as vesicles on an erythematous base, which ulcerate. The vesicles are usually 4 to 8 mm in size, and are very painful. They are located on the buccal mucosa, tongue, soft palate, and gingiva. The exanthem starts as red papules that change to gray vesicles about 3 to 7 mm in size. They are found on the palms and soles, but may occur on the dorsum of the feet and hands and on the buttocks as well. They may be oval, linear, or crescentic and may run parallel to skin lines. They heal in 7 to 10 days.

Herpangina is a febrile disease of children that is associated with many types of coxsackieviruses and echoviruses. The onset is acute with fever to 40°C (104°F), headache, sore throat, dysphagia, anorexia, and occasionally stiff neck. In the pharynx, there are one or more yellowish-white 2-mm vesicles with hyperemic borders. They are located in the posterior pharynx on the tonsils, uvula, soft palate, and anterior faucial pillars. The vesicles usually ulcerate, leaving a shallow, gray-yellow crater 2 to 4 mm in size. The lesions persist for 5 to 10 days.

Boston exanthem is caused by echovirus 16. It is an acute illness with fever, anorexia, pharyngitis, and lymphadenopathy. An enanthem similar to herpangina may be present. The exanthem begins as small, discrete, pink macules that develop into papules. It appears on the face and chest, spreads centrifugally, and may involve the palms and soles. As in roseola, the rash may appear with defervescence of the fever.

Infection due to echovirus 9 is common and produces a typical enteroviral illness. Clinical manifestations include fever, headache, nausea, vomiting, abdominal pain, cough, coryza, pharyngitis, and nuchal rigidity. The exanthem is rubelliform, a maculopapular rash beginning on the face and neck, then extending to the trunk and feet and sometimes the palms and soles. Occasionally, there are lesions on the buccal mucosa and soft palate that resemble Koplik spots. Petechiae may occur. The appearance of this rash and the presence of nuchal rigidity makes this illness occasionally mimic meningococcemia. The exanthem persists for about 5 days.

Infection with coxsackievirus A9 is a common cause of exanthem. It is an acute febrile illness with a discrete erythematous maculopapular rash that begins on the face and neck and extends to the trunk and extremities. Aseptic meningitis may occur. The rash may also be vesicular or urticarial.

The clinical differentiation of enteroviral disease is difficult. Since there is no specific therapy for enteroviral infection, it is more important to consider bacterial diseases in the differential diagnosis in order to exclude treatable causes of sepsis, meningitis, myocarditis, and pneumonia. Symptomatic therapy for enteroviral infections includes adequate hydration, antipyretics, and viscous lidocaine gel for painful oral lesions.

Herpes Virus (Figures 135-3 and 135-4)

Herpes simplex infection is characterized by umbilicated vesicles that become pustules. Lesions occur at the mouth, lips, gingiva, and fingertips. Treatment with oral antiviral therapy is effective for primary infections. Acyclovir, valacyclovir, or famciclovir can be used.

Erythema Infectiosum

Erythema infectiosum (fifth disease) is an acute, febrile illness with a unique exanthem. Outbreaks of erythema infectiosum occur primarily in the spring. During epidemics, the attack rate is highest in children 5 to 15 years of age, but all age groups can be affected. The illness is caused by infection with human parvovirus, a single-stranded DNA virus.

FIG. 135-3. Herpes simplex virus infection: primary gingivostomatitis. (Reproduced with permission from Fitzpatrick TB, Johnson RA, Wolff K: *Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology*, 4th ed. New York, NY: McGraw-Hill, 2001, p. 787.)

The abrupt appearance of the rash is frequently the first manifestation of erythema infectiosum. It begins with a characteristic fiery red rash on the cheeks. The rash is a diffuse erythema of closely grouped tiny papules on an erythematous base. The edges are slightly raised. The erythema is most intense below the eyes and extends over the cheeks in a pattern reminiscent of butterfly wings; it is sometimes re-

FIG. 135-4. Herpes simplex virus infection: herpetic whitlow. (Reproduced from Fitzpatrick TB, Johnson RA, Wolff K: *Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology*, 4th ed. New York, NY: McGraw-Hill, 2001, p. 789.)

ferred to as a *slapped-cheek appearance*. There is circumoral pallor as well as sparing of the eyelids and chin. The facial rash fades after 4 to 5 days. Approximately 1 to 2 days after the appearance of the facial rash, a nonpruritic macular erythema or erythematous maculopapular rash occurs on the trunk and limbs. It is at first localized to the deltoid areas, trunk, and forearms, but usually extends to involve a large area. This stage of the exanthem may last 1 week. A distinctive aspect of the rash is that it fades with central clearing, giving a reticulated or lacy appearance. The palms and soles are rarely affected.

The exanthem may recur in the ensuing 3 weeks, sometimes briefly. The intensity of the recurrent exanthem varies and may be related to exposure to environmental factors such as sunlight, hot baths, and perhaps, physical exertion or emotional upset. Associated symptoms frequently occur and may include fever, malaise, headache, sore throat, cough, coryza, nausea, vomiting, diarrhea, and myalgia. Arthralgias and arthritis can occur, but usually only in adults. These symptoms may occur before or after the onset of the rash.

There is no specific treatment for human parvovirus infection. Symptomatic therapy is all that is required. Recovery is usually complete.

Measles

Prior to a nationwide immunization program in 1965, measles was an expected disease of childhood. It is a highly contagious, endemic myxovirus infection. It is a winter-spring disease in temperate climates, but it occurs throughout the world.

After exposure, the incubation period for the disease is about 10 days. The prodromal period lasts approximately 3 days and is characterized by upper respiratory symptoms. The onset of clinical measles is characterized by general malaise, systemic toxicity, fever, coryza, conjunctivitis, photophobia, and cough.

The exanthem develops about the fourteenth day following exposure. The rash first appears behind the ears and at the hairline of the forehead. It spreads in a centrifugal pattern from the head to the feet. It is initially erythematous and maculopapular but rapidly progresses to confluence, especially on the face. Initially the rash is red and blanches on pressure. As it fades, it takes on a copper-to-brownish hue. With healing there may be some fine desquamation. The rash generally lasts 7 days.

Koplik spots are an associated pathognomonic enanthem. The lesions are white, 1-mm discrete spots that first appear on the buccal mucosa opposite the lower molars and then spread to involve the entire buccal mucosa. The treatment of measles is supportive.

Infectious Mononucleosis

The diagnosis of infectious mononucleosis can be entertained in those children, adolescents, and young adults who present with fever, sore throat, malaise, and fatigue accompanied by tonsillopharyngitis and lymphadenopathy. The Epstein-Barr virus (EBV) is the etiologic agent of this illness. The age of initial (primary) infection varies and appears to depend upon socioeconomic status. The mononucleosis symptom complex is associated with the primary infection. A 2- to 5-day prodromal period of malaise and fatigue with or without fever may precede the full onset of the syndrome. The adenopathy is usually confined to the anterior and posterior cervical chain but may be generalized. There is a 5-percent incidence of a generalized erythematous maculopapular rash associated with an enanthem consisting of petechiae on the soft palate. The incidence of the rash increases to almost 100 percent in those patients taking ampicillin or its congeners. The treatment for infectious mononucleosis is supportive.

Rubella

Rubella (German measles) was once a common childhood disease that had its highest incidence during the spring. The incubation period is 12

to 25 days following exposure with a 1- to 5-day prodrome of fever, malaise, headache, and sore throat.

The exanthem varies and is sometimes difficult to identify. It may present as a short-lived blush, or it may have the more common 2- to 3-day course. The exanthem begins as irregular pink macules and papules on the face spreading to the neck, trunk, and arms in a centrifugal distribution. It coalesces on the face as the eruption reaches the lower extremities and then clears in the same fashion. As enanthem of pinpoint petechiae involving the soft palate (Forschheimer spots) may accompany the rash but is nonspecific.

Lymphadenopathy is a clinical manifestation of rubella, with the enlargement characteristically in the suboccipital and posterior auricular nodes. The clinical diagnosis of the individual case is often difficult, but the epidemic nature of the illness, along with the seasonal variation and high expression rate of the exanthem, help in establishing the diagnosis. A history of inadequate immunizations may assist in the diagnosis. There is no specific therapy.

Varicella

Varicella, or chickenpox, is a result of infection with varicella-zoster virus, a herpes virus.⁴ In normal children it is characterized by a pruritic generalized vesicular exanthem with mild systemic manifestations. Cases generally occur in late winter and early spring. The incidence of varicella has declined dramatically in surveillance areas with significant vaccine coverage. It is highly contagious in the prodromal and vesicular stage. Varicella most frequently occurs in children less than 10 years old, but it may occur at any age.

The exanthem starts on the trunk or scalp and first appears as faint red macules. Within 24 h, the rash acquires the typical vesicular appearance of varicella. The rash consists of teardrop vesicles on an erythematous base, which then dry and crust over (Figure 135-5). Successive fresh crops may appear for a few days. The extent of the rash may be minimal, but usually it will spread centrifugally and become widespread. Palms and soles are spared. Vesicles may occur on mucous membranes and proceed to rupture and form shallow ulcers. Low-grade fever, malaise, and headache are frequently present but are usually mild. The diagnosis of varicella is usually made clinically on the basis of its distinctive rash. A Tzanck smear of the vesicle contents will demonstrate varicella giant cells with inclusion bodies.

Complications of varicella can occur, including encephalitis, pneumonia, nephritis, and infection of the vesicles with staphylococci or streptococci. Neonates born to mothers with perinatal varicella infection may develop serious illness.

Uncomplicated varicella requires no specific therapy. Acetaminophen may be used as needed, but aspirin should be avoided as it may predispose to the development of Reye syndrome. Oral antihistamines may be useful to reduce itching. Most importantly, lesions should be cleansed regularly to prevent secondary infection. In the absence of central nervous system complications, the prognosis is excellent. Routine use of acyclovir for uncomplicated varicella infections in children is not recommended. While limited data are available on pediatric use, no unusual toxicity or problems have been noted.

Immunocompromised patients with varicella require aggressive treatment with antiviral drugs such as acyclovir. The dose of acyclovir is 80 mg/kg per d in four divided doses up to 800 mg/dose. Administration of varicella zoster immune globulin (VZIG) should be considered for immunocompromised patients exposed to individuals with varicella.

With the advent of significant vaccine coverage, surveillance and public health reporting are important for outbreak management.

Variola

Due to an international effort to isolate and eradicate variola, smallpox is now a historical disease. The virus is known to exist only in two

IMAGES OF CHICKENPOX (VARICELLA)

FIG. 135-5. Varicella. [Reproduced from the Centers for Disease Control (CDC), www.bt.cdc.gov/agent/smallpox/diagnosis/pdf/spox-poster-full.pdf]

laboratories worldwide, one in the former Soviet Union and one in the U.S..

With the breakup of the former Soviet Union in the early 1990s, concern regarding biological agent proliferation surfaced. The reach of international terrorism has heightened awareness of the use of nuclear, biological, and chemical threats, including smallpox, as weapons of terror.

Variola or smallpox (Figure 135-6, **Plate 1**) is a highly transmissible poxvirus with a mortality rate that can exceed 30 percent. Transmission is by droplet (from oropharynx, person to person) or through contact with virus from infected persons. An incubation period of 2 weeks allows for known contacts to be successfully immunized through vaccination.

The rash associated with smallpox is quite striking. With careful examination it is easily differentiated from the exanthem of varicella (chickenpox). Varicella causes superficial lesions that occur in crops. The lesions proceed through a cycle of papule, vesicle, pustule, and scab formation, so many different stages of the lesions are present simultaneously. The greatest density of lesions occurs on the trunk with chickenpox.

By contrast, smallpox causes deep lesions of greatest density on the face and extremities, and all lesions present are in the same stage.

IMAGES OF SMALLPOX

FIG 135-6. (PLATE 1). Smallpox. [Reproduced from the Centers for Disease Control (CDC), www.bt.cdc.gov/agent/smallpox/diagnosis/pdf/spox-poster-full.pdf]

These lesions begin as a maculopapular rash: first affecting the mouth and face then proceeding to the trunk and legs. Vesicles form within 2 days and then become pustules. Smallpox is associated with high fever, headache, backache, and the previously described rash. A high percentage of untreated patients die on the sixth day. Among those who survive, the rash forms scabs and crusts by the eighth day.

Smallpox identified in the ED requires activation of the institutional response plan including immediate isolation and consultation with public health and hospital authorities.

Anthrax

Although cutaneous anthrax (Figure 135-7, **Plate 2**) is not uncommon among the farmers of southwestern Texas, the recent threat of bioterrorism and the appearance of virulent strains of both inhalation and cutaneous anthrax has heightened the need for early recognition and continued surveillance.

Spores of *Bacillus anthracis* can be introduced subcutaneously. The clinical manifestations are usually very striking. Most develop lesions on exposed surfaces of the body such as the face, neck, arms, and hands. The lesion usually starts as a small, painless often pruritic

FIG. 135-7. (PLATE 2). Cutaneous anthrax in a 9-year-old girl. [Reproduced with permission from DOIA (Dermatology Online Atlas) University Erlangen, Department of Dermatology, Nürnberg, Germany, www.dermis.net/index_e.htm.]

papule. It progresses rapidly (usually over 2 to 3 days) with initial enlargement of the papule followed by vesiculation and rapid ulceration with eschar formation. Regional adenopathy is often present. The differential diagnosis includes brown recluse spider bite, necrotic herpes simplex, tularemia, accidental vaccinia, and ecthyma.

Gram stain of the vesicular fluid demonstrates sporulating gram-positive rods. Clinically, the presence of edema out of proportion to the size of the lesion, the absence of pain, and the rarity of polymorphonuclear leukocytes on Gram stain make the diagnosis of cutaneous anthrax relatively easy to make. Untreated, the fatality rate can be as high as 20 percent.

B. anthracis is highly susceptible to many antibiotics. For cutaneous anthrax, penicillin has been used historically, but ciprofloxacin or doxycycline are now recommended (www.cdc.gov/ncidod/EID/vol8no2/01-0521.htm).

Roseola Infantum

Roseola infantum, or exanthem subitum, is a common acute febrile illness of childhood. There appears to be no seasonal preponderance to its occurrence. The most likely etiologic agent has been identified as the human herpesvirus 6, although other viruses have been associated with a roseola-like illness.

Roseola is characterized by a febrile period of 3 to 5 days, defervescence, and the appearance of a rash for 1 or 2 days. Primarily, young children are affected, with most patients being between 6 months and 3 years of age. The illness begins abruptly with high fever, sometimes as high as 40.6°C (105.1°F). The child is usually alert and active but may be irritable, especially with very high fever. Associated symptoms are usually mild and may include cough, coryza, anorexia, and abdominal discomfort. Lymphadenopathy may be present. Febrile convulsions may occur. The fever persists for 3 to 5 days, and most often returns to normal by crisis. The child rapidly becomes well.

The exanthem in roseola usually coincides with defervescence of the fever, but it may follow a short afebrile interlude. The rash is an erythematous macular or maculopapular eruption that consists of discrete, rose or pale-pink lesions 2 to 5 mm in size. It is most prominent on the neck, trunk, and buttocks, but the face and proximal extremities may also be involved. The lesions blanch with pressure. There is no mucous membrane involvement. The rash lasts 1 to 2 days but may fade rapidly, usually without desquamation.

There is no specific treatment for roseola. Acetaminophen is useful for fever control and convulsions should be treated vigorously. Recovery is usually complete.

ETIOLOGY UNCLEAR

Erythema Nodosum

Erythema nodosum is an inflammatory exanthem of unknown etiology. It is probably an inflammatory reaction to a stimulus. In the past, erythema nodosum was most closely associated with streptococcal infections, tuberculosis, and sarcoid, although fungal infections, *Yersinia* infections, vasculitis, inflammatory bowel disease, and leukemia are also known to stimulate the syndrome. Now it is more commonly associated with drugs, especially oral contraceptives. Persons of any age can be affected. Constitutional symptoms may be present at the onset, including fever, malaise, myalgias, and arthralgias.

Erythema nodosum presents a distinctive clinical appearance. Bilateral, very tender nodules develop symmetrically. They usually occur on the shins, but can occur on the arms, thighs, calves, and buttocks. The nodules are 1 to 5 cm in diameter, and individual lesions may coalesce to form sizable areas of induration. The skin over the nodules is red, smooth, and shiny. No ulceration occurs. After a week or two, the color of the lesions changes from red to blue and may achieve a dull, purple, bruised appearance. The eruption lasts several weeks.

The diagnosis of erythema nodosum is usually readily made on clinical grounds. A thorough history and physical, and perhaps laboratory evaluation must be performed to exclude an underlying cause. There is no known therapy to alter the course of the disease. Nonsteroidal antiinflammatory drugs may provide relief from the sometimes significant pain associated with these lesions.

Kawasaki Disease (Mucocutaneous Lymph Node Syndrome)

Kawasaki disease, or mucocutaneous lymph node syndrome (MLNS) is a disease of unclear etiology found predominantly in children under 9 years of age.^{5,6}

The diagnosis of this disorder is based on a constellation of clinical findings. The patient must exhibit a prolonged fever associated with at least four of the following: (1) conjunctivitis, (2) rash,

(3) lymphadenopathy, (4) changes in the oropharynx consisting of injection of the pharynx and lips with prominent papillae of the tongue (strawberry tongue), and (5) extremity erythema and edema.

The rash has been described as erythematous, morbilliform, urticarial, scarlatiniform, or erythema multiforme-like. It has a predilection for the perineum. Additional supportive evidence which may help in the presumptive diagnosis includes leukocytosis, elevation of acute-phase reactants, elevated liver function tests, arthritis, arthralgia, and irritability.

In the second phase, there is usually a sharp rise in the platelet count, desquamation of the fingers and/or toes, and the most serious complication, the development of coronary artery aneurysm. A small percentage (1 to 2 percent) of patients with coronary artery aneurysm develop sudden cardiac failure, resulting in death from myocardial infarction with coronary artery thrombosis.

The differential diagnosis includes drug allergy, toxic epidermal necrolysis, staphylococcal toxin-mediated syndromes, erythema multiforme, and scarlet fever. The etiologic speculations include a hyper-immune response to a variety of infections, a viral syndrome, an allergic or toxic response to pollutants, drugs, or toxic agents, and a possibility of a rickettsial disease.

Treatment of Kawasaki disease continues to evolve. Intravenous gamma globulin (IVIG, intravenous immunoglobulin) is now routinely recommended. Aspirin remains an important component of the therapy for Kawasaki disease. Steroids, while somewhat controversial, are assuming an increasingly important role, especially in those cases refractory to IVIG. Bed rest, supportive therapy, and frequent monitoring are mainstays of treatment.

Pityriasis Rosea

Pityriasis rosea is a mild inflammatory exanthem of unknown cause. The available evidence suggests a viral etiology. Pityriasis rosea affects all age groups but occurs most commonly in patients 10 to 35 years old. It tends to occur in spring and fall but not in epidemics. Pityriasis rosea is not contagious. A pityriasis rosea-like eruption has been associated with some drugs and viruses. Occasionally there are prodromal symptoms including malaise, headache, sore throat, fatigue, and arthralgia.

The rash of pityriasis rosea evolves over a period of several weeks. It begins with a "herald patch," a solitary, erythematous lesion with a raised edematous border most frequently occurring on the chest or back. It is 2 to 6 cm in diameter. About 1 or 2 weeks later, there is a widespread, symmetrical eruption of pink- or salmon-colored maculopapular lesions. The patches are oval and are covered with dry epidermis which desquamates to form a ring of scale at the periphery. The lesions are 0.5 to 1.5 cm in diameter and are at first discrete, but can become confluent. The long axes of the patches frequently run parallel to lines of skin tension, giving rise to the "Christmas tree" pattern seen on the back. The eruption is generalized and chiefly affects the trunk, although it can occur anywhere. The lesions can be localized. Mucous membranes can be involved with plaques, hemorrhagic punctate spots, or ulcers. Successive crops of skin lesions can occur, and the entire illness can last 3 to 8 weeks. Healing is complete, without sequelae or evidence of organ involvement.

The diagnosis of pityriasis rosea is made by the clinical appearance. It can be confused with viral exanthem, drug eruptions, syphilis, and seborrheic dermatitis. Potassium hydroxide preparation of skin scrapings will serve to distinguish pityriasis rosea from tinea corporis. A serologic test for syphilis must be done to exclude that diagnosis.

Therapy is directed at alleviating symptoms. There is some early evidence indicating that treatment with erythromycin may speed the resolution of this exanthem. Further studies may be useful in this regard. The rash is sometimes very itchy. Oatmeal baths and oral antihistamines will provide temporary relief. Emollients will help dryness and irritation. Secondary infection must be prevented with thorough cleansing.

MUSCULOSKELETAL DISORDERS IN CHILDREN

Courtney Hopkins-Mann

David Leader

Donna Moro-Sutherland

Richard A. Christoph

GENERAL PRINCIPLES

The anatomy of the pediatric musculoskeletal system is unique and reflects the active growth and development that occurs during childhood. Fracture classification, treatment approach, and types of complications are directly related to this unique anatomy. Perhaps the most helpful way to divide pediatric musculoskeletal injuries is into those occurring before and those occurring after fusion of the physes. In general, both injury patterns and treatment approaches in children in whom closure of the physes has already occurred is similar to those of the adult. Therefore, the major focus of this discussion is directed at injuries occurring in the prepubescent child. In addition, diseases specific to the pediatric population that cause non-traumatic musculoskeletal complaints will also be covered.

The long bones of children consist of discrete anatomic areas. The physis is an area of growth cartilage and may occur at one (e.g., the phalanges) or both (e.g., the tibia and the femur) ends of a long bone. The area of bone between a physis and the adjacent joint is termed the epiphysis. An apophysis is an area of bone between a physis and is a point for muscle or ligament attachment. The midshaft of a long bone is referred to as the diaphysis. The metaphysis of a long bone represents the area between the diaphysis and the physis (see Figure 267-6).

The long bones of children are generally less dense and more porous than the long bones of adults. The resulting increased compliance contributes to the tendency of pediatric long bones to respond to mechanical stress by bowing and buckling, rather than fracturing through and through, as is seen in adult fracture patterns. The periosteum of the diaphysis and the metaphysis is thicker in children and is continuous from the metaphysis to the epiphysis, surrounding and protecting the mechanically weaker physis. The weakness of the physis is in part related to the reduced oxygen tension found in the hypertrophic zone of the physis. This hypertrophic zone is the location of frequent fractures within the physis. The physis is also sensitive to alterations in the blood supply to this hypertrophic zone as well as to nutritional, hormonal, and mechanical influences, and physeal injuries can result in growth disturbance.

The growth of the musculoskeletal system and its response to injury are also influenced by the growth of muscle and connective tissue. The ligaments of children are stronger and more compliant than in adults, and tolerate mechanical forces better than the weaker physis.

Therefore, apophyseal detachments or epiphyseal fractures are much more common than ligamentous injuries during childhood.

FRACTURE PATTERNS

Fractures Involving the Physis

The weakest layer of the physis is the hypertrophic cell zone. This area is particularly susceptible to shearing, bending, and tension stresses, and represents the layer of the physis that is most consistently fractured. Consequently, the reserve and proliferative cartilage cells in the first two zones of the injured physis usually remain with the epiphysis. This is important because the predominant circulatory support of the cells in these two reproductive zones of the physis arises through the epiphyseal vasculature and thus is more likely to be spared in the event of physal injury.

Compression forces alone may also affect bone growth. This is particularly true when compression forces are applied to the epiphyseal side of the physis. The injury to bone growth caused by compression results from interruption of the epiphyseal circulation to the reproductive cells of the physis.

Perhaps the easiest way to divide pediatric orthopedic injuries is into those occurring in children who are skeletally immature with open physes, and those whose physes have closed. The type of injury in the skeletally immature child is usually described with relation to the physis. The Salter and Harris classification system (see Figure 267-7) is based on the relationship of the fracture line to the physis and the prognosis for growth disturbance.

Salter-Harris Type I Fracture

Type I physal injuries occur when the epiphysis separates from the metaphysis. The cleavage is through the hypertrophic cell zone of the physis, with the reproductive cells of the physis remaining with the epiphysis. There are no associated fragments of bone as the thick periosteal attachments surrounding the physis remain intact. The epiphysis may, however, somewhat displace from the metaphysis. Type I injuries have a low incidence of growth disturbances.

The diagnosis of a Salter-Harris type I injury must be suspected clinically in a child who presents with point tenderness over a physis after trauma. Radiographic findings are typically subtle and soft tissue swelling or a joint effusion may be the only abnormality. Epiphyseal displacement can usually be appreciated on x-rays in one or more views; however, in the absence of epiphyseal displacement, the diagnosis is usually a clinical one.

Treatment of most type I fractures consists of immobilization of the suspected fracture using an appropriate splint, cold compresses, and elevation to limit swelling. Referral to an orthopedic surgeon for follow up evaluation allows for monitoring for bone growth disturbances, which is essential.

Salter-Harris Type II Fracture

In a type II injury, the fracture line extends a variable distance along the hypertrophic cell zone of the physis and then out through a piece of metaphyseal bone. The periosteum overlying the metaphyseal fragment remains intact, whereas the periosteum on the opposite side of the fracture is torn away from the diaphysis while remaining adherent to the epiphysis. Growth is preserved since the reproductive layers of the physis maintain their position with the epiphysis and the epiphyseal circulation. Diagnosis is made radiographically by noting a triangular-shaped fragment of metaphysis that is not associated with discernible injury to the epiphysis.

Treatment of a type II fracture consists of closed reduction of any displacement followed by immobilization in a splint, ice, elevation, analgesia, and orthopedic follow up.

Salter-Harris Type III Fracture

Type III physal injuries are intraarticular. The fracture line extends intraarticularly from the epiphysis, through the hypertrophic zone of the physis, with the cleavage plane continuing along the physis to the periphery. The prognosis for subsequent bone growth relates to the preservation of circulation to the epiphyseal bone fragment; however, the prognosis is usually quite favorable.

The diagnosis of a type III injury is made radiographically and is based on the appearance of an epiphyseal fragment, not associated with an apparent metaphyseal fracture. There may or may not be an associated periosteal injury. Occasionally, additional imaging with CT or MRI is used to better evaluate the extent of fracture and articular surface involvement. Treatment is usually open reduction to ensure proper alignment of the articular surface.

Salter-Harris Type IV Fracture

In type IV injuries, the fracture line originates at the articular surface and extends through the epiphysis, the entire thickness of the physis, and continues through the metaphysis. The risk of growth disturbance with this type of fracture is significant and reduction must be precise. The diagnosis of a type IV injury is made radiographically upon identification of epiphyseal and metaphyseal fragments. Treatment is open surgical reduction and internal fixation.

Salter-Harris Type V Fracture

Type V injuries typically involve the knee or ankle and are the result of a profound compressive force transmitted to the physis, resulting in crushing of the chondrocytes in both the reserve and proliferative zones. Displacement of the epiphysis is usually only minimal despite the significant damage to the physis.

The diagnosis of a type V injury may be difficult initially leading to a lack of appreciation of the seriousness of the injury. An initial diagnosis of a sprain or a type I physal fracture may prove incorrect in view of subsequent development of premature growth arrest during follow up. Radiographs may appear normal or may demonstrate focal narrowing of the physal plate. There is also typically a joint effusion. The history will point to a type V injury, however, as a significant mechanism has usually been sustained. Treatment consists of casting and orthopedic monitoring in anticipation of bone growth arrest.

Torus Fractures

The porous nature and resulting compliance of the metaphyses of pediatric long bones, coupled with the relative thickness of the periosteum in this area, confer unique fracture characteristics in children. Compressive forces often result in a bulging or buckling of the periosteum rather than a more complete fracture line. Cortical, or *torus*, fractures are so named to describe prominence or bulging of the bony cortex, usually involving the metaphysis.

A simple torus fracture will not produce a visible deformity to the shape of the extremity; however, there is typically soft tissue swelling and point tenderness over the bony injury. In children who are not obese, the torus fracture is occasionally palpable as a ridge over the metaphyseal area of the long bone.

Radiographically, the torus fracture may be subtle. The contour of the metaphyseal flare should be carefully inspected. Any asymmetry, bulging, or deviation of the cortical margin indicates a torus fracture. Soft tissue swelling is also usually evident. Torus fractures are not typically associated with severe angulation, displacement, or rotational abnormalities, so reduction is rarely necessary. The extremity is splinted in a position of function with orthopedic follow up within 1 week.

Greenstick Fractures

Stress and force may be applied to the porous, compliant bones of children in such a way as to create an incomplete cortical fracture. A *greenstick* fracture is characterized by cortical disruption and periosteal tearing on the convex side of the bone, with an intact periosteum on the concave side of the fracture. Greenstick fractures are more stable and somewhat less painful than complete fractures, since the area of intact periosteum limits bony displacement.

The need for reduction is determined by the degree of angulation of the fracture, the age of the child, and the anatomic location of the injury.

Plastic Deformities (Bowling or Bending Fractures)

Plastic deformities, also referred to as bowing or bending fractures, are almost exclusively limited to the forearm and lower leg long bones. Usually, this type of injury is noted in combination with a completed fracture of the other bone of the forearm or lower leg. The cortex of the diaphysis of the long bone is deformed, but the periosteum along the entire diaphysis is preserved. These injuries result from the compliance and porosity of the child's bones, with the associated tendency to deform or bend rather than fracture in the traditional sense.

The diagnosis of a plastic deformity fracture is made radiographically. Proper interpretation of the radiographs requires an awareness of the normal shape of the long bones involved, since fracture lines and disruptions in the periosteum will be absent. Comparison films of the uninjured extremity may be useful in determining the degree of deformity.

Prompt orthopedic consultation is required for any plastic deformities as proper reduction and realignment is essential. Reduction usually involves completion of the fracture with restoration of proper alignment.

Fractures from Child Abuse

See Chap. 297 for complete discussion of child abuse.

UPPER EXTREMITY INJURIES

Fractures of the Clavicle

Clavicle fractures occur during two distinct time frames: the newborn period and childhood. Fractures of the clavicle in the newborn usually

result from birth injury (Figure 136-1). Risk factors include high birth weight and shoulder dystocia. The infant may demonstrate upper extremity palsy secondary to a brachial plexus injury or may have "pseudoparalysis" of the extremity secondary to pain. Although many clavicle fractures are detected at birth, the diagnosis may be delayed especially if the fracture is nondisplaced. An ED visit may be made when the newborn is not moving one arm during the first week of life, or when a parent notices a small "lump" or callus at the clavicle during the first 2 to 3 weeks of life. Most clavicle fractures in the newborn do not need specific treatment. Pain control and careful handling of the baby are usually all that are required.

Clavicle fractures outside of the newborn period usually result from accidental injury in a mobile child. However, clavicle fractures in children younger than 2 years old should raise the possibility of abuse. The most common mechanism of injury is either a fall onto an outstretched hand or onto the lateral side of the shoulder. The clavicle may fracture in three general sites: the diaphysis, the medial end, or the lateral end. Fractures of the diaphysis usually occur in the middle third of the clavicle and are the most common of all clavicle fractures. Treatment is an arm sling, as tolerated by the child. Even displaced and overlapping fractures tend to heal well with simple immobilization in a simple sling for 3 to 4 weeks. Complete healing and remodeling can take more than 1 year, and a small callus will become palpable in most cases if the fracture was displaced. Routine follow up with the primary care physician is sufficient.

Fractures at the medial end of the clavicle are uncommon. Given the strong ligamentous attachment of the clavicle to the sternum, injuries to this area are usually epiphyseal disruptions. Clinical presentation and treatment depend on the direction of the displacement. When the displacement is anterior, there is usually tenderness, and a palpable protrusion of the distal end of the clavicle. Open reduction and fixation is generally needed. If the displacement is posterior, compression of the trachea and esophagus can lead to complaints of dysphagia and respiratory difficulty. Treatment of a posterior displacement is urgent reduction.

Fractures of the distal end of the clavicle are also uncommon in children and again more likely to be epiphyseal disruptions. Injuries to the distal end of the clavicle are more likely to result from direct trauma to the area. Generally, these types of fractures can be managed by a conservative sling if they are minimally displaced. However, surgical reduction may be needed for more displaced fractures to provide for optimal healing and function of the shoulder.

FIG. 136-1. Nondisplaced clavicle fracture in an infant.

Fractures of the Humerus

Fractures of the humerus can be divided into three groups: fractures of the proximal humerus, humeral diaphysis, and supracondylar fractures. Supracondylar fractures are discussed as part of the elbow.

Fractures of the proximal humerus may occur at the physis or the proximal humeral metaphysis, and they have an extraordinary ability to repair themselves. Physeal fractures occur more commonly in adolescents because this area becomes relatively weak during this time because of rapid growth. Fractures of the proximal humeral metaphysis are more common in preadolescents. Treatment depends on both the age of the child and the degree of displacement. Orthopedic consultation is needed to determine the best approach. In general, the younger child can tolerate a greater degree of displacement. For slightly displaced fractures, treatment is conservative with immobilization in a sling and orthopedic follow up. Fractures displaced >30 degrees often need closed reduction and immobilization.

Fractures of the humeral diaphysis are uncommon in children. Direct trauma can cause a transverse fracture and violent rotation can cause a spiral fracture. The possibility of abuse must be considered in small children presenting with fractures of the diaphysis of the humerus because of the significant force required for fractures in this area. Potential for healing is again good and treatment is usually conservative with immobilization in a long arm plaster splint and orthopedic follow up. Closed reduction may be required for displaced fractures. Transverse fractures tend to be more unstable than spiral fractures. One complication with respect to fractures of the humeral diaphysis is radial nerve injury. The fracture fragment may injury the nerve as it runs in the radial groove. Documentation of radial nerve function is therefore extremely important and should also be noted after any reduction attempt.

Pediatric Elbow

Compared to other fractures, elbow fractures in children are commonly missed in the ED. Radiologic diagnosis of these injuries are extremely challenging because of the large cartilaginous component of the elbow. A thorough understanding of the anatomy of the immature elbow helps to reduce the risk of misdiagnosis. Familiarity with proper alignment, angulation, various stages of development of ossification centers, and quality of fat pads will aid the emergency physician in correctly diagnosing an elbow fracture.

ORDERING RADIOGRAPHS True lateral and anteroposterior (AP) radiographs of the elbow are needed. There are three key points to consider in the interpretation of every radiograph of the pediatric elbow. In a true lateral radiograph, the anterior humeral line should bisect the capitellum in the middle third. If the capitellum falls posterior to the line, one needs to consider an extension-type supracondylar fracture as the most likely diagnosis. Other diagnoses to consider include lateral condyle fractures or, rarely, a transphyseal fracture. The radius should point to the capitellum in all views. If not, lateral condyle fracture, radial neck fracture, Monteggia fracture, or elbow dislocation must be considered in the evaluation. A sensitive indicator of angulation of the distal humerus in the frontal plane is the Baumann angle. The normal angle is 9 to 26 degrees. It is commonly abnormal in supracondylar fractures.^{1,2}

Lateral radiographs are used to evaluate for subtle effusions when an occult fracture is suspected. The normal anterior fat pad is seen as a drop of oil hugging the distal humerus anteriorly. No posterior fat pad should be appreciated. The quality of the anterior fat pad may be the only hint that a fracture is present. The anterior fat pad may be unappreciated due to soft tissue swelling, grainy in appearance, or the classic "sail sign" may be seen, which clues the physician to hunt further for a fracture line in either the humerus, radius, or olecranon. When a posterior fat pad is visualized, it usually suggests a hemarthrosis secondary to an intraarticular injury. If a fracture is not apparent, oblique views can be obtained,

which may detect a subtle fracture. If no fracture line is present, it is an occult supracondylar fracture until proven otherwise.

OSSIFICATION CENTERS There are six ossification centers apparent in the pediatric elbow and are seen at varying ages. It is important to become familiar with the orientation of the ossification centers around the elbow as they may be confused for a fracture. The mnemonic used over the years is CRITOE [capitellum, radial head, internal (medial) epicondyle, trochlea, olecranon, external (lateral) epicondyle]. See Table 136-1.

ELBOW INJURIES Elbow injuries are divided into supracondylar fractures, lateral condylar fractures, medial epicondylar fractures, distal humeral physeal fractures, olecranon fractures, radial head and neck fractures, elbow dislocations, and radial head subluxation.

Supracondylar Fractures Supracondylar fractures are the most common fractures in children under 8 years old. The majority of supracondylar fractures occur in children from 3 to 10 years of age, with the peak incidence occurring between ages 5 and 7. The extension type is by far the most common, accounting for 90 to 98 percent of cases. It is caused by a fall on an outstretched hand (FOOSH) with the elbow hyperextended. The flexion-type fracture is a rare occurrence resulting from falling on a flexed elbow. The complications from this type of injury, though uncommon, can be significant if the injury is missed or treatment is delayed. Complications range from transient neuropraxia to Volkmann ischemic contracture.

Classification of the types of supracondylar fractures is based on the extent of fracture fragment displacement. Type I fractures have minimal or no displacement. Type II fractures are displaced with a variable amount of angulation, but the posterior cortex of the humerus is intact. Type III fractures are completely displaced with no cortical contact. The distal fragment may be posteromedially (IIa) rotated and, as such, can impinge against the radial nerve or be posterolaterally (IIb) rotated. In posterolaterally displaced fractures, the brachial artery and median nerve are at risk for injury. There is a higher incidence of compartment syndrome with IIb supracondylar fractures.^{1,3} If a pulseless, pale, cold hand is present, an orthopedic surgeon should be urgently consulted and the limb elevated. Traction and reduction are indicated if the hand is cool, pale, and pulseless. The simple absence of a pulse in an otherwise viable hand is a contraindication to manipulation in the ED.

The level of displacement and the prereduction physical examination dictates treatment of pediatric supracondylar fractures. Type I supracondylar fractures are inherently stable. The goal of therapy is comfort and immobilization. The arm is placed in a double sugar-tong splint or a long-arm posterior splint with the elbow at 90 degrees and the forearm in pronation or neutral rotation for 3 weeks. Orthopedic follow-up should be within 48 h. Type II and type III fractures need orthopedic consultation in the ED for definitive management.

LATERAL CONDYLAR FRACTURES Lateral condyle fractures account for approximately 10 percent of elbow fractures in children, and are usually Salter-Harris type IV. The mechanism of injury is varus

TABLE 136-1 of Appearance of Ossification Sequence Centers of the

Ossification Center	Age of Appearance
Capitellum	3 mo-2 y
Radial Head	4-5 y
Medial epicondyle (I)	4-6 y
Trochlea	8-10 y
Olecranon	8-10 y
Lateral epicondyle (E)	10-12 y

stress on an extended elbow with the forearm in supination. Swelling and tenderness are usually limited to the lateral elbow, and neurovascular injury is uncommon. Diagnosis can be made with standard AP and lateral views, however, an oblique view should be obtained if clinical suspicion is high, as this is often the best view for evaluating the extent of the fracture and displacement. Treatment is based on amount of displacement and articular congruence. Nonunion, malunion, osteonecrosis, cubitus valgus, and tardy ulnar nerve palsy are well-described complications, so orthopedic consultation is needed to determine the best treatment approach.

MEDIAL EPICONDYLAR FRACTURES Fractures of the medial epicondyle tend to occur in older children, between the ages of 10 and 14 years. They are not true Salter-Harris injuries, as the apophysis rather than the physis is involved. Simple fractures of the medial epicondyle are extraarticular injuries with limited soft tissue involvement, but nearly half of injuries are associated with elbow dislocation. Fractures are classified by the amount of displacement and associated extremity injuries, and orthopedic consultation is needed to determine the best approach.

DISTAL HUMERAL PHYSEAL FRACTURES Most injuries occur in children younger than 2.5 years old. Recognition is both difficult and important, especially in infants, in whom this particular injury is often the result of child abuse. This injury is felt to result from a twisting mechanism that shears off the distal epiphysis.

OLECRANON FRACTURES Olecranon fractures generally result from a fall onto the elbow. Orthopedic consultation is best to guide treatment. If the fracture is displaced less than 5 mm, it should be immobilized in the most stable position, usually 45 degrees of elbow flexion, for 3 to 6 weeks. Open reduction and internal fixation are indicated for unstable fractures. Olecranon fractures occur in association with fractures of the radial head and neck. A "simple" olecranon fracture may be part of a Monteggia lesion, so radial head position should be evaluated carefully.

RADIAL HEAD AND NECK FRACTURES Fractures of the radial head and neck are uncommon in children. The radial neck is fractured more frequently than the radial head, and most radial neck fractures occur through the metaphysis. The most common mechanism is a fall. Orthopedic consultation should be obtained to guide treatment. Open reduction is indicated when angulation is more than 60 degrees or displacement is more than 50 percent.

ELBOW DISLOCATION Elbow dislocations occur most frequently in males (70 percent), usually from a fall on the outstretched hand. The most common type of dislocation is posterior, usually accompanied by some lateral displacement. The radiographs need to be thoroughly scrutinized to rule out the presence of associated fractures, particularly of the medial epicondyle and radial neck. Neurologic injury is associated with approximately 10 percent of elbow dislocations. Ulnar neuropathy is the most common and is usually associated with medial epicondyle entrapment. Radial nerve abnormalities are rare. Median nerve damage is the most problematic. It may be caused by kinking of the nerve inside the joint, coursing behind the medial epicondyle, or entrapment in an epicondyle fracture. Arterial injuries with elbow dislocation are rare, and most reported cases occurred with an open injury. In the presence of neurovascular compromise, an urgent orthopedic consultation is warranted. Postreduction films must be obtained to verify reduction and to rule out any associated fractures. Acute management involves immobilization of the reduced elbow in a posterior mold after closed reduction followed by protected motion in 5 to 7 days. The major long-term complication is stiffness. Long-term results are generally excellent in the absence of prolonged immobilization.

RADIAL HEAD SUBLUXATION (NURSEMAID'S ELBOW) The peak incidence of radial head subluxation is 2 to 3 years of age, with a range from 6 months to 7 years. Girls are seen more commonly than boys. Left-sided injury is more common, presumably because most caretakers are right-handed. The usual mechanism of injury is sudden longitudinal traction on the arm with the elbow extended, such as occurs when a child is pulled up by the arm. The annular ligament of the radius displaces into the radiocapitellar articulation. The clinical examination reveals a toddler who will not move the affected arm, but is otherwise not in any distress. The arm is kept in an adducted, semiflexed, and prone position. On palpation there is no significant point tenderness or swelling. There may be some discomfort on palpation of the radial head on the affected side. Attempts at pronation and supination of the forearm are painful. Radiographs are not necessary if the clinical suspicion of radial head subluxation is high. There are two maneuvers for reduction, the supination technique, and the hyperpronation technique. The supination technique (Figure 136-2) is performed by holding the child's elbow at 90 degrees with one hand, then firmly supinating the wrist, and finally by flexing the elbow so that the wrist is directed to the ipsilateral shoulder. The hyperpronation technique⁴ (Figure 136-3) is reported to be more successful, and it can be used primarily, or as a backup technique when supination fails. The hyperpronation technique is performed by holding the child's elbow at 90 degrees in one hand, then firmly pronating the wrist. Full arm function should return within 30 min, and if it does not, the alternative technique can be applied, or an alternative diagnosis should be considered. An arm sling may be offered until all pain resolves, but is usually not necessary.

Forearm Injuries

Forearm injuries heal well with few complications if appropriately managed. Clinical and radiographic assessment should include the forearm and the joints above and below the primary injury, because there is a high rate of associated fractures or dislocations at those joints. In general, the potential for remodeling is better with more distal injuries. Proximal injuries of the midshaft can be problematic and occasionally require open fixation.

Fractures of the radial and ulnar shafts usually result from a fall onto an outstretched hand. The majority of shaft fractures involve the distal third of the forearm. Clinically, there is point body tenderness, swelling, and obvious deformity. Although all forearm fractures need orthopedic follow-up, the patient's age and degree of deformity determine the need for immediate referral and reduction. Any fracture with rotational deformity or more than 10 degrees of angulation in any plane, requires consultation with an orthopedist to determine the need for reduction. Recognition of a bowing type fracture is also essential because failure to correct the bowing may lead to permanent deformity and disability. However, detection of a bowing fracture may prove difficult, although comparison views may help. As with incomplete yet angulated greenstick fractures, bowing fractures may require completion of the break to establish proper realignment.

Isolated fractures of the ulna are extremely rare. Typically, the same force causes either a fracture or dislocation of the radius. The combination of an ulnar fracture with a dislocation of the radial head is called a *Monteggia fracture*. Clinically, there may be tenderness about the elbow; however, even without significant clinical findings, films of the elbow are essential with fractures of the ulna to evaluate for possible dislocations. Any suspected Monteggia fracture-dislocation requires immediate evaluation by an orthopedist. The *Galeazzi fracture* is a radial shaft fracture with an associated dislocation of the distal radioulnar joint. Although this injury is uncommon, immediate orthopedic consultation is again warranted.

Fractures of the distal radius and ulna are very common. Their propensity to heal with proper management is excellent. Clinically, the child has point tenderness over the distal forearm, frequently associ-

FIG. 136-2. Supination technique. Hold the elbow at 90 degrees, then firmly supinate the wrist and flex the forearm toward the ipsilateral shoulder.

ated with localized swelling. Torus or buckle type fractures are extremely common and are occasionally overlooked given their radiographically subtle nature. Once identified, these types of fractures are well managed in a volar or sugar tong splint with orthopedic follow up in 1 week.

Greenstick or complete fractures with more than 10 degrees of angulation in any plane require consultation with an orthopedist to determine whether reduction is necessary. Otherwise, immobilization in a splint with follow up within the week is adequate treatment. Greenstick and complete fractures of the distal radius and ulna have a tendency to become further displaced if not appropriately immobilized; so placing the child in a sugar tong splint is preferred over a simple volar splint.

Salter-Harris types I and II injuries of the distal radius physis are very common and growth disturbance is rare. Any child with point tenderness or swelling over the physis should be immobilized and have orthopedic follow up arranged. For Salter-Harris types III, IV, and V injuries, immediate orthopedic consultation is necessary.

FIG. 136-3. Hyperpronation technique. Hold the elbow at 90 degrees, then firmly pronate the wrist.

Wrist Injuries

Fractures of the carpal bones are quite rare in children. The scaphoid may be fractured in older adolescents with the typical mechanism being that of a fall to an outstretched hand. There is typically snuff box tenderness and pain with longitudinal compression of the thumb. However, unlike adults, nonunion is less common. Any suspected fracture of the scaphoid should be immobilized in a thumb spica splint and orthopedic followup provided even in the absence of radiographic findings.

Phalangeal Fractures

The most common injury is that to the distal phalanx resulting from a crash injury, typically seen when the child catches his or her hand in a door. Any distal phalanx "tuft" fracture should be immobilized and if there is an associated nail bed injury, the fracture is considered "open" and the child should be sent home on a course of antibiotics and orthopedic follow up arranged in 1 week.

Fractures of the phalangeal shaft should be examined for displacement, rotational deformity, and tendinous disruption. Significantly displaced or rotated fractures need to be reduced and immediate consultation with an orthopedist is warranted to determine the type of reduction.

LOWER EXTREMITY INJURIES

Pelvic Fractures

The infrequent nature of pediatric pelvic fractures is largely related to the relative cartilaginous pliability of the immature pediatric pelvis as compared to the adult pelvis. Therefore, pediatric pelvic fractures usually result from a tremendous force.⁵ The exception is the avulsion-type injury, which usually results from sudden muscle contractions associated with athletic injuries.

The most common mechanism for non-avulsion-type pelvic fractures is pedestrian versus motor vehicle collisions. The incidence of associated injuries is extremely high and include injuries to the genitourinary system, abdomen, chest, and central nervous system. After the child is stabilized, there should be a careful evaluation for associated injuries. Multisystem injury must be assumed in a child with a pelvic fracture, and transfer to a facility equipped to manage the pediatric multiple trauma patient is warranted. In children, life-threatening hemorrhage usually results from injury to other body areas rather than from injury to the pelvic vessels.

Avulsion-type injuries of the pelvis result from sudden contraction of musculature attached to the pelvis and typically occur during athletic activities. These injuries are usually seen in the adolescent after secondary ossification centers develop. Therefore, avulsion injuries are unusual before 8 years of age. Clinically the child will complain of sudden pain and have point tenderness and possibly swelling over the fracture site. Nearly all avulsion fractures can be managed conservatively with rest, limitation of activity until symptoms resolve, and orthopedic follow up.

Hip Injuries

Although fractures of the proximal end of the femur are quite rare in children, trauma can result in an epiphyseal disruption or a fracture of the head, neck, trochanteric, or subtrochanteric region of the femur. Treatment is almost always urgent surgical reduction and stabilization, and immediate orthopedic consultation is indicated. Proximal fractures involving the femoral head or neck have a high risk of complications such as avascular necrosis and growth arrest, unlike those involving the trochanteric or subtrochanteric regions. Treatment is dependent on both age and degree of displacement, with older children more likely to be treated operatively.

Traumatic dislocations of the hip are also rare in the pediatric population and are best divided into those occurring in the older adolescent and those occurring in the skeletally immature child. As with adults, most dislocations in adolescents are posterior and result from significant trauma. The mechanisms of injury are also similar to those of adults. The exception is the dislocation occurring in the immature hip, in children younger than 10 years of age, which can occur with minimal low-energy trauma. Treatment for pediatric hip dislocations is urgent closed reduction. Immediate orthopedic consultation is indicated as any significant delay in reduction is associated with a higher incidence of complications. The amount of time the hip is dislocated is a risk factor for avascular necrosis of the femoral head: there is a 20 times higher risk if reduction is delayed more than 6 h.⁶

Fractures of the Femoral Shaft

The femur is second bone to ossify in the fetus and the largest of the long bones in the body. The strength of the femur continues to increase

in later childhood and therefore significant force is usually required to fracture the femoral shaft. Pediatric femur fractures occur more commonly in boys and seem to follow a bimodal distribution with peaks during late-toddler age and mid-teenage years.

The most common mechanisms of injury are falls, pedestrian versus automobile incidents, and motor vehicle collisions. Child abuse should be considered in children who are not yet walking.

The clinical findings in a child with a femur fracture are obvious. There is typically tenderness and swelling over the fracture site. The child may hold the leg externally rotated and likely refuse to bear weight. Shortening of the extremity may also be noticed. Given the high degree of traumatic force needed to produce the fracture, the child should receive a thorough evaluation for associated trauma. Evidence of hemodynamic instability such as hypotension is usually not related to an isolated femur fracture in a young child and should prompt a search for other injuries.⁷

All femoral shaft fractures require immediate orthopedic consultation. Treatment depends on the child's age, size, degree of malalignment, and reliability of follow up. Management is controversial and institution dependent; however, current trends favor early closed reduction and immobilization in a hip spica cast for closed femur fractures in children weighing less than 40 pounds or who are younger than 5 years of age. Operative repair with flexible nails and plates is gaining popularity in the 7- to 12-year age group.

Slipped Capital Femoral Epiphysis

Slipped capital femoral epiphysis (SCFE) is a disorder of childhood during which there is chronic slipping of the femoral epiphysis of the hip. The morbidity can be significant with complications commonly including avascular necrosis and premature closure of the physis. SCFE is the most common cause of hip disability in adolescents. Etiology is multifactorial and any child may develop SCFE during a growth spurt; however, most children are obese adolescents whose hips are exposed to repetitive minimal trauma. Boys are affected three times more commonly than girls and present at an average age of 14 to 16 years old. Girls typically present earlier, at around 11 to 13 years of age, with occurrence after menarche being rare. Hormonal and genetic factors also appear to play a role in the development of SCFE. Associations are seen in children with juvenile chronic arthritis, certain human leukocyte antigen (HLA) types, endocrinopathies, renal failure, and previous radiation or chemotherapy (Figure 136-4).

The slippage may be chronic, acute, or acute on chronic. Although most children will have some degree of chronic slipping, acute worsening of displacement may occur after minimal trauma. Clinically, the child presents with pain at the hip or referred to the thigh or knee. The pain may be vague and chronic in nature. Any adolescent with chronic pain in the groin, hip, thigh, or knee area deserves bilateral hip radiographs to evaluate for SCFE. Any delay in diagnosis can lead to significant disability, and given the incidence of referred pain to the knee, a high index of suspicion for SCFE needs to be maintained to prevent misdiagnosis and treatment delays.

Radiographically, epiphyseal slippage may be detected by examining the anatomic relationship of the femoral neck to the femoral head (Figure 136-5). Several techniques of measuring the presence or degree of slip have been suggested; however, subtle cases can challenge or even evade the best radiologists on plain radiographs. Therefore, any child with pain history suspicious for SCFE should receive orthopedic consultation in the ED. Once the diagnosis is made, management includes strict non-weight-bearing and definitive operative management.

The differential diagnosis includes a traumatic transphyseal fracture of the proximal femur. Although the location of the abnormality may be the same on radiographic evaluation, the conditions may usually be differentiated based on the clinical history and radiographic evidence of preexisting femoral abnormalities. SCFE has a typically in-

FIG. 136-4. A line drawn along the lateral (superior) aspect of the femoral neck fails to transect the lateral quarter of the femoral head in medical SCFE, seen in A and C. The normal anatomic relationship is illustrated in B and D.

sidious onset, a history of preceding intermittent hip pain, and precipitating trauma is minimal. In contrast, significant and acute trauma is necessary to fracture the femoral physis in a healthy hip.

KNEE INJURIES

Compared to the adult, ligamentous injuries to the pediatric knee are much less common than are fractures. The Ottawa knee rules (see Table 274-1) have been validated for children >2 years of age and can help determine the need for radiographs.⁸

Fractures through the *distal femoral physis* are uncommon yet carry a significant complication rate. The popliteal artery lies close to the distal femoral metaphysis and may be injured along with the peroneal nerve with traumatic distal femoral physeal separations. Growth arrest may also occur secondary to permanent physeal damage. Al-

FIG. 136-5. AP radiograph illustrating a medical SCFE involving the left hip.

though Salter-Harris type I injuries may not be appreciated on x-rays, any child suspected of having a significant injury should receive orthopedic follow up. Any displaced distal femoral physeal disruption needs immediate orthopedic evaluation for reduction (Figure 136-6).

Patellar injuries in children are usually dislocations. In fact, *patellar dislocation* is one of the most common causes of a traumatic hemarthrosis in children. The typical mechanism is one of pivoting the knee on a fixed lower leg. Often reduction has already occurred at the scene although a history of the "knee popped out of place" can usually be obtained. If the patient presents with the patella still dislocated, the displaced patella is usually sitting laterally and the knee held in flexion. Reduction need not be delayed for x-rays and is easily accomplished by gently extending the knee while another provider helps "lift" the patella into place. Although the patella does not actually need to be moved into place, the second provider can help prevent a traumatic reduction resulting in additional fractures. The child should receive x-rays after the reduction to assess for any fractures, which are most typically seen at either the lateral femoral condyle or the medial margin of the patella. Immobilization in a knee immobilizer and orthopedic follow up are indicated. Most patients improve with conservative management and rehabilitation; however, some children are predisposed to chronic dislocations and may eventually need realignment of their extensor mechanism.

Fractures of the *patella* are uncommon in children and occur from either direct traumatic force or more commonly in the adolescent participating in sporting events. Unique to children is the "sleeve" fracture of the patella where the distal patellar "sleeve" is avulsed from the body of the patella. The typical mechanism of an avulsion "sleeve" fracture is that of forceful contraction of the quadriceps against a fixed

FIG. 136-6. Distal femur fracture.

lower leg. Consultation with an orthopedist is advised to determine the appropriate treatment which depends on the degree of displacement.

Proximal tibial injuries include injuries to the *tibial spine*, *tibial tuberosity*, and *proximal tibial physis*. Mechanically speaking, an avulsion fracture of the tibial spine is the equivalent of an anterior cruciate ligament (ACL) rupture in an adult. The ACL inserts on the tibial eminence and this ligament and its insertion are much stronger than the epiphyseal bone in children. Nondisplaced fractures may be managed conservatively with immobilization and orthopedic follow up. However, any displaced fractures need reduction and immediate orthopedic consultation.

Tibial tuberosity fractures are typically avulsion-type and occur most commonly from strong contraction of the quadriceps against a fixed leg. Again, these injuries are most likely sports related. They may be classified as type I, II, or III, depending on the location of the fracture line. Type I injuries are characterized by a fracture through the small distal portion of the tibial tuberosity. Type II fractures occur after the coalescence of the secondary ossification centers of the tuberosity to the metaphysis. The fracture splits the epiphysis of the tuberosity from the epiphysis of the proximal tibia. Type III injuries involve a fracture into the joint and are at risk for developing compartment syndrome. Types I and II fractures are usually treated with immobilization. Displaced type II and type III injuries need reduction and fixation and require immediate orthopedic consultation.

Fractures of the *proximal tibial physis* are relatively uncommon and most are Salter-Harris type I. As with distal femoral physeal fractures, vascular injury to the popliteal artery is a concern and documentation of intact pulses is especially important.

Fractures of the Tibia and Fibula

Most fractures of the tibia and fibula occur at the shaft. If the fracture is minimally displaced and there is no evidence of compartment syndrome, the leg can be immobilized in a long leg posterior splint and orthopedic follow up arranged. However, if there is more than 10 degrees of angulation in any plane, reduction is recommended and immediate orthopedic consultation is indicated.

Of particular interest in the child is the *toddler's fracture*, which refers to an isolated spiral fracture of the distal tibia in a toddler. The typical mechanism is external rotation of the foot with the knee flexed, such as may occur in a child's walker. Parents may notice that the child is limping or refusing to bear weight after seemingly insignificant or occasionally unrecalled history of trauma. Clinically, there appears to be pain with palpation and rotation of the distal tibia, although swelling may be minimal or absent. Radiographically, a fracture line may be noticed at the distal third of the tibial shaft; however, initial standard x-rays may be normal with nondisplaced fractures. The addition of oblique views may show a fracture line when standard views are negative. Immobilization and follow up with a bone scan or repeat x-rays in a week is suggested when a toddler's fracture is clinically suspected and initial radiographs are negative. The child should be immobilized in a long leg splint and given orthopedic follow up for definitive casting and to ensure that proper alignment is maintained during the healing process.

Ankle Injuries

Ankle injuries in children include both ligamentous disruptions as well as fractures. Ligamentous injuries are uncommon before physeal closure because of the generally stronger nature of ligaments when compared to the strength of open physes. Ankle sprains in older children with closed physes are graded and treated as they are in adults.

Fractures of the pediatric ankle may involve the distal tibia, the fibula, or both. A thorough evaluation and appropriate treatment are extremely important because any articular surface disruption in this joint can have long-term complications despite a seemingly benign

initial presentation. Additional imaging techniques such as CT and MRI are frequently used to help define the extent of fracture involvement. Treatment goals are to restore maximum function and prevent complications such as growth arrest, osteoarthritis, and chronic pain.

The most common fractures of the distal fibula are Salter-Harris types I and II, which account for approximately 90 percent of isolated distal fibula fractures. Clinically, findings with a Salter-Harris I fracture may be subtle; however, typically there is tenderness at the growth plate and soft tissue swelling is common. Isolated Salter-Harris I fractures of the distal fibula can be distinguished from a lateral ligamentous ankle sprain by the presence of point tenderness over the physis. Plain radiographs only show soft tissue swelling at the lateral fibula. In general, any type I or II fracture that is nondisplaced may be managed by immobilization and orthopedic follow up.

The most common fractures of the distal tibia are also Salter-Harris types I and II. In general, these fractures may be managed with closed reduction if any displacement is present, followed by immobilization. Salter-Harris III fractures account for approximately 25 percent of distal tibia fractures and typically require open reduction of any displacement. The Tillaux fracture is a Salter-Harris type III fracture of the anterolateral portion of the distal tibia. The location of the Tillaux fracture is a result of the order in which the distal tibial physis closes. Closure occurs centrally, then medially, and finally laterally making the anterolateral portion most vulnerable. Therefore, this type of fracture is typically seen in a child who is nearing skeletal maturity. Treatment is surgical reduction.

Salter-Harris IV fractures include the triplane fracture, which involves fractures in the sagittal, coronal, and transverse planes resulting in multiple fracture fragments. The management is surgical reduction.

Foot and Phalanx Injuries

In early childhood, the pliability and lack of ossification of the foot make fractures in this area rare. As ossification increases with age, fractures become more common; however, significant injuries are still unusual. The foot may be divided into the hindfoot (calcaneus and talus), the midfoot (navicular, cuboid, second and third cuneiforms), and the metatarsals and phalanges. Fractures of the mid- and hindfoot are rare; however, when they occur, they usually result from a fall. Recognition of fractures in these areas may be difficult and CT and MRI may be necessary to identify and define these fractures. Fractures of the metatarsals and phalanges are relatively common in children and typically result from a direct blow from a falling object. They typically heal without sequelae. Crush injury to the foot may cause vascular compromise and compartment syndrome.

Most nondisplaced fractures of the metatarsals and phalanges may be managed by immobilization and follow up with an orthopedist. Significantly displaced fractures of the metatarsals and phalanges as well as those of the great toe that have intraarticular involvement may require fixation, although this can typically be done on an outpatient basis.

SELECTED NONTRAUMATIC MUSCULOSKELETAL DISORDERS OF CHILDHOOD

Acute Septic Arthritis

Septic arthritis occurs in all age groups, but especially in children younger than 3 years of age. The reported incidence of septic arthritis varies from 2 to 5 per 100,000 per year in the general population to 28 to 38 per 100,000 per year in patients with rheumatoid arthritis. The knee is the most commonly involved joint, followed in frequency by the hip and the elbow. Any joint can be infected, and infection of more than one joint can occur.

Bacteria are the usual pathogens in acute skeletal and joint infections. Bacteria may access the joint hematogenously, by direct exten-

sion from adjacent osteomyelitis or from inoculation as in arthrocentesis or femoral venipuncture. Of these routes, hematogenous spread is the most common. The etiologic organisms encountered in septic arthritis vary with the age of the child (Table 136-2).

Even though septic infections of joints in children are uncommon, they are important because of their potential to cause permanent disability. The normal joint has several protective components. Healthy synovial cells possess significant phagocytic activity, and synovial fluid normally possesses significant bactericidal activity. In patients with bacteremia and hematogenous spread, a large number of bacteria are delivered into the vascular synovial membranes. If infection occurs, polymorphonuclear leukocyte (PMN) infiltration, vascular congestion, and lining cell proliferation occur. Early on, increased secretion of synovial fluid occurs and may be serosanguineous, cloudy, or suppurative with PMN counts ranging from 500 to 200,000 and exceeding 50,000/ \times L after the earliest stages. Synovial fluid glucose concentration is decreased, and the protein content is elevated. If this progresses and bacterial proliferation occurs, a persistent purulent effusion develops, accompanied by the clinical findings of a swollen, tender joint. Eventually proteolytic enzymes released by PMN, as well as direct pressure, lead to cartilage and bone destruction.

Children with septic arthritis are frequently misdiagnosed on their initial visit because the earliest signs and symptoms are subtle. This is particularly true of neonates, who characteristically do not appear ill and in half of cases do not have fever. Older infants, toddlers, and children usually have fever and localizing signs. Infants may have only pseudoparalysis of an extremity or apparent pain on movement of the affected extremity. The child with hip or knee septic arthritis will limp or not walk at all. The child maintains the infected hip in flexion, abduction, or internal rotation. On physical examination, the manifestations are those of any localized infection (i.e., erythema, swelling, tenderness, and pain). Older children will appear ill, often with high fever [40 to 40.5°C (104 to 105°F)], with apprehension, and irritability.

Plain film radiographs are frequently nondiagnostic early in the course of infection, but should be obtained to help identify osteomyelitis, fracture, or another process in the differential diagnosis.

Widening of the joint space with joint effusion and distention are late findings. Fat lines are displaced early in the septic arthritis because of capsular distention. Views of the contralateral side may be useful for comparison. Ultrasonography may be useful to document the presence of a joint effusion, and can aid in needle aspiration. CT and MRI both provide improved soft tissue resolution, and can aid in the diagnosis.

The differential considerations are listed in Table 136-3.

If septic arthritis is suspected, a CBC, blood cultures, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and throat cultures should be obtained. About half will have WBC counts of less than 15,000 cells/pJL. In approximately 90 percent of cases the ESR is high, with mean values ranging from 68 to 82 mm/h. The ESR is nonspecific and may be elevated in the presence of other infectious or im-

munologic conditions. The CRP may be useful as values greater than 20 mg/L have high predictive values for septic arthritis.

Joint fluid should be aspirated and sent for cell count, Gram stain, glucose, and culture. Isolation of an organism from the joint fluid is the primary criterion for the diagnosis of septic arthritis. Organisms that may be seen on the smear may not grow in culture, because of the bacteriostatic effect of joint fluid. In approximately one third of cases, a specific pathogen is not identified. If obtained, blood cultures are positive in less than half, and they are the only source from which the causative agent is isolated in about 10 percent.

Concurrent infections at other sites have been reported and may help define the pathogen (e.g., urine gram-negative bacilli; skin/wound *S. aureus*; urethra, cervix, rectum, and pharynx *N. gonorrhea*). Obtaining cultures from these sites should be dictated by the age of the child and the clinical circumstances.

The management of acute septic arthritis consists of prompt joint drainage to remove bacterial products and infectious debris, and antibiotic administration. Table 136-4 lists antibiotic therapy. The prognosis

*Hospital acquired.

depends on the length of time between symptom onset and treatment. More than 4 days increases the likelihood of orthopedic complications, and infants have less-favorable outcomes, possibly because of delays in diagnosis.

Henoch-Schonlein Purpura

Henoch-Schonlein purpura (HSP) is a small-vessel vasculitis characterized by purpura, arthritis, abdominal pain, and hematuria. It is the most common cause of nonthrombocytopenic purpura in children. The specific pathogenesis of HSP is unknown, but the vasculitis involves primarily small vessels and is mediated by immune complexes through IgA and the alternate complement pathways. The cause of HSP is also unknown, but HSP typically follows an upper respiratory infection. A variety of infectious and noninfectious stimuli appear to precipitate the immunologic mechanisms of the vasculitis.

The hallmark of the disease is the rash, beginning as pinkish maculopapules that initially blanch on pressure and progress to petechiae or purpura that are characterized as palpable. This rash has a propensity for the lower trunk, buttocks, perineum, and lower extremities (see Chap. 135). The lesions tend to occur in crops lasting from 3 to 10 days, and may appear at intervals that vary from a few days to several months. In addition, the vasculitis includes involvement of the glomeruli, with the subsequent development of hematuria and with the potential for long-term renal sequelae. Renal involvement occurs in 25 to 50 percent of children, and hepatosplenomegaly and lymphadenopathy may be found during active disease.

Edema and damage to the vasculature of the gastrointestinal (GI) tract may also lead to intermittent abdominal pain that is often colicky in nature. More than half of patients develop occult heme-positive stools, diarrhea (with or without blood) or hematemesis. A small proportion of children with severe abdominal colic caused by Henoch-Schonlein purpura experience massive gastrointestinal hemorrhage or intussusception.

Arthritis may be present in more than two-thirds of children with HSP, and is usually localized to the knees and ankles often with associated edema. The effusions are serous, not hemorrhagic in nature, and resolve after a few day without residual deformity or articular damage.

The clinical diagnosis is usually clear in those children manifesting all or several of the characteristics of the disorder. Making the diagnosis is often more difficult if acute arthritis is the only symptom. The role of the ED is establishing the diagnosis or maintaining a high index of suspicion. The diagnostic evaluation is also influenced by the need to exclude other causes of vasculitis. Otherwise, the care is entirely supportive. Routine laboratory test are neither specific or diagnostic. Affected children often have a moderate thrombocytosis and leukocytosis. The erythrocyte sedimentation rate (ESR) may be elevated. Consideration of specific laboratory or imaging studies is influenced by specific symptoms. In a child presenting exclusively with hematuria and abdominal pain, a urinalysis, urine culture, kidneys, ureters, and bladder (KUB) radiogram, CBC, and chemistry profile to assess renal function may be required. Intussusception in HSP is usually ileo-ileal in location, and barium enema may be used for both identification and nonsurgical reduction. Renal involvement is manifested by red blood cells, white blood cells, casts, or albumin in the urine. In summary, when the entire clinical picture presents itself, the extent of the diagnostic workup is much reduced.

Symptomatic treatment, including adequate hydration, bland diet, and pain control with acetaminophen, is provided for self-limited complaints of arthritis, edema, fever, and malaise. Avoidance of competitive activities and keeping the lower extremities elevated intermittently may decrease local edema. If there is significant edema of the scrotum, elevation of the scrotum and local cooling may decrease discomfort.

Admission to the hospital may be required when the diagnosis is in doubt, for observation and control of abdominal pain, for monitoring of renal function, or for fluid hydration in cases of recurrent emesis. Children with extremely mild symptoms can be safely discharged and

observed as outpatients, with close follow-up with their primary care provider. Intestinal complications (e.g., hemorrhage, obstruction, and intussusception) may be life threatening and managed with corticosteroids and, when necessary, air enema reduction or surgical reduction or resection of the intussusception. Therapy with oral or intravenous corticosteroids is associated with improvement of GI and CNS complications, and high doses may be helpful in advanced renal involvement. Steroid use should be directed by the admitting pediatrician.

The major complications of HSP are renal involvement and development of nephrotic syndrome or bowel perforation. The overall prognosis is excellent for this relatively common, self-limited disease. Chronic renal disease becomes more common in older children. Less than 1 percent of patients with HSP develop persistent renal disease, and fewer than 0.1 percent develops serious renal disease.

Juvenile Rheumatoid Arthritis

Juvenile rheumatoid arthritis (JRA) is one of the most common rheumatic diseases of children and is a major cause of chronic disability. It is characterized by an idiopathic noninfectious synovitis of the peripheral joints, and arthritis with associated soft tissue swelling and effusion. The peak age of onset is between 1 and 3 years, and a second peak occurs in the early teen years. Although the etiology is unknown, an autoimmune response in reaction to exposure to certain viruses is suspected. JRA has three principal types of onset: (1) oligoarthritis (pauciarticular disease); (2) polyarthritis; and (3) systemic-onset disease.

Oligoarthritis (pauciarticular disease) is the most common form of JRA in children. It usually affects the joints of the lower extremities, such as knees and ankles, and typically a single large joint such as the knee. Permanent joint damage is uncommon.

Polyarticular disease occurs in approximately a third of cases, and is characterized by involvement of both large and small joints. As many as 20 to 40 separate joints are often affected, but the involvement of 5 or more joints is the criterion for this classification. There is a female preponderance. Polyarticular disease often resembles the usual presentation of adult rheumatoid arthritis. Rheumatoid nodules over the elbow extensor surfaces and Achilles tendon portend a more severe course. Long-term morbidity is related to progressive joint destruction, particularly of the hips and knees. Cervical spine involvement is common with an increased risk of atlantoaxial subluxation. Rheumatoid factor (RF) serology may be positive or negative, and antinuclear antibody (ANA) titers are positive in 25 percent of RF-negative patients, and in 75 percent of RF-positive patients.

Systemic JRA is associated with high fevers and chills, characteristically with spikes to at least 39°C (102.2°F) for a minimum of 2 weeks. There is also an accompanying characteristic faint erythematous macular coalescing rash on the trunk, palms, and soles. In addition to arthritis, patients with systemic-onset disease often have hepatosplenomegaly, lymphadenopathy, and a serositis, such as pleuritis or pericardial effusion. The arthritis in this form may progress to permanent joint damage. Serology for RF and ANA are negative in this form of JRA.

Laboratory evaluation is not highly specific for JRA. Arthrocentesis may be necessary to exclude acute suppurative arthritis, especially in pauciarticular presentations. Hematologic abnormalities often reflect the degree of systemic or articular inflammation, with elevated white blood cells and platelet counts. The ESR usually mirrors these findings, along with elevation of the CRP, serum globulins, and serum immunoglobulins. However, it is not unusual for the ESR to be normal in some children with JRA. ANAs are present in at least 40 to 85 percent of all children with pauciarticular or polyarticular JRA, but are unusual in children with systemic-onset disease. Early in the course of JRA, radiographs demonstrate only soft tissue swelling and synovial effusions. The findings of bone and cartilage destruction occur later.

The diagnosis of JRA will likely not be made in the ED, and the ED focus should be primarily to exclude other diagnostic considerations.

Hospital admission is recommended for those children in who the diagnosis is in doubt or who are treated empirically for suspected acute suppurative arthritis while synovial fluid cultures are pending.

The initial therapy for patients with an established diagnosis include aspirin or other nonsteroidal anti-inflammatory drug (NSAID). Corticosteroids are used when the diagnosis is certain and for overwhelming systemic illness, including pericarditis, myocarditis, or iridocyclitis unresponsive to other therapy.

A pediatric rheumatologist should direct other management strategies including intraarticular glucocorticoid injections, and use of methotrexate (which has generally replaced gold therapy), chloroquine, anticytokine therapy, or cytotoxic drugs.

Kawasaki Disease

Kawasaki disease (also called mucocutaneous lymph node syndrome) is an acute febrile vasculitis of childhood, involving small and medium size arteries, and characteristic involvement of the coronary arteries. It is an acute, self-limiting disease of unknown etiology.

The disease is recognized worldwide. In the United States, the peak incidence is in children 18 to 24 months of age, with 80 percent occurring in children younger than 4 years of age and 95 percent of cases occurring in children younger than 10 years of age. Males are affected more often than females (1.5:1), and children of Asian descent are at increased risk.

The diagnosis is based entirely on clinical findings. Table 136-5 lists the diagnostic clinical criteria, and the disorder is also discussed in Chap. 135. Fever is commonly the first finding of the acute phase. The fever is high, often exceeding 40°C (104°F), and prolonged, lasting from 1 to 2 weeks in untreated patients. Bulbar conjunctivitis is nonpunctate and bilateral, and has onset shortly after the appearance of fever. Changes involving the oropharynx are prominent during the acute febrile period, and include erythema and cracking of the lips and erythema of the buccal mucosa and posterior pharynx. The tongue may have a strawberry appearance due to prominent lingual papillae. The rash is quite variable and may appear morbilliform, maculopapular, or scarlatiniform. Most commonly the rash is a raised deep-red, plaquelike eruption. It may even present a fine pustular eruption, and vesicular rashes are rare. In infants, this rash may be most prominent on the perineum. Cervical adenopathy is another early symptom, and nodes are usually unilateral, nonsuppurative, and measure > 1.5 cm in size. Changes to the peripheral extremities occur as induration of the dorsum of the hands and feet with erythema over the palms and soles. The palms and soles can become quite painful. A wide variety of associated findings can be present in Kawasaki disease, as listed in Table 136-6. Irritability is profound in Kawasaki disease, and aseptic meningitis frequently is found.

The acute febrile phase of the disease lasts about 10 days, during which most of the diagnostic criteria (see Table 136-5) are likely to be present. The subacute phase of the disease (from days 11 through 21)

TABLE 136-5 Diagnostic Criteria for Kawasaki Disease

- Fever of at least 5 days' duration (100%)
- Presence of at least four of the following five conditions:
 1. Bilateral conjunctivitis (85%)
 2. Changes of the lips and oral mucosa (90%)
 - Dry, red, fissured lips
 - Strawberry tongue
 - Oropharyngeal edema
 3. Changes of the extremities (75%)
 - Erythema of palms and soles
 - Edema of hands and feet
 - Periungual desquamation
 4. Polymorphous rash (80%)
 5. Cervical lymphadenopathy (70%)
- Illness not explained by other known disease process

usually is associated with a decrease in fever, rash, and lymphadenopathy. Conjunctival injection and irritability may persist. Arthralgias and arthritis occur in many children at this time, as well as the dramatic desquamation of the fingers and toes. Thrombocytosis is an important finding in Kawasaki disease and this usually occurs during the subacute phase. At this time the platelet count is generally over 650,000/ μ L and may exceed 1 million. It is during this phase when the patient is at greatest risk for development of coronary artery thrombosis. The convalescent phase begins about day 21, when all clinical and associated signs and symptoms have disappeared, and continues until the ESR and platelet count return to normal in 6 to 10 weeks.

Cardiovascular manifestations of the disease comprise the major complications of Kawasaki disease. An acute carditis develops in 50 percent of patients, with patients developing myocarditis with symptoms of tachycardia and gallop rhythms indicating mild to severe congestive heart failure. Less-frequently occurring manifestations of carditis include pericarditis, conduction disturbances, and valvular insufficiencies. Patients with Kawasaki disease have approximately a 20 percent risk of developing coronary aneurysms without treatment. Patients younger than 1 year of age have an even greater risk. The risk of coronary aneurysm is reduced to 4 to 5 percent following treatment. Most aneurysms develop after the acute phase between days 15 to 45 of the illness. Untreated, the coronary artery aneurysms are quite prone to thrombosis during the subacute phase because of the hypercoagulable state created by the thrombocytosis. Myocardial infarction and dysrhythmia are the most common causes of sudden death and occur in 1 to 2 percent of patients, usually in the third to fourth week.

The laboratory findings are nonspecific in patients with Kawasaki disease. The CBC often shows an elevated WBC count with a left shift. A mild nonhemolytic anemia may be present. A remarkable thrombocytosis appearing during the second week of the illness, and other secondary laboratory abnormalities consistent with a diffuse systemic vasculitis may be present.

The differential diagnosis is extensive because of the nonspecific nature of its clinical features. The emergency department role is primarily that of establishing the diagnosis. Treatment is admission for administration of intravenous gamma globulin (IVGG), aspirin therapy, and cardiac evaluation. The use of IVGG has substantially decreased the morbidity and mortality associated with the disease. If used in the first 10 days of the illness, IVGG reduces the incidence of coronary artery aneurysms to 3 to 4 percent. It also is effective in promoting resolution of established aneurysms. IVGG is administered as a single dose of 2 g/kg infused over 8 to 12 h with specific protocols to monitor the patient. Aspirin therapy is started at 100 mg/kg per d divided in four doses and continued until the fever has resolved. Low-dose aspirin at 3 to 5 mg/kg per d (maximum, 40 to 80 mg per d) is then continued for 2 to 3 months or until the platelet count has normalized. Patients exhibiting coronary aneurysms despite IVGG therapy should receive aspirin for at least 1 year following the resolution of the aneurysm. A cardiologist should be involved in the evaluation

and follow-up of any patient with Kawasaki syndrome. Repeat echocardiograms are usually performed 14 days and 6 to 8 weeks after onset of the illness, or more frequently if there is evidence of cardiac involvement.

Children suspected of having Kawasaki disease who do not fulfill diagnostic criteria may have "atypical" Kawasaki disease. This atypical presentation may be seen more commonly in the younger child. If the emergency physician suspects a child may have an atypical presentation, consultation with a pediatric infectious disease or rheumatology specialist is warranted.

Legg-Calve-Perthes Disease

Legg-Calve-Perthes disease (LCPD) is a hip disorder that generally has onset between the ages of 4 and 9 years in 80 percent of patients, with a range of occurrence from 2 to 13 years. It is the most well-known form of avascular necrosis of the femoral head. Males outnumber females by a ratio of 4:1, and it is bilateral in 10 percent of cases. Most children with the disorder are short, with average or above average weight. They often have delayed skeletal maturation.

The exact cause is unknown, although the pathophysiology is vascular occlusion. LCPD begins with repeated episodes of ischemia of the femoral head, leading to infarction and necrosis. This avascular necrosis of the femoral head is then complicated by a subchondral stress fracture. A process of reossification and remodeling (resorption) takes place and may take from 2 to 4 years. Resultant collapse and flattening of the femoral head may occur, with subsequent potential for subluxation. The outcome is a painful hip joint associated with a restricted range of motion, muscle spasms, and contractures of the soft tissues.

The onset of symptoms in LCPD is usually insidious. Presentation as an acute emergency is rare. Mild hip pain and limp have been present for weeks to months before making the diagnosis. Initially, pain is mild to none and is often referred to the anteromedial thigh or knee. Physical findings include decreased hip abduction and internal rotation. Sometimes the initial presentation is associated with trauma. Proximal thigh atrophy, and in advanced cases, limb shortening may also be noted.

Radiographically, LCPD progresses and is divided into four stages: initial, fragmentation, reossification, and healed. In the initial stage (1 to 3 months), the capital femoral epiphysis fails to grow because of the lack of blood supply. This results in the radiograph of the hip demonstrating only widening of the cartilage space of the affected hip and a smaller size of the ossific nucleus of the femoral head (Figure 136-7). The second radiographic sign is the appearance of the sub-

FIG. 136-7. Legg-Calve-Perthes disease. The right hip illustrates joint-space widening, reduced size of the ossific nucleus of the femoral head, and increased opacification of the femoral head.

chondral stress fracture line in the femoral head (Caffey sign). The third radiologic finding is increased radiopacity of the femoral head caused by new bone deposited on avascular trabeculae. Subsequently, calcification of the necrotic marrow occurs, with resultant crushing of the avascular trabeculae in the dome of the epiphysis. Further distortions of the femoral head evolve during the healing process, along with subluxation and extrusion of the femoral head from the acetabulum.

Diagnosis of LCPD demands a high index of suspicion, because initial radiographs often are normal. Bone scan and MRI are helpful early on to make the diagnosis. The technetium-99m bone scan demonstrates markedly reduced uptake of nuclide within the affected femoral head. These findings precede apparent plain film abnormalities, with possibility to diagnose LCPD months earlier than the x-ray alone. Likewise, MRI also provides superior resolution and sensitivity, with areas of low signal intensity reflecting necrotic regions within the femoral head.

The differential diagnosis includes toxic synovitis, acute rheumatic fever, tuberculosis arthritis, tumors such as eosinophilic granuloma, osteoid osteoma, and osteoblastoma, and lymphoma. Patients diagnosed with LCP disease should be made non-weight bearing and referred to a pediatric orthopedist for management. Current treatment focuses on maintaining containment of the femoral head through the use of splints or occasionally surgery. Factors related to a poorer prognosis include older age at clinical onset, extensive capital femoral epiphyseal involvement, premature epiphyseal closure, and reduced range of hip motion.

Osgood-Schlatter Disease

This very common syndrome is an apophysitis of the tibial tubercle resulting from repeated normal stresses or overuse. These repetitive stresses imposed by the patellar tendon on its site of insertion results in a series of micro-avulsions of the ossification center and the underlying cartilage. An inflammatory process is established, with resultant patellar tendonitis and a remarkable prominence, induration, and tenderness of the tibial tuberosity. No evidence of avascular necrosis of the tibial tubercle is present. Patients are usually between 10 and 15 years of age at time of onset; it more commonly occurs in running or jumping athletes. Boys are affected more often than girls, and most cases are bilateral, although symptoms are commonly asymmetric.

Signs and symptoms of Osgood-Schlatter disease are chronic, intermittent pain and tenderness over the anterior aspect of the knee and the tibial tuberosity. Pain is aggravated by activities such as running, kneeling, squatting, and climbing stairs, and improves with rest. On examination, there is a prominence and soft tissue swelling over the tibial tubercle. Tenderness and thickening of the patellar tendon may be present. The remainder of the knee examination usually is normal, and there is no knee effusion.

While radiographs are not essential, they usually are obtained. Radiographic findings of soft tissue swelling and irregularities of the tibial tubercle are nonspecific. The irregularity of the ossification of the tibial tubercle is normal in this age group. A lateral knee radiograph is best for demonstrating abnormalities, which may show prominence of the tibial tuberosity, calcification in the tibial tubercle region, or separate ossicles from the anterior border of the tubercle.

The disease is self-limited, and most patients respond to conservative care that consists of rest and avoidance of the offending activity. This is perhaps the most difficult instruction to enforce in young athletes. To ensure compliance, a brief period of immobilization or non-weight bearing may be necessary. Flexibility exercises to stretch the quadriceps and hamstrings to alleviate stress on the tubercle and avoid recurrences are helpful. Applying ice after activity may decrease swelling and pain. NSAIDs may be used but have not been shown to decrease the course of disease. A neoprene sleeve on the knee reduces patellar mobility with resultant reduction of forces on the tubercle. Corticosteroid injections into the patellar tendon or para-apophyseal

soft tissues should not be administered. Other than the presence of an ossicle that causes pain with kneeling, there are no long-term disabilities or problems associated with this condition.

Poststreptococcal Reactive Arthritis

Because of increased group A *p*-hemolytic infections, the incidence of poststreptococcal reactive arthritis (PSRA) is also increasing. PSRA is a poorly understood clinical syndrome in which arthritis of one or more joints occurs following a group A streptococcal infection of the pharynx. Like acute rheumatic fever (ARF), PSRA is a reactive arthritis characterized by a streptococcal infection, a symptom-free interval, and subsequent aseptic inflammation of one or more joints. Other major criteria of ARF are absent in PSRA. It is not certain whether PSRA represents a mild or early form of ARF, or whether it is an entirely separate entity.

In addition to group A *p*-hemolytic streptococci, primary infections with *Salmonella*, *Staphylococcus*, and other groups of *Streptococcus* are reportedly associated with reactive arthritis. Unlike ARF, reactive arthritis is not associated with carditis or other major criteria, and is a milder illness. PSRA also begins sooner (approximately 10 days) after streptococcal infection than does ARF (approximately 21 days). The arthritis in PSRA is generally more severe and prolonged and unusually resistant to treatment with salicylates, in contrast to the migratory salicylate-sensitive arthritis generally associated with ARF.

The differentiation between ARF and PSRA is clinical. The arthritis of ARF is classically a migratory polyarthritis, while the arthritis of PSRA is described as a nonmigratory mono- or oligoarthritis. ARF poststreptococcal nonsuppurative sequelae are more commonly observed in younger patients (mean age 12 ± 4 years). The typical patient with reactive arthritis is older, but it may occur in children as young as 4 years of age. Erythema nodosum and erythema multiforme are frequently associated with PSRA, while encountered only infrequently in cases of ARF.

To establish the diagnosis of PSRA, antecedent infection with group A streptococcus must be established, either by culture of the bacterium from the throat or by demonstration of an elevation or a fourfold rise in anti-streptolysin O (ASO) or anti-DNase B titer. If group A streptococcus is recovered from the throat, specific antibacterial therapy should be given. The diagnosis of PSRA should be made only after careful historical and clinical evaluation for nonsuppurative complications or other causes of polyarthritis. The issue of antibiotic prophylaxis as recommended for ARF is controversial with PSRA, but may be considered on a short-term basis. If, after further evaluation, there is no evidence of carditis or chorea, prophylaxis may be discontinued. Treatment of PSRA is nonsteroidal anti-inflammatory medications.

Acute Rheumatic Fever

ARF primarily affects children of school age. The incidence of ARF has steadily fallen in developed countries over the past 50 years. However, a resurgence in cases of group A *P*-hemolytic streptococcal infections over the past 10 years has increased concerns about ARF and other nonsuppurative sequelae of streptococcal infections. Outbreaks of ARF are regularly reported in North America. It is preceded by infection with certain strains of group A (3-hemolytic *Streptococcus* (mucoid types 3, 5, and 18). Different layers of the cell wall of the streptococcal organism appear to stimulate antibody production to variable host tissues. The hallmark histologic feature of rheumatic fever is the Aschoff body, found in the connective tissue and created by edematous, fragmented collagen fibers. The connective tissue of the heart, joints, central nervous system, and subcutaneous tissues and skin are targeted by the immune reaction. The carditis is an endomyocarditis, with valvulitis primarily involving the mitral and aortic valves. The arthritis is characterized by synovial edema and periarticular swelling with joint effusions.

The child develops the disorder 2 to 6 weeks following a streptococcal pharyngitis. While nonspecific symptoms of systemic illness predominate early on, physical examination eventually reveals evidence of arthritis, carditis, choreiform movements, erythema marginatum, or subcutaneous nodules, individually or in combination. Table 136-7 illustrates Jones criteria for establishing a diagnosis of acute rheumatic fever. Either two major criteria or one major and two minor criteria plus evidence of an antecedent streptococcal infection are necessary to establish the diagnosis.

Arthritis occurs in 60 to 75 percent of initial attacks and is characterized as a migratory, fleeting polyarticular arthritis primarily affecting the large joints. The carditis occurs in a third of new cases and may be mild or severe. Its presence is heralded by any combination of a new cardiac murmur, tachycardia, a gallop rhythm, a pericardial friction rub, congestive heart failure, or a hyperactive precordium. Sydenham chorea occurs in 10 percent of cases and may have its initial appearance months following a streptococcal infection. Chorea may be the sole manifestation of acute rheumatic fever. The skin rash of acute rheumatic fever (erythema marginatum) is described as serpiginous and persists only for several days. It usually coexists with the presence of carditis in some form. Subcutaneous nodules are more rare and are located on the extensor surfaces of the wrists, elbows, and knees. The greatest morbidity and mortality is associated with the development of carditis.

Diagnostic studies are used to clarify the associated antecedent infection by group A streptococcus (a pharyngeal swab for culture, antistreptolysin titers, or streptozyme titers), or are employed to identify and assess the presence and extent of carditis. An electrocardiogram is obtained to assess for conduction delays or hypertrophy. A chest x-ray serves to identify cardiac dilatation or pulmonary vascular congestion or edema. Echocardiography is used to identify evidence of valvulitis or valvular insufficiency and also to exclude other diagnostic considerations.

The differential diagnosis includes JRA, septic arthritis, Kawasaki disease, viral or other forms of cardiomyopathy, leukemias, and other forms of vasculitis, including drug reactions. Rarely, tumors of the central nervous system require differentiation from ARF when the child's sole clinical manifestation is chorea.

Treatment of ARF in the emergency department is directed primarily toward the management of complicating features of carditis. In the absence of cardiac or hemodynamic instability (and such is the rule), early consultation with a pediatric cardiologist is recommended, and admission to the hospital is generally advised in the early stages until the diagnosis is confirmed. Arthritis is managed with high-dose aspirin therapy (75 to 100 mg/kg per d) to achieve a serum salicylate level of 20 to 30 mg/dL. The aspirin dose is reduced after approximately 1 week to 50 mg/kg per d for an additional 4 to 6 weeks. Significant carditis or congestive heart failure is managed with prednisone, 1 to 2 mg/kg per d. This is continued for 2 weeks following the resolution of symptoms and the return of the ESR to normal. The

TABLE 136-7 Revised Jones Criteria for the Diagnosis of Acute Rheumatic Fever

Major	Minor
Carditis	Fever
New or changing murmurs	Arthralgia
Cardiomegaly, congestive heart failure	History of previous attack of ARF
Pericarditis	Elevated ESR, C-reactive protein
Migratory polyarthritis	Prolonged PR interval on electrocardiogram
Chorea	Rising titer of antistreptococcal antibodies
Erythema marginatum	
Subcutaneous nodules	

Note: Diagnosis is likely when two major criteria or one major and two minor criteria are met. Group A *Streptococcus* may be documented by a history of scarlet fever, isolation of group A *Streptococcus* from throat culture, or rising titers of antistreptococcal antibodies.

duration of glucocorticoid therapy requires a subsequent taper of the steroids over a 4- to 6-week period. Chorea can be managed with haloperidol, 0.01 to 0.03 mg/kg per d in four divided doses. All children with ARF are treated with penicillin, even if the cultures for group A *Streptococcus* are negative. The dose of benzathine penicillin is 600,000 units IM if <27 kg, and 1.2 million units IM if >27 kg. Benzathine penicillin G can be administered in a single dosage of 1.2 million units. Penicillin V administered PO is also effective. Erythromycin may be substituted for the penicillin-allergic patient. All therapy, if pursued, is administered for 10 days.

Long-term prophylactic therapy against group A *Streptococcus* is begun upon completion of the acute phase of therapy. Acceptable prophylactic regimens include benzathine penicillin G, 1.2 million units administered IM every month, or daily oral penicillin V or sulfadiazine. Five years of prophylactic antibiotics for those children without cardiac involvement is recommended. Patients with manifestations of carditis are placed on life-long prophylaxis.

Transient Synovitis of the Hip

Toxic or transient synovitis is a benign, self-limiting inflammatory process of the hip. It afflicts males more than females and is the most common cause of acute hip pain in children less than 10 years of age. The peak incidence is between ages 3 and 6 years, but has been reported from 9 months to adolescence. It is eight times more frequent than septic arthritis of any joint. The etiology is unknown and believed to be a post-viral illness sequelae most often, but trauma, bacterial infection, and postvaccine or drug-mediated reactions have also been cited as possible causes. Arthralgia and arthritis are secondary to a transient inflammation and hypertrophy of the synovial membrane.

Symptoms are characterized by an abrupt onset of unilateral hip pain, limp, and restricted hip motion (preferentially held in abduction and external rotation). The child may complain of pain in the antero-¹/₇ medial or anterolateral thigh and knee. Although children complain of C.E. discomfort with movement of the limb, it generally remains possible to put the hip through a full range of motion. This is in contrast to the septic hip in which pain and spasms are more severe, and range of motion is decreased. The child is nontoxic appearing, and other signs of systemic illness are absent. There can be either no fever, or a low grade temperature elevation. The mean WBC and ESR are significantly lower than in septic arthritis, but they cannot be used to distinguish between transient synovitis and septic arthritis and septic arthritis in individual patients. Patients at risk for septic arthritis usually have temperature >38.5°C (101.3°F), an ESR >20, leukocytosis, severe pain, tenderness on palpation, spasm, and refusal to walk.

Radiographs of the hip may be normal or may demonstrate an effusion, and are obtained to exclude pathologic osseous conditions. There are no bone changes associated with transient synovitis. Ultrasound is more sensitive than plain films at detecting joint effusions, although accuracy is decreased in patients younger than 1 year of age. Reports of an effusion of the hip by ultrasound in toxic synovitis vary from 50 percent to 95 percent.

The differential diagnosis includes slipped capital femoral epiphysis and other hip fractures, Legg-Calve-Perthes disease, and septic arthritis of the hip. Less-common causes include acute rheumatic fever, juvenile rheumatoid arthritis, and, rarely, tuberculosis of the hip.

Joint aspiration is only necessary if septic arthritis is in the differential diagnosis. When obtained, synovial fluid is sterile, and clearly transudative with negative organisms on Gram stain. If the peripheral WBC and ESR are substantially elevated and a hip effusion is noted on radiograph or ultrasound, a diagnostic arthrocentesis should be performed to exclude a septic joint. Synovial fluid should be sent for Gram stain, aerobic and anaerobic cultures, and acid-fast bacilli with culture. If an infection is demonstrated, an orthopedic consultation should be obtained with consideration for open irrigation of the hip in the operating room and admission for intravenous antibiotics.

Rest and non-weight bearing until the pain resolves for a usual period of 3 to 7 days, followed by limited activity for 1 to 2 weeks, are the treatments of choice. Nonsteroidal anti-inflammatory medications are the first-line therapy for pain. The duration of pain is typically 3 to 4 days, but may last as long as 2 weeks. Exacerbations of symptoms can occur if the child resumes normal activity too early.

There is no evidence of serious sequelae resulting from toxic synovitis. As long as the diagnosis is certain, reevaluation by the primary care physician can be arranged within 2 weeks.

SICKLE CELL DISEASE

Peter J. Paganussi Thom
Mayer Maybelle Kou

Sickle cell disease (SCD) is among the most common pediatric genetic conditions encountered in emergency medicine (especially in urban settings) and is found primarily in people of African, Mediterranean, Indian, or Middle Eastern heritage.

In the United States about 8 percent of the African-American population carries the hemoglobin (HgbS) gene and about 0.15 percent (approximately 1/500) are homozygous (HgbSS).¹ These individuals have a predominance of "sickled" hemoglobin, thus resulting in symptomatic SCD. Patients with this hemoglobinopathy have both sickle (A₂) and fetal hemoglobin. The most frequently encountered heterozygous sickle genotypes are HgbSA (sickle cell trait), Hgb-p thalassemia (sickle f⁺ thalassemia), and HgbSC (sickle cell-hemoglobin SCD). These less common variants of the homozygous disorder have similar, but far less severe, clinical manifestations. While patients with sickle cell trait have a normal life expectancy, those with SCD have a significant mortality rate, with 20 to 30 percent of all deaths from SCD occurring before 5 years of age and a mean age at death of 14 years.² Current survival has been greatly improved as a result of more aggressive infection prophylaxis and advances in therapy. Nonetheless, the highest mortality occurs in children between 1 and 3 years of age, with sepsis being the leading cause of death.³

Clinical effects of the disorder can begin in infancy but usually are not seen until 5 to 6 months of age, because high levels of fetal hemoglobin are present following birth, and the P-Hgb subunit is not predominant until about 3 months of age. SCD is characterized by abnormal sickle-shaped cells that are less deformable than normal red blood cells. Aggregation of these less pliant, abnormally-shaped cells leads to obstruction and thrombosis of small vessels, resulting in ischemia and tissue infarction, leading to end-organ dysfunction.

This chapter discusses sickle cell disease in children. Chapter 221 reviews sickle cell disease in adults.

PATHOPHYSIOLOGY

The genetic abnormality responsible for the disease is caused by a single amino acid substitution of valine for glutamic acid in the β subunit of the hemoglobin molecule. The resultant hemolytic anemia is caused by the abnormal properties of HgbS. Affected red blood cells undergo repeated cycles of sickling and unsickling, with the HgbS strands polymerizing abnormally in response to deoxygenation. Without an attached O_2 molecule, they tend to coalesce and stretch into long monofilaments, thereby resulting in the distorted sickle shape of the red cell membrane. These irreversibly sickled cells diminish blood viscosity, causing hemolysis and obstructing the microcirculation of end-organ tissues. Capillary obstruction deprives tissues of oxygen and metabolic nutrition. It has long been presumed that the resultant hypoxia and ischemia cause the pathologic and clinical features of the disease. This entire process is felt to be self-perpetuating and sustains continued sickling. Others have recently proposed that plasma proteins, endothelial cells, and other genetically driven mechanisms play a major role in this complex process. A few investigators have even questioned whether vasoocclusion exists at all, theorizing that tissue ischemia and infarction result from shunting of blood away from end-organ vascular beds rather than occlusion by deformed, sickled cells.⁴

CLINICAL PRESENTATION AND DIAGNOSIS

Patients with SCD classically present with signs and symptoms classified by the type of crisis they manifest: vasoocclusive, hematologic, or infectious (Table 137-1). The National Heart, Lung, and Blood Institute has recently published treatment guidelines on the management of sickle cell patients, which summarize the current understanding of this disease.⁵

Vasoocclusive Crises

Vasoocclusive crises are the classic "sickle crises" characterized by painful events, often involving the back, chest, extremities, or abdomen, but which may also involve the central nervous, renal, or genitourinary systems. They are the most common reason for ED visits by children with SCD.⁶ These vasoocclusive events account for more morbidity and hospitalizations than any other set of complications. The episodes are highly variable from patient to patient, with many patients reporting no crises at all, whereas others experience them on a regular basis, varying in location, duration, and severity. Typical sickle cell patients average about four severe attacks per year, with few patients reporting crises daily.

TABLE 137-1 Types of Sickle Cell Crises

Vasoocclusive crises
Musculoskeletal
Long bones
Lumbosacral
Dactylitis
Abdominal pain
Generalized
Right-upper-quadrant syndrome
Acute chest syndrome
Central nervous system crisis
Renal crises
Priapism
Hematologic crises
Acute splenic sequestration
Aplastic crises
Infectious crises

Some of these vasoocclusive crises seem to have triggers, that include stress (emotional or physical), cold water immersion/exposure (especially as associated with shivering postexposure), dehydration, high altitudes/hypoxia, or infection (bacterial or viral, with the latter being the most common trigger in children under the age of 10 years).

Most vasoocclusive crises occur without any obvious cause. They result from the classic mechanism of sludging of sickled red blood cells into the microcirculation, resulting in tissue hypoxia and infarction. The associated pain may recur in the same location(s), but it can be anywhere in the body. Young children tend to have pain in the limbs, whereas adolescents more commonly complain of abdominal pain. *Musculoskeletal* crises are the most common vasoocclusive crises followed by *abdominal pain*. With musculoskeletal pain, the location can be anywhere, but mostly involves the long bones, i.e., the femur, tibia, and humerus. Lumbosacral pain is also commonly reported. Often there are no demonstrative physical findings, but point tenderness may be found in the painful locations. Inguinal pain with difficulty in weight bearing and walking should raise the suspicion of avascular necrosis of the femoral head. Radiographs and/or a bone scan will aid in the diagnosis.

Infants may present with sickle dactylitis, also known as hand and foot syndrome. This occurs secondary to ischemia and infarction in the bone marrow of the extremities. Nutrient arteries that supply the metacarpals and the metatarsals become occluded and cause avascular necrosis. Clinically one sees swelling and pain of the hands and feet, often with an accompanying low-grade fever (i.e., less than 38.6°C or 101.5°F). One or all four extremities may be involved. Dactylitis is usually seen in children under the age of 2 years and is rare after the age of 5.

Abdominal pain is the next most common type of vasoocclusive crisis seen in children with SCD and is characterized by its abrupt onset, lack of localization, and recurrence. Patients often complain of diffuse, generalized abdominal pain, typically in the absence of significant peritoneal signs. Bowel sounds usually remain present and auscultate normally during these attacks. It can be extremely difficult to differentiate whether the pain is caused by vasoocclusive crisis or by a more common type of surgically correctable condition. While peritoneal signs are often absent in crisis, abdominal guarding and rebound tenderness may be present to cloud the diagnosis. Mesenteric infarction as well as splenic and hepatic infarction are the most likely causes of the pain, but the differential also should include pancreatitis, hepatitis, appendicitis, perforated viscus, and pelvic inflammatory disease or other gynecologic pathology. It is important to determine if the abdominal pain in SCD patients has substantially changed in character, quality, duration, severity, and associated symptoms. If such changes are present, infection or other related diagnoses should be explored.

Because of the rapid turnover of red blood cells, bilirubin gallstones commonly form. This can result in biliary colic and/or cholecystitis with a secondary gallstone ileus [right-upper-quadrant (RUQ) syndrome]. Any sickle cell patient in crisis with RUQ pain should be carefully evaluated for this possibility. Approximately 75 percent of sickle patients have demonstrable bilirubin gallstones; fortunately only about 10 percent become symptomatic.

RUQ syndrome is characterized by the sudden onset of RUQ pain, anorexia, extreme hyperbilirubinemia (greater than 50 mg/dL), and progressive hepatomegaly. RUQ syndrome is usually benign and self-limiting in the pediatric patient population. It is felt to result from intrahepatic cholestasis and is usually reversible with intravenous fluids and other supportive measures. However, in a small number of adult patients, this syndrome can progress to liver failure. With all of the aforementioned conditions, ultrasound examination and/or computed tomography (CT) of the abdomen and pelvis may be useful. Prompt surgical consultation is initiated in patients in whom the diagnosis cannot be clarified.

Infections can cause vasoocclusive crises; therefore, determining the presence of an infectious process is critical. Painful crises are

often associated with a low-grade fever and leukocytosis, but any temperature above 38.4°C (101.1°F) (or an absolute band count greater than 300 cells per cubic millimeter) is more likely to represent an infectious etiology than tissue ischemia.

General Treatment of Vasoocclusive Crises

Regardless of the end-organ involved, acute pain management, assuring adequate hydration, and provision of supplemental oxygen in appropriate settings are all essential features of the treatment of SCD.

ACUTE PAIN MANAGEMENT By definition, the patient in acute pain in the ED has exhausted the therapeutic options used at home and indicates the need for aggressive pain control, which will nearly always need to be provided by the parenteral route. Selection of the agent, route, and dose should be based on consideration of: (1) effective agents used at home; (2) drugs, dosages, and side effects providing relief in previous episodes; and (3) timing of medications recently taken by the patient. SCD patients or their family members are the best source for determining which medications (and at what dose) have been most effective in previous episodes. When available, consultation with a patient's physician can be invaluable in providing information and coordinating treatment. The patient's pain should be quantitated using a numerical scale or a modified Wong-Baker scale in younger children (see Chap. 134).⁷ Pain relief should be assessed frequently (no less than every 15 to 30 min) with a goal of 50 to 60 percent pain relief from previous intervals (Table 137-2). Intravenous morphine sulfate, usually at a dose of 0.1 to 0.15 mg/kg, or hydromorphone (0.02 to 0.05 mg/kg) may be given initially, followed by one-quarter to one-half the loading dose at subsequent reevaluation intervals. Pain intensity, pain relief, mood, and sedation level should be assessed and documented at each reassessment interval. Patient-controlled anesthesia pumps may also be used as well.

HYDRATION THERAPY Hydration status of all SCD patients should be assessed clinically and by use of blood chemistries, blood count, and urine specific gravity. Fluid overload should be avoided by using D5 J4NS or MNS. Fluid replacement should not exceed 1.5 times maintenance levels (2250 mL/m² per d), except in cases in which SCD patients are hypotensive, in which case fluid boluses of 10 to 20 mL/kg of RL or NS may be needed initially.

Other Vasoocclusive Events
