Acute chest syndrome, the second most common reason for hospitalization in a SCD patient, is an acute illness characterized by fever and development or worsening of respiratory symptoms, accompanied by a new pulmonary infiltrate on chest radiograph.⁵ However, chest radiographic changes typically are delayed by hours to days, which may make the diagnosis of acute chest syndrome somewhat more difficult. Patients often present with pleuritic chest pain, cough, dyspnea, hypoxia, and leukocytosis. Two multicenter studies [the Multicenter Acute Chest Syndrome Study (MACSS)^{8,9} and the Cooperative Study of Sickle Cell Disease (CSSCD)¹⁰] have delineated the nature of pulmonary end-organ pathology, which includes acute chest syndrome, pulmonary infarction, pneumonia, reactive airway disease, and fat embolism syndrome. Diagnostic workup of acute chest syndrome includes chest radiograph, pulse oximetry and/or arterial blood gases,

TABLE 137-2 Pain Medication Guidelines for SCD in Children

Intravenous route (avoid intramuscular)
Morphine sulfate 0.1-0.15 mg/kg IV
Hydromorphone 0.02-0.05 mg/kg IV
One-quarter to one-half the loading dose at 15- to 30-min intervals
Medication titrated to pain relief, pain intensity, mood, and sedation

CBC, and reticulocyte count. Treatment is guided by the severity of the disease, but always includes hydration, pain control, and oxygen therapy (Table 137-3).

Stroke or CNS crises (Table 137-4) occur in 5 to 10 percent of children (15 to 25 percent in all age categories) with SCD, and may be characterized by acute onset of hemiparesis, seizures, headaches, transient ischemic attacks, dizziness/vertigo, sensory hearing loss, cranial nerve palsies, paresthesias, and inexplicable coma. These crises tend to be painless but are abrupt in onset. Cerebral infarction is more common in children, while cerebral hemorrhage is more typical in adults. The overall rate of subarachnoid hemorrhage (SAH) is increased in sickle disease patients.¹¹ Computed tomography (CT) scan, lumbar puncture, and magnetic resonance imaging (MRI) are all helpful for diagnosis.

Renal vasoocclusive events are common but generally asymptomatic. Symptoms of renal infarction may include flank pain, renal colic, and costovertebral angle tenderness to percussion or palpation. Gross or microscopic hematuria may be evident, and some patients may actually pass renal tissue in their urine secondary to papillary necrosis. Monitoring of baseline renal function (i.e., BUN and creatinine) is always recommended in SCD patients.

Priapism consists of a painful, sustained erection of the penis in the absence of sexual stimulation and is the result of the accumulation of sickled cells in the corpora cavernosa. Severe and prolonged attacks can cause impotence. This occurs in up to 30 percent of males with SCD; surgical decompression is usually required in such prolonged attacks (Table 137-5).¹²

Newer approaches to priapism include oral administration of α -adrenergic agonists (terbutaline and pseudoephedrine) or intrapenile injection of vasodilators such as hydralazine, and/or needle aspiration of the corpora cavernosa.

Hematologic Crises

The hallmarks of these crises are an acute drop in serum hemoglobin levels and clinical symptoms of generalized weakness and malaise, fatigue, shortness of breath or exertional dyspnea, progressive congestive heart failure, and/or shock. There are two types of hematologic crisis—splenic sequestration and aplastic crisis (Table 137-6).

TABLE 137-3 Treatment of Acute Chest Syndrome

<i>Oxygen Therapy</i>
Assessment
Continuous pulse oximetry
Baseline arterial blood gases
Calculation of the alveolar-arterial (A-a) gradient
Treatment
Moderately hypoxic patients
PAO ₂ 70-80 mm Hg SaO ₂
92-95 percent Oxygen 2-4
L/min Pain control
Severely Hypoxic Patients PAO ₂
<70 mm Hg SaO ₂ <90 percent
Worsening A-a gradient 10%
Drop from baseline status
Ventilatory support Transfusion
therapy
Antibiotic Therapy (febrile or severely ill patients)
Intravenous broad-spectrum coverage
Macrolide or quinolone (to cover atypical pneumonia)
Cephalosporin
Pain Control (see Table 137-2)
Hydration
D5%NS or D5KNS (see Chap. 132)

TABLE 137-4 Treatment of CNS Crises

Acute Ischemic Stroke
Thrombolytic therapy (guided by current indications and contraindications, the most important of which is age < 18 years)
Hydration
Monitor by blood count, chemistries, and urine specific gravity
D5 KNS or D5 14NS as indicated clinically and by lab studies
Replacement not to exceed 1.5 times maintenance (maintenance = 2250 mL/M ² per d)
Exchange transfusion
Avoids increased blood viscosity of normal transfusion
Must be titrated to avoid hypotension (which could lower cerebral perfusion further)
Seizure control
Seizures should be treated
Prophylactic treatment or corticosteroids are not recommended Maintain normoglycemia Treat hypothermia <i>Transient Ischemic Attacks (TIAs)</i>
Exchange transfusion if the patient has significant large vessel disease on TCD, CT, MRI
Antiplatelet therapy (aspirin, clopidogrel, dipyridamole/aspirin) TCD screening for asymptomatic patients; chronic transfusion for those with confirmed abnormalities
Subarachnoid hemorrhage
Neuro/pediatric ICU monitoring
Exchange transfusion with a goal of <30% HbS
Nimodipine (guided by empiric results)

Abbreviation: TCD = transcranial Doppler.

ACUTE SPLENIC SEQUESTRATION This occurs primarily in infants and young children and is the second most common cause of death in children with SCD under the age of 5 years. The spleen enlarges, accompanied by a decline in hemoglobin concentration; hence patients present with splenomegaly and hypovolemic shock. These symptoms may occur suddenly or insidiously, and repeated episodes are common, as a result of sickled cells blocking splenic outflow and drainage, thus causing pooling of both peripheral blood and sickled cells in the spleen. These crises are often preceded by a viral infection, often with parvovirus B19, although rhinoviruses and echoviruses have also recently been implicated.¹³

Splenic sequestration crises are often divided into major and minor types. In major sequestration, the spleen enlarges rapidly and the serum hemoglobin levels drop to less than 6 g/dL, or to 3 g/dL from that particular patient's baseline. A minor episode is more insidious and leads to progressive splenomegaly, with hemoglobin levels generally greater than 6 g/dL. Reticulocyte counts tend to be higher than normal, reflecting the compensatory increase in bone marrow activity. Management includes transfusion of packed RBCs and exchange transfusions. Ultimately splenectomy may become necessary.

APLASTIC CRISIS Among the most life-threatening of all complications related to SCD, this complication occurs when bone marrow erythropoiesis slows or completely ceases, resulting in erythroid aplasia. It is characterized by fatigue, dyspnea, increased headache and severe anemia (with hematocrit levels of 10 percent or lower, hemoglobin levels of 1 to 3 g/dL or less, and reticulocyte counts as low

TABLE 137-6 Comparison of Findings in Sequestration and Aplastic Crises in Sickle Cell Disease

	Sequestration Crisis	Aplastic Crisis
Onset	Sudden	Gradual
Pallor	Present	Present
Jaundice	Normal	Normal
Abdominal pain	Present	Absent
Hemoglobin level	Very low	Low or very low
Reticulocytes	Unchanged or increased	Decreased
Marrow erythroid activity	Unchanged or increased	Decreased

as 0.5 percent).¹⁴ White blood cell (WBC) counts and platelet counts tend to remain stable despite the lack of erythropoiesis. Many of these crises are precipitated by human parvovirus B19, although folic acid deficiency and bone marrow suppressive/toxic drugs such as phenylbutazone have also been implicated.¹⁵ Fortunately these crises tend to occur only once in the lifetime of a patient with SCD and are usually self-limiting. RBC transfusions are usually necessary secondary to the severe anemia. This helps to avoid any secondary cardiopulmonary complications.

Infections/Infectious Crises

Children with SCD are markedly more at risk for development of serious infection, particularly sepsis from encapsulated organisms, both because of splenic malfunction and the inability to form specific IgG antibodies to polysaccharide antigens. Indeed, *Streptococcus pneumoniae* sepsis is the most common cause of death in children with SCD.¹⁶ Two primary prevention strategies have been undertaken to reduce this risk: vaccination and prophylactic penicillin therapy.

Current standard practice in children with SCD is to administer 23-valent polysaccharide *S. pneumoniae* vaccine at 24 months of age.¹⁷ While the antigen response in SCD patients is markedly less than in normal patients, there still appears to be some benefit to vaccination.¹⁸ The use of prophylactic penicillin is the single most important advance in preventing *S. pneumoniae* sepsis in SCD patients, preventing 80 percent of such episodes (Table 137-7). The widespread use of *Haemophilus influenzae* vaccine has dramatically reduced the incidence of infection by this organism.

Acute bone pain is a common presenting complaint in SCD and there is substantial overlap in the clinical, radiologic, and laboratory findings of marrow ischemia, osteomyelitis, and septic arthritis. Current NHLBI recommendations suggest an unambiguous bacterial diagnosis be confirmed and blood, subperiosteal, or joint fluid cultures be obtained prior to antibiotic therapy, which should include coverage for *Salmonella*.⁵

Fever without a known source should be treated as a serious illness in children with SCD (Table 137-8). Parents and children should be

TABLE 137-5 Treatment of Priapism

Analgesia
IV hydration
Urologic consultation
Oral α -adrenergic agents (terbutaline or pseudoephedrine)
Intracavernosal injection of hyalalazine
Needle aspiration of corpora cavernosa
Exchange transfusion (if not relieved in 2-3 h)

TABLE 137-7 Prophylactic Penicillin Therapy

Newborns to 36 months
Penicillin VK 125 mg PO twice daily
3 years to 5 years
Penicillin VK 250 mg PO twice daily
>5 years
Alternate therapies include:
Discontinuing therapy
Continuing penicillin VK 250 mg twice daily Immediate treatment of febrile episodes ("just-in-time" therapy)

TABLE 137-8 Treatment of Fever of Unknown Origin

Toxic-appearing children or those with T >40°C
Immediate parenteral antibiotics while work-up proceeds
Admission and close observation Lumbar puncture
Non-toxic appearing children or T <40°C
Parenteral antibiotics if: Abnormal oxygen saturation or chest x-ray Peripheral WBC count >30,000 or <5000 History of sepsis Hemoglobin <5 g/dL Platelet count <100,000/ \times L Antibiotic coverage
Coverage for encapsulated organisms (e.g., ceftriaxone 75 mg/kg)

instructed that any temperature over 38.5°C (101.3°F) is a serious emergency, the diagnostic work-up of which should include CBC, chest radiograph, UA, pulse oximetry, and cultures of blood, urine, and throat.¹⁹ Therapy in such children is summarized below.

Only those children who have remained clinically stable for three or more hours after their first antibiotic dose, and who have close follow-up arranged within 24 h should be considered for outpatient treatment. These children should receive parenteral antibiotics followed by oral therapy with broad-spectrum agents (e.g., ceftriaxone 75 mg/kg followed by cefixime 8 mg/kg loading dose, followed by 4 mg/kg q12h).²⁰

Transfusion Therapy

Blood transfusions are often necessary in children undergoing splenic sequestration crisis and severe aplastic crisis. In addition, transfusions may be needed in the management of cerebrovascular accident (CVA), priapism, or as perioperative management prior to surgery. Naturally, transfusion carries risk: alloimmunization, HIV infection, hepatitis, volume overload, and iron toxicity (secondary to repeated transfusions). Transfusion can also markedly decrease erythropoiesis.

The decision to institute transfusion therapy can be difficult. In general, if the patient is stable and laboratory values indicate a serum hemoglobin ≤ 6 g/dL and a high reticulocyte count >20 percent or >250,000/ \times L, transfusion therapy can be avoided. However, if patients show evidence of heart failure, hypotension resistant to intravenous fluid bolus, dyspnea resistant to oxygen therapy, or marked fatigue, transfusion may be necessary, in which case a hematologist should be consulted. In cases of acute deterioration requiring immediate restoration of oxygen-carrying capacity, an initial infusion of 10 mL/kg of packed RBCs can be started while exchange transfusion is arranged.

Other Therapies for SCD

Increased concentrations of hemoglobin F inhibit sickle hemoglobin polymerization and sickling of red cells, thereby improving the clinical course of the disease in some patients. The most common agent used to increase HgbF concentrations is hydroxyurea, which can decrease hospitalizations and crises.²¹ Hydroxyurea is not used to treat acute crises.

DISPOSITION

Disposition depends upon ED findings, observation, and response to initial therapy. The following is a list of guidelines to aid ED physicians in determining which children with SCD require hospitalization:

1. Temperature greater than or equal to 38.5°C (101.3°F), WBC counts greater than 30,000/ μ X, or left shift and/or other hematologic parameters greatly altered from baseline values
2. Any signs of respiratory distress, hypoxia, and/or lobar infiltrate on chest x-ray
3. Any new CNS findings or presence of neurologic crisis
4. Splenic sequestration or aplastic crisis
5. Acute abdomen on physical exam
6. Prolonged priapism
7. Any type of vasoocclusive crisis that does not respond to intravenous hydration and analgesia (usually after about 4 to 6 h of therapy)
8. Inability to maintain adequate oral hydration
9. Patients in whom the diagnosis remains uncertain
10. Follow-up (i.e., telephone contact, return visit, etc.) is uncertain or unlikely because of distance, inconvenience, or poor compliance

If patients with vasoocclusive crisis are discharged home, they should be advised to maintain adequate oral hydration, take pain medication (a 2- to 3-day supply should be provided), and return immediately if fever over 38°C/100.4°F occurs, the pattern of pain worsens or changes, or vomiting begins. All patients treated and released from the ED should be reevaluated in 24 to 48 h by their private pediatrician, physician, or hematologist (generally 24 h for children and 24 to 48 h for adults).

Variants of Sickle Cell Disease

SICKLE CELL TRAIT (SCT) This is the carrier state of SCD and the most frequently encountered sickle cell variant. It is erroneous to consider this a mild form of SCD. Hematologically these patients are normal. Their RBCs have a normal lifespan; therefore there is no demonstrable anemia. The peripheral smear should not reveal sickled cells except in the presence of extreme hypoxia.

Clinically these patients have minimal complications, with the kidney being the most commonly affected organ. Hematuria is found in about 1 percent of patients with SCT and is most likely due to papillary necrosis following microinfarcts in the renal medullary tissue. Severe hypoxia and/or exposure to high altitudes can cause splenic infarction and CNS complications; there is also an increased incidence of sudden death in these patients during physical exertion or training. This is thought to be secondary to increased sickling under these extreme conditions. In general, the vast majority of these patients are asymptomatic and lead normal lives with a normal life expectancy.

SICKLE CELL HEMOGLOBIN-SC DISEASE This heterozygous variant results when the gene for HgbS is inherited from one parent and the gene for HgbC is inherited from the other parent. These patients can have a mild to moderate anemia and usually a mild reticulocytosis. Their peripheral smear reveals an abundance of target cells and a few sickle-shaped cells. Additionally HgbC may be seen precipitated as rhomboid crystals in the RBCs. Splenomegaly is the major feature of HgbSC disease and persists into adulthood in about 60 percent of patients.

Patients with HgbSC disease can have painful crises and organ infarcts; they are also at higher-than-normal risk for bacterial infections. Avascular necrosis of the femoral head, ocular complications or visual loss, and renal medullary infarcts have all been reported in these patients. Women with SC disease have an increased incidence of complications during pregnancy. Overall, while some patients have complications as profound as those with SCD, most patients with HgbSC disease have few clinical complications.

SICKLE CELL BETA-THALASSEMIA DISEASE Also a heterozygous sickle cell variant, this occurs when the gene for sickle hemoglobin is inherited from one parent and the gene for β -thalassemia is inherited from the other. The clinical severity of the disease, frequency of complications, and the degree of the resultant anemia depends on the type of β -thalassemia gene inherited. Approximately 80 to 90 percent of affected individuals have a β -thalassemia gene that allows for the production of some normal beta chains; thus some normal HgbA is produced. These patients in general do quite well; they have a mild hemolytic anemia (with near normal Hgb levels), suffer few painful crises, and sustain minimal end-organ damage. The remaining 10 to

20 percent of patients inherit a (3-thalassemia gene that produces no beta chains; therefore they have no normal hemoglobin. These individuals have a severe hemolytic anemia and vasoocclusive symptoms similar to those seen with SCD. Splenomegaly is found in 70 percent of patients with this variant.

ioral, or emotional conditions and who require health and related services of a type or amount beyond that required by children in general (Table 138-1).¹

A 1994 survey suggested that 18 percent of U.S. children fit the definition of having special health care needs (Table 138-2). Prevalence increases with age, with school-age children being twice as likely as toddlers to require additional services. Children from families with lower income and less advanced education and living in urban centers make up most of this population.² Since the landmark ruling allowing the care of Katie Beckett, a ventilator-dependent child, to be managed at home, technologic innovations and progressive parental advocacy have increased the feasibility of non-hospital-based care for this expanding pediatric population.³

Many children with special care needs now receive in-home care and participate in activities that assist them to integrate into the community. This patient population often requires special equipment and assistance to perform their daily activities and a specialized and focused approach to medical management. Special equipment may include apnea monitors, tracheostomies, feeding tubes and pumps, central venous lines or percutaneous intravenous catheters and pumps, ventilators, internal pacemakers or defibrillators, colostomies, oxygen, nebulizers, or ventricular peritoneal shunts.⁴ Providing care to these patients may be particularly stressful if information about their problems and needs is unavailable. All resources, including family, primary care pediatricians, specialists, and home health nurses, should be sought to facilitate care in times of need.

Formulation of an emergency care plan has been advocated by the Emergency Medical Services for Children program through its Children with Special Health Care Needs Task Force and the American Academy of Pediatrics' Committee on Children with Disabilities. Essential components of a program of providing care plans include: use of a standardized form; a method of identifying at-risk children; completion of a data set by the child's physicians and other health care professionals; education of families, other caregivers, and health care professionals in the use of the emergency plan; regular updates of the information; 24-h access to the information by authorized emergency health care professionals; and maintenance of patient confidentiality. Emergency hospital and prehospital care is believed to be negatively affected by a frequent lack of accurate, timely information about the children's special needs and particular histories.⁵

If the child is at risk for future medical emergencies, the child and family should participate in developing a written emergency care plan. Copies of this plan should be kept in easily accessible places at the child's home and any other location where the child regularly spends time. The plan should include provisions for any special training that will be needed by emergency medical personnel, family members, or other persons who may be called on to provide emergency care for the child.⁵

TABLE 138-1 What to Keep in Mind When Treating Children with Special Needs

Some patients have baseline vital signs outside the normal range for the child's age
Vital signs may be controlled by the child's medical device, i.e., ventilator or pacemaker
Weight may be significantly higher or lower than expected for the child's actual age
Standard prehospital quick reference charts or a Broselow tape may prove inaccurate for these patients
Difficulty tolerating respiratory distress or shock
Consider urgent any medical or traumatic event the child experiences
Expect and prepare for potential rapid patient deterioration
Many have a sensitivity or allergy to latex
Localized reaction or anaphylaxis could develop
Be proactive
Have latex-free items on hand
Ask about medications given before or during transport

EVALUATING THE CHILD WITH SPECIAL HEALTH CARE

NEEDS Douglas R. Trocinski
Donna Moro-Sutherland

In the United States, more than 12 million children have special health care needs. Children with special health care needs are those who have or are at increased risk for chronic physical, developmental, behav-

TABLE 138-2 Congenital or Developmental Disorders and Associated Medical Conditions

Chromosomal disorders	Down syndrome (trisomy 21 syndrome)
	Seizure disorder (12-15%); cataracts (15%); serous otitis media (50-70%); deafness (75%); congenital heart disease (50%); ASD, VSD, AV canal, PDA, tetralogy of Fallot, pulmonary hypertension; gastrointestinal atresias (12%); Hirschsprung disease (1%); constipation, fecal impaction from medications or hypothyroidism; thyroid disease (15%); diabetes mellitus; leukemia (1%); atlantoaxial instability (14-22%); acquired hip dislocation (6%); and psychiatric disorders (22%)
	Fragile X syndrome
	Recurrent serous otitis media (60% in males), strabismus (30-56% in males), seizures (14-50% in males), autism (16% in males), self-abusive, and mitral valve prolapse (22-77% in males)
	Trisomy 18
	Congenital heart disease (99%); VSD, ASD, and PDA
	Cri-du-chat syndrome (partial deletion 5p-)
	Catlike cry in infancy, microcephaly, and downward slant of the palpebral fissures
	Turner syndrome (XO syndrome)
	Short stature in females, horseshoe kidney, heart disease (bicuspid aortic valve in 30%, coarctation aorta in 10%, valvular aortic stenosis, mitral valve prolapse, aortic dissection later in life, and hypertension)
	Noonan syndrome
	Webbing of the neck, pectus excavatum, cryptorchidism, and pulmonic stenosis
Disorders with facial defects as major feature	Pierre Robin syndrome
	Micrognathia, glossoptosis, and cleft soft palate; primary defect: early mandibular hypoplasia
	Waardenburg syndrome
	Lateral displacement of medial canthi, partial albinism, and deafness
	Occasional associations: VSD, Hirschsprung disease, esophageal atresia, and anal atresia
	Treacher Collins syndrome
	Malar hypoplasia with downward slanting palpebral fissures, defect of lower lid, and malformation of the external ear
Disorders with limb defects as major feature	Holt-Oram syndrome
	Upper limb defect, cardiac anomaly (ASD, VSD, arrhythmia), and narrow shoulders
	Fanconi pancytopenia syndrome
	Radial hypoplasia, hyperpigmentation, pancytopenia, and renal anomaly
	Radial aplasia thrombocytopenia (TAR syndrome)
Inherited metabolic disorders	
	Phenylketonuria (autosomal recessive)
	Light pigmentation, eczema (33%), poor coordination, seizures (25%), and autistic behavior
	Hunter syndrome (X-linked recessive)
	Developmental lag after age 6-12 mo, coarse facies, growth deficiency, stiff joints by age 1-4 y, clear corneas, and hepatosplenomegaly
	Hurler syndrome (autosomal recessive)
	Developmental lag after age 6-10 mo, coarse facies, stiff joints, mental deficiency, cloudy corneas by age 1-2 y, hepatosplenomegaly, and rhinitis
	Lesch-Nyhan syndrome (X-linked recessive)
	Spasticity, choreoathetosis, self-mutilation, autistic behavior, and growth deficiency
Connective tissue disorders	Marfan syndrome
	Arachnodactyly with hyperextensibility, lens subluxation, and aortic dilatation
	Ehlers-Danlos syndrome
	Hyperextensibility of joints, hyperextensibility of skin, and poor wound healing with thin scar
	Osteogenesis imperfecta congenita
	Short, broad, long bones; multiple fractures; and blue sclera
Hamartoses	
	Sturge-Weber sequence
	Flat facial hemangiomas and meningeal hemangiomas with seizures
	Tuberous sclerosis syndrome
	Hamartomatous skin nodules (thumb print macules), seizures, angiomyolipomas (45-81%), phakomas, and bone lesions
	Neurofibromatosis syndrome
	Multiple neurofibromas, café-au-lait spots, presence or absence of bone lesions, seizures and/or EEG changes in 20%, cerebrovascular compromise, and headaches
	Peutz-Jeghers syndrome
	Mucocutaneous pigmentation, intestinal polyposis, 35% of patients have extraintestinal malignancies
Environmental agents (toxins)	Fetal alcohol syndrome
	Vision problems (94%), recurrent serous otitis (93%), hearing loss (66%), heart defects (29-41%), renal hypoplasia, duplication of the kidney and collecting system, and bladder diverticula (10%)
	Other environmental exposures include fetal hydantoin syndrome, fetal trimethadione syndrome, fetal valproate syndrome, fetal warfarin syndrome, and retinoic acid embryopathy
Trauma	
	Traumatic brain injury
	Visual and hearing disturbances; cranial nerve damage; spasticity, incoordination, ataxia, and feeding disorders; GERD
	Cerebral palsy
	Seizures (33%), strabismus (50%), hearing loss (10%), hip dislocation, scoliosis, contractures, gait disorder, GERD (8-10%), chronic aspiration and recurrent RAD, pulmonary fibrosis and bronchiectasis

(continued)

TABLE 138-2 Congenital or Developmental Disorders and Associated Medical Conditions (Continued)

Miscellaneous Angelman syndrome (happy puppet syndrome)
Puppet-like gait, paroxysms of laughter, and characteristic features; seizures vary from major motor to akinetic, beginning usually at age 18-24 mo
Beckwith-Wiedemann syndrome
Macroglossia, omphalocele, macrosomia, and ear creases; neonatal polycythemia and hypoglycemia in early infancy; associated with Wilms' tumor
CHARGE syndrome Coloboma, Aert disease (tetralogy of Fallot, PDA, double-outlet right ventricle with an atrioventricular canal, VSD, ASD, and right-sided aortic arch),
atresia choanae, retarded growth and development and/or CNS anomalies, genital anomalies and/or hypogonadism, and ear anomalies and/or deafness
Prader-Willi syndrome
Mental retardation, hypotonia, hypogonadism, obesity, hyperphagia, gastric perforation, hypoventilation, obstructive sleep apnea, cor pulmonale, NIDDM, scoliosis, strabismus, inability to vomit, decreased sensitivity to pain, seizure disorder, hypoxia, right-sided heart failure, and pulmonary hypertension Rett syndrome
Hyperventilation, breath holding, air swallowing, bruxism, ataxia, muscle wasting, poor circulation, scoliosis, seizures, and intermittent flushing
Vater syndrome
Vertebral defects and VSD, imperforate anus, tracheoesophageal fistula, renal anomalies, and single umbilical artery
Williams syndrome
Elfin-like syndrome, cardiovascular disease, supraaortic stenosis, pulmonic stenosis, coarctation of the aorta, strabismus, joint contractures, hypertension, urethral stenosis, vesicoureteral reflux, constipation, ulcers, and hypercalcemia

Abbreviations: ASD = autistic spectrum disorder; AV = atrioventricular; CNS = central nervous system; EEG = electroencephalogram; GERD = gastroesophageal reflux disease; NIDDM = non-insulin-dependent diabetes mellitus; PDA = patent ductus arteriosus; RAD = reactive airway disease; TAR = thrombocytopenia-absent radius; VSD = ventricular septal defect.

Emphasis on each child as an individual and the importance of the parents and caregivers as valuable resources for the prehospital and emergency room providers should not be overlooked. The emergency information set or passport should improve the emergency care of children with special health care needs.

GENERAL MANAGEMENT

Emergency management of a child with special health care needs should focus on two points: management of the child's ABCs and using the most valuable resource, the child's caregiver. These long-term caregivers know the child's baseline status and are familiar with the medications and supportive equipment the child requires. The child's "go-bag" is a valuable resource containing specialized, individualized medical equipment, such as extra tracheostomy tubes, appropriate size suction catheters, equipment necessary to change a tracheostomy tube, syringes and adapters necessary to decompress a feeding catheter, a bag-valve-mask resuscitator, and needles necessary to access central lines.

Cerebral Palsy

The term *cerebral palsy* describes a collection of nonprogressive disorders of movement and posture originating from an injury sustained by the developing brain within the first 3 to 5 years of life. This relatively common disorder has a prevalence of approximately 2 per 1000 individuals and may be associated with other central nervous system sequelae, including seizures, cognitive impairments, and sensory, communication, and behavioral abnormalities. It may be classified by motor abnormality (spastic, dyskinetic, ataxic, hypotonic, and mixed), distribution (diplegia, hemiplegia, quadriplegia, etc.), and degree of involvement. Although most children sustain their injuries in the prenatal or perinatal period, many etiologies over many different developmental periods have been suggested. Prenatal injury may occur from teratogen exposure, genetic syndromes, intrauterine infections, brain malformations, or fetal placenta unit malfunctions. The perinatal period may be complicated by preeclampsia, complications of labor and delivery, sepsis or central nervous system infection, asphyxia, or prematurity. The young child may develop cerebral palsy by way of meningitis, traumatic brain injury, or toxic exposures. Approximately 25 percent of all cases have no obvious source of injury.⁶

Cerebral palsy patients often present to the ED as a result of the many varied medical problems directly and indirectly associated with this disorder. Seizures may affect up to two-thirds of children with cerebral palsy, predominating in the spastic subtypes. The nature and complexity of the seizure syndromes may differ considerably between patients but, as with most epileptic syndromes, is generally consistent within the individual. The initial evaluation and management generally follow accepted tenets of seizure interventions, including protecting the airway, protecting the patient from injury, and treating the acute episode with anticonvulsants. However, the seizure history may be quite complex, and adequate seizure control may require multiple medications, necessitating attention to potential drug interactions and consultation with the primary neurologist when therapeutic adjustments are required.⁶ See Chap. 125 for a detailed discussion of seizure management in children.

Oral motor dysfunction and gastroesophageal reflux often lead to a multitude of respiratory symptoms, including aspiration, wheezing, pneumonia, and chronic congestion. Evaluation of acute respiratory complaints must include a thorough history of past respiratory function to delineate underlying pulmonary abnormalities associated with prematurity, reactive airway disease, or tracheomalacia. Physical examination should include response to repositioning the child with poor head control to improve airway mechanics and decrease pooling of saliva, evaluation of air movement, accessory muscle use, nasal flaring, and retractions. The clinician also should entertain the possibility of a foreign body aspiration in light of the presentation and cognitive level of function of the individual patient. Ancillary tests, including x-ray evaluation, blood gas analysis, and gastroesophageal reflux investigation, may be completed as indicated by the clinical situation. Impaired respiratory function determined to be secondary to a reactive airway process should be treated with bronchodilators and steroids, as indicated. However, poor response to bronchodilator therapy should prompt consideration of an aspiration etiology and other treatment options. Admission is warranted for secondary pneumonia, persistent respiratory compromise, or removal of a foreign body in consultation with the appropriate primary physician.

Gastrointestinal complaints may include dehydration, feeding tube complications (discussed later in this chapter), and constipation. Dehydration may be the result of oral motor dysfunction or an infectious process. Children with severe involvement, growth retardation (in particular below the 5th percentile), or marginal reserves may dehydrate

in response to relatively minimal vomiting and diarrhea. In addition to the clinical signs of dry mucous membranes, tachycardia, and physical sequelae of dehydration, close involvement with the family with regard to weight loss, baseline level of functioning, and ability to orally hydrate will help the emergency physician anticipate the need for rehydration therapy and admission. Intravenous access may be difficult in these children and may require the use of central or intraosseous access in addition to tube feeds, if available. Constipation, stemming from increased tone, impairment of sphincter relaxation, and limited fluid and fiber intake, may present as pain, change in bowel habits, anorexia, or overflow diarrhea. Acute therapy may include judicious use of enemas, suppositories, or dietary adjustments. Mineral oil should be avoided in children with aspiration histories to avoid pulmonary complications and impaired fat-soluble vitamin absorption. Fleets enemas should not be used chronically to avoid electrolyte abnormalities. Often, these children have home programs in place for chronic constipation and will require the involvement of their gastroenterologist or pediatrician for acute management and disposition.

The child with cerebral palsy may develop pain or cutaneous complications from orthopedic braces. The risk of orthopedic injuries is increased secondary to disuse and nutritionally induced osteopenia. Although fractures may occur from therapy, falls from beds or wheel chairs, or accidental injury, there must be a high index of suspicion for inflicted injury, particularly in displaced fractures. Orthopedic injuries may have subtle clinical findings and should be suspected in the irritable, severely impaired, or nonverbal child. Treatment should be completed in consultation with an orthopedic surgeon and may include hospitalization, casting, or soft wraps on the child with limited mobility.

Meningomyelocele and Neural Tube Defects

Neural tube defects, resulting from the failure of the neural tube to spontaneously close in the early embryonic stage of development, account for most congenital abnormalities of the central nervous system. The etiology of neural tube defects is thought to be multifactorial, but folic acid deficiency has been associated and supplementation is currently recommended as early as possible in pregnancy. The most severe form of neural tube defect, occurring with an incidence approaching 1 in 1000 live births, is the meningocele, which includes involvement of the spinal cord, meninges, and vertebral column. Complex medical problems result from the impairment of sensory and motor control of voluntary and autonomic activities at or below the site of the lesion. The spectrum of medical complications includes neurogenic bowel and bladder dysfunction, contractures, scoliosis, hydrocephalus, Chiari II malformation, tethering of the spinal cord, spinal cord syrinx, vesicoureteral reflux, recurrent urinary tract infections, constipation, growth failure, latex allergy, gastroesophageal reflux, respiratory compromise, seizures, vision impairment, osteoporosis, and cognitive impairment, among others.

Hydrocephalus, requiring early shunt placement, is present in 75 percent or more of patients with meningocele. Symptoms suggestive of shunt malfunction include altered mental status, irritability, nausea and vomiting, vision disturbances, neck pain, headache, seizures, or swelling along the shunt path. The presentation of shunt malfunction may, in some cases, be vague, necessitating reliance on parents and other primary care givers for information regarding symptoms of past malfunction, baseline neurologic functioning, and determination of the severity of the presenting symptoms, as discussed in detail later in this chapter.

Chiari II malformation is present in many children with meningocele and consists of malformation of the cerebellum, hindbrain, and brainstem. Infants may present with apnea, vocal cord paralysis, stridor, oral motor dysfunction, vision disturbances, upper extremity weakness, and incoordination, whereas the older child most often presents with vision dysfunction, motor incoordination, headache, and hand weakness. These symptoms may result from even minor cervical hyperflexion and extension injuries. New-onset stridor in the child

with meningocele should be aggressively evaluated for Chiari II malformation by magnetic resonance imaging of the craniocervical junction and closely monitored for the progression of stridor to complete airway obstruction. If respiratory function is not severely compromised and the history is found to be static, outpatient disposition may be considered in consultation with subspecialists caring for the child. Aggressive immobilization and evaluation for upper cervical spine injury should be completed for the child with Chiari II malformation involved with any deceleration mechanism secondary to the instability of the craniocervical junction and increased likelihood of injury.

Urinary tract complaints include recurrent urinary tract infection, urinary retention or incontinence, complications of straight catheterization, or complications of urologic surgery. Children may be receiving medications or prophylactic antibiotics to enhance continence and minimize damage to the upper urinary tract. Because bacterial colonization of the urine is common, only children with symptomatic infection should receive broad-spectrum antibiotic coverage. Formation of a false channel during self-catheterization is suspected with difficult catheter passage, pain, or urethral bleeding. Recatheterization should not be attempted in the ED for these symptoms for fear of compounding the underlying injury. Rather, urologic consultation should be obtained. Long-term indwelling catheterization predisposes the patient to the development of latex allergy.

The insensate areas distal to the neural tube defect are susceptible to burns and pressure sore development. Local wound care, padding, frequent repositioning, and discontinuing of bracing may be required for superficial wound healing. Careful evaluation is required to differentiate cellulitis, abscess, or osteomyelitis. Deep infections and osteomyelitis may require admission, surgical intervention, and long-term antibiotic therapy.

Autism

Autism describes a heterogeneous disorder of brain development that affects behavior; impairs social interaction, language, and communication skills; and, often, features repetitive motor activities. The term *autistic spectrum disorder* is used to encompass the wide variety of clinical expressions, severity, and level of functioning. Autistic spectrum disorder has a prevalence of 2 per 1000 (autistic disorder approximates 1 in 1000), with recent evidence suggesting that these numbers are increasing with improved and earlier detection.⁷ In general, most children with autism do not have associated medical disorders and will have emergency medical needs similar to those of age-matched, developmentally normal children. Exceptions include, but are not limited to, an association of autism in children with tuberous sclerosis and rare coincidence of autism with Williams syndrome and neurofibromatosis. Although the medical problems may not be unusual, interactions with autistic children may be difficult secondary to sensory defensiveness, unusual social behaviors, and potentially aggressive self-protective responses to medical procedures and examinations. Parents and primary care givers can inform the physician of the most effective means of communication for each patient. Judicious use of sedation for painful or difficult procedures should be employed with specific attention to patient safety and potential medication interactions.

Mental Retardation and Developmental Delay

Mental retardation occurs in approximately 2.5 percent of the population and is classically defined by cognitive impairment and decreased adaptive behaviors resulting from injury, disease, or abnormality occurring before the age of 18 years. Mental retardation is associated with disorders, such as Down syndrome, Rett syndrome, Williams syndrome, fragile X, and fetal alcohol syndrome, but has no such associations in the majority of patients. The intellectual impairment and associated behavior difficulties create challenges for medical care providers. Mentally retarded children are often difficult to approach,

have impaired social and communication skills, and may become aggressive or combative when confronted by new or painful stimuli. As with the autistic child, the parent or primary care giver is an essential source of information for effective interaction strategies. In addition, all potential sources of information should be investigated to complete a history clouded by a decreased level of intellectual function. The various medical problems found in these patients can be specific to the underlying syndrome but generally can be approached in ways similar to those with developmentally normal children. Medication profiles should be reviewed to prevent drug interactions and to identify potential drug side effects.

Down Syndrome

Down syndrome is a relatively common genetic disorder, most often resulting from a trisomy of chromosome 21, occurring in slightly more than 1 in 1000 live births. The syndrome is characterized by developmental delay, mental retardation, congenital heart defects, gastrointestinal system abnormalities, increased risk of upper respiratory and ear infections, and atlanto-occipital instability. Congenital heart defects affect 40 to 60 percent and include atrioventricular canal defects, ventricular and atrial septal defects, tetralogy of Fallot, and patent ductus arteriosus. These defects generally are detected in early infancy, but pulmonary hypertension and congestive heart failure may develop with time if treatment is not successful. Common gastrointestinal tract abnormalities include esophageal atresia, tracheoesophageal fistula, pyloric stenosis, duodenal atresia, Meckel diverticulum, Hirschsprung disease, and imperforate anus. Feeding difficulties in the infant with Down syndrome therefore should prompt further investigation and immediate surgical intervention, if indicated. There is also an increased risk of gastroesophageal reflux, which responds to standard therapy. Midfacial malformations affect the normal functioning of eustachian tubes, leading to recurrent and chronic infections of the ear, sinuses, and upper respiratory tract. Deceleration injuries raise the possibility of atlantoaxial subluxation or dislocation.

Spinal Cord Injury

More than 1000 new cases of traumatic spinal cord injury occur each year in children as a result of motor vehicle accidents, athletic activities, falls, inflicted trauma, and birth trauma. Spinal cord injuries may result in complications similar to those described for meningomyelocele but also may include pain, heterotopic bone ossification, hypercalcemia, renal calculi, and autonomic dysreflexia. Upper thoracic and cervical injuries also may lead to respiratory insufficiency secondary to phrenic nerve impairment or weakness of abdominal and chest wall musculature.

Autonomic dysreflexia is a serious, potentially life-threatening complication of cord injuries proximal to the mid-thoracic level. It consists of paroxysmal sympathetic and parasympathetic hyperactivity initiated by stimuli below the level of the lesion, such as bladder overdistention, fecal impaction, or fracture. The symptoms of autonomic dysreflexia are sweating, flushing, pounding headache, hypertension, bradycardia, and piloerection. The primary intervention is to determine and eliminate the offending stimulus through bladder emptying, disimpaction with local anesthesia, discontinuation of painful procedures, or repositioning. If elevated blood pressure does not respond to repositioning or stimulus reduction, standard treatment of a hypertensive emergency should be instituted.

Chronic dysesthesias or paresthesias become more frequent as the child reaches adolescence. Pain management should consist of analgesics and other pain-control strategies in concert with the primary physician. Prolonged narcotic use should be avoided.

Heterotopic bone formation may present with pain, heat, swelling, and restricted movement, most commonly in the hips, knees, elbows, or shoulders. Underlying fracture, infection, or skin breakdown should be excluded.

Spinal cord-injured patients of any age are at increased risk for psychiatric and emotional difficulties related to loss of function and body image. Depression, anxiety, uncontrolled anger, or temper tantrums usually can be handled in the outpatient setting, but hospitalization may be required for suicidal ideation or extreme behavioral and emotional difficulties.

TECHNOLOGY-DEPENDENT CHILDREN

Definition: one who needs both a medical device to compensate for the loss of a vital body function and substantial and ongoing nursing care to avert death or further disability.⁸

Examples of technology-dependent children include those who require ventilator support or who have pacemakers, tracheostomies, gastrostomy tubes, or central venous catheters.^{8,9} The primary care physician and home health nurse should be contacted early in the evaluation process to avoid unnecessary tests and admissions and to simplify care.

Tracheostomy Care

Complications related to tracheostomy tubes include decannulation, obstruction, tube reinsertion into a false passage, pneumomediastinum, and pneumothorax. Granuloma or stricture formation at the stoma or where the tip of the tube meets the tracheal wall can lead to localized bleeding with manipulation of the cannula. Erosion into the innominate artery is a rare occurrence usually related to an inferiorly placed tracheostomy stoma. Infections related to tracheostomy care include tracheitis, pneumonia, and asthma. See Chap. 244 for further discussion of airway devices.

Mechanical Ventilation

Ventilator-related complications, such as pneumothorax, are managed according to accepted standard principles. Bag ventilation is necessary in the case of ventilator failure.

Complications of Feeding Tubes

The special needs child with a nasogastric tube may develop sinusitis, nasal and esophageal irritation, tube dislodgement or clogging, or pulmonary aspiration. Gastrostomy tubes can be associated with gastroesophageal reflux, peristomal wound infection, peritonitis, gastric perforation or hemorrhage, gastrocolic fistula, gastric ulceration, and gastric outlet obstruction. Complications of gastrojejunostomy tubes include diarrhea, tube migration, small bowel perforation, and intussusception. Stomal complications include dermatitis, allergic hypersensitivity, granulation, cellulitis, and fungal infections.

Complications of parenteral feeding include catheter obstruction or occlusion, air embolism, catheter breakage, catheter displacement, or catheter-related infection. Other complications include cholestasis that may lead to irreversible liver disease or metabolic bone disease.

Cerebrospinal Fluid Shunts

Complications related to ventricular peritoneal shunts include mechanical malfunction, overdrainage, and infection. Approximately 75 percent of patients with ventricular peritoneal shunts experience a shunt malfunction in their lifetime. Signs and symptoms of ventricular peritoneal shunt obstruction include headache, visual disturbances, vomiting, lethargy, irritability, papilledema, bulging fontanelle or enlarged head, engorged head veins, and Macewen sign (cracked-pot sound during skull percussion). Neurologic findings may include increased deep tendon reflexes or lower extremity tone, positive Babinski sign, lateral (6th) or upward (4th) gaze (sunsetting), and respiratory compromise. Seizures are generally accompanied by other signs and symptoms and are seldom, if ever, the only sign of shunt malfunction.

Shunt infections are characterized by nonspecific signs and symptoms, including change in sensorium, fever, irritability, shunt malfunction, vomiting, or abdominal pain. Antibiotics should be selected

to treat gram-positive (most commonly, coagulase-negative *Staphylococcus*, *Staphylococcus aureus*, and *Streptococcus* species) and gram-negative (*Escherichia coli*, *Enterococcus* species, and *Haemophilus influenzae*) species. Infections most commonly occur within a few months of shunt placement, many within the first few weeks, and they generally decrease in frequency with time.

Shunt malfunction evaluation should include shunt series (plain radiographs of the skull, neck, chest, and abdomen) and head computed tomography to assess ventricular size and shunt positioning. Increased cerebral ventricle size, particularly when compared with previous studies, is indicative of shunt malfunction. However, malfunction may be present with unchanged ventricular size, due to a loss of surrounding tissue compliance. If shunt malfunction or infection is suspected, neurosurgical consultation should be obtained for further evaluation, including shunt aspiration, admission, and monitoring.

Urinary Diversions

Urinary diversions seen with the special needs child include vesicostomies, ureterostomies, ileal loop conduits, and bladder augmentations. Complications with vesicostomies include prolapse and stomal stenosis; ureterostomies leading to stenosis; ileal loop conduits leading to prolapse, peristomal hernia, or stenosis; bladder ruptures and perforations; and small bowel obstruction. Most complications should be managed in consultation with the child's attending urologist.

swelling include Henoch-Schonlein purpura, orchitis, tuberculosis, and rarely in children, tumors.

HISTORY AND PHYSICAL EXAMINATION Age is a factor in diagnosis. Testicular torsion is most common in neonates and postpubertal boys. Appendiceal torsion and Henoch-Schonlein purpura are more common in school-aged males (prepubertal). Epididymitis more often presents in adolescents and adults. Hydroceles are often found in the first 2 years of life, whereas varicoceles are uncommon before the age of 10.

Time course of symptoms is important in establishing diagnosis. Abrupt onset of symptoms within minutes to hours raises the suspicion of torsion. Intermittent, acute pain associated with scrotal swelling suggests intermittent torsion with spontaneous detorsion. More gradual onset of symptoms over 1 to 3 days is more indicative of epididymitis or appendiceal torsion. Hernias and hydroceles often are reported as a gradual onset of swelling over a prolonged period of time, frequently with variations in the amount of swelling. A history of swelling that progresses toward the end of the day or with prolonged ambulation suggests a communicating hydrocele or hernia. Ask about any history of *genital trauma* because children and adolescents often are reluctant to disclose such episodes.

Determining the *severity and location* of symptoms can aid in diagnosis. The pain of testicular torsion is severe from the onset and can radiate to the abdomen and be associated with nausea and vomiting. Urinary symptoms such as frequency, urgency, and dysuria suggest epididymitis. Painless scrotal swelling suggests more benign etiologies such as hernias, hydroceles, or varicoceles.

The *physical examination* includes inspection and palpation of the phallus, scrotum, testicles, epididymis, and inguinal region. The position of the testes in the scrotum should be evaluated—one testicle riding higher in the scrotum than the other or a transverse lie of the testicles indicating a bell-clapper deformity is associated with testicular torsion. The inguinal canal should be evaluated for hernias or communicating hydroceles. Assess the degree of swelling, redness, or thickening of the scrotum. In both epididymitis and testicular torsion, the affected hemiscrotum typically displays significant erythema and swelling after 24 h. The abdomen should be examined in all those with genital complaints, and the genitals should be examined in all those with abdominal complaints, because the differential diagnoses of pain in both areas overlap.¹

The normal testicle should be examined first. The testicle is examined by gently grasping the testicle between the thumb and forefinger. Evaluate the epididymis similarly. The epididymis should be felt at the posterosuperior aspect of the testicle. A swollen, tender testicle is indicative of torsion, but the epididymis is usually more tender than the testicle in epididymitis. Tenderness limited to the upper pole of the testicle indicates torsion of the appendix. The pathognomonic blue-dot sign, a bluish discoloration at the superior pole of the testis indicates a torsed appendage. This bluish discoloration represents the necrotic torsed appendage and is often visible through the skin at the upper pole. Late in the course of epididymitis and appendiceal torsion, loss of testicular landmarks occurs and makes it very difficult to differentiate these entities from testicular torsion.

The cremasteric reflex should be assessed by stroking or pinching the inner aspect of the thigh and watching for unilateral elevation of the testicle. An intact cremasteric reflex lowers the probability of testicular torsion. Normal boys between 30 months and 12 years of age should have an intact cremasteric reflex. The cremasteric reflex may be difficult to assess if there is severe scrotal edema.

ANCILLARY STUDIES Laboratory evaluation should include a routine urinalysis. Blood work is not routinely indicated except in patients with fever or other systemic symptoms. Pyuria suggests a urinary tract infection, and in younger patients the urinary tract may be the source of epididymitis, but a small number of children with torsion may have pyuria.

UROLOGIC AND GYNECOLOGIC PROBLEMS IN CHILDREN

Samy Saad
Oily Duckett

BOYS

Scrotal Pain and Swelling

Scrotal swelling must be categorized clinically into either an emergent or benign disease process. The most important condition to identify is testicular torsion. Common causes of scrotal swelling include testicular torsion, epididymitis, torsion of the appendix testes, varicoceles, hernias, hydroceles, and trauma. Less common causes of scrotal

All boys with acute testicular pain and swelling should be referred for immediate imaging to rule out testicular torsion. *Color Doppler imaging* has a sensitivity of over 95 percent for the diagnosis of torsion, is noninvasive, and is readily available and so is the preferred study. Absent or decreased flow in one testis indicates testicular torsion. The accuracy of nuclear scanning is similar to that of Doppler imaging. Its disadvantages include the lack of routine availability, delay in instituting the study, and inability to display scrotal anatomy. In nuclear scanning, little or no isotope reaches the testis in testicular torsion, whereas uptake is normal or increased in patients with epididymitis.

Testicular Torsion

Testicular torsion is the twisting of the spermatic cord and its contents within the tunica vaginalis causing decrease or absence of blood flow to the affected testicle. Testicular salvage is usually possible when duration of symptoms is less than 12 h, but the rates decrease significantly after 12 h, approaching zero after 24 h of symptoms. Ideally, surgical repair should be undertaken within 6 h of symptoms. The history is usually abrupt onset of testicular pain, followed by scrotal swelling and edema, often with associated nausea, vomiting, and lower abdominal pain. There may be a history of a sudden movement, position change, or genital trauma precipitating the event. A history of similar painful episodes with spontaneous resolution may represent previous episodes of torsion/detorsion. The classic signs of torsion are an enlarged, exquisitely tender testicle that rides higher in the scrotum than the normal testicle and usually has a transverse lie. Rarely, there may be a palpable mass in the spermatic cord where the blood vessels have twisted. In most cases the cremasteric reflex is absent in the affected testicle. The scrotal wall is usually erythematous and edematous. In cases of prolonged symptoms, the scrotum may be too edematous to evaluate cremasteric reflex or to accurately examine the testicular structures. As the process of torsion becomes more chronic, the testicle becomes fixed to the overlying, often thickened scrotal wall.²

Adolescence is the most common age for testicular torsion, but torsion may affect children of all ages (Table 139-1). Roughly 10 percent of cases of testicular infarction are caused by *neonatal torsion*. This entity differs from pubertal torsion in that in neonatal torsion the peritoneal attachments are inadequate or absent, and the testis, epididymis, and tunica vaginalis twist as a unit. This type of torsion is known as *extravaginal torsion*. Neonatal torsion occurs in utero or in the first 10 days of life. If torsion occurred in utero, the testis is not salvageable. However, if the child develops scrotal swelling with a history of a normal scrotum at birth, immediate pediatric surgical consultation may salvage the testis.³

When the diagnosis of torsion is considered, a pediatric surgeon or urologist should be consulted immediately. At that time, a decision of surgical exploration versus imaging must be made. This decision most often is based on the experience of the surgeon and duration of symp-

toms. Treatment of testicular torsion is surgical exploration. At the time of exploration, if the affected testicle is nonviable after being detorsed, it should be removed. The contralateral healthy testicle should be fixed or pexed to prevent future torsion. As a temporizing measure, the emergency physician may attempt to *manually detorse* the testicle by elevating the affected testicle toward the inguinal ring and rotating the epididymis medially (see Chap. 95). Manual detorsion is unsuccessful most of the time and should be abandoned if the patient experiences any further discomfort. Relief of pain indicates correct detorsion and may allow for some blood return to the testicle. Surgical consultation remains necessary despite relief of pain.

Torsion of the Appendix

Torsion of the appendix testis or appendix epididymis may present with similar symptoms as testicular torsion but has a more gradual onset and is managed quite differently. **The most common age of presentation is between 7 and 12 years, although it can occur at any age.** The pain is typically less intense than the pain of testicular torsion. The scrotum is usually normal or mildly erythematous. The testes are equal in size, and early on, the tenderness is localized to the superior pole of the testicle. Commonly, there will be a bluish discoloration of the overlying skin giving the pathognomonic blue-dot sign at the superior aspect of the affected testicle. Imaging reveals normal blood flow to the testicle. Treatment includes scrotal elevation, bed rest, and analgesia with nonsteroidal anti-inflammatory drugs. Inflammation usually resolves within 1 week.³

Epididymitis

Epididymitis is rarely seen in *prepubertal* children, but when present, urologic evaluation, including renal/bladder sonogram and a voiding cystourethrogram, is warranted to rule out associated genitourinary abnormalities. Before puberty, coliform bacteria (*Escherichia coli*) and other urinary pathogens predominate. *Chlamydia trachomatis* and *Neisseria gonorrhoeae* are the most common infectious organisms in *sexually active adolescents*?

Symptoms include fever, chills, and urinary symptoms (e.g., dysuria, frequency, urgency, and urethral discharge). Symptoms also may begin with flank pain that gradually spreads to the epididymis and scrotum. The epididymis becomes tender and edematous. The testicle is not tender unless the infection is complicated by epididymo-orchitis. The overlying hemiscrotum is usually red, swollen, and tender. Prehn's sign (elevation of the scrotum above the pubis) relieves pain in epididymitis but not in torsion. However, this sign is not reliable in children. Urinalysis and urine cultures should be obtained, and while pyuria suggests epididymitis, pyuria also can be present with testicular torsion. The most frequent misdiagnosis of testicular torsion is epididymitis. Consequently, if there is any question about the accuracy of the diagnosis of epididymitis, imaging studies are indicated (see above).

Treatment in prepubertal boys is trimethoprim-sulfisoxazole 10 mg/kg per 24 h, divided twice a day, for 7 to 10 days. In sexually active adolescents, treatment for sexually transmitted pathogens is indicated (see Chap. 141). Analgesia and scrotal elevation may help with symptoms. Hospitalization is warranted if the patient has constitutional symptoms (i.e., fever, vomiting, or chills) or epididymo-orchitis. In some cases of untreated epididymitis or orchitis, abscess formation develops and requires surgical intervention.⁴

Hernia

Hernia is a defect in the abdominal wall, usually in the area of the inguinal ring. The hernia sac most commonly contains ileum, but it may contain omentum. In girls, an ovary or fallopian tube may be encountered within the hernia sac. The chief complaint is usually that of an intermittent mass in the scrotal area. The mass is usually painless,

TABLE 139-1 Differential Diagnosis of Scrotal Pain and Swelling

	Testicular Torsion	Appendiceal Torsion	Epididymitis
Age	All ages	Prepuberty	Prepuberty with UTI, adolescence
Onset	Abrupt or intermittent	1–3 days	1–3 days
Severity	Painful	Painful	Moderate pain
Other	Horizontal lie	Blue dot sign	Tender epididymis, testis normal

although some patients do report mild discomfort. Inability to reduce the hernia and severe pain are indications of incarceration and require emergency surgical consultation. Reducible hernias should be referred for elective surgical correction (see Chap. 80). Parents should be instructed to observe for signs of incarceration or strangulation while awaiting repair.⁵

Hydrocele

A hydrocele is a fluid-filled remnant of the processus vaginalis that surrounds the testis. Hydrocele is noted most often in infancy and is more prevalent in premature boys. By 12 to 18 months of age, the processus vaginalis obliterates, and the hydrocele resorbs. Persistence beyond 2 years of age usually requires surgical repair.⁶

It can be very difficult to differentiate hydrocele from hernia, and hydrocele also can coexist with hernia. The examiner must be able to palpate above the mass and palpate normal cord to exclude any associated hernia. Both hernias and hydroceles can be reduced or compressed, and both can transilluminate. Referral to a specialist is often needed to distinguish between the two and to exclude other causes such as lymph nodes, varicocele, spermatocele, epididymal cyst, or tumor.⁵

Varicocele

Varicocele is a painless scrotal swelling that is due to dilatation and elongation of the veins of the pampiniform plexus. Varicocele is more common on the left side because the left spermatic vein drains into the left renal vein, whereas the right one drains into the inferior vena cava. The examination should be performed in the erect position. Varicocele presents as a vermiform mass of dilated veins superior and posterior to the testis. The mass tends to increase in size with the Valsalva maneuver. Right-sided varicocele or any varicocele at a young age should prompt a search for pelvic or abdominal pathology. If left untreated, testicular atrophy may occur. Urologic referral for surgical repair is necessary if the varicocele is painful, bilateral, or of significant size. Uncomplicated varicocele requires no surgery.⁷

Disorders of the Foreskin

PHIMOSIS Phimosis is a condition in which the foreskin cannot be retracted over the glans penis. In congenital (physiologic) phimosis, males have a tight foreskin with the inner prepuce adhered to the glans penis at birth. This phimosis resolves spontaneously but may remain present for several years. Most physiologic phimosis resolves by 3 to 5 years of age such that the glans can be fully exposed. Acquired phimosis is a condition in which a previously retractable foreskin is no longer retractable. Acquired phimosis occurs as a result of poor hygiene, poorly performed circumcision, repetitive forceful retraction of the foreskin, or balanitis, which leads to scar formation and formation of tight opening of the foreskin.⁸ Phimosis (congenital or acquired) is not a reason for circumcision as long as there is no urinary obstruction, pain, or hematuria, only reassurance and proper hygiene are recommended. One of the few indications for treatment is persistent ballooning of the foreskin during voiding. Daily cleaning without forceful retraction of the foreskin is the only treatment necessary for phimosis. Some studies have demonstrated success with topical steroid cream for acquired phimosis. Many parents seek medical attention for their sons who have been circumcised in the newborn period and have a secondary phimosis. The treatment is revision of the circumcision under general anesthesia. Referral to a pediatric urologist also is warranted if there is any urinary obstruction, pain, recurrent infection, or hematuria.¹

PARAPHIMOSIS Paraphimosis is a true urologic emergency. Paraphimosis is the inability to bring the foreskin back over the glans pe-

nis once the foreskin has been retracted. If the foreskin remains retracted for a prolonged time, it may form a constricting ring that will cause venous congestion, with progressive swelling of the glans penis and foreskin. Arterial occlusion secondary to edema and swelling can lead to gangrene of the glans penis. Paraphimosis occurs only in uncircumcised or partially circumcised males and occurs most commonly after forceful retraction of the foreskin without timely reduction, such as after urethral catheterization or penile examination. Poor hygiene may predispose to acquired phimosis, which can lead to paraphimosis from tight fibrotic tissue.⁹

Patients usually present with pain, erythema, and swelling of the shaft skin and glans penis. Partial or complete urinary retention may occur in infants and children. On examination, there is a constricting band just proximal to the glans penis. The rest of the penile shaft appears normal. Paraphimosis should be reduced as soon as possible with the aid of conscious sedation or penile block using lidocaine hydrochloride without epinephrine. The most common technique for foreskin reduction is to hold a gauze sponge with the index and third fingers of each hand proximal to the foreskin and use the thumbs to push the glans back into the foreskin. It may take a minute or two of constant pressure before the glans slips through the paraphimotic ring. Ice and pressure may help to reduce the swelling before reduction. If manual reduction is unsuccessful, emergent urologic consultation is necessary.³

Invasive procedures should be done by a urologist or pediatric surgeon but, if gangrene is imminent, must be done by the emergency physician. Options include a dorsal incision at the level of the constricting ring that will release the foreskin. Single or multiple punctures of the foreskin using a 21-gauge needle to drain some of the edema from the edematous foreskin followed by manual reduction is another commonly employed technique. Injection of hyaluronidase into the edematous foreskin is effective in decreasing the swelling and permits the foreskin to be reduced. Following emergency reduction, referral to a urologist is necessary for eventual circumcision to avoid recurrence of the condition.

BALANITIS/POSTHITIS Balanitis is an infection of the glans penis, and posthitis is an infection of the foreskin. Poor hygiene predisposes to these infections. *Candida albicans* can be causative in prepubertal children, and sexually transmitted organisms can be causative pathogens in sexually active adolescents or victims of sexual abuse. On examination, the foreskin, glans penis, or both are swollen, tender, and red. Management includes oral and topical antistaphylococcal/antistreptococcal antibiotics, warm baths, and good local hygiene.¹

Disorders of the Penile Shaft

PRIAPISM Priapism is a prolonged, frequently painful erection of the penis without any sexual stimulation or desire. Priapism is divided into low flow (ischemic) and high flow (arterial) based on the status of penile arterial blood flow. Low-flow priapism is more frequent than the high-flow type. *Low-flow priapism* is a true urologic emergency that requires rapid intervention to prevent long-term complications such as corporal fibrosis and erectile dysfunction. It results from decreased penile venous outflow. Common causes are sickle-cell disease (the most common etiology in children), tumor infiltration (leukemia), medications, illicit drugs (marijuana), and idiopathic. *High-flow priapism* is caused by increased arterial blood flow; it is usually caused by arterial-cavernosal shunt formation secondary to a groin or straddle injury. This type of priapism does not cause ischemia and therefore is not a true emergency condition because the patient is at low risk for permanent complications.¹⁰

Diagnosis and management depend largely on the patient's history and physical examination. Penile examination during the acute state is helpful in differentiating between the two types. Low-flow priapism

usually involves the corpus cavernosum but spares the glans and corpus spongiosum; therefore, the penile shaft will be painful and hard, while the glans penis is soft. In high-flow priapism, the whole penis is partially rigid and painless. Management is the same in both types of priapism. Urologic consultation should be initiated at the time of presentation. In sickle-cell priapism, the combination of hydration, pain control, and partial or complete exchange transfusion is successful in up to 80 percent of the patients. The aim of transfusion is to achieve a target hemoglobin S concentration of 30 percent or less. If supportive measures fail, aspiration of the corpus cavernosum followed by injection of phenylephrine or epinephrine may be effective.¹¹

HAIR TOURNIQUET Young boys occasionally present to the ED with acute strangulation injury of the penis. The causative agent is usually a hair or a thread. The child may present with a chief complaint of penile swelling, redness, or pain. Occasionally, the parents will report urinary retention or inconsolable crying in an infant or nonverbal child. The physician should perform a genital examination in the inconsolable infant. On physical examination, the physician often will find an edematous, erythematous, tender penis with a circumferential constriction. Often the hair or thread will not be visible, even with thorough examination. The extent of damage is directly related to the duration of strangulation. Complication includes urethrocuteaneous fistula and gangrene of the glans penis. Cutting the hair or applying a hair-removal agent such as Nair may relieve constriction. If this does not work or removal of the hair or the constricting agent is not certain, immediate urologic evaluation should be initiated.

ZIPPER INJURY The skin of the penis or scrotum can get caught in the movable part or between the teeth of a zipper. Gentle manipulation, after local infiltration with 1% lidocaine, is the most successful way to release the entrapment. Release of the skin can be achieved by cutting the median bar of the movable part of the zipper with a bone-cutting plier. If all procedures fail, removal under general anesthesia or circumcision by the urologist may be required.

MEATAL STENOSIS Meatal stenosis is a benign condition of circumcised boys, usually after toilet training. It is usually caused by frequent meatal inflammation from prolonged exposure to the moist environment of the diaper (ammoniacal dermatitis). Other etiologies include balanitis, recurrent catheterization, or complication of reconstructive surgery of the penis. The delicate meatal edge becomes adherent to itself in a side-to-side fashion secondary to inflammation and loss of the superficial epithelial lining. The adhesion usually occurs from the ventral side toward the dorsal side. Boys usually complain of difficulty controlling urinary stream, burning, or blood spotting in the underwear. Patient may demonstrate a prolonged voiding time during observation. There is a characteristic dorsal deflection of the stream due to a ventral lip of scar tissue as a result of fusion of the meatal edges. Treatment is urethral meatotomy by a pediatric urologist.^{1,8}

GIRLS

Evaluation and examination of the female child with gynecologic complaints provokes anxiety in parents, patients, and physicians. The physician must understand the different anatomy and illnesses seen in prepubertal children as compared with adolescents (Table 139-2). Prepubertal females lack secondary sex characteristics, and the labial and vaginal tissue is thinner and more atrophic due to lack of estrogen stimulation. The age of menarche in North American females is 12.5 years, with a lower limit of 10 years of age.

A thorough history will determine the extent of the gynecologic examination. The child should be informed that the parent or caretaker approves the examination. The physician should explain everything that will happen during the examination and why the examination is necessary. The child needs to have as much control over the examina-

TABLE 139-2 Sexual Maturity Ratings (SMRs, Tanner Stages) in Girls

SMR Stages	Pubic Hair	Breast	Age, Years
I	None	None	
II	Sparse, slightly pigmented over mons or labia	Breast and papilla elevated, areola diameter increased	10-13
III	Dark, increased amount, coarse on mons	Breast and areola enlarged	12-14
IV	Adult in character confined to mons	Mounding of areola above plane of breast	12-14
V	Adult feminine triangle	Mature, nipple projects	14-17

tion as feasible. Forcible restraint is contraindicated. An examination under sedation or anesthesia is indicated for agitated or uncooperative patients whose symptoms require complete pelvic examination.

The parent or caretaker should be present during the physical examination. The physician should leave the room as the girl disrobes and prepares for the examination, giving the caretaker time to explain and comfort the child. The best position for examination of the external genitalia is the frog-legged position, where the child lies supine with the feet together and the knees spread apart. The vestibule and hymen can be visualized by gently pressing the labial pads downward and laterally. The patient can be examined in the caretaker's lap in the frog-legged position. The prone knee-chest position is another option that allows for good visualization of the lower half of the vaginal vault and the anal area. Magnification of the genitalia may be achieved with an otoscope with the eardrum removed or a culposcope, if available.¹²

Labial Adhesions

Labial adhesions are a midline fusion of the labia minora (Figure 139-1). Adhesions can occur secondary to labial irritation, abrasions, or trauma, following which epithelialization occurs. The etiology of the irritation may be irritants such as harsh soap, bubble bath, or diaper rash. Trauma of the labia minora from sexual abuse may predispose to adhesions. These adhesions may be thin or dense, partial or complete. Labial adhesions may be asymptomatic and only diagnosed on routine physical examination or may be observed by the caregiver. Rarely, urethral obstruction may occur, resulting in urinary tract infection or

FIG. 139-1. Labial adhesions. Agglutination and adhesion of the labia minora, as a result of healing after inflammation, produce the appearance of a smooth flat surface overlying the introitus, divided centrally by a thin lucent line. (Courtesy Dr. D. Lloyd.)

voiding symptoms.³ The adhesions usually resolve spontaneously during puberty. Management includes good hygiene and application of estrogen cream to the adhesion area twice a day for 2 to 3 weeks (reversible secondary sexual changes can occur as a side effect). Separation of the adhesions can be achieved by traction following the application of topical anesthetic or under general anesthesia if the child is uncooperative. After separation of the adhesions, lubrication of the vulva and good hygiene are advised to prevent recurrences.⁸

Precocious Puberty and Menarche

Precocious puberty is the appearance of physical signs of sexual development in children prior to age 9. It is usually idiopathic in origin but can be associated with endocrine or neurologic disorders.¹³ Specialist referral is needed. Premature menarche is cyclic vaginal bleeding in prepubertal girls in the absence of pubertal development. It is a diagnosis of exclusion after other serious causes of vaginal bleeding have been eliminated.

Ovarian Torsion

Ovarian torsion results from twisting of the ovary at its pedicle. An ovarian mass or cyst predisposes to ovarian torsion. Complete ovarian torsion compromises the vascular supply and, if untreated, will lead to ischemia and atrophy of the ovary. The child usually presents with lower abdominal pain, nausea, and vomiting. A tender pelvic mass may or may not be palpable. Diagnosis is difficult because of the non-specific symptoms and findings. Sonography may demonstrate an edematous ovary with prominent follicles. However, Doppler flow is not always absent in torsion. Patients with suspected ovarian torsion need urgent surgical evaluation.

Vaginal Obstruction

Vaginal obstruction can be due to imperforate hymen or transverse vaginal septum (Figure 139-2).¹⁴ Girls with vaginal obstruction may be missed until the age of menarche, at which time the symptoms of failure to menstruate, cyclic abdominal pain, abdominal mass, or urine retention develop. Imperforate hymen usually presents as a bulging, shiny, blue- to purple-colored mass seen at the genital area. The urethral meatus is distinct from the mass. Girls with imperforate hymen require evaluation for associated vaginal, urethral, anorectal, and spinal abnormalities. Transverse vaginal septa may occur in the lower, middle, or upper vagina. Most of the septa are in the upper vagina. Treatment is surgical repair.

Urethral Prolapse

Urethral prolapse occurs primarily in young African-American females. The mucosa of the distal urethra prolapses and forms a circular mass surrounding the urethral meatus. The child usually presents with blood spotting in the underwear, dysuria, obstructive voiding symptoms, or a mass. On physical examination, a doughnut-shaped mass that is usually friable and hyperemic protrudes from the urethral opening. The examiner should locate the vaginal opening posterior to the prolapsed urethra. Differential diagnosis includes periurethral abscess, prolapsed urethral polyp, ectopic ureter, prolapsed ectopic ureterocele, papilloma, condyloma accuminata, and sarcoma botryoides. Specialty referral is needed for proper diagnosis and treatment.³

Vaginal Foreign Bodies

Foreign bodies should be considered when a child presents with vaginal bleeding, foul-smelling discharge, or irritation. Symptoms may persist for long periods and usually are not resolved by antibiotics or proper hygiene unless the foreign body is removed. Toilet paper is the

FIG. 139-2. Imperforate hymen with neonatal hematocolpos. A dark purplish bulge at the introitus was noted by the mother during a diaper change.

most common foreign body in the prepubertal girl. Other objects, including toy parts, coin, erasers, beads, and nuts, have been reported. Examination of the girl in the knee-chest position is usually helpful to visualize the vaginal vault and possibly the foreign body. If the foreign body is observed, removal may be successful with a forceps, cotton-tipped swab, or gentle vaginal irrigation with warm NS. If all these methods fail, examination and removal under conscious sedation or anesthesia should be considered. The complications of retained foreign bodies include vaginitis, rectovaginal or vesicovaginal fistula formation, endometritis, or salpingitis.¹⁴

Vaginitis

Vaginitis is the most common cause of pruritus vulvae and vaginal bleeding in children. Prepubertal girls are prone to bacterial vaginitis because of their thin, atrophic, and more alkaline vaginal mucosa. Wiping from back to front after urination or a bowel movement, bubble baths, tight clothing, or perfumed soap can predispose to vaginitis. *Bacterial vulvovaginitis* frequently presents with copious yellow-green vaginal discharge, pruritus, bleeding, or erythema.^{8,15} The most common bacteria are respiratory or enteric pathogens such as group A beta-hemolytic streptococci, *Haemophilus influenzae*, *Staphylococcus*

aureus, *Shigella*, and *E. coli*. *Gardnerella* and *Trichomonas* are rare in prepubertal girls because these pathogens prefer a more estrogenized vagina. Management is usually achieved by following proper hygiene and taking the appropriate antibiotics.¹⁶

Candida vaginitis is less common in prepubertal girls than in older females because of the alkaline pH of the vagina. Predisposing factors are depressed cellular immunity, poor perineal ventilation, recent antibiotic intake, diabetes mellitus, pregnancy, and the use of oral contraceptives. The patient usually presents with nonodorous discharge, pruritus, dysuria, and vulvar erythema. The classic thick, white, cheesy discharge is present in only a few patients. In young girls and infants, an erythematous perineal rash and satellite lesions are common. Inspection of the lower third of the vagina may reveal thick discharge and whitish plaques adherent to the vaginal mucosa. Microscopic examination of the discharge (see Chap. 108) usually confirms the presence of yeast buds or hyphae. In infants and young children, the topical application of antifungal medications such as clotrimazole (Lotrimin) or nystatin (Mycostatin) cream four times daily for 7 to 10 days is usually effective.¹⁷

Genital Trauma

Accidental genital trauma is commonly the result of falls, bicycle, or straddle injuries. Other sports-related injuries such as those common to water sports and horseback riding also can cause genital trauma. Sexual assault or abuse also should be in the differential diagnosis.¹⁸ The most common injuries are hematomas or lacerations of the labia majora. These injuries may be associated with injuries to the vagina, rectum, urethra, or perineum. Urethral injuries may cause urinary retention; the patient must be able to void before leaving the emergency department. In girls with penetrating trauma, the length of the penetrating object should be estimated to determine if it could penetrate the pelvic floor. Examination includes a careful evaluation of the urethra, external genitalia, vulva, vagina, and rectum. Patients with lesions that are actively bleeding, lacerations that extend beyond superficial layers, any rectal bleeding, positive stool guaiac examination, or hematomas need emergency evaluation by a gynecologist. Since the perineal/vulvar area is extremely vascular, lesions that continue to bleed also need gynecologic consultation. Small hematomas can be observed in the ED until the physician feels comfortable that the hematoma is not expanding. Discharge instructions include strict bed rest for 12 to 24 h (may ambulate for bathroom and meals).

Vaginal Bleeding

Vaginal bleeding is common in early puberty. The most common cause is irregular or delayed periods due to the lack of regular ovulation. These anovulatory periods are most common during the first 2 years after menarche. Stress, excessive weight loss, and intense exercise regimens can all cause abnormal menstrual bleeding. Pregnancy should be considered. Medications and systemic disorders such as hypothyroidism, hyperthyroidism, hyperprolactinemia, Cushing disease, liver disease, or renal failure may all lead to increased or irregular vaginal bleeding. Excessive bleeding since menarche should prompt an evaluation for coagulopathies such as von Willebrand disease, platelet abnormalities, or factor deficiencies. Polycystic ovary disease (PCO) is a common cause of vaginal bleeding due to increased unopposed estrogen. Patients with PCO display physical characteristics such as hirsutism, increased acne, and obesity. Other considerations include a vaginal foreign body, trauma, or vaginal neoplasms.

Dysfunctional Uterine Bleeding

The overwhelming majority (95 percent) of vaginal bleeding in adolescents is dysfunctional uterine bleeding (DUB). DUB is a diagnosis of exclusion, and the differential diagnosis includes all the causes of

vaginal bleeding mentioned earlier.^{19,20} The possibility of pregnancy always must be considered in pubertal children. For further discussion of DUB, refer to Chap. 101.

PEDIATRIC URINARY TRACT INFECTIONS

Michael F. Altieri Mary Camarca Thorn Mayer

EPIDEMIOLOGY

Urinary tract infections (UTIs) are an important cause of febrile illnesses in infants and children in the United States. UTI occurs in 4 to 7 percent of febrile infants.¹ Symptomatic UTIs occur in approximately 2 percent of children from 1 to 5 years of age and in up to 3 to 5 percent of school-aged girls.² Since the presenting signs and symptoms are often nonspecific, especially in younger infants, the index of suspicion of UTI should be high. The incidence of UTI varies greatly with age, gender, historical factors such as prematurity, and history of previous UTI. Proper initial evaluation, interpretation of laboratory data, treatment, and follow-up are essential to avoid renal scarring. The American Academy of Pediatrics recommendations for UTI are contained in this chapter.³

PATHOPHYSIOLOGY

In the neonatal period, UTI originates via hematogenous spread resulting in bacterial seeding of the renal parenchyma. After the neonatal

period, bacteria gain access to the urinary tract via perineal and periurethral colonization, with subsequent retrograde contamination of the lower urinary tract structures. Virulence of the pathogen, host immunity, and structural and functional aspects of the urinary tract all play important roles in the development of UTI. Much is known about structural and functional factors contributing to the risk of UTI. Congenital urinary tract anomalies, vesicoureteral reflux, and urolithiasis are associated with a higher incidence of UTI.³ⁿ⁶ However, it is now clear that pyelonephritis in the absence of vesicoureteral reflux is far more common than previously thought. Behavioral and functional factors, such as poor hygiene, voluntary urinary retention, and constipation, have been associated with increased risk of UTI.^{7,8}

There are several host factors that increase susceptibility to bacteriuria and UTI. These are listed in Table 140-1.

It has also recently been shown that circumcision in males decreases the rate of positive urine cultures. Therefore, circumcision could possibly be considered as part of UTI therapy.^{9,10}

Renal stones in children vary with geographic region. Stones are more common in Asia and the Middle East than in the United States, and are more often bladder stones. In the United States, stones are more common in the southeast and occur more frequently in white children with a relatively even incidence distribution between boys and girls. Stones are most often found in the renal pelvis and ureter. Stone formation is more common in children with congenital malformation of the urinary tract, chronic UTI, and metabolic disorders.¹¹ Although bacteriuria and UTI may complicate renal stones, sterile pyuria may also be found.¹² One study found UTI associated with 47 percent of patients with renal stones.¹³ Certain urease-producing bacteria, most commonly *Proteus*, may lead to stone formation (struvite stones). These stones are the result of crystallization of magnesium and phosphorus in an alkaline urine. Antibiotics alone are unsuccessful in treating struvite stones since the causative bacteria are encased within the stone.¹⁴ Treatment includes stone removal and subsequent urine sterilization with appropriate antibiotics.

CLINICAL FEATURES

Other than fever, few symptoms are consistently found in infants and children diagnosed with UTI. Neonates may present with jaundice, poor feeding, irritability, and lethargy. Older infants and young children commonly present with gastrointestinal complaints, such as abdominal pain, vomiting, and change in appetite. The classic signs of dysuria, urinary frequency, urgency, or hesitancy are more likely to be present in older children and adolescents. The clinical signs and symptoms of UTI also vary with the primary site of infection along the urinary tract. The symptoms of dysuria, frequency, and urgency are more often associated with lower tract (uncomplicated) infections, such as

cystitis and urethritis. More systemic symptoms, such as fever, chills, vomiting, and dehydration, suggest upper tract (complicated) infection. However, pyelonephritis often occurs in the absence of such symptoms. Since the signs and symptoms of UTI are nonspecific, the diagnosis should be considered in all febrile neonates and children. Furthermore, UTIs may be associated with bacteremia. Ginsburg and McCracken noted an inverse relationship between age and bacteremia in young infants: 31 percent in neonates, 21 percent in children aged 1 to 2 months, 14 percent in children aged 2 to 3 months, and 5.5 percent in children older than 3 months.¹⁰ Follow-up diagnostic studies are often needed to distinguish between lower and upper tract disease and to identify potential long-term sequelae.^{15,16}

DIAGNOSIS

Gram-negative enteric bacteria are the most commonly isolated organisms in UTI. While P-fimbriated *Escherichia coli* accounts for the vast majority of infections, *Klebsiella*, *Proteus*, and *Enterobacter* species are also important pathogens. *Enterococcus* species, *Staphylococcus aureus*, and group B streptococci are the most frequently isolated gram-positive organisms and are more likely to be causative organisms in the neonatal period. Coagulase-negative staphylococcal UTI occurs in teens and young adults. *Chlamydia trachomatis* infection of the urinary tract should be suspected in children and adolescents who present with microhematuria.¹⁷ The diagnosis of a urogenital chlamydial infection can be made by inoculating cell cultures with urethral smears or by utilizing polymerase chain reaction tests (PCR) for *Chlamydia*. Direct immunofluorescence testing can also be used. Adenovirus may cause acute cystitis, occurs more commonly in young boys, and is clinically indistinguishable in many cases from bacterial disease.

While urine culture is the gold standard for the diagnosis of UTIs in children, emergency physicians must rely on clinical data and urinalysis pending the results of urine culture to subsequently confirm the diagnosis.

With a child who is not toilet-trained, a specimen for urinalysis and culture should be obtained through catheterization or suprapubic sampling. Bagged urine specimens are not acceptable because of the high degree of contamination. Urine specimens from older children with voiding control should be obtained from a cleanly voided midstream clean catch. Parents should be instructed on the proper technique for avoiding contamination of specimens. Periurethral contamination of specimens can be avoided by having girls sit backward (facing the rear of the toilet). This position favors labial retraction and better exposure of the urethral meatus. Because bacterial contaminants grow rapidly at room temperature, a urine specimen that cannot be cultured immediately should be kept on ice or at a temperature of 4°C (39.2°F) until culturing can be accomplished.

Urine chemical test strips are screening tests for the detection of leukocyte esterase and urinary nitrites. Esterases are released into the urine after the breakdown of white blood cells, providing presumptive evidence of infection. Neonates and infants may have false-negative leukocyte esterase because their leukocyte response may be limited. Nitrates are converted to nitrites by gram-negative urinary pathogens, so infections from gram-positive organisms would be expected to provide negative test strips. **In most studies, the sensitivities of a positive test result for urinary leukocyte esterase or nitrite compared to a positive urine culture result are less than 50 percent, so a negative urine test strip does not rule out a UTI.** Hematuria, proteinuria, and pyuria are commonly associated with UTIs, but are nonspecific findings and can occur in the absence of infection.

Microscopic urinalysis improves diagnostic sensitivity and specificity. **The combined presence of pyuria (more than five white blood cells per high-power field) and bacteriuria on urine microanalysis improves the sensitivity to approximately 65 percent, with a positive predictive value of about 81 percent.**

Urine culture must be obtained in all cases in which UTI is suspected, regardless of the results of test strip or microscopic urinalysis. A guide to interpreting urine culture results based on the various methods of obtaining urine samples is contained in Table 140-2.

TREATMENT

Table 140-3 summarizes the approach to management of children with UTI. Inpatient management should be instituted for any child less than 3 months of age with a febrile UTI. Older infants and children who have significant dehydration or appear toxic; have urinary stents or other urinary foreign bodies or renal insufficiency; and those who are immunocompromised should be considered for inpatient management. In addition, if a child's compliance and follow-up are questionable, inpatient treatment should be considered.

Children older than 3 months with febrile UTIs who appear non-toxic and only mildly dehydrated and who do not have persistent vomiting may be rehydrated in the ED. These children may initially receive intravenous antibiotic therapy and may then be discharged home on a course of oral antibiotics. Prior to discharge, they should demonstrate adequate oral intake and retention of fluids and have arrangements made for follow-up care within 48 h. Specific antibiotics and their dosing for both inpatient and outpatient therapy are contained in Table 140-4, but therapy should be guided with an understanding of the antibiotic resistance patterns in the hospital and community. As noted in Table 140-4, there has been an increasing use of third-generation cephalosporins. There is now increasing development of bacterial resistance to third-generation cephalosporin drugs. Cefepime and other fourth-generation cephalosporins have remained active against these organisms. Cefepime has been shown to be very effective in children with UTIs from the age of 1 month upwards. It is administered at a dose of 50 mg/kg per dose IV q8 to 12h.¹⁸ Instructions should be given to the caregiver regarding the need for follow-up of culture results.

DIAGNOSTIC IMAGING

The most appropriate radiologic studies for the follow-up of children with UTIs have been debated,¹⁹ and various algorithms have been proposed.^{15,16,20} Although imaging studies for UTIs are rarely indicated as part of the diagnostic work-up in the ED (except in cases in which there is a palpable mass), it is important to arrange follow-up for all children with febrile UTIs. The following is a reasonable approach to diagnostic to diagnostic imaging. First, the goals of radiologic imaging are to (1) identify existing upper tract disease capable of causing cortical scarring so that appropriate antibiotic therapy can be instituted, (2) identify treatable lesions of the genitourinary system, and (3) guide an approach to prevent further renal scarring and subsequent impairment of renal function.

TABLE 140-2 Interpretation of Positive Urine Culture Results

Method of Collection Quantitative Culture: UTI Present	
Suprapubic aspiration	Growth of urinary pathogens in any number (exception of up to $2-3 \times 10^3$ coagulase-negative staphylococci)
Catheterization	Febrile infants or children with $>5 \times 10^4$ CFU/mL of single pathogen
Midstream clean void	Symptomatic patients with $>10^5$ CFU/mL of a single urinary pathogen
Midstream clean void	Asymptomatic patients with two specimens on different days with $>10^5$ CFU/mL of the same organism

Abbreviation: CFU = cell-forming units.

TABLE 140-3 Management of Urinary Tract Infections

Age Range and Clinical Status	Management
<3 months Febrile UTI	Hospitalize; IV antibiotics for 4–5 d with good clinical response, discharge when tolerating oral medication and diet; 10 d of therapeutic doses of medication and then suppressive medication
>3 months through adolescence Acute pyelonephritis, ill or dehydrated, or with comorbidities	Hospitalize; IV antibiotics until afebrile 24–36 h and able to take oral medication and fluids; discharge on 10-d course of oral medication If renal scarring on RCS, IV therapy may be extended to 7 d
>3 months through adolescence Acute pyelonephritis, but not ill or dehydrated, no comorbidities	IM or IV antibiotic; start oral medication at therapeutic doses after 12–18 h; contact physician after 24 h if unable to take oral medication or adequate fluids; contact physician at 48 h for adjustment in medication and to schedule F/U urine and imaging studies
Infancy to adolescence Acute cystitis	5–7 d of therapeutic doses of oral antibiotic for UTI; urinalysis and culture after 4–5 d Sitz baths and/or analgesia for symptomatic relief
Adolescence Acute cystitis	Single IM or IV dose of ceftriaxone or aminoglycoside; single oral dose of trimethoprim-sulfamethoxazole; 3-d oral regimen with trimethoprim-sulfamethoxazole or nitrofurantoin; F/U urinalysis and culture after 4–5 d

Abbreviations: F/U = follow-up; RCS = renal cortical scan.

Source: Adapted from Hellerstein,²⁰ with permission.

In the past, indications for imaging of pediatric patients with UTI included neonates, females with recurrent UTI (two or more episodes), and males of any age with UTI. However, one of the recent recommendations from the AAP Committee on Quality Improvement Subcommittee on Urinary Tract Infection states that:

infants and young children two months to two years of age with UTI who do not demonstrate the expected clinical response within two days of antimicrobial therapy should undergo ultrasonography promptly and either voiding cystoureterogram (VCUG) or radionuclide cystography (RNC) should be performed at the earliest convenient time. Infants and young children who have the expected response to antimicrobials should have a sonogram and either VCUG or RNC performed at the earliest convenient time.

Acutely febrile and/or toxic children with UTI as the documented or presumed source of fever should have a renal cortical scan (RCS) to assess for renal involvement. If renal scarring and/or active infection is present, the patient should have intravenous antibiotic therapy extended by 7 to 10 days to reduce scarring and eliminate infection. If the RCS results are negative, males should have a voiding cystourethrogram (VCUG) and females an isotope cystogram (IC) to assess for vesicoureteral reflux. In afebrile children, the VCUG for males and IC for females should initially be assessed, followed by RCS if the results are positive. Renal sonography may be done at the time of RCS, VCUG, or IC to assess for dilatation of the collection system, although its utility has recently been questioned.

While such radiologic imaging is not necessarily coordinated by the ED, it is important for emergency physicians to be aware of the necessity of follow-up and the reasons for imaging so that it can be coordinated with the patient's inpatient physician or primary care provider.

TABLE 140-4 Common Antimicrobial Drugs Used in Pediatric Urinary Tract Infections

Drug	Dosage and Interval
Parenteral Therapy	100 mg/kg per d q12h (<1 week) q6-8h(>1 week)
Ampicillin	
Ceftriaxone	75 mg/kg per d
Cefotaxime	150 mg/kg per dq6-8h
Gentamicin	5 mg/kg per d q12h (<1 week) 7.5 mg/kg per d q8h (>1 week)
Cefepime	150 mg/kg per dq8-12h
Oral Therapy	20-40 mg/kg per d q8h
Amoxicillin	
Augmentin (amoxicillin-elavulanate)	50 mg/kg per d q8h
Trimethoprim-sulfamethoxazole (TMP-SMX)	8-12 mg/kg per d TMP, 30-60 mg/kg per d SMX q12h
Cephalexin	25-50 mg/kg per d q6h
Cefixime	8 mg/kg per dq12h

INFECTIOUS DISEASES

SEXUALLY TRANSMITTED DISEASES Joel Kravitz Susan B. Promes

Sexually transmitted diseases (STDs) are encountered commonly in ED and urgent care settings. About 50 million people in the United States are infected with genital herpes simplex virus (HSV), an estimated 600,000 gonococcal infections are diagnosed each year, and up to 4 million cases of chlamydial infection were estimated to be diagnosed in the United States in 1993.¹

Infection with some of the STDs discussed in this chapter increase the likelihood of acquiring HIV and/or hepatitis B, and these disorders are discussed in Chaps. 144 and 86, respectively. Thus diagnosis of an STD suggests the need for HIV and hepatitis counseling and testing.

Diagnosis and treatment of the STDs consists of three principles: protecting the health and future fertility of the patient, protecting the health of the patient's sexual contacts, and providing a "gateway" into the health care system for future screening and education with an emphasis on prevention. Prevention methods for STDs include male latex condoms, female condoms, contraceptive sponges, and diaphragms.² Vaginal spermicides are not protective against gonorrhea, chlamydia, or HIV.² *The Morbidity and Mortality Weekly Report* (<http://www.cdc.gov/mmwr/>) of the Centers for Disease Control and Prevention (CDC) is an excellent source of updates given the frequent changes in STD treatment guidelines and development of new antibiotics.²

DIAGNOSIS

The most important aspect of STD diagnosis is maintaining a high level of awareness. In one inner-city ED, half the patients with a urinary tract infection (UTI) had one or more positive STD cultures.³ The signs and symptoms of an STD may be obvious, such as a genital lesion or vaginal discharge, or less specific, such as dysuria or lower abdominal pain. Obtaining a thorough sexual history will help determine the risk of STD, HIV, or hepatitis and also will direct the extent of the physical examination and laboratory testing. Special populations with a high morbidity risk from STDs include pregnant women, sexually active adolescents, and homosexual men.² When evaluating for potential STDs, pregnancy status should be determined, and questions should be asked about sexual assault, domestic violence, and sexual practices.

Careful examination of the genital area, including a speculum examination in female patients, is important. In males, retracting the foreskin and carefully examining between skin folds, particularly in obese patients, is an important part of the physical examination. Vaginal or urethral cultures or polymerase chain reaction (PCR) assays for gonorrhea and chlamydia should be obtained. Viral and bacterial cultures for disorders such as HSV infection or lymphogranuloma venereum should be obtained if clinically indicated.

STDs Presenting with Urethritis, Cervicitis, and/or Discharge

CHLAMYDIAL INFECTIONS *Chlamydia trachomatis* is one of the causes of nongonococcal urethritis. It commonly coexists with gonorrhea infection. The prevalence of chlamydial infection ranges from

3 to 5 percent in the general population to 15 to 20 percent among individuals attending STD clinics.^{1,4} In men, chlamydial infection is often asymptomatic but can cause urethritis, epididymitis, proctitis, or Reiter's syndrome (urethritis, conjunctivitis, and rash). In women, mild, asymptomatic cervicitis is the most common presentation. Symptoms, when present, usually include vaginal discharge and dysuria. The discharge may be mucopurulent when *Neisseria gonorrhoeae* is a coinfectant. Urethral chlamydial infection should be considered in the differential diagnosis of sterile pyuria. Complications in women include pelvic inflammatory disease (PID) and infertility.

Diagnosis The yield from culture is low. Indirect detection methods such as direct immunofluorescence, enzyme-linked immunosorbent assays (ELISAs), and DNA probes are available. The sensitivity range for all of them is 70 to 95 percent.² The CDC has recommended that a nucleic acid amplification test (NAAT) such as Amplicor, Abbot LCx, BD ProbeTEC, or Gen-Probe APTIMA be used as a screening tool for *C. trachomatis* infections due to their high sensitivity.⁵

Treatment Treatment is with azithromycin 1 g PO in a single dose or doxycycline 100 mg PO bid for 7 days. Both regimens are equally efficacious.² Table 141-1 lists alternative treatment options. Sexual partners should be referred for testing and treatment if there has been sexual contact in the last 60 days. In pregnant women, azithromycin is safe, and cultures should be repeated 3 weeks later. To minimize transmission, patients should be counseled to avoid sexual contact for 7 days, regardless of 1- or 7-day treatment regimens.

GONOCOCCAL INFECTIONS *N. gonorrhoeae* is a gram-negative diplococcus. Like its frequent coinfectant, *C. trachomatis*, asymptomatic gonococcal infection is believed to be the most common presentation, particularly in women. Subclinical gonorrheal infections coupled with poor detection methods yield complications ranging from ectopic pregnancy (9 percent) to chronic pelvic pain (20 percent) to acute PID (10 to 40 percent).¹⁻⁴⁶ Women tend to present with non-specific lower abdominal discomfort and mucopurulent cervicitis after a 7- to 14-day incubation period. In contrast, 80 to 90 percent of men develop symptoms within 2 weeks. Dysuria and purulent penile discharge are the most common presenting symptoms for men, but presentations also can include acute epididymitis and prostatitis. Rectal infection with micropurulent anal discharge and pain occurs in 30 to 50 percent of women with gonococcal cervicitis and can be the only site of infection in homosexual men. *N. gonorrhoeae* also can be isolated from the pharynx but rarely causes pharyngitis. Disseminated gonococcal infection occurs in approximately 2 percent of untreated primary gonorrhea. Disseminated gonococcemia is characterized by petechial or pustular acral skin lesions on an erythematous base (50-70 percent), asymmetric arthralgias, tenosynovitis or septic arthritis (30-40 percent), and fever or general malaise (80 percent).

Diagnosis Cervical or urethral culture on a selective medium is the standard for diagnosis, having a sensitivity of 80 to 90 percent. If the transport and storage conditions are not conducive to maintaining the viability of the endocervical or urethral swab specimen, the CDC recommends that a NAAT be performed on endocervical or urethral swab specimens or a NAAT be performed on the urine as a screening tool for gonorrhea infections.⁵ A Gram stain of a urethral smear showing intracellular gram-negative diplococci is sensitive and specific in men but much less useful in women. Diagnosis of disseminated gonococcal infection is more difficult, with only 20 to 50 percent of blood, lesion,

TABLE 141-1 Antimicrobial Therapy for STDs

Disease	First-Line Treatment	Alternate(s)
Chlamydia	Azithromycin 1 g PO single dose <i>or</i> Doxycycline 100 mg PO bid X 7 d	Erythromycin 500 mg PO qid X 7 d <i>or</i> Ofloxacin 300 mg PO bid X 7 d <i>or</i> Levofloxacin 500 mg PO qd X 7 d
Gonorrhea	Cefixime 400 mg PO single dose <i>or</i> Ceftriaxone 125 mg IM single dose <i>or</i> Ciprofloxacin 500 mg PO single dose <i>or</i> Ofloxacin 400 mg PO single dose <i>or</i> Levofloxacin 250 mg PO single dose	Spectinomycin 2 g IM single dose <i>or</i> Norfloxacin 800 mg PO single dose <i>or</i> Gatifloxacin 400 mg PO single dose
Trichomoniasis	Metronidazole 2 g PO single dose	Metronidazole 500 mg PO bid X 7 d
Bacterial vaginosis	Metronidazole 500 mg PO bid X 7 d <i>or</i> Metronidazole vaginal gel 0.75% qd for 5 d	Clindamycin 2% cream intravaginally qhs X 7 d
Syphilis (primary, secondary, early tertiary)	Benzathine penicillin G 2.4 million units IM in a single dose	Doxycycline 100 mg PO bid X 14 d
Syphilis (latent, tertiary)	Benzathine penicillin G 2.4 million units IM weekly X 3 weeks	
HSV (primary)	Acyclovir 200 mg PO 5 times a day X 7-10 d Acyclovir 400 mg PO tid X 7-10 d <i>or</i> Famciclovir 250 mg PO tid X 7-10 d <i>or</i> Valacyclovir 1 g PO bid X 7-10 d	
HSV (recurrent)	Acyclovir 400 mg PO tid X 5 d <i>or</i> Famciclovir 125 mg PO bid X 5 d <i>or</i> Valacyclovir 500 mg PO bid X 5 d	Acyclovir 800 mg PO bid X 5 days <i>or</i> Valacyclovir 1 g PO qd X 5 days
Chancroid	Azithromycin 1 g PO single dose <i>or</i> Ceftriaxone 250 mg IM single dose <i>or</i> Ciprofloxacin 500 mg PO bid X 3 d	Erythromycin base 500 mg PO qid X 7 d
Lymphogranuloma venereum	Doxycycline 100 mg PO bid X 3 weeks	Erythromycin base 500 mg PO qid X 3 weeks
Donovanosis	Doxycycline 100 mg PO bid X 3 weeks <i>or</i> TMP-SMX DS PO bid X 3 weeks	Ciprofloxacin 750 mg PO bid X 3 weeks <i>or</i> Azithromycin 1 g PO weekly X 3 weeks <i>or</i> Erythromycin base 500 mg PO qid X 3 weeks

and joint cultures being positive. Obtaining cervical, rectal, and pharyngeal samples may improve the chance of a culture-proven diagnosis.

Treatment Ceftriaxone 125 mg IM, cefixime 400 mg PO, ciprofloxacin 500 mg PO, ofloxacin 400 mg PO, or levofloxacin 250 mg PO, all in single doses, are all acceptable treatments (see Table 141-1). Patients also should be treated for presumed chlamydial infection. Although penicillin may be effective, over the years some strains of *N. gonorrhoeae* have grown resistant to this antibiotic. Areas of Asia and the West Coast of the United States (i.e., California and Hawaii) are seeing an emergence of quinolone-resistant *N. gonorrhoeae* (QRNG).²⁷ The CDC currently recommends avoiding quinolones for infections that may have been acquired in Asia, the Pacific, or California.² Pregnant women should be treated with a cephalosporin or, if allergic, 2 g spectinomycin IM in a single dose. Instructions to sexual contacts are the same as with chlamydial infections. PID or disseminated disease is usually treated with higher doses of ceftriaxone. Gonococcemia requires hospitalization for antibiotics (cefotaxime 1 g q8h, levofloxacin 500 mg

PO daily) and evaluation for possible endocarditis and meningitis. Patients with gonococcal arthritis also may require orthopedic surgical drainage and irrigation. Decisions to admit patients are based on their overall clinical picture as well as their ability to follow up on an outpatient basis.

NONGONOCOCCAL URETHRITIS (NGU) NGU is diagnosed when the *N. gonorrhoeae* diplococci are not seen on urethral smears. While the causative agent is most commonly *C. trachomatis* (30 to 50 percent), the prevalence of *Chlamydia* infection is lower in older men. Other agents include *Ureaplasma urealyticum* (20 to 25 percent), *Mycoplasma genitalum*, and *Trichomonas*, with 20 to 30 percent being idiopathic in etiology. Specific tests for *U. urealyticum* and *M. genitalum* are not indicated. Treatment is as for chlamydial infection.

TRICHOMONAL INFECTIONS *Trichomonas vaginalis* is a flagellated protozoan that causes urogenital infections in men and women. The World Health Organization (WHO) estimates that 180 million

cases occur annually worldwide. The prevalence is less than 1 percent in women overall but up to 15 percent in those attending STD clinics. Because of the organism's ability to phagocytize viral particles, *T. vaginalis* has been proposed to increase the host's susceptibility to viral infections such as HIV and HSV. Incubation ranges from 3 to 28 days. Disease is characterized most commonly by vulvar irritation and a malodorous, yellow-green discharge. Lower abdominal pain can be present occasionally. In men, the disease is often asymptomatic, but it can cause urethritis. In women, trichomoniasis in pregnancy has been associated with premature rupture of the membranes, preterm delivery, and low birth weight.

Diagnosis Microscopic examination of wet preparations of cervical smears or spun urine samples that reveal the classic motile parasites is diagnostic, although sensitivity is 60 to 70 percent. Culture is the most sensitive test available.

Treatment Metronidazole 2 g PO in a single dose is the usual treatment, or alternatively, 500 mg PO bid for 7 days. Avoidance of alcohol while on this treatment should be stressed because of the disulfiram-like reaction that can occur. Sexual partners should be treated due to the high likelihood of retransmission. Metronidazole gel is available, but treatment efficacy is less than 50 percent compared with oral preparations. With respect to pregnant patients, data do not indicate that treatment of asymptomatic infection prevents adverse outcomes; several studies, including a Medicaid cohort study, a large case-control study, and two meta-analyses, suggest that use of metronidazole in pregnancy has not demonstrated a consistent association with teratogenic or mutagenic effects above the baseline population rate.³ Oral metronidazole is still considered a class C drug by many sources, and many clinicians avoid oral treatment in the first trimester, although the CDC guidelines state that pregnant women may be treated with a single 2-g dose of metronidazole.

STDs with Genital Ulcers

Disorders characterized by genital ulcers are syphilis, herpes virus, chancroid, lymphogranuloma venereum, and granuloma inguinale. Characteristics of the lesions and their accompanying signs and symptoms are provided in Table 141-2.

SYPHILIS *Treponemapallidum*, a spirochete, is the causative agent of syphilis as well as yaws and pinta. The organism enters the body through mucous membranes or nonintact skin. It remains very sensi-

tive to penicillin; thus diagnosis rather than treatment is the main difficulty in controlling this disease. Unfortunately, the last 7 years has seen a marked increase in syphilis thought to be secondary to behavior associated with drug use.^{1,2,8}

Syphilis consists of three phases: primary, secondary, and tertiary or latent syphilis.

Primary. The initial stage of infection is characterized by a painless chancre with indurated borders on the penis, vulva, or other areas with sexual contact. The incubation period is about 21 days, with lesions then disappearing after 3 to 6 weeks. There are no constitutional symptoms, and a lesion may even be absent with primary disease.

Secondary. This stage, which occurs 3 to 6 weeks after the end of the primary stage, includes nonspecific symptoms such as sore throat, malaise, fever, and headaches. Rash and lymphadenopathy are the most common symptoms. The rash often starts on the trunk and flexor surfaces of the extremities, spreading to the palms and soles. It takes on many forms but is often dull red-pink and papular (resembling pityriasis rosacea). Like primary syphilis, secondary syphilis also resolves spontaneously.

Tertiary (latent). This syndrome is seen in about one-third of patients who have had latent secondary syphilis. Involvement of the nervous and cardiovascular systems is characteristic of this stage, which occurs 3 to 20 years after the initial infection. Granulomatous lesions (gummas) are widespread. Specific manifestations include meningitis, dementia, neuropathy (tabes dorsalis), and thoracic aneurysm.

Diagnosis Dark-field microscopy can identify treponemes in scrapings from primary lesions as well as from secondary lesions. Several serologic tests are also available, including nontreponemal tests (RPR, VDRL) and specific treponemal antibody tests (fluorescent treponemal antibody absorption, or FTA-ABS). Nontreponemal tests are positive about 14 days after the appearance of the chancre and falsely positive in 1 to 2 percent of the population. Nontreponemal antibodies can persist in some patients for years after treatment (the *serofast reaction*). FTA-ABS tests are slightly more sensitive and specific but more difficult to perform.

Treatment The treatment of primary and secondary syphilis is benzathine penicillin G 2.4 million units IM in a single dose. Doxycycline 100 mg PO bid for 2 weeks may be used for penicillin-allergic individuals. Treatment of tertiary or latent syphilis is 2.4 million units of benzathine penicillin G IM given 1 week apart for 3 weeks.

TABLE 141-2 Clinical Features of Genital Ulcers

Disease	Clinical Diagnosis	Painful Ulcers	Inguinal Adenopathy	Comment
Syphilis	Indurated, relatively clean base; heals spontaneously	No	Firm, rubbery nodes; tender	Primary (chancre); secondary (rash, mucocutaneous lesions, lymphadenopathy); tertiary (cardiac, ophthalmic, auditory, CNS lesions)
Herpes simplex infection	Multiple, small, grouped vesicles coalesce and form shallow ulcers; vulvovaginitis	Yes	Tender bilateral adenopathy	Cytologic detection insensitive; false-negative culture common; type-specific serologic test
Chancroid	Multiple, painful, irregular, purulent ulcers	Yes	Painful, suppurative, inguinal lymph nodes	Cofactor for HIV transmission; 10% have HSV or syphilis
Lymphogranuloma venereum	Small and shallow ulcer, associated proctocolitis with fistulas and strictures	No	Tender lymph nodes	Caused by <i>C. trachomatis</i> L1, L2, L3
Granuloma inguinale	Painless, beefy red, bleeding ulcers	No	No	Endemic in Africa, Australia, India, New Guinea; rare in U.S.

Source: Adapted from Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines—2002. *MMWR* 51(RR-6), 2002.

HERPES SIMPLEX INFECTIONS HSV type 1 or type 2 can cause genital herpes infections by infection of mucosal surfaces or nonintact skin. Many herpes infections are transmitted by those with undiagnosed or asymptomatic infections. Genital infections are caused more commonly by HSV type 2 (HSV-2).

Infections can be asymptomatic. When symptomatic, infections present as painful vesiculopustular lesions on an erythematous base. The painful lesions occur 7 to 10 days after contact with an infected individual, often preceded by 1 to 2 days of a tingling or burning sensation at the site. Primary infections sometimes can be associated with profuse, watery vaginal discharge. Lesions ulcerate after 3 to 5 days, at which time infectivity is at its highest. It is important to note that infections can be asymptomatic. Systemic symptoms are seen in 70 percent of primary infections and include fever and chills, headache, myalgias, and tender inguinal adenopathy. Dysuria is common and may progress to urinary retention secondary to severe pain. Complete healing usually occurs within 3 weeks, and viral shedding persists for 10 to 12 days after the onset of the rash. Recurrent infections due to the latent virus occur in 60 to 90 percent of patients. These are usually milder and of shorter duration, and systemic symptoms are less common.

Diagnosis Diagnosis of the classic lesions is often made on clinical grounds. A Tzanck smear may be taken of the lesions to demonstrate large intranuclear inclusions, although this is less sensitive than direct culture. Viral cultures can be done, but sensitivity drops as the lesions heal. PCR is available in some laboratories for detection of HSV in spinal fluid, but its role in genital herpes detection is not yet clear.

Treatment For a first clinical episode, treatment is with acyclovir 400 mg PO tid for 7 to 10 days, or acyclovir 200 mg PO five times a day for 7 to 10 days, or famciclovir 250 mg PO tid for 7 to 10 days, or valacyclovir 1 g PO bid for 7 to 10 days. Treatment duration can be extended if the lesions persist. For treatment of proctitis or oral infections, higher doses are used (acyclovir 400 mg five times a day for 7 to 10 days). Acyclovir at 5 to 10 mg/kg may be given IV every 8 h for 5 to 7 days to patients requiring hospitalization. Famciclovir and valacyclovir have high oral bioavailability. Episodic recurrent infection should be treated for 5 days with acyclovir 400 mg PO tid, or acyclovir 800 mg PO bid, or famciclovir 125 mg PO bid, or valacyclovir 500 mg PO bid. Effectiveness requires beginning treatment either at the onset of the prodrome or within 1 day of the onset of the lesions. Suppressive therapy is available for people with more than six episodes per year; this reduces but does not eliminate viral shedding.

CHANCROID *Haemophilus ducreyi* is a pleomorphic gram-negative bacillus that causes painful genital ulcers and lymphadenitis. Though more common in developing countries, it has seen a resurgence in recent years in the United States. Chancroid, when present, is a clue to search for other infections; 10 percent of infected patients in the United States are coinfecting with HSV or *T. pallidum* (this number is higher in developing countries), and chancroid is a cofactor for HIV transmission (more so than other ulcerative diseases, for as yet unknown reasons).

After an incubation period of 4 to 10 days, a papule, often painful, on an erythematous base appears at the site of infection. One to two days later, the lesion becomes eroded, ulcerated, and often pustular (not vesicular, like HSV). The ulcers are usually 1 to 2 cm in diameter with sharp, undermined margins and are very painful. The friable base of the ulcer is covered with yellow-gray necrotic exudates. Multiple lesions may be present in up to 50 percent of patients (more so in women), and "kissing lesions" (infection of adjacent skin areas due to autoinoculation) are seen. Half of patients develop acute, painful inguinal lymphadenopathy 1 to 2 weeks after primary infection. If untreated, the lymph nodes necrose and suppurate, leaving an abscess or perianitis involving the overlying skin and forming a bubo. Constitutional symptoms are rare with this STD.

Diagnosis Diagnosis can be made on clinical grounds, but other diseases (such as syphilis) need to be excluded. A swab of a lesion or pus from a suppurative lymph node (bubo) can be cultured but requires special media and is met with only limited success.

Treatment Azithromycin 1 g PO in a single dose, or ceftriaxone 250 mg IM in a single dose, or ciprofloxacin 500 mg PO bid for 3 days, or erythromycin base 500 mg PO qid for 7 days are all effective (see Table 141-2). Symptoms improve in about 3 days, and lesions are visibly improved within a week. Larger ulcers may require 2 to 3 weeks to heal. Partners should be treated if they have had sexual contact in the last 10 days, regardless of symptoms.

LYMPHOGRANULOMA VENEREUM (LGV) Specific serotypes of *C. trachomatis* cause this disease, known in other countries as *struma*, *tropical bubo*, or *Nicolas-Favre-Durand disease*. Although endemic in other parts of the world, LGV is seen only sporadically in the United States. The primary lesion can take on many forms and can be confused with other STDs (see Table 141-2).

The painless primary chancre is almost never noticed and lasts only 2 to 3 days. Generally, 1 to 3 weeks (rarely as long as 6 months) following the initial lesion, inguinal lymphadenopathy is noted. The lymphadenopathy is unilateral in 60 percent of patients. Often the overlying skin has a purplish hue. It progresses to suppurative lymphadenopathy, resulting in either spontaneous abscess rupture or firm inguinal masses. Scarring of these masses can give linear depressions parallel to the inguinal ligament, forming the so-called groove sign. LGV infections can have associated systemic symptoms of fever, chills, arthralgias, erythema nodosum, and rarely, meningoenitis.

Diagnosis Serologic tests and culture are the mainstays of diagnosis. Complement fixation titers for LGV greater than 1:64 are also consistent with LGV infection.

Treatment Doxycycline 100 mg PO bid for 21 days is the usual regimen. Bubo may require drainage. Mild untreated cases will resolve spontaneously in 8 to 12 weeks. Table 141-1 gives alternative treatments.

DONOVANOSIS Granuloma inguinale, also called *donovanosis*, is caused by *Calymmatobacterium granulomatis*, a gram-negative intracellular bacterium. It is rare in the United States but is endemic in India, southern Africa, and Pacific nations.

After a variable incubation period of 2 weeks to 6 months, donovanosis begins as subcutaneous nodules on the penis or labia/vulvar area. The nodules then progress to the more classic painless, ulcerative lesions that are highly vascular, explaining both the appearance (beefy red) and their tendency to bleed easily. There is no significant lymphadenopathy.

Diagnosis *C. granulomatis* is difficult to culture, and diagnosis often requires visualization of Donovan bodies on tissue biopsy.

Treatment Doxycycline 100 mg PO bid or TMP-SMX DS PO bid, both for 3 weeks, will stop progression of the lesions, although longer treatment may be needed to allow complete healing of the ulcers. Ciprofloxacin and azithromycin are alternatives.

GENITAL WARTS Human papillomaviruses (HPVs) are DNA viruses that cause genital warts by direct transmission. Visible genital warts generally are due to HPV type 6 or type 11, whereas other genotypes have been associated with the development of cervical cancer. The flesh-colored papules or cauliflower-like projections usually appear after an incubation period of 1 to 8 months and may coalesce to form condylomata acuminata. In women, they are seen on the external genitalia, are often painless, and often enlarge during pregnancy. In-

affected males often complain of nonhealing penile lesions, occasionally with pruritus and urethral discharge. Perianal condylomata have been seen in up to 80 percent of women with vulvar condylomata and are seen frequently in homosexual males.

Diagnosis PCR is the most sensitive method for detecting subclinical cases. Soaking of the genital area with dilute acetic acid for 3 min can differentiate between normal skin (shiny white) and areas of neoplasia (dull gray-white) to detect subclinical infections. For the most part, diagnosis is clinical, with care to exclude other STDs.

Treatment Treatment decisions are based on the size and number of lesions, the amount of discomfort they are causing, and patient preferences. Recommended treatment is podofilox 0.5% solution or gel applied with a cotton swab or a finger to the visible warts twice a day for 3 days, followed by 4 days of no therapy, with the cycle repeated up to four times. Also recommended is imiquimod 5% cream applied at bedtime three times a week for up to 16 weeks. The treatment area should be washed 6 to 10 h after treatment with imiquimod. Most patients experience a local inflammatory reaction after treatment. Cryotherapy or trichloroacetic acid (TCA) in a physician's office is used with failure of patient-applied methods.

STDs IN SPECIAL POPULATIONS

STD Treatment during Pregnancy

Pregnant patients with STDs should be referred to the physician providing their prenatal care. Penicillin, ceftriaxone, azithromycin, cefixime, metronidazole, and acyclovir are felt to be safe for use during pregnancy.

Sexual Assault Prophylaxis

Sexual assault is discussed in detail in Chap. 298, but a review of prophylactic regimens follows in this chapter as well.

Once all appropriate forensic investigations and cultures have been taken, prophylaxis in the form of single doses of ceftriaxone 125 mg IM, metronidazole 2 g PO, and azithromycin 1 g PO should be given, with adjustments as needed for allergy and pregnancy. Hepatitis B vaccination (and the subsequent complete three-shot course), without HBIG, should be given to those unimmunized. Postexposure therapy with zidovudine has shown a decreased risk for HIV infection in health care workers exposed to blood, but these studies cannot be extrapolated to the sexual assault patient. While the CDC does not endorse a particular recommendation on HIV prophylaxis, the decision should be made on a case-by-case basis. The assault survivor should be reevaluated in 72 h to further discuss this risk. Repeat evaluation for STDs should be done in 1 to 2 weeks to make sure that infection has been eradicated.

GENERAL RECOMMENDATIONS FOR STD TREATMENT AND FOLLOW-UP

When treating patients for STDs in the ED, it is important to remember that many STDs occur together, follow-up and compliance are poor, and lack of treatment can contribute to infertility. For these reasons, a standardized approach is suggested for patients with suspected STDs. This should include:

1. Treating even when an STD is only suspected, especially for gonorrhea and chlamydia, with emphasis on single-dose treatments that are administered in the ED
2. Ascertaining pregnancy status and consulting obstetrics if the patient is pregnant
3. Obtaining a serologic test for syphilis

4. Reporting appropriate diseases to the state health department
5. Providing counseling for STD prevention and HIV testing
6. Advising partner(s) to seek treatment
7. Arranging for appropriate follow-up
8. Documenting treatment, counseling, and follow-up on the medical record

TOXIC SHOCK SYNDROME AND STREPTOCOCCAL TOXIC SHOCK SYNDROME Shawna J. Perry Ashley E. Booth

TOXIC SHOCK SYNDROME

Toxic shock syndrome (TSS) is a severe, life-threatening syndrome characterized by high fever, profound hypotension, diffuse erythroderma, mucous membrane hyperemia, pharyngitis, diarrhea, and constitutional symptoms. It can progress rapidly to multisystem dysfunction with severe electrolyte disturbances, renal failure, and shock. It was first described in 1978 by Todd in seven children with *Staphylococcus aureus* infections. In 1981, however, a nationwide epidemic of TSS associated with extended tampon use was widely recognized among otherwise healthy young women.¹ The incidence of TSS has dropped precipitously over the past 20 years, with the majority of cases unrelated to menses and crossing all segments of society. A similar but more menacing TSS-like syndrome, streptococcal toxic shock syndrome (STSS), has emerged over the last decade. It is associated with invasive and noninvasive streptococcal infections and has a rapidly progressive course and a very high case-fatality rate.

The case definition for TSS by the Centers for Disease Control and Prevention (CDC) is given in Table 142-1. In the absence of a definitive laboratory marker, the strict application of the case definition is warranted but undoubtedly excludes the less severe (subclinical)

Epidemiology

CDC surveillance of TSS from 1979 through 1996 reported 5296 definite and probable cases (Figure 142-1). TSS was initially a disease of young, healthy, menstruating women; 50 percent of cases reported in 1986 and 1987 were found in this group. Tampon use increased the

TABLE 142-1 Case Definition of Toxic Shock Syndrome**An illness with the following clinical manifestations:**Fever: temperature $>102.0^{\circ}\text{F}$ ($>38.9^{\circ}\text{C}$)

Rash: diffuse macular erythroderma

Desquamation: 1-2 weeks after onset of illness, particularly on the palms and soles

Hypotension: systolic blood pressure ≤ 90 mm HG for adults or less than fifth percentile by age for children aged <16 years; orthostatic drop in diastolic blood pressure greater than or equal to 15 mm Hg from lying to sitting, orthostatic syncope, or orthostatic dizziness Multisystem involvement (three or more of the following) Gastrointestinal: vomiting or diarrhea at onset of illness Muscular: severe myalgia or creatine phosphokinase level at least twice the upper limit of normal

Mucous membrane: vaginal, oropharyngeal, or conjunctival hyperemia

Renal: blood urea nitrogen or creatinine at least twice the upper limit of normal for laboratory or urinary sediment with pyuria (greater than or equal to 5 leukocytes per high-power field) in the absence of urinary tract infection

Hepatic: total bilirubin, alanine aminotransferase enzyme, or aspartate aminotransferase enzyme levels at least twice the upper limit of normal for laboratory

Hematologic: platelets less than 100,000/mL Central nervous system: disorientation or alterations in consciousness without focal neurologic signs when fever and hypotension are absent

Laboratory criteria: negative results on the following tests, if obtained:Blood, throat, or cerebrospinal fluid cultures (blood culture may be positive for *Staphylococcus aureus*)Rise in titer to Rocky Mountain spotted fever, leptospirosis, or measles. **Case****classification:** Probable: a case in which five of the six clinical findings described above are present

Confirmed: a case in which all six of the clinical findings described above are present, including desquamation, unless the patient dies before desquamation occurs

risk of TSS in susceptible females 33 times. Only 135 cases of TSS were reported in the year 2000, of which 3 cases occurred in men and 2 fatalities were from menstrual-related cases of TSS (MRTSS).³ The decline in cases is presumably due to changes in the composition of tampons, general public awareness of the risks of tampon use, and increased medical awareness and detection. Tampons are now composed of cotton and rayon. Since 1990, the U.S. Food and Drug Administration (FDA) has required a limit on tampon absorbency into one of four ranges (junior, regular, super, and super-plus) corresponding to the level of flow. Tampons should be changed every 4 to 8 h, and patients with a history of MRTSS should not use tampons.

Although the use of contraceptive sponges and diaphragms places the individual at risk, occurring in 12 percent of non-menstrual-related TSS (NMTSS), their exact contribution to the development of TSS is unclear. The proportion of NMTSS cases has increased since 1980 primarily because of the decrease in the number of menstruation-related cases. The absolute number of cases of NMTSS has remained relatively constant, however, with 41 percent of TSS cases being NMTSS.³ There is an increasing incidence of NMTSS in males. Men constitute one-tenth of patients with TSS, with a mortality rate 3.3 times that of MRTSS in women. Nonsurgical skin lesions are associated most frequently with NMTSS in children 2 years of age or younger.

The means by which *S. aureus* enters the host in TSS are numerous and have been well documented in a wide variety of clinical settings. *S. aureus* has been isolated from the vaginas of 98 percent of women with TSS, compared with an 8 to 10 percent carrier rate in control subjects. It is presumed that women who develop menstrual TSS are colonized with *S. aureus* before the onset of menstruation. TSS also has been reported following influenza and influenza-like illnesses and is associated with a significant mortality rate (43 percent). Nasal packing (nasal tampons) is also associated with TSS, with 20 to 40 percent of the adult population carrying *S. aureus* in the nasal vestibule. The recent increase in body art and piercing has introduced another pathway for infection.⁴

Summary of Notifiable Diseases --- United States, 2000

TOXIC-SHOCK SYNDROME (TSS). Reported cases by quarter --- United States, 1985-2000

* Includes cases meeting the CDC definition for confirmed and probable cases of staphylococcal TSS. Data for 4th quarter 2000 are yet available.

In 2000, a total of 13 cases of staphylococcal TSS were reported to NCID. Of those cases, six persons (46%) had menstrual TSS as of July 11, 2001.

FIG. 142-1. Toxic shock syndrome by quarter in the United States, 1981-2000.

Pathophysiology

Most cases of TSS have been associated directly with colonization or infection with *S. aureus*. An exotoxin, toxic shock syndrome toxin (TSST-1), has been implicated as a significant factor in the production of symptoms associated with TSS either through direct toxic effects on the host or through stimulation of secondary mediators in response to TSST-1. The biologic properties of TSST-1 include the ability to (1) induce fever directly on the hypothalamus or indirectly via interleukin 1 (IL-1) and tumor necrosis factor (TNF) production, (2) promote T-lymphocyte "superantigenization" and overstimulation, (3) induce interferon production, (4) enhance delayed hypersensitivity, (5) suppress neutrophil migration and immunoglobulin secretion, and (6) enhance host susceptibility to endotoxins.

Ninety percent of MRTSS are caused by *S. aureus* strains that produce TSST-1, which is present in less than half of NMTSS cases. Enterotoxins B and C have been identified from isolates of NMTSS and have a biochemical structure almost identical to that of TSST-1. This explains the similarity in clinical manifestations of MRTSS and NMTSS. NMTSS may be mediated by unidentified precursors and toxins or by-products of TSST-1.⁵

The amount of TSST-1 produced by toxigenic strains of *S. aureus* in MRTSS is enhanced by certain vaginal conditions: temperature of 39 to 40°C (102.2-104°F), a neutral pH, a P_{O_2} of greater than 5 percent, and supplemental CO_2 . These conditions can be met with the change in vaginal pH from acidic to neutral during menses and an increase in O_2 and CO_2 content of the vagina with the introduction of tampons or intravaginal devices. Other influences include synthetic fibers in tampon composition and a synergistic relationship between *S. aureus* and *Escherichia coli*.⁶

The most impressive aspect of the pathophysiology is the massive vasodilatation and rapid movement of the serum proteins and fluids from the intravascular to the extravascular space. Hypotension is accounted for by (1) decreased vasomotor tone, causing pooling of blood in the periphery and decreasing venous return, (2) nonhydrostatic leakage of fluid into the interstitium, causing decreased intravascular volume and generalized nonpitting edema, primarily of the head and neck, (3) depressed cardiac function, including decreased wall motion and decreased shortening fraction, and (4) total-body water deficits secondary to vomiting, diarrhea, and fever.

Hypoalbuminemia, hypoferrinemia, and proteolysis caused by IL-1 are consistent with the peripheral edema, anemia, and rhabdomyolysis seen in TSS. TNF induces profound acidosis, shock, and multisystem organ failure in animal models similar to the effects of TSS. The multisystem organ failure may be a reflection of either a direct effect of the toxin on tissues or the rapid onset of hypotension and decreased perfusion. Low convalescent titers to TSST-1 and enterotoxins B and C are found in the majority of patients with TSS for up to 1 year after infection.⁵

Clinical Features

TSS should be considered in any unexplained febrile illness associated with erythroderma, hypotension, and diffuse organ pathology. Diagnostic criteria for TSS are listed in Table 142-1. Patients with MRTSS usually present between the third and fifth day of menses. The median time to onset of illness in postoperative NMTSS is 2 postoperative days. There appears to be a spectrum of severity of TSS. Mild cases of TSS may be excluded from the CDC case definition. *Mild TSS* generally is characterized by fever and chills, myalgias, abdominal pain, sore throat, nausea, vomiting, and diarrhea. Hypotension is usually not present, and the illness is self-limited. *Severe TSS* is an acute-onset multisystem disease with symptoms, signs, and laboratory abnormalities reflecting multiple-organ involvement. Headache is the most common complaint. Some patients may experience a prodrome consisting

of malaise, myalgias, headache, nausea, vomiting, and diarrhea. Sudden onset of fever and chills occurs approximately 1 to 4 days prior to presentation. Diffuse myalgias, particularly in the proximal aspects of the extremities, abdomen, and back, are reported by virtually all patients; arthralgias are also common. Profuse, watery diarrhea and repeated vomiting are reported by 90 to 98 percent of patients. Orthostatic light-headedness or syncope may be present. Patients may complain of sore throat, headache, paresthesias, photophobia, abdominal pain, or cough.

Physical examination reveals hypotension or an orthostatic decrease in systolic pressure of 15 mm Hg in all patients. In general, victims of TSS appear acutely ill. The initial state usually lasts about 24 to 48 h; the patient may be obtunded, "disoriented, oliguric, and hypotensive. There may be nonpitting edema of the face and extremities. Other prominent signs may include profound muscle weakness and tenderness or abdominal tenderness. Diarrhea is usually watery and profuse, frequently with associated incontinence. One-half to three-quarters of patients have pharyngitis, with a strawberry red tongue; conjunctival hyperemia and vaginitis are also seen. Tender, edematous external genitalia, diffuse vaginal hyperemia, "strawberry" cervix, scant purulent cervical discharge, and bilateral adnexal tenderness are seen in 25 to 35 percent of patients with MRTSS.

The rash of TSS is a diffuse, blanching erythroderma, classically described as painless "sunburn," that fades within 3 days of its appearance and is followed by full-thickness desquamation, especially of the palms and soles, during convalescence. This CDC criterion is missed most often because it may be subtle or difficult to detect in darkly pigmented patients. Variations include patchy erythroderma and localized maculopustular eruptions. In all cases, a fine, generalized desquamation of the skin, with peeling over the soles, fingers, toes, and palms, occurs from 6 to 14 days after the onset of illness. Most severely ill patients experience loss of hair and nails 2 to 3 months later.

Specific focal neurologic findings occur rarely. Patients present with varying degrees of altered consciousness. Approximately 75 percent of patients have nonfocal neurologic abnormalities without signs of meningeal irritation. Confusion, disorientation, agitation, hysteria, somnolence, and seizures have been reported, consistent with a toxic encephalopathy from cerebral edema. If the clinical picture is unclear, a computed tomographic (CT) scan and lumbar puncture should be performed. Figure 142-2 illustrates the temporal relationships of the major manifestations of TSS.

Abnormal laboratory values reflect the multisystem involvement in TSS. Leukocytosis, lymphocytopenia, and mild anemia with peripheral smears consistent with microangiopathic hemolytic anemia may be present. Azotemia, myoglobinuria, and abnormal urinary sediment (sterile pyuria and red blood cell casts) are seen as acute renal failure develops. Liver function abnormalities and hyperbilirubinemia are seen in approximately 3 percent of patients with clinical evidence of coagulopathy. Metabolic acidosis secondary to hypotension is also seen. Electrolyte abnormalities, including hypocalcemia, hypophosphatemia, hyponatremia, and hypokalemia, are common. Hypocalcemia is out of proportion to the degree of hypoalbuminemia and may be difficult to correct if there is a concomitant decrease in the serum magnesium level.

Acute renal failure secondary to acute tubular necrosis is a complication of TSS. It appears to be secondary to prerenal deficits, renal ischemia caused by hypotension, rhabdomyolysis, and possibly direct damage from TSST-1 mediators. Ventricular arrhythmias, bundle-branch block, first-degree heart block, and T-wave and ST-T-wave changes have been reported. Echocardiography of patients with TSS shows wall motion abnormalities and decreased shortening fraction, suggestive of toxic cardiomyopathy. Adult respiratory distress syndrome (ARDS) with refractory hypotension represents the ultimate end-organ damage secondary to TSS.

FIG. 142-2. Composite drawing of major systemic, skin, and mucous membrane manifestations of toxic shock syndrome. (From Chesney PJ, David JP, Purdy WK, et al: Clinical manifestations of toxic shock syndrome. *JAMA* 246:741, 1981, with permission.)

Differential Diagnosis

Other systemic illnesses characterized by fever, rash, diarrhea, myalgias, and multisystem involvement resemble TSS (Table 142-2). Kawasaki disease (see Chap. 135) is characterized by fever, conjunctival hyperemia, and erythema of the mucous membranes with desquamation. It is primarily a disease of children. Staphylococcal scalded-skin syndrome (SSSS; see Chap. 246) is seen most commonly in children younger than 5 years of age and is characterized by fever, generalized painful erythroderma, and conjunctivitis. Staphylococcal scarlet fever is so similar to TSS, with full-thickness desquamation, that only pathologic specimens or serologic evidence of the exfoliatin toxin will differentiate the two entities. In streptococcal scarlet fever, the "sandpaper" rash is distinct from the macular "sunburn" rash of TSS.

Rocky Mountain spotted fever (see Chaps. 135 and 248) has a presentation similar to that of TSS, but the rash is usually petechial and delayed in onset. Toxic epidermal necrolysis (see Chap. 246) resembles SSSS and occurs primarily in adults. Erythema multiforme (see Chap. 246) can be associated with fever, pharyngeal erythema, and toxemia. The rash is multiform, with symmetric involvement of the lower extremities.

Septic shock (see Chap. 32) always must be considered in the differential diagnosis of TSS. In general, the appearance of a rash and the laboratory abnormalities associated with TSS will aid in distinguishing these two entities.

TABLE 142-2 Differential Diagnosis of Toxic Shock Syndrome

Acute pyelonephritis	Acute viral syndrome
Septic shock	Leptospirosis
Acute rheumatic fever	Systemic lupus erythematosus
Streptococcal scarlet fever	Rocky Mountain spotted fever
Staphylococcal scarlet fever	Tick typhus
Staphylococcal scalded skin syndrome	Gastroenteritis
Legionnaire disease	Kawasaki disease
Pelvic inflammatory disease	Reye syndrome
Hemolytic uremic syndrome	Toxic epidermal necrolysis
	Erythema multiforme

Treatment

The most important aspect of initial treatment is the aggressive management of circulatory shock. Continuous monitoring of the heart rate, respiratory rate, blood pressure, oxygen saturation, urinary output, and central venous pressure is essential. Pulmonary capillary wedge pressure monitoring also may be needed in severe cases. During the first 24 h, patients may require 4 to 20 L of crystalloid and fresh-frozen plasma. There have been reports of patients requiring up to 20 L of fluid in the first 24 h of hospitalization. A dopamine infusion beginning at 5 to 20 $\mu\text{g}/\text{kg}$ per min may be used if volume correction fails to restore normal arterial pressure. Large amounts of IV fluid and pressors to treat refractory hypotension can result in the rapid onset of pulmonary edema. ARDS may then complicate TSS and require mechanical ventilation with positive end-expiratory pressure.

Evaluation must include arterial blood gas analysis, a complete blood count with peripheral smear, serum electrolyte determinations including magnesium and calcium, coagulation studies, urinalysis, and chest radiograph. Patients with abnormal coagulation profiles and evidence of bleeding require colloid replacement, fresh-frozen plasma, or transfusions. Thrombocytopenia may require platelet transfusions. An electrocardiogram and echocardiogram also may be indicated.

A focus of infection should be sought aggressively and treated promptly. Cultures of all potentially infected sites and blood should be obtained prior to initiating antibiotic therapy. Foreign bodies such as tampons or nasal packing should be removed. Early consultation with a surgeon or a gynecologist is recommended if drainage or debridement of infectious sites is warranted.

Although antimicrobial agents have not been shown to affect the outcome of the acute illness, they are recommended and are given to most patients to eradicate the focus of toxin-producing staphylococci as well as to decrease the recurrence rate. Antibiotic selection should include an antistaphylococcal penicillin or cephalosporin with 3-lactamase stability. Nafcillin or oxacillin in doses of 2 g IV every 4 h provides adequate antimicrobial coverage. Cefazolin 2 g IV every 6 h, also provides adequate coverage, but the first-generation cephalosporins are less P-lactamase-stable than the antistaphylococcal

penicillins. In penicillin-allergic patients, clindamycin, vancomycin, and first-generation cephalosporins can be used. Vancomycin may be used if methicillin-resistant strains are encountered. Although data on the optimal duration of antimicrobial therapy are not available, it seems prudent to administer parenteral antibiotics for at least 3 days or until the patient improves clinically. Oral antistaphylococcal antibiotics (dicloxacillin or clindamycin in penicillin-allergic patients) then should be administered for an additional 10 to 14 days. Methylprednisolone and IV immunoglobulin have shown improvement in some cases of TSS.^{7,8}

Most patients become afebrile and normotensive within 48 h of hospitalization. Initial laboratory abnormalities resolve within 1 to 2 weeks, although full anemia correction occurs in 4 to 6 weeks.

Numerous sequelae of TSS have been reported and include late onset of maculopapular rash, decreased renal function, reversible loss of hair and nails, prolonged neuromuscular abnormalities, and cyanotic extremities. Neurologic deficits are common, with 50 percent of patients exhibiting residual memory deficits, decreased ability to concentrate, and diffuse electroencephalographic abnormalities.

The mechanism responsible for these sequelae is not yet clear; it has been suggested that they are due to either the delayed effects of the toxin or circulating immune complexes or are drug-mediated.

Patients not treated with p-lactamase-stable antimicrobial drugs can have recurrence of the disease.⁷ Most recurrent episodes of MRTSS in women are seen by the second month following the initial episode and happen on the same day of menses as the prior attack, although some have recurred in less than 1 month and some more than 1 year later. In the majority of patients having recurrence, convalescent antibody titers are low and nonprotective. The initial episode is the most severe, although deaths have resulted from recurrences of initially mild cases of TSS.

STREPTOCOCCAL TOXIC SHOCK SYNDROME

The decline in the incidence of TSS in the late 1980s was followed closely by the emergence of an even more serious illness. Initially classified as streptococcal toxic shock-like syndromes (TSLs) by the CDC, a consensus definition was formulated in 1993. It was identical to the case definition for TSS except that TSLs develop in association with a severe soft tissue infection, and culture results from a normally sterile site must be positive for *Streptococcus pyogenes* [group A streptococcus (GAS)]. The current case definition, as published in 1997, is shown in Table 142-3.⁹

STSS is defined as any group A streptococcal infection associated with invasive soft tissue infection, the early onset of shock, and organ failure. Similar in presentation to TSS, STSS has a higher mortality rate, may occur in patients of all ages, and occurs in most countries of the world. Labeled the "flesh-eating bacteria," the most serious GAS soft tissue infections associated with STSS are streptococcal necrotizing fasciitis and streptococcal myositis.

STSS associated with GAS invasive infections, in contrast to previous reports of GAS bacteremia, most commonly affects individuals between the ages of 20 and 50 without predisposing illnesses.¹⁰ There is regional variability in the populations at risk for developing STSS and necrotizing fasciitis from GAS infections. Extremes of age, diabetes, alcoholism, drug abuse, treatment with nonsteroidal anti-inflammatory drugs (NSAIDs), and immunodeficiency appear to be risk factors for GAS invasive infections.^{11,13} STSS rarely develops from symptomatic pharyngitis.

It is estimated that in the United States each year there are 2000 to 3000 cases of STSS and 500 to 1500 cases of necrotizing fasciitis.⁹ The mortality rate is very high for STSS, at 30 to 80 percent.¹² In patients with STSS, 70 percent of the soft tissue infections progress to necrotizing fasciitis or myositis requiring surgical intervention. The morbidity rate of STSS is 65 to 80 percent with surgical intervention to control the infection.^{11,14} The mortality rate for streptococcal

TABLE 142-3 Case Definition of Streptococcal Toxic Shock Syndrome

An illness with the following clinical manifestations occurring within the first 48 h of hospitalization or, for a nosocomial case, within the first 48 h of illness:
Hypotension defined by a systolic blood pressure less than or equal to 90 mm Hg for adults or less than the fifth percentile by age for children aged less than 16 years
Multiorgan involvement characterized by two or more of the following:
Renal impairment: creatinine greater than or equal to 2 mg/dL (a 177 [x/L] for adults or greater than or equal to twice the upper limit of normal for age; in patients with preexisting renal disease, a greater than twofold elevation over the baseline level
Coagulopathy: platelets less than or equal to 100,000/mL (100 X 10 ⁶ /L) or disseminated intravascular coagulation, defined by prolonged clotting times, low fibrinogen level, and the presence of fibrin degradation products
Liver involvement: alanine aminotransferase, aspartate aminotransferase, or total bilirubin levels greater than or equal to twice the upper limit of normal for the patient's age; in patients with preexisting liver disease, a greater than twofold increase over the baseline level
Acute respiratory distress syndrome: defined by acute onset of diffuse pulmonary infiltrates and hypoxemia in the absence of cardiac failure or by evidence of diffuse capillary leak manifested by acute onset of generalized edema, or pleural or peritoneal effusions with hypoalbuminemia
A generalized erythematous macular rash that may desquamate
Soft tissue necrosis, including necrotizing fasciitis or myositis, or gangrene
Laboratory criteria for diagnosis
Isolation of group A streptococcus
Case classification
Probable: a case that meets the clinical case definition in the absence of another identified etiology for the illness and with isolation of group A streptococcus from a nonsterile site
Confirmed: a case that meets the clinical case definition and with isolation of group A streptococcus from a normally sterile site (e.g., blood or cerebrospinal fluid or, less commonly, joint, pleural, or pericardial fluid)

myositis is 85 to 100 percent, and up to 60 percent for necrotizing fasciitis even with aggressive treatment.^{12,13} The rate of recurrence is unknown.

Epidemiology

Although severe invasive infections caused by *S. pyogenes* (GAS) have been reported with increasing frequency during the past decade, it is not entirely clear whether these reports reflect an actual increase in the incidence of disease or increased awareness. The latter is likely due to the dramatic nature of the infections and the coining of the phrase "flesh-eating bacteria" by the tabloid press to describe invasive necrotizing infections caused by GAS. It is believed that there has been a true recent increase in the GAS virulence properties that may account for the changes in clinical diseases caused by GAS. Few population-based studies exist on its prevalence. Reports on the incidence range from 1 to 5 per 100,000.¹³ STSS may be underdiagnosed when associated with GAS invasive infections, since 90 percent of patients are in shock or develop shock within 4 to 6 h of admission. Prospective population-based surveillance studies from Canada from 1991 through 1995 demonstrated an incidence of STSS associated with necrotizing fasciitis of 13 to 46 percent.^{11,14} There also have been recent reports of TSLs caused by non-group A streptococcal infection, specifically groups B, C, and G. In 1998, a documented group B streptococcal necrotizing fasciitis and TSLs was reported in three patients with significant underlying disease; the authors postulated that group B streptococcus has acquired an increased ability to cause fasciitis and may be the cause of a new clinical syndrome in adults.^{15,17}

Pathophysiology

The resurgence of GAS invasive infections appears to be the result of the production of more virulent exotoxins from the M-type isolates of GAS. Streptococcal pyogenic exotoxins (SPEs) are produced by 90 percent of GAS isolates.¹⁷ Multiple exotoxins (SPEs A, B, C, F, G, H, I, and J) have been identified.⁸ SPE A, also known as the *scarlet fever toxin*, is the most powerful and most frequently found SPE in STSS. It has a molecular structure similar to that of enterotoxin B of NMTSS. The SPEs A and B display features similar to those of TSS-mediated exotoxins, including pyrogenicity, superactivation of T cells, and synthesis of TNF, IL-1, and IL-6.¹⁷ These powerful cytokines can induce severe acidosis, shock, and multisystem organ failure, as in TSS. The effects of the "superantigens" SPE A and SPE B are hypothesized to be similar to yet more profound than those of TSST-1, with greater induction of TNF, IL-1, IL-6, and other cytokines, thereby causing more severe signs and symptoms.¹⁷ The patients suspected of being most at risk for developing STSS are those without immunity to M-type 1 SPE A- or B-producing strains of GAS. SPE C has been found in fewer GAS isolates, and its role in STSS is not clear.

The portal of entry for streptococci include the vagina, pharynx, mucosa, and skin in 50 percent of cases of STSS but is not identifiable in most patients.¹³ Most commonly, infection begins at a site of minor local trauma, usually without disruption of the skin. Cases have developed from burns, lacerations, abrasions, hematomas, minor nonpenetrating muscle injuries, surgical and orthopedic procedures, and recent infections with varicella or influenza.^{12,13}

Clinical Features

Pain is the most common initial symptom of STSS, usually of abrupt onset, severe, and preceding local tenderness or physical findings.¹² Eighty percent of patients have signs of soft tissue infection; this progresses to necrotizing fasciitis or myositis in 70 percent of patients. Although most commonly affecting the extremities, the location of the pain may suggest an intra-abdominal process, such as peritonitis or pelvic inflammatory disease, or other conditions, such as pneumonia or pericarditis. Up to 20 percent of patients may experience a prodromal influenza-like episode including fever, chills, myalgias, and diarrhea. Fever is the most common early sign. Confusion is present in 55 percent of patients, and coma or combativeness also may occur. Other early signs and symptoms of STSS may include dizziness, diffuse rash, and abdominal pain. The initial diagnosis of STSS may be difficult, if not impossible, to distinguish from TSS. If necrotizing fasciitis is present, fever, severe pain, swelling, and redness at the site of the wound are seen. Myositis is an uncommon complication of invasive GAS infection with a very high fatality rate. The most common symptom is severe pain; swelling and erythema may be the only early physical findings. Muscle compartment syndromes may develop rapidly.

On physical examination, fever is the most common presenting sign, followed closely by shock. Shock is apparent at presentation or develops within 4 to 8 h of admission in virtually all patients with STSS. It may be refractory to treatment or require massive volume replacement. The development at the site of the soft tissue infection of vesicles and bullae with progression to violaceous or blue discoloration is considered an ominous sign of necrotizing fasciitis or myositis. ARDS develops in 55 percent of patients, usually following the onset of hypotension; intubation is required in the majority of cases. A diffuse erythematous rash is much less prevalent in STSS (10 percent), but if it does occur, there is desquamation.

Laboratory evaluation shows mild elevation in the white blood cell count (13,000/L) with a profound bandemia as high as 40 to 50 percent. Liver function test values may be two times normal; decreased platelet levels and disseminated intravascular coagulopathy may be seen. Renal dysfunction persists or progresses in all patients; dialysis is required commonly. Creatinine kinase levels become elevated if the

soft tissue infection becomes necrotizing. Blood cultures are positive for GAS in 60 percent of patients, and more than 90 percent of patients with STSS have positive tissue culture results with a known site of infection.¹¹ One recent report suggests that magnetic resonance imaging may be useful in the early diagnosis of GAS necrotizing fasciitis.¹⁸ Definitive diagnosis of STSS is made by positive GAS culture results from a normally sterile site in addition to the clinical and laboratory parameters defined in the case definition (see Table 142-3).

Diagnosis

The differential diagnosis is the same as for TSS (see Table 142-2) with the significant addition of invasive and noninvasive GAS infections, necrotizing fasciitis, myositis, and serious infections caused by *Clostridium perfringens*, *C. septicum*, and mixed organisms, such as anaerobic and aerobic bacteria. Although pain usually involves an extremity, symptoms also may suggest peritonitis, pelvic inflammatory disease, pneumonia, or pericarditis.

Treatment

The initial treatment of STSS is similar to that of TSS, with aggressive management of shock and early use of vasopressors (see "Treatment" under "Toxic Shock Syndrome"). Antibiotic therapy should be initiated immediately in the ED to treat STSS and the associated infection if present: intravenous penicillin G 24 million U/d in divided doses, and clindamycin 900 mg IV every 8 h.¹² Erythromycin 1.0 g IV every 6 h should be used in penicillin-allergic patients or the combination of ceftriaxone 2 g IV every 24 h and clindamycin 900 mg IV every 8 h. Intravenous immunoglobulins (IVIGs) have been observed to improve 30-day survival rates as an adjunctive therapy for patients with STSS, perhaps by neutralizing bacterial exotoxins associated with STSS.^{8,19} The recommended dose of IVIGs is 2 g/kg with a repeat dose in 48 h should the patient remain unstable. IgA deficiency is an absolute contraindication to the use of IVIGs.¹⁹

Although antibiotics are important, prompt and aggressive exploration and debridement of suspected deep-seated *S. pyogenes* infection sites are mandatory. If STSS is suspected, immediate surgical consultation is indicated because 70 percent of patients with STSS require debridement, fasciotomy, or amputation.

Disposition

All patients suspected of having STSS should be admitted to an intensive care unit with emergent surgical debridement if warranted. Early surgical consultation on these patients is needed.

twice with neuraminidase in this century (thus we have H1, H2, and H3 and N1 and N2). Antigenic shifts are responsible for the flu pandemics, such as in 1918.

Epidemiology

Flu occurs worldwide—in the winter months in the northern and southern hemispheres and sporadically year round in the tropics. In the United States, flu generally occurs from November to April. Droplets generated by coughing spread influenza. During epidemics, attack rates are in the 20 to 30 percent range and may be as high as 50 percent during pandemics.¹ The Centers for Disease Control and Prevention (CDC) and local health departments track influenza activity monthly. Influenza A attack rates are higher for children than for adults, but the disease carries a higher mortality rate in adults, especially the elderly. Influenza B produces a similar illness with high attack rates for children and lower attack rates for adults, probably because of preexisting immunity due to a lower rate of antigenic drift.

After exposure, the incubation period is usually about 2 days. Viral shedding (contagiousness) starts approximately 24 h before the onset of symptoms, rises to peak levels within 48 h, and then declines over the next 3 to 7 days. In young children, viral shedding is prolonged.

Pathophysiology

Following exposure, the virus enters the columnar cells of the respiratory tract epithelium. Host defenses include mucociliary clearance, nonspecific proteins, and if present, specific immunoglobulin A (IgA) molecules. The invaded epithelial cells release large numbers of virions before cell death; thus large numbers of virions are available for spread with respiratory secretions. Influenza viral particles are rarely found outside the respiratory tract.

Clinical Features

Classic flu symptoms include fever of 38.6° to 39.8°C (101°–103°F), with chills or rigor, headache, myalgia, and generalized malaise. Respiratory symptoms include dry cough, rhinorrhea, and sore throat, frequently with bilateral tender, enlarged cervical lymph nodes. The onset of symptoms typically is rapid and dramatic; many patients recall the exact time of onset. Ocular symptoms include eye pain, light sensitivity, tearing, and pain with lateral gaze. Myalgias and arthralgias, but not arthritis, are extremely common. The myalgias often affect back muscles in adults and calf muscles in children. Almost half of affected children have gastrointestinal symptoms, but these are unusual in adults. The elderly usually do not have classic symptoms and may have only fever, malaise, confusion, and nasal congestion.

The fever generally lasts 2 to 4 days, followed by rapid recovery from most of the systemic symptoms. Cough, fatigue, and occasionally depression may last for several weeks.

Diagnosis

Traditionally, diagnosis has been through the use of viral cultures or serologic tests, which do not yield results for several days. These tests are not useful in individual patients except to confirm diagnosis after recovery from acute illness, but they do provide useful epidemiologic data. Some studies have shown that a clinical diagnosis of flu during a known outbreak has an accuracy of approximately 85 percent,^{2,3} but bacteremia also should be considered in patients with rigor and myalgias. New rapid antigen tests are available that may change the approach to flulike illnesses. These tests enable rapid diagnosis and institution of antiviral agents and may decrease the empirical use of antibiotics. Commercially available tests require less than 1 h to perform and have sensitivities of 57 to 81 percent, with specificities of 93 to 100 percent.⁴

COMMON VIRAL INFECTIONS: INFLUENZAVIRUSES AND HERPESVIRUSES

Robert A. Brownstein

Viral illnesses are among the most common reasons for ED visits. Although some may be trivial, such as the common cold, others are life-threatening, and still others cause chronic diseases and contribute to the development of certain malignancies. Effective therapies for some viruses are now available, with more drugs and vaccines in development. Influenzaviruses and the herpesvirus family are discussed in this chapter.

INFLUENZA A AND B

Influenzaviruses are single-stranded RNA viruses of the orthomyxovirus family. There are three types—A, B, and C—as determined by their genetic material. Type C does not cause significant human disease and does not warrant further discussion. The virions have surface glycoproteins that contain either hemagglutinin or neuraminidase activity. Different subtypes of influenza (i.e., influenza A-H1N1 versus influenza A-H2N2) have large differences between the hemagglutinin (H) or neuraminidase (N) molecules, whereas different strains of the same subtype have minor differences in the H or N molecules.

Antigenic drift is caused by minor mutations in the RNA genome of either the H or N molecule causing a change in antigenicity. Influenza A has much more frequent drift than B, and H more than N, so that the H molecules of influenza A show virtually annual changes, accounting for decreased antigenicity and facilitating annual epidemics.

Antigenic shift occurs by genetic reassortment within a host infected by two different influenzaviruses, producing a new virus with little or no antigenic similarity to the old viruses. The population lacks immunity against the new virus but has high levels of immunity against the old virus, giving the new virus a competitive advantage. This type of shift has occurred three times with hemagglutinin and

Complications

The complications of acute influenza infection include primary influenza pneumonitis, secondary bacterial pneumonia, croup, exacerbation of chronic obstructive pulmonary disease, and Reye syndrome. Other rare complications include Guillain-Barre syndrome, myocarditis, and pericarditis.

Primary influenza pneumonitis occurs most commonly in those with preexisting cardiac or pulmonary disease, but in large outbreaks it has occurred in previously healthy adults. The initial symptoms are typical flulike symptoms with progression to cough and dyspnea. There is significant hypoxia. Radiologic findings are bilateral infiltrates similar to acute respiratory distress syndrome (ARDS). Bacterial cultures and Gram stains are negative, and antibiotics do not help. Treatment is primarily supportive. Most clinicians support the use of anti-influenza agents, but there are no good studies demonstrating efficacy. The mortality rate of influenza pneumonitis remains high.

Secondary pneumonia is similar clinically to pneumonia occurring without antecedent flu. This complication presents 1 to 2 weeks after the flu, with a brief well period in between. Secondary pneumonia is most common in the elderly and in those with diabetes mellitus or cardiopulmonary disease. Treatment is initially with broad-spectrum antibiotics and pulmonary support, with narrowing of antibiotic coverage when culture results become available.

Reye syndrome has been associated with influenza B and varicella-zoster infections and with the use of aspirin. It occurs primarily in children between the ages of 2 and 16 years and begins with vomiting and progresses to altered mental status or coma. There is hepatomegaly due to fatty infiltration of the liver. There are elevated levels of liver enzymes, elevated ammonia levels, and an elevated prothrombin time. Hypoglycemia is common. The case-fatality rate is from 10 to 40 percent. The American Academy of Pediatrics has recommended that aspirin not be used for fevers caused by influenza or varicella.⁵

Treatment

Amantadine and rimantadine are currently approved for the treatment of influenza A. Neither has activity against influenza B. For maximal effectiveness, both need to be started within 48 h of onset of symptoms and can reduce the duration of systemic symptoms by 1 to 2 days. The dose is 100 mg bid for 5 days for both drugs. Amantadine is cleared renally, and the dose needs to be adjusted in the elderly and in patients with renal insufficiency. The recommended dose for persons older than age 65 is 100 mg daily. Amantadine causes an increase in seizure activity in patients with a preexisting seizure disorder. Rimantadine is cleared hepatically, and a 50 percent dose reduction is recommended in patients with severe liver dysfunction. Rimantadine has a significantly lower incidence of central nervous system (CNS) side effects than does amantadine. Neither drug should be used during pregnancy. Both amantadine and rimantadine can be used in children older than 1 year of age, although only rimantadine is officially approved for prophylaxis in children. Amantadine costs approximately \$10 for a course of therapy versus about \$25 for a course of rimantadine in adults.

Oseltamivir and zanamivir (Tamiflu and Relenza) are neuraminidase inhibitors that are active against both influenza A and B. Both have been shown to reduce systemic symptoms of influenza if started in the first 48 h after onset of clinical illness. Both reduce the duration of illness by about 1 day. Zanamivir is an inhaled medicine, dosed twice a day for 5 days, for about \$55 for a course of treatment. Zanamivir can cause bronchospasm and should not be given to patients with underlying pulmonary disease. Oseltamivir is dosed at 75 mg twice a day PO for 5 days for around \$65. Nausea is reported frequently with oseltamivir and can be decreased by taking the drug with food.

Prophylaxis

The flu vaccine is formulated annually and contains two strains of influenza A and one of influenza B. It is 70 to 90 percent effective in preventing illness in those under age 65. For patients over age 65 and not in chronic care facilities, it is 30 to 70 percent effective in preventing hospitalizations due to flu and pneumonia. For those in chronic care facilities, it is 50 to 60 percent effective in preventing hospitalizations due to flu and pneumonia and approximately 80 percent effective in preventing excess deaths due to flu and pneumonia.⁶ The vaccine is recommended for all persons over age 65; for residents of chronic care facilities; for adults and children with chronic cardiopulmonary disease; for persons with diabetes mellitus and other chronic metabolic diseases, renal disease, or hemoglobinopathies; and for the immunosuppressed and health care workers. Children and teenagers who require aspirin therapy should be immunized because of the risk of Reye syndrome. Women who will be pregnant during flu season should be immunized. The vaccine is safe for pregnant and lactating women. A whole-virus vaccine is used in adults, whereas a split-virus vaccine is used in children younger than age 12. The only contraindication to immunization is known allergy to egg protein or other vaccine components.

All four anti-influenza medicines are effective in preventing flu, with efficacy rates of 75 to 90 percent when used at the same doses as for treatment but for a prolonged duration (zanamivir is not approved by the Food and Drug Administration for prophylaxis). Consideration should be given to instituting chemoprophylaxis in a chronic care facility where flu has been definitively diagnosed, regardless of vaccination status of patients, because there is added benefit for patients with both vaccine and chemoprophylaxis. The medicines should be given for at least 14 days and then until the outbreak has subsided for a full week. For those at high risk who cannot be vaccinated, a 6- to 8-week course of chemoprophylaxis during peak flu season is indicated. Postexposure prophylaxis consists of immunization followed by 14 days of chemoprophylaxis.

HERPESVIRUSES

The herpesviruses are a ubiquitous class of enveloped DNA viruses that cause an expanding list of human illness. The herpesviruses all have the ability to dwell in the host as a lifelong latent infection and may cause clinical disease at a time distant from the primary infection. Some have been shown to be carcinogenic. Each herpesvirus has distinguishing clinical characteristics and will be discussed individually. Human herpesviruses 6 and 7, which cause roseola, and human herpesvirus 8, implicated in Kaposi sarcoma, are not discussed in this chapter. As a class, the herpesviruses are transmitted by close contact, since they are unable to survive in the environment and are unable to penetrate intact skin. The varicella-zoster virus (VZV) can be spread via aerosolized particles as well as by close contact. Most transmission of the herpes simplex virus (HSV) and of Epstein-Barr virus (EBV) occurs during asymptomatic shedding. Viruses discussed below are HSV, VZV, EBV, and cytomegalovirus (CMV).

HERPES SIMPLEX VIRUSES 1 AND 2

Epidemiology

HSV has been found in all populations throughout the world. Transmission is via contact of infected secretions (saliva or genital) with mucous membranes or with open skin. There is serologic evidence of exposure to HSV-1 in most persons by the time of puberty, and the rates are higher among lower socioeconomic classes. HSV-2 is spread primarily sexually, and its rates are variable among different adult populations, depending on sexual behavior.

Pathophysiology

After exposure, the virus replicates locally in the epithelial cells, causing lysis of the infected cells and producing an inflammatory response. This response results in the characteristic rash of HS V, which is indistinguishable from the rash of VZV. The rash consists of small, thin-walled vesicles on an erythematous base. Continued replication results in viremia in immunocompromised hosts but rarely in normal hosts. Following primary infection, the virus becomes latent in a sensory nerve ganglion.

Clinical Features

ORAL HSV HSV-1 primarily causes oral lesions but may cause genital infection. HSV-2 causes identical lesions, primarily genital, but may cause oral lesions. The primary oral infection of HSV-1 is often mild or asymptomatic. In children under age 5, it may present as a pharyngitis or gingivostomatitis associated with fever and cervical lymphadenopathy. The lesions are distributed throughout the mouth, unlike the limited posterior involvement of herpangina. Admission of the young may be necessary due to poor oral intake and dehydration. In teenagers and young adults, there simply may be a posterior pharyngitis or tonsillitis. The primary lesions generally last 1 to 2 weeks. The diagnosis is largely clinical. Viral cultures take days to weeks to be performed and thus are of little use in an ED setting. The use of intravenous acyclovir at a dose of 5 mg/kg has been recommended for severe gingivostomatitis that requires admission and intravenous hydration.⁷ Oral acyclovir has been shown to shorten the duration of symptoms in children if begun within the first 72 h of symptoms. No treatment other than oral hygiene is required for mild or moderate disease.

Recurrent oral lesions occur in 60 to 90 percent of infected individuals, are usually milder, and generally occur on the lower lip at the outer vermilion border, but considerable variation exists, with individuals usually having recurrences at the same site as prior recurrences. The recurrences often are triggered by local trauma, sunburn, or stress. The outbreaks frequently are preceded by prodromal symptoms of local adenopathy and pain or tingling. The lesions usually follow the prodrome within the first 48 h and may last for up to 10 days, but they are usually crusted over by 48 h. Treatment of recurrent oral herpes labialis with oral acyclovir 400 mg five times per day in adults shortens duration of symptoms. Topical acyclovir is ineffective. Topical penciclovir applied every 2 h for 4 days shortens duration of symptoms.⁸ In patients with severe or frequent recurrences, prophylaxis with oral acyclovir can reduce outbreaks by 50 to 75 percent.⁷

GENITAL HSV HSV-1 and 2 cause identical genital infections, with HSV-2 causing the majority. These are also covered in Chap. 141 on sexually transmitted diseases. A few items of importance are presented here. Recurrent genital lesions carry a small threat of intrauterine infection in pregnant patients, as does primary genital HSV (1 or 2), and initiation of oral acyclovir and consultation with an obstetrician or perinatologist and follow-up within 72 h are recommended. Cesarean section is recommended for all women with active lesions present when labor commences, whether primary or recurrent.⁹ Primary lesions carry a higher risk of transmission to the neonate.¹⁰

OCULAR HSV HSV infections of the eye can lead to corneal blindness and usually are caused by HSV-1. An ulcerative keratitis is the most common manifestation. Herpetic vesicles can be seen on the conjunctiva or on the lid margin as a blepharitis. There is a regional adenopathy. Fluorescein staining may show a diagnostic dendritic ulceration of the cornea. Due to the threat of permanent vision loss, consultation with an ophthalmologist is mandatory, and antiviral therapy should be begun immediately. Superficial keratitis usually heals com-

pletely in several weeks. Recurrent ocular infections may involve the deeper structures, with a high risk of visual loss, and if deeper structures are involved, immediate consultation with an ophthalmologist and the administration of intravenous acyclovir are appropriate. Following acute treatment, long-term treatment with acyclovir can reduce recurrences of ocular HSV.¹¹

ENCEPHALITIS Herpes simplex encephalitis, which is usually caused by HSV-1, is rare but is one of the most common types of viral encephalitis. The mechanism of entry into the CNS is not known definitely but is believed to be along neural routes. The temporal lobes are the major targets. Temporal abnormalities seen by computed tomography (CT), magnetic resonance imaging (MRI), or electroencephalography increase the likelihood of HSV encephalitis if present. Clinically, there may be a preceding viral-like illness, or the onset may be sudden. There may be no cutaneous manifestation of an HSV infection. There may be headache, fever, and altered mental status, indicated by speech disturbances or focal seizures. Temporal lobe seizures may present as olfactory hallucinations. The cerebrospinal fluid (CSF) findings are nonspecific, showing an elevated white blood cell count with mononuclear predominance. Cultures usually are negative for HSV. Immediate diagnosis is not possible, and if a suspicion of HSV encephalitis exists, empirical treatment should be initiated as soon as possible. The test of choice for diagnosis is the CSF detection of HSV DNA by polymerase chain reaction (PCR). The sensitivity is 90 to 95 percent, with a specificity of greater than 95 percent.¹² The PCR results can be available in 8 to 12 h if it is done on site. There are reports of false-negative results early in the course of disease.¹³ The traditional "gold standard" for diagnosis has been a brain biopsy, with sensitivity and specificity of 96 and 99 percent, respectively; however, the biopsy method has a 3 percent surgical complication rate and a significant delay in obtaining the biopsy specimen and the results. For untreated persons, the mortality rate is close to 70 percent. Treatment should be initiated in the ED if the diagnosis is suspected. Treatment is with intravenous acyclovir at 10 mg/kg every 8 h.

BELL PALSY HSV may affect the peripheral branches of the cranial nerves. HSV-1 is a frequent cause of Bell palsy, which has been described classically as an idiopathic palsy of the peripheral branch of cranial nerve VII (CN VII). It occurs equally among men and women and occurs most frequently in the middle aged and has been reported in children. CN VII controls the facial muscles and the stapedius muscle, taste sensation of the anterior two-thirds of the tongue, and lacrimal gland secretory function. Clinical features include facial hemiplegia or hemiparesis, taste disturbance in greater than 50 percent of the patients, decreased blinking, variably dry eyes or increased tearing, jaw or face pain, and numbness of the face and/or neck in 60 percent of patients. The diagnosis is made by definite findings of peripheral nerve VII involvement and exclusion of other treatable causes. The motor control of the muscles of the forehead are from bilateral motor cortices to the CN VII motor nuclei, so central CN VII lesions spare the forehead but cause unilateral weakness of the lower face. A peripheral lesion results in paralysis of the forehead, along with the face. Attempting to close the eye on the affected side results in an upward gaze (Bell phenomenon). Paralysis of the stapedius muscle results in hyperacusis on the affected side.

Ruling out of other conditions is important in making the diagnosis. The results of a detailed examination of the cranial nerves should be normal except for the aforementioned findings associated with CN VII. The findings on examination of the ear, tympanic membrane, mastoid, and parotid gland should be normal in order to make a diagnosis of Bell palsy. A CN VII palsy in association with otitis media, mastoiditis, or parotitis is a potential ear, nose, and throat (ENT) emergency and should prompt immediate consultation. The presence of vesicles on the tympanic membrane or in the ear canal is diagnostic of

the Ramsay Hunt syndrome and is discussed in the section on VZV. A history of chronic ear infections, prior ear surgery or tumor, or recent head trauma excludes a diagnosis of Bell palsy. If the presentation and examination are consistent with Bell palsy, imaging of the CNS (CT or MRI) is not indicated, but if there are atypical features, recent trauma, or doubt, then imaging is recommended along with ENT consultation. The differential diagnosis includes stroke, tumor, atypical Guillain-Barre syndrome, and Lyme disease, especially if in endemic areas and if bilateral.

Treatment with prednisone for anti-inflammatory effect at 60 mg PO daily or 1 mg/kg per d for 5 days and then tapered over the next 5 days, along with acyclovir 400 mg five times per day for 10 days, has been recommended by some.¹⁴ Other groups have reviewed the data and found them to be inconclusive¹⁵ or trending toward favoring treatment, but without sufficient evidence to make recommendations.¹⁶ Follow-up is with either ENT or neurology as an outpatient. The prognosis is generally good for total recovery, but patients with total paralysis are at increased risk of long-term or permanent paralysis and should be seen in follow-up within 2 to 3 days, and patients with incomplete paralysis should be instructed to return if the weakness becomes total paralysis. Among patients with incomplete paralysis, 6 percent will have residual weakness at 1 year. Among the patients with complete paralysis, 84 percent had total or good recovery at 1 year, with 16 percent having poor to fair recovery.¹⁷

Eye care is important in preventing damage due to impaired blinking and decreased tearing. Artificial tears should be used frequently during the day at any sign of dryness or every 2 h. At night, a lubricating ointment with or without an eye patch should be used. Care of the eye is the most important therapeutic intervention that can be made by emergency physicians.

HERPETIC WHITLOW Herpetic whitlow is a primary or recurrent HSV infection of the finger. HSV-1 is seen in children who autoinoculate their fingers during an episode of oral herpes. HSV-1 is also seen in health care workers who are exposed to infected oral secretions. HSV-2 is more common among adults due to digital/genital contact in the community. The disease is usually limited to a single digit. Herpetic whitlow frequently is painful and accompanied by axillary adenopathy. Vesicles, which may be recognizable early in the course of the disease, coalesce and may appear to contain pus but actually contain necrotic epithelial cells causing the purulent appearance. Healing occurs spontaneously over 2 to 3 weeks if local wound care and pain control are used. Whitlow may be misdiagnosed as a paronychia and incised, which may delay healing or allow a secondary infection to occur. When incised, no purulent material will be expressed. For patients with frequent painful recurrences, suppressive therapy with acyclovir may be effective.⁷

IMMUNOCOMPROMISE Immunocompromised patients are at increased risk of disseminated or severe typical and atypical HSV disease, usually resulting from reactivation of latent virus. HSV infection in immunocompromised patients may cause esophagitis, proctitis, colitis, and pneumonitis, as well as encephalitis. Definitive diagnosis is difficult without a biopsy of the affected tissue because these patients generally all have latent HSV and frequently are shedding HSV in their secretions. Any evidence of disseminated or CNS disease mandates admission and intravenous acyclovir. The decision to admit or treat an immunocompromised patient with mucocutaneous HSV on an outpatient basis is based on severity of disease, reliability of the patient, and ability of the patient to stay hydrated. Each decision is made on a case-by-case basis, in conjunction with the patient's primary care provider. Additionally, patients with large areas of skin involvement by burns or eczema are at risk of severe or fatal HSV infection, although most commonly resolution will occur without treatment. Consultation and consideration for admission for these patients are recommended.

HERPES ZOSTER: CHICKENPOX

Epidemiology

Herpes zoster virus (VZV, human herpesvirus 3) is the cause of chickenpox as a primary infection, which may reactivate later in life as zoster (shingles). Prior to the use of the varicella vaccine, 90 percent of primary infection occurred among children 10 years of age or younger, with the majority of these in children younger than age 3. Only approximately 10 percent of individuals over age 15 remain susceptible to VZV. Chickenpox is endemic, occurring year round, but there are annual epidemics in late winter and early spring. After exposure, attack rates are close to 80 percent among susceptible household contacts. The route of spread is presumed to be respiratory. Patients are infectious for approximately 48 h before the appearance of the rash until the vesicles are crusted over.

Pathophysiology

After exposure, viral replication occurs at an unknown site, followed by a viremia. Viral replication in the skin results in degenerative changes in epithelial cells, leading to multinucleated giant cells in vesicles. The rash usually appears 14 to 15 days after exposure. The rash then fades, and the virus becomes latent in a dorsal root ganglion.

Clinical Features

Chickenpox in children is discussed in Chap. 135. Dermatologic features are similar in adults and children. However, the mortality rate among adults is about 15 times that in children, or 30 per 100,000. The disease process is more prolonged and severe in adults than in children. The most serious complications are encephalitis, cerebellar ataxia, and pneumonitis. The typical prodrome of 1 to 2 days of low-grade fever and malaise is followed by the appearance of clear vesicles with an erythematous base on the face and trunk. Vesicular fluid quickly becomes turbid due to the accumulation of cellular debris. As the lesions continue to age, they scab over. The rash spreads centripetally to involve the extremities. Over the next several days, new lesions appear in crops. A hallmark of chickenpox is the presence of lesions in various stages. Accompanying the rash is fever, malaise, pruritus, and anorexia. Varicella encephalitis is characterized by an altered level of consciousness, fever, vomiting, headaches, and seizures. Cerebellar ataxia is characterized by ataxia, vomiting, tremor, and altered speech, with complete resolution within a month. A serious potential complication in children is Reye syndrome, so even in adults, aspirin-containing products should be avoided. Varicella pneumonitis presents with cough, tachypnea, and dyspnea approximately 4 days after the onset of illness. Chest x-rays reveal a diffuse pneumonitis. Women in the second or third trimester of pregnancy are at higher risk of severe pneumonitis. Women in the immediate perinatal period are at increased risk of severe disease, as are neonates. Chickenpox during pregnancy can cause fetal anomalies.⁵

Treatment

Oral acyclovir is recommended for patients older than age 12 and those with chronic illnesses or on chronic salicylate therapy. For adults, the dosage of acyclovir is 800 mg PO qid for 5 days. For maximal benefit, acyclovir should be started within 24 h of development of the rash. All patients with varicella encephalitis or pneumonitis should be admitted for intravenous acyclovir. Treatment of pregnant or peripartum women who develop chickenpox should be discussed with an obstetrician or perinatologist because some physicians will elect to admit for intravenous acyclovir. Neonates who develop chickenpox or whose mothers develop postpartum chickenpox should be

admitted for intravenous acyclovir. Immunocompromised patients tend to have more severe disease and should be admitted for intravenous acyclovir.

Varicella-zoster immune globulin (VZIG) is available to confer passive immunity to exposed susceptible adults or immunocompromised children and pregnant women. VZIG also should be given to any neonate with chickenpox or whose mother developed chickenpox within 5 days before delivery or 48 h after delivery.⁵

Varicella vaccine is now recommended for children who are 1 year of age or older. It is also recommended for adults with either a reliable history of never having chickenpox or with serologic evidence of susceptibility. The vaccine is a live attenuated cell-free vaccine. Because it is a live vaccine, it is contraindicated in immunocompromised patients, household contacts of immunocompromised patients, and pregnant or lactating women.

HERPES ZOSTER: SHINGLES

Herpes zoster (shingles) is the reactivation of latent VZV infection. There is a lifetime incidence of almost 20 percent, with the majority of cases being among the elderly. It occurs only in people who have had chickenpox. After a single occurrence in an immunocompetent host, there is a 4 percent likelihood of a second occurrence.

The lesions of shingles are identical to those of chickenpox but are limited to a single dermatome in distribution. Thoracic and lumbar dermatomes are most common. The cranial nerves may be affected as well, with the potential complications of herpes zoster ophthalmicus (HZO) and Ramsay Hunt syndrome. What triggers the reactivation is unknown. The disease begins with a prodrome of pain in the affected area for 1 to 3 days, followed by the outbreak of a maculopapular rash that quickly progresses to a vesicular rash. The course of the disease is usually around 2 weeks, but it may persist for a full month.

HZO is due to involvement of the ophthalmic branch of CN V and is a vision-threatening condition. The Hutchinson sign (lesions on the tip of the nose) may be seen before ocular involvement is recognized, but its absence does not rule out HZO.¹⁸ Ocular involvement can be seen in the presence of only a slight rash on the forehead. HZO induces a keratitis and may be followed by involvement of deeper structures. There is usually facial pain, regional adenopathy, and occasionally, a red eye preceding the appearance of the rash. A dendriform corneal ulcer often can be identified with fluorescein staining. The presence of a skin rash helps differentiate HZO from ocular HSV. HZO or suspected HZO mandates an ophthalmologic consultation due to the threat to vision.

CN VII also can be affected. Involvement of the maxillary or mandibular branches can result in intraoral lesions. Involvement of the geniculate ganglion of CN VII results in Ramsay Hunt syndrome, which presents clinically as a facial palsy resembling Bell palsy with a unilateral motor weakness, loss of taste on the anterior two-thirds of the tongue, and vesicles in the ear canal or on the tympanic membrane (the only sites of CN VII cutaneous innervation). Ramsay Hunt syndrome also has been described as a cause of altered mental status in the elderly.¹⁹ This is treated in the same fashion as Bell palsy. Immunocompromised patients should be admitted for intravenous acyclovir.

The most common complication of shingles is postherpetic neuralgia (PHN). This is uncommon in younger patients but increases in frequency with age. The pain at times may be so severe as to be debilitating. Occasionally, the anterior horn cells become involved, causing a transient local weakness or paralysis, with these patients being particularly prone to severe pain. PHN occurs in 10 to 20 percent of all patients after an episode of acute zoster but in up to 70 percent of patients aged 70 years or older. It generally resolves in 1 to 2 months but may last greater than a year in some patients.

The treatment of zoster in the normal host is aimed at decreasing the risk of PHN, since the antivirals have a clinically small but statis-

tically significant effect on the duration of the acute disease. Treatment should begin as soon as possible and within 72 h of onset of disease for maximal benefit. The present literature shows that all three currently available antiherpes agents are more effective than placebo at reducing the duration of PHN but not at reducing its incidence.^{20,22} Corticosteroids have not been shown to be effective but have been shown to improve quality-of-life indices in affected elderly, and a 21-day taper beginning at 60 mg PO daily should be considered in patients older than age 50 if no contraindications exist.²³

Initial treatment of patients with PHN is typically systemic analgesia, often narcotics. Patients should be referred back to their primary care provider because first-line agents often fail, and a trial of amitriptyline or carbamazepine may be tried as second-line therapy.

Immunocompromised patients have an increased risk of disseminated disease. This can be recognized clinically by evidence of the rash involving more than a single dermatome or crossing the midline. Disseminated disease may occur in patients with skin lesions limited to a single dermatome. Patients with disseminated disease may develop pneumonitis, hepatitis, meningoencephalitis, or other organ system involvement and should be admitted for intravenous acyclovir. Immunocompromised patients with shingles without evidence of dissemination can be treated as outpatients with oral acyclovir at the standard dosing, with instructions to return if the rash spreads or if they develop respiratory symptoms, headaches, or other signs of organ system disease. Close follow-up with their primary care provider is recommended.

EPSTEIN-BARR VIRUS: INFECTIOUS MONONUCLEOSIS

Human herpesvirus 4, known as Epstein-Barr virus (EBV), is the primary cause of the infectious mononucleosis syndrome. EBV is found in humans throughout the world. Serologic testing reveals that 90 to 95 percent of the adult population has developed antibodies to EBV.²⁴ Approximately half the population will seroconvert as young children, with a second peak occurring during the teen and young-adult years.

EBV is spread by close contact between an individual shedding the virus and a susceptible individual. EBV is not able to survive outside the human host for any significant amount of time, and spread via fomites has not been demonstrated. Transmission among teenagers is often via the exchange of saliva during kissing. Adults may shed EBV asymptomatically for up to 18 months after clinical recovery, and EBV may be demonstrated in the throats of up to 20 percent of all adults. In immunocompromised persons, up to 50 percent may demonstrate EBV.

After infection, there is a 1- to 2-month incubation period during which viral replication occurs in B lymphocytes in the reticuloendothelial system. The presence of EBV induces the production of specific anti-EBV antibodies, as well as the production of the heterophil antibodies. Heterophil antibodies react with antigens on the red blood cells of sheep, horses, and cows. Heterophil antibodies are not specific for EBV and can be produced by infection with CMV or toxoplasmosis, as well as other infections. Heterophil antibodies are rarely produced in infants.

Following asymptomatic incubation, EBV can produce a wide array of illnesses. Classic infectious mononucleosis is manifested by fever, exudative pharyngitis, lymphadenopathy, splenomegaly, and an atypical lymphocytosis. Infants and young children frequently have asymptomatic infections. A prodrome of malaise, fatigue, and fever may be present for several days before the onset of the symptoms in classic mononucleosis. An elevated liver transaminase level is found uniformly in mononucleosis. Hepatomegaly and jaundice are unusual in children and young adults but common in older adults. A severe sore throat is a common presenting complaint, and the appearance may be of a severe bilateral exudative tonsillitis/pharyngitis. Bilateral tender cervical adenopathy is virtually universal. At some point in the

illness, approximately half of patients will have palpable splenomegaly. Splenomegaly is most prominent during week 2 of illness and then resolves over the next 1 to 2 weeks. The majority of patients have an uncomplicated course and recover fully. Chronic fatigue syndrome is not caused by EBV infection.

Generally, the treatment is supportive in the absence of complications. If ampicillin is given to a patient with EBV to treat a possible strep throat infection, there is an approximately 95 percent incidence of rash due to transient production of EB V-induced antibodies against ampicillin. Acyclovir has in vitro effects on EBV replication, but in vivo clinical studies have failed to show any clinically significant effect.²⁵

Complications of EBV infections are uncommon and usually do not result in long-term morbidity. The upper airway in approximately 3 percent of children may be obstructed by severe tonsillitis/pharyngitis. Management includes ENT consultation for airway control, if required. Prednisone 1 to 2 mg/kg per d should be given to patients with airway compromise. Humidified oxygen and a nasopharyngeal airway are also helpful. Tonsillectomy is usually not necessary and should be reserved for patients who fail to respond to conservative measures. If endotracheal intubation is required, a prolonged period of intubation should be anticipated due to the extent of edema.

The spleen may rupture spontaneously or secondary to minor trauma. The incidence of splenic rupture is believed to be 0.1 to 0.5 percent of patients with EBV. It occurs most commonly during week 2 or 3 of illness. Presenting complaints may be abdominal pain, left scapular pain, or hypotension. Abdominal pain is unusual in infectious mononucleosis and should prompt consideration of splenic rupture. Patients with EBV should be instructed to avoid contact sports and strenuous activity for 4 weeks following the onset of clinical disease. Patients with splenic rupture should be admitted to a surgical service.

Hematologic complications include autoimmune hemolytic anemia and thrombocytopenia. Corticosteroids will benefit some patients with hematologic complications and should be initiated in the ED for those admitted with severe anemia or severe thrombocytopenia. Refractory severe thrombocytopenia may be treated with splenectomy.

Neurologic complications of EBV are quite rare but may include encephalitis, meningitis, cranial nerve palsies, and the Guillain-Barre syndrome. The CSF usually contains atypical lymphocytes. Recovery is usually complete.

In immunocompromised patients, EBV may be a cause of B-cell lymphomas and other lymphoproliferative syndromes. EBV has been implicated as a causal agent in African Burkitt lymphoma and in nasopharyngeal carcinomas. Death may be caused by overwhelming EBV infection in patients with Duncan disease (an X-linked recessive disorder), which is clinically silent until EBV infection. Patients with HIV may develop hairy leukoplakia that will respond to acyclovir therapy.

The diagnosis of EBV is based on clinical findings and nonspecific laboratory tests. Confirmatory EBV-specific antibody testing is available, but same-day results generally are not available, so these tests have little value in the setting of the ED. The complete blood count is usually moderately elevated, with elevated percentages of lymphocytes and monocytes. Atypical lymphocytes usually are found and may be up to 30 percent of the white blood cells.

The heterophil antibodies are produced in 80 to 90 percent of patients older than age 4. More than 50 percent of children younger than age 4 will not have detectable heterophil antibodies.²⁶ Commercially available tests for heterophil antibodies (Monospot, Mono-plus, Mono-latex, and Mono-lex) have a sensitivity of 78 to 83 percent, with a specificity of 98 to 100 percent.²⁷ False-negative results may occur more frequently during the first week of illness. Patients with classic symptoms of infectious mononucleosis, atypical lymphocytes, and a positive heterophil antibody test generally require no further testing to

confirm the diagnosis. Patients with classic symptoms who have a negative heterophil antibody test should have repeat heterophil testing performed in a week, and if they are still negative, specific EBV antibody testing may be indicated. Viral capsid antigen (VCA) antibodies of the IgG and IgM classes are present in high titers during acute disease, with IgG persisting for life and IgM persisting for 4 to 8 weeks. The presence of IgM antibodies to VCA is a sensitive and specific indicator of acute EBV infection. Antibodies to Epstein-Barr nuclear antigen develop 4 to 6 weeks after the onset of clinical illness and persist for life; their presence is evidence against acute EBV infection. Other illnesses that may present with a similar clinical picture but with negative EBV tests include CMV mononucleosis, acute toxoplasmosis, primary HIV infection, and strep throat.

CYTOMEGALOVIRUS

Cytomegalovirus (CMV, or human herpesvirus 5) is another ubiquitous virus with worldwide distribution. It is, like the other members of the herpesvirus family, capable of causing a primary illness and then existing in a latent state in the human host indefinitely with the ability to reactivate at a later time. It is present in approximately 1 percent of newborns and in 40 to 100 percent of adults, depending on geographic location, socioeconomic status, attendance at day care, and sexual behavior. There are two peaks of seroconversion, the first in the perinatal period and the second during young adulthood, presumably related to sexual activity. CMV is not spread easily by casual contact but requires repeated or prolonged intimate contact for transmission. It is found in milk, saliva, urine, semen, and cervical secretions. CMV is also transmitted by blood transfusions containing viable leukocytes, as well as solid organs or bone marrow during transplantation.

CMV is one of the TORCH agents [toxoplasmosis, other (viruses), rubella, CMV, and herpes (simplex viruses)] and is capable of causing intrauterine infection. Fewer than 25 percent of neonates with intrauterine CMV will display symptoms. Those at highest risk are those whose mother acquires primary disease during the first half of the pregnancy. A seropositive mother's antibodies to CMV appear to provide the fetus some protection. Classic intrauterine CMV (congenital cytomegalic inclusion disease) involves multiple organs, including jaundice, hepatosplenomegaly, microcephaly, petechiae, and inner ear problems, as well as CNS defects. Children who are asymptomatic at birth still may have hearing loss that results in lower IQ scores and learning disabilities later in life.

In contrast to intrauterine infection, perinatal infection (presumably acquired from the cervix of the mother during birth or from breast milk) is usually asymptomatic and has no long-term consequences.

In healthy immunocompetent children and adults, CMV infection is also usually asymptomatic. When CMV does cause disease in this setting, it is typically an illness resembling EBV infectious mononucleosis. Typical presenting complaints include fever, chills, myalgia, and headache. Clinical features include a prolonged fever (1-5 weeks), an atypical lymphocytosis, lymphadenopathy, splenomegaly, and mild elevations of the liver transaminase levels. Pharyngitis and tonsillitis usually are not present. There are rarely complications or long-term health consequences. The diagnosis of CMV mononucleosis should be considered in individuals who have a mononucleosis-type illness but are heterophil-antibody negative. The complications of CMV in immunocompetent patients include the Guillain-Barre syndrome, viral pneumonitis, hepatitis, hemolytic anemia, and thrombocytopenia.

In patients with HIV, CMV can cause illness with significant morbidity. Symptomatic infections generally do not occur in patients who are simply HIV-positive, but they do occur in those with more advanced disease, such as AIDS-related complex (ARC) or AIDS. The most common illness is CMV retinitis, which occurs in more than 10 percent of AIDS patients. Typical complaints are of floaters or decreased vision. Careful funduscopic examination may reveal characteristic retinal hemorrhages and exudates. Progression to blindness

will occur without chronic suppressive therapy with intravenous ganciclovir or foscarnet. CMV may cause gastrointestinal disease as either esophagitis or colitis. Additionally, CMV can cause an adrenalitis resulting in adrenal insufficiency.

CMV causes significant morbidity and mortality in transplant patients. It can infect numerous different organs, causing colitis, hepatitis, pneumonia, and CNS disease. The most serious infection is CMV pneumonia, which is most common in recipients of bone marrow transplants. The CMV seen in transplant patients may represent primary infection after exposure from the transplanted tissue or transfused blood products or reactivation of latent infection. The primary infections tend to be more severe. CMV infections occur 4 to 8 weeks after transplantation typically, and CMV should be included in the differential diagnosis for patients presenting with a febrile illness within the first 3 months after transplantation. CMV also may contribute to rejection of the transplanted organ.

The diagnosis of CMV is difficult because most people are seropositive. The presence of IgM antibodies is helpful but not very sensitive or specific because of false-negative results during some acute infections and their persistence beyond acute infection in others. To make a definitive diagnosis based on serologies, a conversion from seronegative to seropositive or an acute rise in antibody titer should be seen, and this will require samples from before the illness and during the illness. Another method of diagnosis is by viral culture, which, using the "shell" method, takes only 48 h. Children can shed virus in their urine and respiratory secretions for extended periods following infection, but in healthy adults, virus usually is not shed in the urine or respiratory tract except during acute illness. Healthy adults may shed virus in semen and cervical secretions. In immunocompromised individuals, a biopsy of the organ suspected to be infected with CMV is the preferred method of diagnosis because of the prevalence of false-positive cultures in immunocompromised patients. Biopsy specimens of infected organs will show characteristic CMV inclusion bodies. In the ED, definitive diagnosis is not available, and suspicion of CMV should be based on clinical grounds such as presentation and time from transplantation. A review of transplant records may yield clues, such as the recipient and donor CMV status prior to transplantation. The disposition of the patient depends on the clinical setting, not on the diagnosis of CMV, and should be discussed with the patient's primary care provider.

CMV is treated with either ganciclovir or foscarnet. Ganciclovir is approved for therapy of CMV retinitis in AIDS patients and for prevention of CMV in transplant patients. It is also used for treating CMV infections in other organ systems. In AIDS-associated CMV retinitis, ganciclovir is given initially at higher doses for 2 to 3 weeks, followed by lifetime suppressive therapy. For other CMV infections, ganciclovir is given for a period of 2 to 3 weeks and then stopped. Foscarnet is used for resistant CMV infections or for patients unable to take ganciclovir. Neither medication cures patients of CMV but instead suppresses the acute disease process.

HIV INFECTION AND AIDS

Richard E. Rothman
Catherine A. Marco
Gabor D. Kelen

Patients with HIV present at various stages of infection, with a wide spectrum of illnesses involving virtually every organ system.

EPIDEMIOLOGY

As of December 2001, approximately 21.8 million individuals have died from HIV-related illnesses throughout the world, and an estimated 40 million people are living with HIV/AIDS. The epidemic has disproportionately affected the poorest countries due to lack of resources for implementing effective preventive programs and inadequate access to therapies known to delay progression of HIV-related diseases. HIV prevalence is greatest in sub-Saharan Africa with 28.5 million people infected. The epidemic is fastest growing in central Asia and eastern Europe, with 250,000 new infections reported in 2001. The Joint United Nations Program on AIDS (UNAIDS) predicts that by 2020, HIV will be responsible for more than one-third of all infectious disease-related deaths worldwide.¹

In the United States, the Centers for Disease Control and Prevention (CDC) estimate that 900,000 people are currently living with HIV and that approximately 40,000 new HIV infections occur each year. As of June 2001, 460,000 deaths from HIV/AIDS have been reported.² Although mortality from HIV infection dropped by more than 70 percent from 1996 to 1999 (largely attributable to highly active antiretroviral therapy), rates of decline have slowed more recently. Factors likely responsible for this slowing include delayed test seeking in certain populations, limited access to health care, and limitations of new therapies.

Risk factors associated with HIV infection include homosexuality or bisexuality, injection drug use, heterosexual exposure, receipt of a blood transfusion prior to 1985, and vertical and horizontal maternal-neonatal transmission. Changes in the distribution of AIDS cases in adults/adolescents by mechanism of transmission since the start the HIV epidemic are shown in Table 144-1.³ In homosexual and bisexual men, rates of newly acquired HIV, HIV progression to AIDS, and AIDS-related deaths have all declined (largely due to access to antiretroviral therapy and, in part, to effective prevention strategies). Similarly, substantial declines in perinatal transmission have occurred, primarily attributable to increased use of zidovudine (AZT) in pregnant women. Meanwhile, rates of new HIV infection have continued to rise among young, disadvantaged minority populations (many of whom

TABLE 144-1 Trends in Distribution of AIDS Cases by Mechanism of Transmission in Adults/Adolescents (% Cases Shown)

Primary Risk Factors*	1985	1990	1995	2000	Cumulative Total
Male homosexual contact	78	58	42	32	46
IDU	15	23	26	20	25
Male homosexuality + IDU Heterosexual contact	0	6 6	5 11	4 16	6 11
Transfusion recipient	1	2	1	1	1
Hemophilia/coagulation disorder	1	6	1	0	1
Other/no risk reported!	5	6	15	27	9

*Perinatal transmission not included here.

[†]Primarily refers to persons whose mode of exposure was not reported and who have not been followed up to determine their mode of exposure and a smaller number of persons who are not reported with one of the exposures listed above after follow-up; includes 34 persons who were exposed to HIV-infected blood or body fluids in health care, laboratory, or household settings.

Abbreviation: IDU = injection drug use.

Source: Modified from CDC HIV/AIDS Surveillance Reports (1985-present).

use the ED for both primary and emergency care). During the past several years, the highest percentages of increase in reported AIDS cases have occurred among women and minority populations. These changes are principally due to an increase in HIV prevalence among injection drug users and their women partners. AIDS remains the leading cause of death among black males aged 25 to 44 and is the third leading cause of death among black women of the same age group.

Increasing use of ED services by HIV-infected persons is due in part to changes in the demographic distribution of HIV cases and AIDS-related illnesses. Seroprevalence studies in one inner-city ED reflect these trends, with rates of HIV infection among unselected adult patients rising from 6 to 11.4 percent over a 4-year period.⁴

PATHOPHYSIOLOGY

HIV is a cytopathic retrovirus of the lentivirus family that kills infected cells. The virus is extremely labile and is neutralized easily by heat and common disinfecting agents such as 50% ethanol, 35% isopropyl alcohol, 0.3% hydrogen peroxide, Lysol, or a 1:10 solution of household bleach. There are two major subtypes of HIV, HIV-1 and HIV-2. HIV-1 is the predominant subtype worldwide and is the cause of AIDS. HIV-2 causes a similar immune syndrome but is restricted primarily to western Africa and seen rarely in the United States.

The HIV virion is composed of a central RNA molecule and a reverse-transcriptase protein surrounded by a core protein encased by a lipid-bilayer envelope. Following infection, HIV selectively attacks host cells involved in immune function, primarily CD4⁺ T-cell counts. Within the host cell, HIV-encoded RNA is reverse-transcribed into DNA by the enzyme reverse transcriptase. The viral genome then becomes permanently integrated into the host's genome, where it may lie dormant or be actively transcribed and translated to produce virally encoded proteins and new HIV virions. As a result of infection, immunologic abnormalities eventually occur, including lymphopenia, qualitative CD4⁺ T-cell function defects, and autoimmune phenomena. Profound defects in cellular immunity ultimately result in a variety of opportunistic infections and neoplasms.

HIV has been isolated from saliva, urine, cerebrospinal fluid (CSF), pus, brain, tears, alveolar fluid, synovial fluid, and amniotic fluid. Transmission of HIV has been shown to occur via semen, vaginal secretions, blood or blood products, breast milk, and transplacental transmission in utero. Transmission has never been documented to occur by casual contact. There is only one documented case of transmission from health care provider to patient in the United States involving an infected dentist in Florida who transmitted the virus to six patients.

NATURAL HISTORY/CLINICAL STAGES OF HIV INFECTION

Symptoms of acute HIV infection are reported to occur in 50 to 90 percent of patients.⁵ The diagnosis is missed in up to 75 percent of cases due to nonspecific presentation (resemblance to a flulike or mononucleosis-like syndrome) and a low index of suspicion. Symptoms of acute HIV syndrome usually develop 2 to 4 weeks develop after exposure and last for less than 14 days. The most common presentations of acute HIV infection are fever (>90 percent), fatigue (70-90 percent), pharyngitis (>70 percent), rash (40-80 percent), headache (30-70 percent), and lymphadenopathy (40-70 percent); other commonly reported symptoms include weight loss, headache, and diarrhea.^{6,7} Benefits and implications of early disease detection are discussed below (see "Diagnosis").

Seroconversion reflects detectable antibody response to HIV and usually occurs 3 to 8 weeks after infection, although delays of up to 11 months have been reported. This is followed by a long period of asymptomatic infection during which patients generally have no find-

ings on physical examination except for possible persistent generalized lymphadenopathy, characterized by enlarged lymph nodes involving at least two noncontiguous sites other than inguinal nodes. The mean incubation time from exposure to the development of AIDS in untreated patients is estimated at 8.23 years for adults and 1.97 years for children under age 5. Virologic studies of patients during this period suggest that a steady state of HIV replication and CD4⁺ T-cell death and replacement exists until increased levels of HIV replication occur. Variables most predictive of disease stage are viral burden and CD4⁺ T-cell counts, with a steeper decline in CD4⁺ T-cell count and a higher viral burden associated with rapid progression and poor outcome.⁸

Early symptomatic infection is characterized by conditions that are more common and more severe in the presence of HIV infection but, by definition, are not AIDS-indicator conditions. Examples include thrush, persistent vulvovaginal candidiasis, peripheral neuropathy, cervical dysplasia, recurrent herpes zoster infection, and idiopathic thrombocytopenic purpura. These conditions occur with increased frequency as the CD4⁺ T-cell count drops below 500 cells/pX. As the CD4⁺ T-cell count drops below 200 cells/xL, frequency of opportunistic infections increases dramatically. AIDS is defined by the CDC as the appearance of any indicator condition (Table 144-2) or a CD4⁺ T-cell count of less than 200 cells/jxL. Median survival time after the CD4⁺ T-cell count has fallen to less than 200 cell/xL is 3.7 years; median survival after an AIDS-defining complication is 1.3 years. Late symptomatic or advanced HIV infection exists in patients with a CD4⁺ T-cell count of less than 50 cells/jxL or clinical evidence of end-stage disease, including disseminated *Mycobacterium avium* complex or disseminated cytomegalovirus (CMV). Immune reconstitution with potent antiretroviral therapies and effective prophylaxis significantly delay the time to onset of opportunistic infections and death, even in patients with AIDS-defining conditions.

DIAGNOSIS

HIV infection may be diagnosed using a number of methods: detection of viral-specific antigen, identification of HIV nucleic acid, isolation of the virus by culture, and detection of antibodies to HIV. The standard and most common method is detection of antibodies to the virus. Testing involves sequential use of an enzyme-linked immunosorbent

assay (ELISA) and a Western blot (WB) assay. ELISA is approximately 99 percent specific and 98.5 percent sensitive; WB is nearly 100 sensitive and specific if performed under ideal laboratory conditions. Criteria for positive results are a repeatedly positive ELISA followed by a positive WB. ELISA detects the binding of specific serum antibodies to HIV antigens that are adherent to a microtiter plate. WB detects HIV antibodies to discrete viral antigens that are electrophoretically separated and transferred to nitrocellulose paper. A positive WB requires detection of at least two gene products. Reasons for indeterminate tests are not well understood but may be indicative or early seroconversion.

Diagnosis of acute-stage HIV infection cannot be made with standard serologic tests because seroconversion usually has not yet occurred. Methods for earlier detection of HIV-1 include techniques to detect DNA, RNA, or HIV antigens. None of these assays is considered more accurate than routine serology, but they should be considered in patients suspected to be in the window period who present with an acute retroviral syndrome. Sensitivity of the various tests differs with stage of disease and test technique but generally is reported as greater than 99 percent for DNA polymerase chain reaction (PCR), 95 percent for quantitative HIV RNA or viral load, 95 to 100 percent for viral culture of peripheral blood mononuclear cells (PBMCs), and up to 100 percent for the most recent p24 antigen detection assays (which are used for screening blood donors). Real-time nucleic acid tests also may hold promise for screening acute HIV infection in ED patients as these tests become more sensitive, specific, and feasible.

Although acute HIV infection is missed in up to 75 percent of all cases, the benefits of early recognition generally are considered to outweigh the risks and costs of offering testing to patients in whom suspicion for acute HIV infection exists. For the individual patient, potential benefits include early and aggressive antiretroviral therapy, which can lead to immune reconstitution, prevention of viral mutation and drug resistance, slowing of disease progression, and improved long-term prognosis. Additional health outcomes may be realized due to the recognized public health benefits (i.e., decreased disease transmission) associated with modification of high-risk behavior in those found to be HIV-positive.^{6,9} For patients in whom acute HIV infection is suspected but is not confirmed (i.e., those with a high-risk profile presenting with fever of unknown origin and/or a syndrome suspicious for acute seroconversion), counseling and urgent referral to outpatient follow-up for appropriate testing should be initiated in the ED.

There are two other rapid HIV tests with which the ED physician should be familiar. The single-use diagnostic system (SUDS) is used to screen rapidly for antibodies to HIV-1 in plasma or serum. SUDS tests are used in most hospital laboratories in cases of occupational exposure. Reported sensitive and specificity are greater than 99 percent, but the tests require performance by well-trained laboratory technicians. OraSure manufactures both a saliva-based and finger-stick blood-based assay for rapid HIV testing. Sensitivity and specificity are comparable with standard serology, and advantages include availability of results in less than 20 min and minimal training required for performance. The blood-based test has been approved recently by the Food and Drug Administration (FDA).

Knowledge of recent CD4⁺ T-cell counts and HIV viremia load can be extremely helpful in placing patients' ED presentation in an appropriate context. CD4⁺ T-cell counts of less than 200 cells/xL and a viral load of greater than 50,000 is associated with increased risk of progression to AIDS-defining illnesses and often are used as indicators for initiation of antiretroviral therapy. When this information is unavailable or the stage of disease is unknown, the total lymphocyte count may be used to approximate the CD4⁺ T-cell count, since a total lymphocyte count of less than 1000 cells/xL has been shown to be strongly predictive of a CD4⁺ T-cell count of less than 200 cells/xL.

Testing for HIV in the ED generally has been considered to be of limited utility, except in situations where health care workers are exposed to patients' blood or in cases of sexual assault.¹⁰ Although HIV

screening in the ED remains controversial, both primary data and systematic review of the literature support the value of EDs offering HIV screening to either high-risk patients (i.e., those with identifiable risk factors) or high-risk populations (i.e., those in whom HIV seroprevalence is at least 1 percent).^{11,12} Benefits of recognition may be particularly important with acute seroconversion, where early initiation of therapy may lead to improved outcomes and decreased transmission of disease. Time limitations, cost, difficulty with follow-up, and confidentiality frequently are cited as reasons for not testing. The development of rapid, easy-to-use diagnostic testing methods that offer immediate results likely will stimulate further investigation and possibly CDC or other national support for ED-based HIV screening programs in the near future.

CLINICAL FEATURES AND TREATMENT

The spectrum of disease caused by HIV infection varies greatly. Many patients with asymptomatic infection may come to the ED for complaints unrelated to HIV disease.¹³ Other patients may have involvement of virtually any organ system, commonly with multiple interrelated problems. The protean manifestations of HIV and the complex array of related opportunistic infections can make ED evaluation and diagnosis of HIV-positive patients difficult.

Evaluation of HIV-infected patients should be carried out with the same priority-based logical approach used for all ED patients, with attention to concerns particular to this population. Attempts to develop specialized triage guidelines for HIV-positive patients have as yet been unsuccessful.¹⁴ Patients with unstable vital signs require attention to the ABCs and rapid stabilization. Universal precautions (in some hospitals termed *standard precautions*) must be used in all cases. The history and physical examination should focus on identifying the clinical stage of disease in order to direct attention to the most likely complications. History gathering must include a thorough review of past and current medications and previous infections and attention to the activities of daily living. Physical findings that might assist with staging include the presence of thrush, evidence of temporal wasting, or dementia. Diagnostic and therapeutic maneuvers are directed toward recognition of organ system involvement, assessment of the severity of disease, and institution of symptomatic and specific therapy. An overview of the more common HIV-related presentations and treatment follows. For the most up-to-date information, as well as more details on drug dosing, the reader is referred to the CDC Web site (www.cdc.gov/hiv) or an annually updated guide to care of the HIV-positive patient, which provides an excellent clinical resource tool.¹⁵

Constitutional Symptoms and Febrile Illnesses

Systemic symptoms, such as fever, weight loss, and malaise, are common in HIV-infected patients and account for the majority of HIV-related presentations.^{13,14} In the ED, systemic infection and malignancy must be excluded. Appropriate laboratory investigation may include electrolyte determinations, complete blood count, blood cultures (aerobic, anaerobic, and fungal), urinalysis and culture, liver function tests, chest radiograph, and serologic testing for syphilis, cryptococcosis, toxoplasmosis, CMV infection, and coccidiomycosis. Lumbar puncture may be considered if there are neurologic signs or symptoms or unexplained fever.

When evaluating fever in patients with later-stage HIV and AIDS, it is important to remember that this population may not manifest the typical signs and laboratory findings associated with systemic infection. Clinical impression therefore is critical in determining appropriate disposition. Ill-appearing patients should receive fluid resuscitation and empirical antibiotics in the ED and then be admitted for further evaluation and management. Outpatient evaluation and treatment are indicated only when all the following conditions are met: The source of the fever does not dictate admission, appropriate laboratory

studies have been initiated, the patient is able to function adequately at home (e.g., can maintain sufficient oral intake), and timely medical follow-up can be arranged.

In HIV-positive patients without obvious localizing signs or symptoms, sources of fever vary by stage of disease. Patients with CD4⁺ T-cell counts greater than 500 cells/ μ L generally have causes of fever similar to nonimmunocompromised patients, whereas those with CD4⁺ T-cell counts between 200 and 500 cells/ μ L are most likely to have early bacterial respiratory infections.¹⁶ For patients with CD4⁺ T-cell counts less than 200 cells/ μ L, most common causes of fever without obvious localizing findings are early *Pneumocystis carinii* pneumonia (PCP), central-line infection, *M. avium* complex, *M. tuberculosis*, CMV, drug fever, and sinusitis. Less common causes include endocarditis, lymphoma, *Histoplasma capsulatum* and *Cryptococcus neoformans*. Fever caused by HIV infection alone tends to occur in the afternoon or evening and generally is responsive to antipyretics.

Prior to the widespread use of highly active antiretroviral therapy, disseminated *M. avium* complex (MAC) was the most common opportunistic bacterial infection in AIDS patients, causing disseminated disease in up to 50 percent of patients at some time during their illness. MAC occurs predominantly in patients with CD4⁺ T-cell counts of 100 cells/ μ L or less. Persistent fever and night sweats are typical. Associated symptoms include weight loss, diarrhea, malaise, and anorexia. Dissemination to the bone marrow, liver, and spleen result in anemia and elevated alkaline phosphatase levels. Diagnosis may be made by acid-fast stain of stool or other body fluids or by blood culture. Cultures using the lysis-centrifugation method are more sensitive for MAC (and histoplasmosis) and should be ordered in patients with late-stage disease and fever of unknown origin. Treatment for MAC, which reduces bacteremia and improves symptoms (but does not eradicate disease), is with clarithromycin combined with ethambutol and rifabutin.

With increased use of highly active antiretroviral therapy, a more focal and invasive form of MAC has emerged called *immune reconstitution illness to MAC*.¹⁷ Typical presentation is lymphadenitis, with symptoms commonly starting weeks to months after starting highly active antiretroviral therapy; pathogenesis may be cytokine-mediated and attributable to restoration of a pathogen-specific immune response to infection. Current treatment guidelines advise continuing antiretroviral therapy and starting antimicrobials; steroids may be beneficial. Immune reconstitution illness also has been seen with a group of other infections including tuberculosis, CMV, *Cryptococcus*, hepatitis, herpes zoster, and progressive multifocal leukoencephalopathy (PML).

CMV is the most common cause of serious opportunistic viral disease in HIV-infected patients. Disseminated disease commonly involves the gastrointestinal, pulmonary, and CNS systems. The most important manifestation is retinitis (see below). Treatment is with foscarnet or ganciclovir; oral ganciclovir can be used for prophylaxis.

Fever in injection drug users (IDUs) always should raise concern for infective endocarditis, which often has a nonspecific presentation in the ED (see Chap. 145). While previous studies have failed to identify reliable clinical or laboratory predictors of this disease, recent developments indicate that expedited approaches to ruling out infective endocarditis in febrile IDUs may be forthcoming¹⁸ and ultimately may include molecular diagnostic assays such as PCR.¹⁹ Current standard of care, however, is to admit all febrile IDUs and await the results of blood cultures and echocardiography due to the significant morbidity and mortality rates of missed endocarditis and the difficulties associated with outpatient follow-up in this population.

The most common noninfectious causes of fever are neoplasm and drug fever. Non-Hodgkin lymphomas are the most frequently occurring neoplasm and typically present as high-grade, rapidly growing mass lesions. New CNS symptoms, particularly a change in mental status in the presence of fever, should be evaluated with neuroimaging. Definitive diagnosis requires biopsy. Radiotherapy and chemotherapy

are effective treatment regimens. Drug fever may be secondary to intravenous drug abuse or adverse drug reactions (see below).

Neurologic Complications

CNS disease occurs in 90 percent of patients with AIDS, and 10 to 20 percent of HIV-infected patients present initially with CNS symptoms. Neurologic disease is caused by a variety of opportunistic infections and neoplasms, as well as by the direct and indirect effects of HIV infection on the CNS. Common presenting symptoms indicative of CNS pathology include seizures, altered mental status, headache, meningismus, and focal neurologic deficits. The most common causes of neurologic symptoms include AIDS dementia, *Toxoplasma gondii*, and *C. neoformans*. Since the widespread use of highly active antiretroviral therapy, rates of CNS infections and malignancy have declined significantly, whereas rates of AIDS dementia remain unchanged.

ED evaluation should include a complete neurologic examination and, when appropriate, computed tomography (CT) and lumbar puncture (LP). In general, CT should precede LP. Fever, meningismus, altered mental status, or headache are independent predictors of space-occupying lesions.^{20,21}

Although there are no uniform consensus guidelines on workup of HIV-positive patients with headache, the following approach is recommended.²¹ Evaluation of HIV-positive patients with headache should proceed as in the non-HIV-infected population; neuroimaging and LP are indicated for those in whom an alternative explanation is not found or for those who have a clear indication for workup (e.g., worst headache of life). For those with CD4⁺ T-cell counts of less than 200 cells/ μ L, a more aggressive approach is advocated.²¹ Headache in combination with altered mental status, seizures, or focal findings requires emergent imaging; LP should be performed if imaging is unrevealing. Isolated headaches that are protracted or changed in quality (even in the absence of other neurologic findings) also should prompt immediate neuroimaging.²⁰

Non-contrast-enhanced CT is an appropriate initial imaging study in the ED in HIV-infected patients with neurologic deficits because the addition of contrast material has been shown to be of marginal value in patients with completely normal non-contrast-enhanced CT scans.^{22,23} In patients in whom clinical suspicion for central nervous system (CNS) pathology is high but the CT scan is equivocal or negative, contrast-enhanced CT scanning or magnetic resonance imaging (MRI) should be arranged in the ED. Specific CSF studies that may be of value include opening and closing pressures, cell count, glucose, protein, Gram stain, India ink stain, bacterial culture, viral culture, fungal culture, toxoplasmosis and cryptococcosis antigen, and coccidioidomycosis titer. If possible, excess CSF should be held for additional testing if the diagnosis remains unclear after initial workup. Even if the ED evaluation is unrevealing, all patients with new or changed neurologic signs or symptoms should be admitted to the hospital for further workup.

AIDS DEMENTIA AIDS dementia complex (also referred to as HIV encephalopathy or subacute encephalitis) is a progressive process commonly heralded by subtle impairment of recent memory and other cognitive deficits caused by direct HIV infection; it occurs in 10 to 15 percent of HIV-positive patients. In the early stages, diagnosis can be confused with depression, anxiety disorders, or substance abuse. Later phases of the illness are characterized by obvious changes in mental status and more severe disturbances, including aphasia and motor abnormalities. Patient with an established diagnosis of AIDS dementia who present to the ED with progressive signs or symptoms warrant further emergent workup to rule out other systemic or CNS processes. A CT scan in AIDS dementia typically shows cortical atrophy and ventricular enlargement. AIDS dementia is associated with elevated protein levels in the CSF in 50 to 70 percent of cases.

TOXOPLASMOSIS Toxoplasmosis is the most common cause of focal encephalitis in patients with AIDS. Symptoms may include headache, fever, focal neurologic deficits, altered mental status, and seizures. Serologic tests are not useful in making or excluding the diagnosis because antibody to *T. gondii* is prevalent in the general population. The presence of antibody to *T. gondii* in the CSF is helpful if present, although there is a high rate of false-negative results. On a non-contrast-enhanced CT scan, toxoplasmosis typically appears as multiple subcortical lesions with a predilection for the basal ganglia.

In general, only a non-contrast-enhanced CT scan is indicated in the ED, with follow-up studies to further delineate the lesion done in the inpatient setting. With contrast enhancement, toxoplasmosis lesions are ring-enhancing, with surrounding areas of edema. MRI is slightly more sensitive than contrast-enhanced CT scan in detecting the extent and number of lesions with toxoplasmosis. Other causes in the differential diagnosis of ring-enhancing lesions on contrast-enhanced CT include lymphoma, fungal infection, and cerebral tuberculosis. In the ED, it is often not possible to differentiate these causes based on initial imaging studies, but general patterns in the appearance of lesions, based on underlying pathology, have been described. Toxoplasmosis tends to have a greater number of lesions with a predilection for the basal ganglia and corticomedullary regions, whereas lymphoma is characterized more often by singular lesions, typically in the periventricular white matter or corpus callosum. Tuberculosis is distinguished by a characteristic inflammatory appearance on CT, with a thick, isodense exudate filling the basal cisterns.

Patients with suspected toxoplasmosis should be admitted and treated with pyrimethamine (100- to 200-mg load, then 50-100 mg per d) and sulfadiazine (4-8 g per d), with folinic acid added (10 mg per d) to reduce hematologic toxicity. Steroids (Decadron 4 mg IV q6h) are beneficial for significant edema or mass effect. Failure to improve suggests an alternative diagnosis, which may require biopsy. For patients responsive to toxoplasmosis therapy, chronic suppressive therapy with pyrimethamine, sulfadiazine, and folinic acid is usually indicated after initial treatment. Oral TMP-SMX, one DS tab qd is recommended for prophylaxis in patients with positive toxoplasmosis serologic test results and CD4⁺ T-cell counts of less than 100 cells/ μ L.

CRYPTOCOCCOSIS Cryptococcal CNS infection may be seen in up to 10 percent of AIDS patients, although, as with toxoplasmosis, the incidence has declined recently due to use of highly active antiretroviral therapy. Infection can produce either focal cerebral lesions or diffuse meningoencephalitis. The most common presenting signs are fever and headache, followed by nausea, altered mentation, and focal neurologic deficits. Presentation may be subtle, and meningismus is uncommon. Neuroimaging studies are usually normal. Diagnosis relies on identifying organisms in CSF by cryptococcal antigen (nearly 100 percent sensitive and specific), culture (95-100 percent sensitive), or staining with India ink (60-80 percent sensitive). Serum cryptococcal antigen is also useful but has slightly lower sensitivity (approximately 95 percent). Elevated intracranial pressure is associated with cryptococcal meningitis, and an opening pressure of greater than 25 cm H₂O should prompt drainage of fluid until pressure is less than 20 cm H₂O or 50 percent of opening pressure. Patient with CNS cryptococcosis shall be admitted for antibiotic therapy; preferred treatment is intravenous amphotericin B 0.7 mg/kg per d with oral flucytosine 100 mg/kg per d for 14 days. Sixty percent of patients may be expected to respond to therapy, and side effects are frequent, most notably bone marrow suppression. Initial therapy should be followed by 8 to 10 weeks of oral fluconazole. Lifelong maintenance therapy with fluconazole (200 mg per d) is indicated for patients but may be discontinued if immune reconstitution is shown.

OTHER NEUROLOGIC DISORDERS Other, less common CNS infections that should be considered in the presence of neurologic

symptoms include bacterial meningitis, histoplasmosis (usually disseminated), CMV infection, PML, herpes simplex virus (HSV) infection, neurosyphilis, and tuberculosis. Noninfectious CNS processes include CNS lymphoma (typically manifested as a subacute neurologic deterioration over several months with a single ring-enhancing lesion on CT), cerebrovascular accidents, and metabolic encephalopathies.

The most common disorder of the peripheral nervous system occurring in up to 50 percent of HIV-infected patients is HIV neuropathy, characterized by painful sensory symptoms in the feet. Although HIV infection itself is the most common culprit, HIV therapies also should be considered as a possible cause, and changing treatment regimens may be helpful. Symptomatic relief with pain-modifying agents such as nortriptyline should be used judiciously because of their potential for causing delirium in patients with concurrent HIV dementia. Narcotic analgesia may be helpful in severe cases.

Ophthalmologic Manifestations

Seventy-five percent of patients with AIDS develop ocular complications. Although a wide range of ophthalmic diseases occurs, recognition of a few is most critical. The most common ophthalmic finding in patients with AIDS is retinal microvasculopathy, which is characterized by retinal cotton-wool spots identical in appearance to those of diabetes or hypertension. Retinal microaneurysms are also seen, primarily in the periphery. These lesions are believed to be incidental and do not cause visual disturbances. The diagnostic dilemma is to distinguish these findings from early CMV infection, and ophthalmologic consultation is recommended.

CMV retinitis is the most frequent and serious ocular opportunistic infection and the leading cause of blindness in AIDS patients. In the highly active antiretroviral therapy era, the incidence of CMV infection has been reduced due in large part to immune reconstitution associated with the therapy.¹⁶ Presentation of CMV retinitis is variable. It may be asymptomatic early on but later causes changes in visual acuity, visual field cuts, photophobia, scotoma, or eye redness or pain. Findings on indirect ophthalmoscopy are characteristic, with fluffy white perivascular lesions and areas of hemorrhage within them. First-line treatment is intraocular ganciclovir implant with oral ganciclovir 1.0 to 1.5 g PO tid; alternative first-line therapy is ganciclovir 5 mg/kg IV bid for 14 to 21 days. Visual loss and blindness occur in all cases without early detection and prompt treatment. Even with treatment, there are frequent relapses and progression of disease, with 10 percent of affected patients ultimately going blind.

Herpes zoster ophthalmicus usually presents with paresthesia and discomfort in the distribution of cranial nerve V₁, followed by the appearance of the typical zoster skin rash. Ocular complications include conjunctivitis, episcleritis, iritis, keratitis, secondary glaucoma, and rarely, retinitis.^{24,25} Early recognition and treatment are essential to prevent ocular damage. Preferred treatment is intravenous acyclovir (30–36 mg/kg per d) for at least 7 days. The role of maintenance therapy is unclear.

A number of lesions can affect the areas around the eye in HIV patients, most notably Kaposi sarcoma and molluscum contagiosum. Patients with such lesions may be referred to an ophthalmologist for local excision or cryotherapy.

Pulmonary Complications

Pulmonary complications occur frequently in HIV-positive patients at both early and later stages of immunosuppression. Presenting complaints frequently are nonspecific and include cough, hemoptysis, shortness of breath, and chest pain. ED evaluation should be directed toward determining the likely diagnosis because early treatment has a significant impact on morbidity and mortality rates. Appreciation of the epidemiologic characteristics and common findings associated with various pathogens can assist the emergency physician in arriving at an appropriate differential and working diagnosis, leading to sound treatment and disposition decisions.

The most common causes of pulmonary abnormalities in HIV-infected patients include community-acquired bacterial pneumonia, PCP, *M. tuberculosis* (MTB) infection, CMV infection, *C. neoformans* infection, *H. capsulatum* infection, and neoplasms. In addition to the history and physical examination, evaluation of patients with pulmonary complaints may be assisted by pulse oximetric analysis, arterial blood gas determination, sputum culture, Gram staining, acid-fast staining, blood culture, and chest x-ray. Pulmonary radiographic findings are helpful in determining likely causes (Table 144-3). Admission should be considered for patients with new-onset pulmonary symptoms, especially those with hypoxia. Decisions regarding patients with known pulmonary involvement are based on comparison with baseline status, the effectiveness of ongoing or previous treatment, and the individual's ability to obtain outpatient follow-up. Of note, the widely used Patient Pneumonia Outcome Research Team (PORT) criteria²⁶ for guiding hospitalization decisions in patients with community-acquired pneumonia did not include HIV-positive patients in their derivation and therefore cannot be applied; further study to address this gap is will be important. Specific symptoms are discussed below with selected common causes.

Despite substantial decreases in the incidence of PCP due to effective prophylaxis and the increased use of highly active antiretroviral therapy, it continues to be the most common opportunistic infection among AIDS patients.²⁷ Approximately 70 percent of HIV-infected patients will acquire PCP at some time during their illness, and PCP is often the initial opportunistic infection that establishes the diagnosis of AIDS. This disease is the most frequent serious complication of HIV infection in the United States and the most common identifiable cause of death in patients with AIDS. The classic presenting symptoms of PCP are fever, cough (typically nonproductive), and shortness of breath (progressing from being present only with exertion to being present at rest).

Symptoms are often insidious and accompanied by fatigue. Chest x-rays most often show diffuse interstitial infiltrates (see Table 144-3). Although typical radiographic findings occur in up to 80 percent of

TABLE 144-3 Chest Radiographic Abnormalities: Differential Diagnosis in the AIDS Patient

Finding	Etiologies
Diffuse interstitial infiltration	PCP CMV MTB MAI Histoplasmosis Coccidioidomycosis Lymphoid interstitial pneumonitis
Focal consolidation	Bacterial pneumonia <i>M. pneumoniae</i> <i>P. carinii</i> MTB MAI
Nodular lesions	Kaposi sarcoma MTB MAI Fungal lesions Toxoplasmosis
Cavitary lesions	PCP MTB Bacterial infection Fungal infection
Adenopathy	Kaposi sarcoma Lymphoma MTB Cryptococcosis

patients, negative x-rays are reported in 15 to 20 percent of patients with PCP.²⁸ In patients with nondiagnostic x-ray findings and signs and symptoms suggestive of PCP, further testing should be pursued. The lactate dehydrogenase (LDH) level is elevated in patients with PCP, but the test for LDH has relatively low sensitivity and specificity, making its use in the ED impractical. Arterial blood gas analysis usually demonstrates hypoxemia and an increase in the alveolar-arterial (A-a) gradient. Early PCP should be suspected if a patient demonstrates a decrease in pulse oximetric values with exercise. Presumptive diagnosis of PCP is often assumed in the emergency department if there is hypoxia without any other explanation. Inpatient diagnostic testing may include bronchoscopy with lavage, biopsy, and culture or examination of induced sputum by indirect immunofluorescence using monoclonal antibodies.

Initial therapy for PCP is TMP-SMX (TMP 15 mg/kg per d and SMX 75 mg/kg per d) either PO or IV for 3 weeks in two or three divided doses (typical oral dosage 2 DS tablets tid). Adverse reactions (most commonly rash, fever, and neutropenia) occur in up to 65 percent of AIDS patients. Pentamidine isothionate 4 mg/kg per d is one of a number of effective alternative agents. Steroid therapy should be instituted for patients with a Pao₂ of less than 70 mm Hg or an alveolar-arterial gradient of greater than 35.²⁹ The usual regimen is oral prednisone 40 mg bid for 5 days, then 40 mg daily for 5 days, and then 20 mg daily for an additional 11 days. Seventy percent of patients will have reinfection within 18 months. Prophylactic therapy is an important step in preventing reinfection and also has been shown to reduce the risk of developing bacterial pneumonia; oral TMP-SMX 1 DS tablet daily is the preferred agent. Prophylaxis is also recommended in all patients with CD4⁺ T-cell counts below 200 cells/ μ L. Repeat infections may be less responsive to therapy.

The incidence of MTB is increasing, particularly among the homeless, institutionalized, immigrant, and intravenous drug using populations. Reactivation of prior infection is common, and there is a much greater risk of direct progression of disease from recently acquired infection. The incidence of tuberculosis (TB) in the AIDS population is estimated to be 200 to 500 times that in the general population.³⁰ Prevalence studies demonstrate significant regional variations, attributed to both the demographic characteristics of the populations and the efficacy of local public health control measures. Clinical manifestations of TB in HIV infection vary significantly according to the severity of immunosuppression. Whereas PCP does not occur until the CD4⁺ T-cell count is approximately 200 cells/ μ L, TB frequently occurs in patients with CD4⁺ T-cell counts of 200 to 500 cells/ μ L. Classic pulmonary manifestations include cough with hemoptysis, night sweats, prolonged fevers, weight loss, and anorexia. With worsening immunosuppression, atypical and extrapulmonary manifestations are more common. Frequent sites of dissemination are peripheral lymph nodes, bone marrow, and the urogenital system. Classic upper lobe involvement and cavitary lesions are less common, particularly among late-stage AIDS patients.³⁰ Negative purified protein derivative (PPD) TB test results are frequent among AIDS patients due to immunosuppression. Definitive diagnosis may be made by stain and culture of sputum, although in some cases bronchoscopy with biopsy may be required. In the ED, physicians should maintain a high index of suspicion for TB among HIV-infected patients with pulmonary symptoms due to the high rates of person-to-person transmission. Immediate isolation should be instituted until the diagnosis is ruled out. Specific procedures for ruling out TB vary by region and site and have been found to be inadequate in some EDs.³¹ Any patient identified as high risk based on clinical presentation should be placed in isolation, with the decision for further isolation based on results of chest x-ray and detailed historical and clinical information. Current treatment guidelines recommend a four-drug initial empirical therapy (see Table 144-4). Multidrug-resistant TB remains an issue of concern and should increase the awareness of the need for early isolation. All HIV-infected patients with positive PPD test results should receive prophylaxis with isoniazid plus pyridoxime for 1 year or rifampin plus pyrazinamide for 2 months.

Bacterial pneumonias are the most common pulmonary infections in HIV-infected patients. Common pathogens include *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Staphylococcus aureus*. Productive cough, leukocytosis, and the presence of a focal infiltrate suggest bacterial pneumonia, especially in those with earlier-stage disease. The response to empirical therapy tends to be good; a specific diagnosis can be established by Gram staining and culture.

Patients with severe immunosuppression are predisposed to disseminated fungal infections such as *C. neoformans* and *Aspergillus fumigatus*. Other noninfectious disorders of the lung seen in HIV-infected patients include neoplasms (e.g., Kaposi sarcoma) and lymphocytic interstitial pneumonitis. CMV or MAC infections are unlikely unless the CD4⁺ T-cell count drops below 50 cells/ μ L.

Cardiovascular Manifestations

Cardiovascular manifestations of HIV infection are changing in the era of highly active antiretroviral therapy. Common in late-stage disease and often difficult to diagnose in the ED (in part because they mimic more generalized or systematic symptoms such as fever and malaise), these complications may be related to opportunistic infections, structural defects, or drug toxicity. HIV-associated cardiovascular conditions include cardiomyopathy, infective endocarditis (injection drug users), pericardial effusion, congestive heart failure (CHF), coronary artery disease (CAD), arrhythmias, and HIV-associated pulmonary hypertension.³² Following standard ED workup for these conditions, consultation with a cardiologist and infectious disease specialist may be indicated.

Gastrointestinal Complications

Gastrointestinal manifestations of HIV infection are common. Approximately 50 percent of AIDS patients will present with gastrointestinal complaints at some time during their illness. The most frequent presenting symptoms include odynophagia, abdominal pain, bleeding, and diarrhea. ED evaluation should focus on recognizing the severity of symptoms and obtaining appropriate initial diagnostic studies. Therapy should include volume and electrolyte repletion and initiation of antibiotic therapy when appropriate. Disposition should be based on the duration of symptoms, the clinical appearance of the patient, and the response to ED therapy.

ORAL/ESOPHAGEAL MANIFESTATIONS Oral lesions are common in HIV-infected patients, frequently contributing to malnutrition. The appearance of oral lesions in HIV patients may serve as a potential clinical marker for viral load and degree of immunodeficiency.³³ Oral candidiasis or thrush affects more than 80 percent of AIDS patients. The tongue and buccal mucosa are commonly involved, and the plaques characteristically can be easily scraped from an erythematous base. Differentiation from hairy leukoplakia (usually manifested as adherent, white, thickened lesions on the lateral tongue borders) may be challenging, but microscopic examination on potassium hydroxide smear can be used to confirm the diagnosis. The development of oral candidiasis is a poor prognostic sign and is predictive of progression to AIDS. Most oral lesions can be managed symptomatically on an outpatient basis. Clotrimazole or nystatin suspension or troches (five times daily) are the preferred treatment. Refractory or recurrent disease can be managed with oral fluconazole. Amphotericin B is reserved for severe cases.

Other causes of painful oral and perioral lesions include oral hairy leukoplakia, HSV infection, and Kaposi sarcoma. HSV infection usually can be recognized by typical vesicular lesions, with diagnosis confirmed by identifying multinucleated giant cells from scrapings or by culture. Both HSV infection and hairy leukoplakia are responsive to oral acyclovir. Oral Kaposi sarcoma appears as a nontender,

well-circumscribed, slightly raised violaceous lesion. Diagnosis requires biopsy; topical treatments may be palliative.

Esophageal involvement may occur with *Candida*, HSV, and CMV. Complaints of odynophagia or dysphagia are usually indicative of esophagitis and may be extremely debilitating. Disease typically occurs in patients who have oral thrush and CD4⁺ T-cell counts of less than 100 cells/ μ L. Treatment of esophagitis in the ED is usually presumptive. Endoscopy, histologic staining, culture, and biopsy are reserved for patients who fail to respond or have atypical presentations. Presumptive treatment for *Candida*, which accounts for 50 to 70 percent of cases, is with oral fluconazole (100[^]00 mg per d for 2-3 weeks) or oral ketoconazole (200[^]1-00 mg per d for 2-3 weeks). Intravenous caspofungin or intravenous amphotericin B may be used for oral treatment failures.³⁴ Relapses are common, and intravenous amphotericin B may be required occasionally. Treatment failures endoscopically discovered to be caused by CMV and HSV are treated with gancyclovir and acyclovir, respectively.

DIARRHEA Diarrhea is the most frequent gastrointestinal complaint and is estimated to occur in 50 to 90 percent of AIDS patients. Causes include bacteria (*Shigella*, *Salmonella*, enteroadherent *Escherichia coli*, *Entamoeba histolytica*, *Campylobacter*, *M. avium intracellulare*, *Clostridium difficile*, and others), parasites (*Giardia lamblia*, *Cryptosporidium*, *Iso spor a belli*, and others), viruses (CMV, HSV, HIV, and others), and fungi (*H. capsulation*, *C. neoformans*, and others). In 20 to 30 percent of cases, a pathogen is never found. Diarrhea is also a known side effect of protease inhibitors, most notably nelfinavir and ritonavir.

ED evaluation of patients with diarrhea should include microscopic examination of stool for leukocytes, ova, and parasites and acid-fast staining and bacterial culture of stool. Clinical clues regarding the cause of diarrheal illnesses may be provided by patient history and confirmed by supplementary testing. Results usually are not available during the ED visit. Bacterial pathogens generally follow a more acute and fulminant course, whereas parasitic infections are more frequently indolent. If bacterial infection is suspected, empirical treatment with ciprofloxacin, which covers the common bacterial pathogens, can be started. *Cryptosporidium* and *Iso spor a* infections are common parasitic causes and are associated with profuse watery diarrhea. Both can be identified by a modified acid-fast stain. *I. belli* infection is usually responsive to TMP-SMZ, but relapse is common. *Cryptosporidiosis* tends to be difficult to treat.³⁵

In patients with end-stage disease, the most common pathogens are CMV and *M. avium intracellulare*; both diagnoses usually require biopsy. Prolonged antimicrobial therapy is indicated for treatment. Resistance and relapse are frequent for both entities. About 15 percent of patients with late-stage AIDS suffer from severe, high-volume watery diarrhea with no pathogen identified even after thorough investigation. The presumed diagnosis is AIDS-related enteropathy. Patients often require admission for correction of electrolyte abnormalities and rehydration. Octreotide, the somatostatin analogue, may be helpful in some cases.

ED management should be directed toward repletion of fluid and electrolytes. Patients who appear nontoxic and can tolerate liquids can be referred for outpatient follow-up of test results. Patients with severe diarrhea who do not require antibiotics may benefit from symptomatic therapy, such as attapulgite (Kaopectate), psyllium (Metamucil), and if necessary, diphenoxylate hydrochloride with atropine (Lomotil).

OTHER GASTROINTESTINAL MANIFESTATIONS Hepatomegaly occurs in approximately 50 percent of AIDS patients. Elevation of the alkaline phosphatase level is seen frequently. Jaundice is rare. Coinfection with hepatitis B and hepatitis C is common, especially among injection drug users. Opportunistic infections with CMV, *Cryptosporidium*, *M. avium intracellulare*, and MTB also may cause signs of hepatitis.

Anorectal disease is common in AIDS patients. Proctitis is characterized by painful defecation, rectal discharge, and tenesmus. Common causative organisms include *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, syphilis, and HSV. Proctocolitis includes the same symptoms in the presence of diarrhea, and multiple bacterial organisms may be responsible (most commonly *Shigella*, *Campylobacter*, and *E. histolytica*). Diagnostic evaluation should include anoscopy, with microscopic examination, Gram stain, and culture of pus and/or stool.

Renal Manifestations

Renal insufficiency among AIDS patients may be secondary to prerenal azotemia, drug nephrotoxicity, or HIV-associated nephropathy, which may cause chronic renal insufficiency due to focal and segmental glomerulosclerosis. Renal tubular acidosis is common and may explain a finding of hyperchloremic metabolic acidosis. Management decisions should be made in conjunction with nephrology.

Cutaneous Manifestations

Generalized cutaneous conditions, such as xerosis (dry skin), seborrheic eczema, and pruritus, are common and may be manifested prior to development of opportunistic infections. Treatment is with emollients and, if necessary, mild topical steroids. Pruritus may respond to oatmeal baths and antihistamines. Other infections, including *S. aureus* (manifested as bullous impetigo, ecthyma, or folliculitis), *Pseudomonas aeruginosa* (which may present with chronic ulcerations and macerations), and syphilis, are seen frequently and should be treated with standard therapies. Several specific dermatologic conditions are discussed in more detail below.

Kaposi sarcoma (KS) appears more often in homosexual men than in other risk groups. Clinically, it consists of painless, raised brown-black or purple papules and nodules that do not blanch. Common sites are the face, chest, genitals, and oral cavity; however, widespread dissemination involving internal organs may occur. Since cutaneous KS is not generally associated with significant rates of morbidity or mortality, therapy is indicated only for extensive, painful, or cosmetically disfiguring lesions. Cryotherapy or radiation can be used for localized disease; widespread disease may be responsive to chemotherapy with vincristine, vinblastine, or doxorubicin.

HSV infections are common and may be localized or systemic. In patients with significant immunosuppression, infection may become progressive, manifested as chronic ulcerative mucocutaneous lesions. Diagnosis and treatment are the same as for other patients with HSV infection (see Chap. 143). Recommended regimens are described in Table 144-4. Intravenous therapy with an antiviral agent (acyclovir 5-10 mg/kg per d, famciclovir 250 mg PO tid, or valacyclovir 1 g bid) is needed for extensive disease.

Reactivation of varicella-zoster virus is more common in patients with HIV infection and AIDS than in the general population. The clinical course is prolonged, and complications are more frequent. In HIV-positive patients, oral acyclovir 800 mg five times a day, oral famciclovir 500 mg tid for 7 days, or oral valacyclovir 1 g tid for 7 days is usually sufficient. However, in patients with disseminated disease or ophthalmic zoster, admission is indicated for intravenous acyclovir.

Intertriginous infections with either *Candida* or *Trichophyton* are seen frequently in HIV-positive patients and can be diagnosed by microscopic examination of potassium hydroxide preparations of lesion scrapings. Treatment includes topical imidazole creams, such as clotrimazole, miconazole, or ketoconazole.

Scabies occurs in about 20 percent of HIV-infected patients, but classic intertriginous lesions are less common. Any patient with a scaly, persistent pruritic eruption should be treated with permethrin 5 percent cream, ivermectin, or crotamiton. Norwegian scabies is a particularly invasive variant of scabies and poses a challenging treatment difficulty. Norwegian scabies may be seen in immunosuppressed

TABLE 144-4 Treatment Recommendations for Common HIV-Related Infections

Organ System	Infection	Therapy
Systemic	MAI	Clarithromycin 500 mg PO bid and Ethambutol 15 mg/kg per d PO +
	CMV	Rifabutin 300 mg/kg per d PO Ganciclovir, 5 mg/kg IV bid X 2 weeks, then 5 mg/kg per d or Foscarnet 90 mg/kg q12h X 3 weeks, then 90 mg/kg per d
Pulmonary	<i>P. carinii</i>	TMP-SMX 15-20 mg TMP/kg per d and 75-100 mg SMX/kg per d, PO or IV X 3 weeks or Pentamidine 4 mg/kg per d, IV or IM, X 3 weeks
	<i>M. tuberculosis</i> *	Isoniazid 5 mg/kg per d PO and Rifampin 10 mg/kg per d PO and Pyrazinamide 15–30 mg/kg per d PO and Streptomycin 15 mg/kg per d IM
CNS	Toxoplasmosis	Pyrimethamine 50-100 mg/kg per d PO X 6-8 weeks and Sulfadiazine 4–8 mg/kg per d X 6–8 weeks and Folinic acid 10 mg per d PO X 6–8 weeks
	Cryptococcosis ^J	Amphotericin B 0.7 mg/kg per d IV X 2 weeks and Flucytosine 100 mg/kg per d IV X 2 weeks then Fluconazole 400 mg per d PO X 8-10 weeks
Ophthalmologic	CMV [#]	Ganciclovir implant and Ganciclovir 1.0-1.5 g PO tid or Ganciclovir 5 mg/kg IV bid X 2-3 weeks
GI	Candidiasis	Clotrimazole, 10 mg, 5X/d troches or
	Thrush (<i>Candida</i>)	Nystatin 500 K units 5X/d, gargle
	Esophagitis (primarily <i>Candida</i>)	Fluconazole, 100-400 mg per d, PO
	Salmonellosis	Ciprofloxacin, 500 mg bid PO (2-4 wks); maintenance therapy required
Cutaneous	Cryptosporidiosis	No known effective cure; best results with HAART [§]
	HSV	Acyclovir, 200 mg PO 5X/d X 7 d or Famciclovir 125 mg PO bid X 7 d or Valacyclovir 1 g PO bid X 7 d or for severe disease Acyclovir 5-10 mg/kg q8h IV X 7 d Acyclovir 800 mg PO 5X/day X 7-10 d or Famciclovir 500 mg PO tid X 7- 10 d or Valacyclovir 1 g PO tid X 7-10 days or for ocular or disseminated disease Acyclovir 5-10 mg/kg q8h X 5-7 d
	Herpes zoster	Topical clotrimazole bid or tid X 3 weeks or Topical miconazole bid or tid X 3 weeks or Topical ketoconazole bid or tid X 3 weeks
	<i>Candida</i> or <i>trichophyton</i>	

*Specific drug regimen must be adjusted if on HAART.

^fMaintenance therapy required.

^JMaintenance therapy required, may discontinue if CD4 > 150 for > 16 weeks.

[#]Maintenance therapy required until CD4⁺ T-cell count >150.

[§]HAART: highly active antiretroviral therapy.

patients, and patients typically exhibit extensive hyperkeratosis and crusting of the hands, feet, and scalp. Pruritus is less impressive than is seen in typical scabies. Extensive mite proliferation and high contagion are common. Treatment failures and secondary infection also are common. Human papillomavirus infections occur with increased frequency in immunocompromised patients. Treatment is cosmetic or symptomatic and may include cryotherapy, topical therapy, or laser therapy. Other dermatologic conditions that occur with increased frequency among HIV-infected patients include psoriasis, atopic dermatitis, and alopecia. Referral for dermatologic consultation is appropriate.

Psychiatric Disorders

Epidemiologic studies of patients infected with HIV and AIDS show a high lifetime prevalence of psychiatric disorders compared with the general population. Persons at highest risk for HIV infection (i.e., injected drug users and homosexual men) frequently suffer from mood disturbances prior to contracting HIV. Infection with HIV produces brain injury and is associated with a variety of CNS and metabolic disturbances that can produce psychiatric symptoms. HIV infection is also a significant psychosocial stressor, leading to social isolation, poverty, and hopelessness.

Evaluation of psychiatric symptoms in the ED should focus on an aggressive search for underlying organic causes of the acute presentation.³⁶ Delirium suggests the presence of a primary physiologic disease; the workup should include laboratory studies, neuroimaging, and LP. The differential diagnosis includes CNS and toxic-metabolic derangements. Frequently, a period of observation may be required if a patient is found to be intoxicated or experiencing withdrawal symptoms.

AIDS psychosis is poorly understood. Patients may present with psychiatric symptoms, such as hallucinations, delusions, or other abnormal behavioral changes. The cause is unclear, and treatment has been identical to that for other psychoses. Acute episodes require admission.

Depression occurs in 20 percent of patients, most commonly in those with lower CD4⁺ T-cell counts.³⁷ Depressive illnesses are often responsive to hospitalization and psychosocial intervention. Antidepressant therapy may be considered if symptoms of depression continue longer than 2 weeks. However, due to the increased propensity to develop medication side effects, close patient monitoring is required. Patients with suicidal ideation usually require inpatient psychiatric management.

An increased incidence of mania is observed in both the early and late stages of HIV infection. Late-stage mania is closely associated with dementia and carries a poor prognosis. Management of HIV-positive patients with psychiatric complaints must include attention to violent behavior and suicidality. Assessment and stabilization may require physical restraints and acute pharmacologic intervention. Neuroleptics and benzodiazepines may be used in combination. Haloperidol and diazepam are used frequently. Droperidol has a more rapid onset and shorter half-life than haloperidol but can cause torsades de pointes and sudden death, particularly in patients with prolonged QT_c syndromes. Lorazepam offers improved intramuscular absorption over diazepam. Medications should be used judiciously due to frequent polypharmacy.

Sexually Transmitted Diseases

Sexually transmitted diseases (STDs) are epidemiologically associated with HIV infection. Diseases that cause genital ulcers, such as herpes, chancroid, and syphilis, are believed to provide vascular portals of entry for HIV. Prevalence studies demonstrate a three- to fivefold increased odds ratio of HIV seropositivity in patients with genital ulcers.³⁸ A similarly increased risk of HIV infection has been recently found among patients with gonorrhea and chlamydial infections.

These studies, along with recent ED-based prevalence surveys, have led to a recommendation for increased surveillance of STDs as a means of controlling HIV transmission.³⁹ All patients with symptoms

suggestive of an STD should be tested for gonorrhea, chlamydia, and syphilis. Primary (chancres) and secondary (rash, mucocutaneous lesions, and adenopathy) syphilis should be treated with a single intramuscular dose of benzathine penicillin, 2.4 million units. For latent syphilis or unknown duration of secondary syphilis, three weekly injections are recommended. Any patient with known or suspected syphilis should be evaluated for the possibility of neurosyphilis, which is known to have an increased incidence in the HIV-infected population. Therapy for other STDs is based on current CDC guidelines (see Chap. 141).

Immunizations of HIV-infected Patients

According to the U.S. Public Health Service Immunizations Practices Advisory Committee, HIV-infected persons should not receive live virus or live bacteria vaccines. The one exception to this is the measles-mumps-rubella (MMR) vaccine, which is indicated in all HIV-positive patients prior to onset of severe immunosuppression. In those with severe immunosuppression, MMR vaccination should be withheld due to increased risk of complications and decreased likelihood of benefit.

Killed vaccines pose no danger to immunosuppressed patients.⁴⁰ Since symptomatic HIV-infected persons have a suboptimal response to vaccines, all single-dose vaccines are advised to be given as early as possible in the course of HIV infection. Table 144-5 summarizes the CDC recommendations for common immunizations. Pneumococcal vaccine is recommended for all patients over 2 years of age because the risk for invasive pneumococcal infection is 50 to 100 times greater than in the general population. Tetanus-diphtheria vaccine is recommended as a booster every 10 years for those who have completed primary series. Hepatitis B vaccine is recommended for all high-risk individuals, including injected drug users, sexually active homosexual men, and sexually active men and women with STDs or more than one sexual partner in the past 6 months. Patients should be referred to a primary care provider for routine immunization.

Antiretroviral Therapy (ART)

The most notable recent advance in the management of HIV is the advent of highly active antiretroviral therapy (HAART) in 1996. Since then, sharp declines in AIDS incidence occurred through 1999 (although they have leveled off recently), and numbers of deaths among

TABLE 144-5 Immunization Recommendations for HIV-infected Patients

Vaccine	Asymptomatic	Symptomatic
DPT (to age 7)	Yes	Yes
Td	Yes	Yes
OPV (oral polio vaccine)	No	No
IPV (inactivated polio vaccine)	Yes	Yes
MMR (measles-mumps-rubella)	Yes	No*
Haemophilus B (Hib) flu (HbCV)	No (although not contraindicated)	Yes
Pneumococcal	Yes	Yes
Influenza (inactivated)	No (although not contraindicated)	Yes
Hepatitis B	Yes	Yes

*Severely immunocompromised children should not receive MMR. Source: Bartlett JG: *Medical Management of HIV Infection*. Baltimore, Johns Hopkins University, Division of Infectious Diseases, 2002; and Centers for Disease Control and Prevention: Standard for pediatric immunization practices: Recommended by the National Vaccine Advisory Committee. *MMWR* 42:1, 1993.

persons with AIDS have declined steadily.^{3,41} Explanations for the slowing of the decline in AIDS incidence include poor patient compliance with treatment regimens, costs, adverse side effects, and development of drug-resistant strains of HIV.

The fundamental goal of HIV therapeutics is long-term management of a chronic infection. Specific treatment recommendations are evolving constantly based on both advances in drug modalities and increasing information from clinical trials on response to therapy. General therapeutic goals, which remain constant, include (1) clinical: prolongation of life and improved quality of life; (2) virologic: greatest possible reduction in viral load to halt disease progression and prevent/reduce resistant variants; (3) immunologic: immune reconstitution, both quantitative ($CD4^+$ T-cell count) and qualitative (pathogen-specific immune response); and (4) therapeutic: rational sequencing of drug to attain virologic goals while reducing side effects and maintaining therapeutic options.

The emergency physician should be familiar with general classes of antiretroviral drugs, principles for initiating therapy, and common adverse reactions. Three main classes of drugs that independently interrupt the normal HIV life cycle include the nucleoside reverse-transcriptase inhibitors (NRTIs), the nonnucleoside reverse-transcriptase inhibitors (NNRTIs), and the protease inhibitors (Pis). Mechanisms of action and example of agents in each class are as follows: (1) NRTIs interfere with the action of reverse transcriptase [e.g., AZT (Retrovir)]; (2) NNRTIs bind to reverse transcriptase and block RNA- and DNA-dependent DNA polymerase activity [e.g., efavirenz (Sustiva)]; and (3) Pis block HIV protease, a key enzyme in establishing HIV infectivity [e.g., Indinavir (IDV)]. Eighteen antiretroviral drugs are currently approved by the FDA. A complete list and up-to-date guide for their use can be found on the CDC Web site (www.cdc.gov/hiv/pubs/mmwr). Initial preferred treatment regimens include 2 NRTIs + 1 PI; 2 NRTIs + 2 Pis or 2 NRTIs and 1 NNRTI. Factors that are considered in initiation include likelihood of adherence, potential for long-term side effects, potential for drug interaction, and preservation of future treatment options.

The optimal time to initiate therapy and the best drugs to use are still being evaluated. Treatment should be offered to all patients with symptoms ascribed to HIV infection. For the asymptomatic patient, treatment should be offered to those with $CD4^+$ T-cell counts below 350 cells/ μ L at any viral load and at higher $CD4^+$ T-cell counts (>350 cells/ μ L) with higher viral loads ($>55,000$ copies/mL).⁴²

Education and counseling also constitute an integral part of ART therapy. For these reasons, decisions regarding initiation of and changes in ART always should be made in consultation with the primary care physician and an infectious disease consultant.

PRECAUTIONS FOR HEALTH CARE WORKERS

Health care workers are often exposed to the blood and body fluids of HIV-infected patients or patients at high risk of harboring the HIV virus. ED-based studies have demonstrated that substantial numbers of patients continue to have unsuspected HIV infection and that HIV seropositivity cannot be predicted accurately, even with the aid of risk factors assessment. Universal precautions should be practiced, and all contacts with blood or body fluids should be considered potentially infectious. Universal precautions include gloves, gown, mask, and eye protection for any situation with the potential for exposure by splash, spray, touch, puncture, or immersion. These measures are also indicated for all ED procedures, including examination of bleeding patients, chest tube placement, central line placement, suturing, wound care, and LP.⁴³

The risk of acquiring HIV through occupational exposure is low. The likelihood of contracting AIDS after a parenteral exposure has been estimated at 0.32 percent; for mucocutaneous exposure, risk is approximately 0.09 percent. HIV transmission through nonintact skin has been documented, but the estimated risk is considerably lower than for mucocutaneous exposure. Approximately 80 percent of documented occupational exposure cases have resulted from hollow-bore

needle-stick injuries. As of June 2000, the CDC had documented 56 cases of HIV seroconversion temporally associated with an occupational exposure and an additional 138 cases of possible occupationally related seroconversion (i.e., seroconversion after a specific exposure was not clearly documented but was suspected by history).

Postexposure Prophylaxis

OCCUPATIONAL Guidelines for postexposure prophylaxis (PEP) of health care workers following an occupational exposure are based on a case-control study of needle-stick injuries from an HIV-infected source (which included 33 patients who seroconverted and 739 control subjects). This study reported that AZT prophylaxis was associated with a 79 percent reduction in disease transmission.⁴⁴ Risks for seroconversion include (1) deep injury, (2) visible blood on the device, (3) needle placement in a vein or an artery, and (4) a source with late-stage HIV infection. The most recent PEP recommendations were released in 2001 and advise treatment based on exposure category and risk of the source; decisions should be made in consultation with an infectious disease specialist.⁴⁵

PEP should be initiated as quickly as possible, preferably within 1 to 2 h. The interval after which there is no benefit for starting PEP is not known, although animal studies suggest little benefit if PEP is started 24 to 36 h after exposure. For these reasons, the decision should not delay initiation of PEP because modifications can be made after treatment has started. Decisions about PEP are based on assessments of type of exposure (superficial, deep, cutaneous, mucosal, hollow-bore needle, etc.) and exposure risk category (risk of HIV-infected material from the source). Treatment regimens vary by type of exposure. CDC guidelines recommend two basic alternatives: a basic regimen, which consists of two-drug therapy, often consisting of AZT and lamivudine (3TC), and an expanded regimen, which adds a third drug, such as indinavir (Crixivan) or nelfinavir (Viracept). Typically, the expanded regimen is recommended for high-risk exposures (defined as large-bore needle, visible injury, visible blood in device, or needle from patient artery/vein) and/or high-risk source (defined as symptomatic HIV, AIDS, acute seroconversion, or high viral load). Appropriate testing and treatment for other, more highly infectious agents such as hepatitis should be initiated as well. PEP treatment duration is 4 weeks. Gastrointestinal and constitutional side effects can be considerable; those who start treatment thus should be counseled and referred for timely follow-up.

NONOCCUPATIONAL Management of patients with possible sexual, injected drug use, or other nonoccupational exposure to HIV has become relevant because the U.S. Public Health Service issued a recommendation for the use of antiretroviral drugs to reduce the risk of acquisition of HIV following occupational exposure. The CDC has withheld making definitive statements regarding PEP for nonoccupational exposures because of the lack of available data regarding the use of antiretroviral agents in this setting. Recommendations may be forthcoming shortly as experience and data accumulate.

Patient adherence, the lack of data on the long-term effects of antiretroviral treatments, drug resistance, and a possible increase in high-risk behaviors have all been cited as reasons against offering PEP for nonoccupational exposures. However, further evaluation of PEP in patients with nonoccupational exposure to HIV infection may prove beneficial from both a clinical and a public health perspective.

Since the ED is often the initial site for evaluation and treatment of patients who have had these high-risk contacts, it is important for emergency physicians to develop a rationale approach. In ED patients with high-risk exposure, clinical workup should include a thorough history of the exposure and past high-risk behaviors, baseline laboratory and HIV testing, and consultation with a specialist.^{46,47} PEP must be considered on a case-by-case basis and generally should be restricted to situations in which the risk of infection is high, the intervention can be

initiated promptly (<36 h), adherence to the regimen is likely, and the individual is most likely to maintain risk-reduction behavior over time.⁴⁸ Advantages of therapy also must be balanced carefully with the risk of medication side effects. All sexual assault victim should be counseled about the risk and benefits of treatment.

In the ED, when the physician is faced with a case in which PEP is being considered, the assistance of experts should be sought. Risks and benefits of therapy should be considered in consultation with an infectious disease specialist and the patient's primary care provider. The CDC has a 24-h telephone hotline for physicians designed to assist with appropriate decision making regarding PEP (PEP Hotline: 1-888-448-4911).

DRUG REACTIONS

When managing HIV-positive and AIDS patients, emergency physicians must take into consideration the various drug interactions, reactions, and toxicities that can be causative of the clinical presentation of an HIV or AIDS patient. Current highly active antiretroviral therapies include a standard three-drug regimen that may cause a range of changes in metabolic or physiologic functions and also may be toxic. These interactions may be compounded by antibiotic prophylaxis being taken to fight against opportunistic infections. Drug reactions and interactions in seropositive patients should be considered when other diagnoses have been ruled out in specific presentation.

Drug interactions may be categorized as pharmacokinetic interactions [changes in level(s) of one or more drugs] or pharmacodynamic interactions (changes in effect, therapeutic response, or side effect of one or more drugs).⁴⁹ As antiretroviral drugs and combination therapies continue to be widely used and further developed, the possible drug reactions and interactions also will become more complex.

Review of current reference sources and consultation with a hospital pharmacologist and an infectious disease specialist are indicated when drug reactions are suspected.

ETHICAL CONSIDERATIONS

Many ethical considerations are involved in testing and treatment of HIV-infected patients. Confidentiality regarding HIV-related diagnoses is paramount to providing appropriate care for ED patients.⁵⁰ Treatment without discrimination, as with all disease states, should be initiated in all patients unless they specifically request otherwise.

Resuscitation of patients with advanced AIDS may be controversial, but decision making is no different than for patients with other debilitating conditions. Since ED physicians often have limited information about individual patients, their wishes, and the state of their disease, it is recommended that appropriate therapy and resuscitative measures be undertaken unless advance directives are available. Care should be taken that the label *HIV* or *AIDS* does not bias the judgment that resuscitative efforts are futile. Contact with a patient's primary care physician and family early during the ED stay helps in decision making about care.

DISPOSITION

Consultation with an infectious disease specialist and sometimes others with expertise in HIV infection is often necessary to provide proper therapy and disposition. Disposition decisions, as for all patients, are based on the need for definite inpatient evaluation or management and determination of the patient's ability to function as an outpatient (with special consideration regarding oral intake, ambulation, and availability of appropriate medical follow-up).

indolent or fulminant course. Diagnosis relies on a set of explicit criteria, which include findings from blood culture, echocardiography, and several days of inpatient observation. Unrecognized disease is associated with a wide range of complications and mortality approaching 100 percent.

EPIDEMIOLOGY

In developed countries, the incidence of IE ranges from 2.4 to 11.9 cases per 100,000 patient-years.^{1,4} Incidence is higher in urban versus rural populations, likely reflecting the impact of injection drug use (IDU). Currently just over 25 percent of cases occur in patients less than 30 years of age; approximately 50 percent occur in patients aged 31 to 60; and slightly less than 25 percent occur in those greater than 60 years of age. Factors contributing to the age distribution include decreased incidence of rheumatic heart disease, increased prevalence of degenerative valvular disease (due to aging), and increasing use of invasive medical procedures, including hemodialysis, intravenous catheters, and intracardiac devices. The disease is uncommon among children, where it is associated primarily with structural congenital heart disease, rheumatic heart disease, or nosocomial catheter-related bacteremia. IE affects men more commonly than women in a ratio of 1.7:1. The aortic valve is most commonly affected, followed in decreasing frequency by the mitral, tricuspid, and pulmonary valves. Significant variation in mortality occurs based on organism, presence of complications, and treatment modality (medical versus surgical).

The majority of cases of IE occur either in those with a predisposing identifiable cardiac structural abnormality (congenital or acquired) or a recognized risk factor for disease [including IDU, indwelling catheters, poor dental hygiene, or infection with human immunodeficiency virus (HIV)]. Recent reviews of IE cases in two suburban hospitals in North America showed distribution of cases of IE as follows: native valve related IE (NVE), 59 to 70 percent, IDU, 11 to 16 percent, and prosthetic valve IE (PVE), 14 to 30 percent.^{5,6} Studies in inner-city populations, however, find IDUs to account for up to 40 percent of cases.⁷

For NVE in the developed world, mitral valve prolapse is now the most commonly recognized predisposing cardiac lesion for IE. Incidence in this population is 100 per 100,000 patient years. Other commonly recognized underlying structural defects found in those with IE include congenital defects (most commonly bicuspid aortic valve), degenerative cardiac lesions (particularly calcific aortic stenosis), and rheumatic heart disease. In developing countries, rheumatic heart disease remains the leading underlying risk factor for IE. For NVE, left-sided disease predominates and mortality ranges from 16 to 27 percent. Risk factors associated with mortality for patients with left-sided native valve endocarditis include comorbidity, abnormal mental status, congestive heart failure, bacterial etiology other than *Streptococcus viridans* and *Staphylococcus aureus*, and medical therapy without valve surgery.⁸

Although the exact incidence is difficult to determine, estimated risk for IE in IDUs is 2 to 5 percent per year. Mean age of disease is 30 years. When IE occurs in IDUs it has a predilection for the right side, with tricuspid valve involvement occurring in the vast majority of cases. Mortality (< 10 percent) is lower than that seen in NVE. Other features of IDU-related IE include increased susceptibility to recurrence (approximately 40 percent) and increased mortality (56 percent) in those with concurrent HIV and evidence of immunosuppression (as measured by a CD4⁺ T-cell count of less than 200).^{7,9}

Prosthetic valve endocarditis (PVE) occurs in 3 to 6 percent of prosthetic valve recipients. Risk for IE is greatest during the initial 6 months after valve surgery and thereafter declines to a lower risk at 0.2 to 0.4 percent per year. No significant difference in risk for IE exists between those with mechanic versus bioprosthetic valves. Cases with onset within 60 days after surgery are called *early PVE* and are

INFECTIVE ENDOCARDITIS

Richard E. Rothman
Samuel Yang Catherine A.
Marco

The majority of patients with infective endocarditis (IE) have an identifiable predisposing cardiac abnormality or risk factor for disease. Clinical presentation is often nonspecific and can be highly variable, as the disease can affect nearly every organ system and have either an

usually acquired in the hospital. Cases occurring beyond 60 days post-surgery are called *late PVE* and are usually community acquired. Mortality rates are highest for those with early (30 to 80 percent) versus late PVE (20 to 40 percent) and are largely attributable to the greater virulence of the causative organisms involved.¹⁰

PATHOPHYSIOLOGY

The normal endothelium is resistant to infection and thrombus formation unless it is injured by high pressure gradients and turbulent flow states. These abnormal hemodynamic states occur most commonly in those with preexisting valvular or congenital cardiac defects. Turbulent blood flow then strikes against the endocardium, ultimately leading to denuding of the endothelium. In IDUs, endothelial damage likely occurs by a different mechanism, as a result of repetitive bombardment with particulate matter (i.e., talc) present in injected material, or as a result of ischemia brought on by vasospasm from the injected drug. Cocaine is known to be particularly associated with increased rates of IE.^{11,12} The resultant endothelial damage promotes deposition of platelets and fibrin, which form sterile vegetations called nonbacterial thrombotic endocarditis (NBTE). NBTE can also arise as a result of hypercoagulable states, such as in patients with malignancy (marantic endocarditis) or systemic lupus erythematosus (Libman-Sacks endocarditis), and in areas surrounding foreign bodies, such as intracardiac catheter or prosthetic valves.

In the setting of preexistent NBTE, transient bacteremia may result in colonization of vegetations and ultimately conversion of NBTE to IE. Transient bacteremia can occur from trauma to the skin or mucosal surfaces of the oropharynx or gastrointestinal or genitourinary tracts (all of which are normally laden with endogenous flora). Even in the absence of trauma, however, spontaneous bacteremia can occur in patients with severe periodontal disease or other localized infections. In cases of bacteremia, the bacterial load usually does not exceed 10 organisms per milliliter of blood, and the bloodstream is usually sterilized in less than 30 min. In the presence of NBTE, however, this time interval is believed to be sufficient for bacteria to adhere to the vegetation and transform it into an infected lesion.

The coexistence of bacteremia and NBTE does not uniformly result in IE. In order to cause IE, the infecting organism must be able to adhere to the NBTE on the endothelium. Different organisms vary in this ability based on their intrinsic cellular factors. Furthermore, although NBTE is generally believed to be present in those who develop IE, it not an absolute prerequisite, and highly invasive organisms (e.g., *S. aureus*) can directly invade the endocardium.¹¹ Adherent organisms stimulate further deposition of platelets and fibrin, leading to sequestration into a "protected site," into which phagocytic cells have difficulty penetrating. Metabolically inactive and nongrowing organisms,

common in IE, also provide relative protection from the bactericidal effects of antibiotics. As the disease progresses, the vegetation continuously fragments, shedding surface organisms into the circulation and resulting in sustained bacteremia.

MICROBIOLOGY

A wide range of bacteria and fungi, as well as *Rickettsia* and *Chlamydia* species can cause endocarditis. Bacteria are the predominant cause overall, with only a small number of species responsible for the majority of cases. Causative microorganisms vary based on the specific conditions (i.e., native versus prosthetic valve) and risk factors (injection drug use) that predispose patients to IE (Table 145-1). *Staphylococcus aureus* is the single most common cause.¹³

Native Valve Endocarditis (Non IDU)

Among non-IDUs with NVE, streptococcus is responsible for more than 50 percent of cases, followed by staphylococci and enterococci.¹⁴ Infection occurs most frequently in those with preexisting valvular abnormalities. Disease course with streptococci-associated IE tends to be indolent.

Staphylococci-associated IE occurs both in patients with previously normal valves and those with known valvular abnormalities. Most are caused by coagulase-positive organisms (*S. aureus*) which cause rapid destruction of valves, multiple distal abscesses, myocardial abscesses, conduction defects, and pericarditis.

Patients with enterococcal endocarditis generally have underlying valvular disease and multiple predisposing abnormalities, most commonly diabetes mellitus. Enterococcal NVE may occur following manipulation of the genitourinary or lower gastrointestinal tract.

Negative culture can occur in approximately 5 percent of patients with IE and in one-third to one-half of these cases cultures are negative because of prior antibiotic exposure.¹⁵ The remainder of cases are caused by infection with fastidious organisms, such as the HACEK group (*Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella*, and *Kingella*), *Bartonella* species, or *Coxiella burnetii*. In patients who meet diagnostic criteria for culture-negative IE, the clinician should advise the laboratory of the suspected diagnosis, to allow initiation of specialized testing to recover these fastidious organisms, which is critical for appropriate antimicrobial therapy.

IDU-Associated IE

Skin flora and contaminated injection devices are the most frequent sources of microorganisms involved in IDU-associated IE. *S. aureus* accounts for more than 50 percent of cases, followed in decreasing fre-

quency by streptococcal species (including enterococci), gram-negative bacilli (predominantly *Pseudomonas* and *Serratia* species), and fungi (5 percent, mostly *Candida* species). *S. viridans* is a relatively infrequent cause of IDU-associated IE. Polymicrobial infective endocarditis, although relatively uncommon, is seen most often in association with IDU.

Prosthetic Valve Endocarditis

Microorganisms involved in early PVE most often reflect contamination during the perioperative period, with *S. epidermidis* being the most frequently isolated organism. Early PVE is often associated with valve dysfunction and has a fulminant clinical course. Late PVE has similar bacteriology and clinical manifestations as native valve endocarditis, with streptococcus accounting for 30 percent of cases; disease course tends to be less fulminant. *Aspergillus* and *Candida albicans* account for the majority of cases of mycotic PVE, and are associated with large vegetations and embolic complications.

CLINICAL FEATURES

Classically, the clinical course of IE has been categorized as either acute or subacute. Acute IE is characterized by rapid onset, with high fevers and rigors, hemodynamic deterioration, and death within days to weeks if left untreated. Typically, acute IE has been associated with highly virulent organisms such as *S. aureus*. Subacute IE is characterized by an indolent course with progressive constitutional signs and symptoms and gradual deterioration. Patients often have symptoms for several weeks prior to diagnosis; progression of disease is more insidious and complications may take months to develop. Subacute IE has been generally associated with relatively avirulent organisms such as viridans streptococci. While it is important to be familiar with these traditional distinctions, these terms are less widely utilized today as correlation of disease course with its infecting pathogen has been found to be variable, certain pathogens have been found to cause either form of disease, and classic presentations are rarely encountered. IE can thus better be understood as a continuum, with an understanding of clinical conditions as they relate to the pathophysiologic process and the organ systems that are affected.

Bacteremia

Early bacteremia produces signs and symptoms that are often nonspecific and protean (Table 145-2), usually beginning within 2 weeks of the precipitating infection. The patient with IE often presents to the ED early in the course of the disease, with vague constitutional complaints such as fever, chills, nausea, vomiting, fatigue, and malaise. Fever ($>38^{\circ}\text{C}$) is present in almost all patients with IE (>90 percent overall, and >98 percent in those with IDU-associated IE). It may be absent, however, in elderly persons or patients with a history of antibiotic or antipyretic use, severe congestive heart failure, or renal failure. Since prevalence of IE among febrile IDUs is extremely high (10 to 15 percent), and it has been well demonstrated that clinical findings are insufficient to reliably exclude the diagnosis of IE in this population, all febrile IDUs should be admitted to evaluate for bacteremia and IE.^{16,18} Unexplained fever in a patient with a prosthetic valve should also prompt careful evaluation for PVE, as should prolonged unexplained constitutional symptoms in patients at risk (see section on diagnosis). As the level of bacteremia increases, sepsis ultimately occurs with the usual features of hemodynamic compromise.

Cardiac

Cardiac findings in patients with IE are common and due to local invasion. Heart murmurs are useful if present and are most often regurgitant in nature due to destruction of the valves or adjacent structures

TABLE 145-2 Clinical Features of Infective Endocarditis

Symptoms	Percent	Signs	Percent
Fever	80	Fever	90
Chills	40	Heart murmur	85
Weakness	40	New murmur	3-5
Dyspnea	40	Changing murmur	5-10
Anorexia	25	Skin manifestations	18-50
Cough	25	Osier nodes	10-23
Malaise	25	Splinter hemorrhages	15
Skin lesions	20	Petechiae	20-40
Nausea/vomiting	20	Janeway lesions	<10
Headache	20	Splenomegaly	20-57
Stroke	20	Embolic phenomena	>50
Chest pain	15	Septic complications	20
Abdominal pain	15	Mycotic aneurysm	20
Mental status	?e 10-15	Renal failure	10
Back pain	10	Retinal lesions	2-10

by enlarging vegetations. While murmurs are reportedly present in up to 85 percent of cases of IE, they may be difficult to detect in the ED. In patients with right-sided IE, less than 50 percent have murmurs detectable on admission.

Acute or progressive congestive heart failure, now the leading cause of death in patients with IE, occurs in up to 70 percent of patients. Causes of CHF include distortion or perforation of valvular leaflets, rupture of the chordae tendineae or papillary muscles, or perforation of cardiac chambers (a devastating but rare complication). Valvular abscesses and pericarditis are caused by local extension of infection into valve rings or the pericardium, respectively. Other important cardiac complications include heart blocks and arrhythmias that result from extension of infection through the interventricular septum to the conduction system.

The extracardiac manifestations of IE are usually the result of arterial embolization of fragments of the friable vegetation, and are second to CHF as the leading cause of complications of IE. Embolization to any major artery may occur. Infarcts or abscesses of remote tissues may occur, depending on whether emboli are bland or septic.

Central nervous system complications occur in 20 to 40 percent of cases of IE. Most common is embolic stroke. The middle cerebral artery is affected most frequently, and hemiplegia is a common presentation. Mycotic aneurysms of the cerebral circulation are also relatively frequent. Rupture of the aneurysm results in subarachnoid hemorrhage. Retinal artery emboli may cause acute monocular blindness. Pulmonary complications are most common in IDUs, who are predisposed to right-sided disease, typically involving the tricuspid valve. Clinical manifestations include pulmonary infarction, pneumonia, empyema, or pleural effusion. Coronary artery emboli usually arise from the aortic valve, and may cause acute myocardial infarction, or myocarditis with arrhythmias. Embolic splenic infarction may cause left upper quadrant abdominal pain with radiation to the left shoulder. Patients with suspicious presentations should have an abdominal CT performed. Splenomegaly occurs in up to 60 percent of cases of IE and is usually suggestive of indolent disease. Renal emboli may present with flank pain or hematuria. Emboli lodging in the

mesenteric arteries may result in acute abdominal pain and guaiac-positive stool, while those involving arteries of the extremities may produce acute limb ischemia.

Circulating Immune Complexes

The persistent bacteremia of IE stimulates the host humoral and cellular immune systems. This results in circulating immune complexes, which have been detected in virtually all patients. A variety of classic cutaneous and peripheral manifestations have been described in IE as a result of local immune-mediated vasculitis or microemboli. Although common (occurring in greater than 50 percent of cases), they are not specific for IE, and may be seen in other disease states including systemic lupus erythematosus, hemolytic anemia, and gonococcal infections. Petechiae are initially red, nonblanching lesions that become brown after several days and are found in 20 to 40 percent of patients. They occur most frequently on the conjunctivae, buccal mucosa, and extremities. Splinter or subungual hemorrhages appear as linear dark streaks under the fingernails or toenails; they occur in approximately 15 percent of cases, but may also be caused by local nail trauma. Osier's nodes are small, tender subcutaneous nodules that develop on the pads of the fingers or toes. They are found in up to 25 percent of cases, but usually disappear within hours or days. Janeway lesions are small hemorrhagic painless plaques located on the palms or soles. Roth spots are oval retinal hemorrhages with pale centers located near the optic disc. Digital clubbing is an infrequent finding and usually found only in those with longstanding disease. Immune complex deposition may also occur along the glomerular basement membrane, resulting in the development of focal or diffuse glomerulonephritis. Renal insufficiency and azotemia are resulting complications.

DIAGNOSIS

From the standpoint of the emergency physician, diagnosis of infective endocarditis still requires hospitalization, as results from the cornerstone components of the current diagnostic criteria (culture, echocardiography, and clinical observation) require time to accrue. Studies that have attempted to establish prediction rules for identification of patients with IE in acute care settings have failed.¹⁷ All patients

in whom the suspicion for IE exists (see below) should therefore be admitted and evaluated using the diagnostic criteria described below.^{16,18}

Diagnostic Criteria

The Duke criteria are now the most widely utilized scheme for diagnosing IE.¹⁹ Application of the criteria requires gathering critical diagnostic data (i.e., blood culture results, echocardiographic and clinical findings, and determination of the presence of recognized risk factors for disease) which compromise major or minor Criteria (Table 145-3). As a second step, specific combinations of these criteria are used to assign a final diagnostic category of definite, possible, or rejected IE (Table 145-4). Sensitivity of the Duke criteria is about 90 percent, although investigations continue in an attempt to improve specificity.

Pilot studies provide promising data indicating that immediate echocardiography combined with 24-h blood culture results may provide comparable sensitivity and specificity relative to the Duke criteria for the evaluation of febrile IDUs.²¹ However, these studies are ongoing and will require validation. Current recommendations are to admit all patients in whom IE is suspected for formal evaluation.

Differential Diagnosis and Consideration of IE

The differential diagnosis is extremely broad and includes viral illnesses, HIV-related fevers, acute rheumatic fever, systemic complications of collagen vascular disorders, drug reactions, and many other disorders. Endocarditis should be considered in all patients with known risk factors and/or unexplained febrile illnesses. General recommendations regarding decision making are: (1) all febrile IDUs with fever should be admitted because of the high incidence of disease (up to 15 percent) and noncompliance with outpatient follow-up; (2) patients with a cardiac prosthesis and fever (or persistent malaise, vasculitis, or new murmur) should be hospitalized due to increased risk of IE and the high morbidity and mortality associated with prosthetic valve infections; (3) patients with a new murmur or change in murmur with evidence of vasculitis or embolization should be admitted. Explicit admission guidelines are less clear for others, but the diagnosis

TABLE 145-3 Definitions of Major and Minor Criteria Used in the Duke Criteria*

Major criteria

- Positive blood culture for IE
 - Typical microorganism consistent with IE from two separate blood cultures* as noted below:
 - Streptococcus bovis*, *Viridans streptococci*, HACEK group, or
 - Community-acquired *Staphylococcus aureus* or enterococci in the absence of a primary focus, or
 - Microorganisms consistent with IE from persistently positive blood cultures defined as: At least two positive cultures of blood samples drawn > 12 h apart, or
 - All of three or a majority of four or more separate blood cultures (with first and last sample drawn at least 12 h apart)
 - Evidence of echocardiographic involvement
 - Positive echocardiogram for IE defined as:
 - Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation, or
 - Abscess, or
 - New partial dehiscence of prosthetic valve
 - New valvular regurgitation (worsening or changing of preexisting murmur not sufficient)

Minor criteria

- Predisposition: predisposing heart condition or injection drug use
- Fever: temperature >38°C
- Vascular phenomena: major arterial emboli, septic pulmonary conjunctival hemorrhages, and Janeway lesions
- Immunologic phenomena: glomerulonephritis, Osier nodes, Roth spots, and rheumatoid fever
- Microbiologic evidence: positive blood culture but does not meet a major criterion as noted in Table 145-4* or serologic evidence of active infection with organism consistent with IE
- Echocardiographic findings: consistent with IE but do not meet a major criterion as noted in Table 145-4

*Excludes single positive cultures for coagulase-negative staphylococci and organisms that do not cause IE.
 Abbreviations: HACEK = *Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella*, and *Kingella*; IE = infective endocarditis.
 Source: From Durack et al.

TABLE 145-4 Definitions of Infective Endocarditis According to the Duke Criteria*Definite infective endocarditis*

Pathologic criteria

Microorganisms demonstrated by culture or histologic examination of a vegetation or in a vegetation that has embolized, or in an intracardiac abscess, *or* Pathologic lesions: vegetation or intracardiac abscess present, confirmed by histology showing active endocarditis Clinical criteria, using specific definitions listed in Table 145-2 Two major criteria, *or* One major and three minor criteria, *or* Five minor criteria. *Possible infective endocarditis*

Findings consistent with infective endocarditis, that fall short of "definite," but not "rejected."

Rejected

1. Firm alternate diagnosis for manifestations of endocarditis, *or*
2. Resolution of manifestations of endocarditis, with antibiotic therapy for 4 d or less, *or*
3. No pathologic evidence of infective endocarditis at surgery or autopsy after antibiotic therapy for 4 d

must be strongly considered in patients with any other known cardiac risk factor presenting with unexplained febrile illness or systemic complaints, as well as any patient with a prolonged (>2 weeks) unexplained fever.

Evaluation of Bacteremia (Culture and PCR)

All patients with suspected IE should have blood cultures drawn in the ED prior to initiation of antibiotic therapy. Blood cultures should be drawn from three separate sites. Since low-grade bacteremia is known to be common in patients with IE, it is recommended that a minimum of 10 mL of blood be used for each bottle. Additional sets of blood cultures have been shown to be useful in patients already receiving antibiotics. It is recommended that there be at least 1 h between the first and last blood culture. However, for those patients who are ill-appearing or have any evidence of systemic complications, antibiotics should not be withheld to await retrieval of delayed sets of cultures.

Polymerase chain reaction (PCR) techniques are currently under evaluation for the more rapid diagnosis of infective endocarditis.^{22,23}

Other Diagnostic Tests

An ECG should be done in all patients with suspected IE. Although usually nonspecific, important conduction abnormalities may be uncovered that indicate extension of the infection. Prolonged PR interval, new left bundle-branch block, or new right bundle-branch block with left anterior hemiblock suggest spread of infection from the aortic valve into the conduction system. Junctional tachycardia, Wenckebach block, or complete heart block in the setting of suspected IE indicate likely extension of infection from the mitral annulus into the AV node or proximal bundle of His. If these are uncovered, cardiology and cardiothoracic surgery should be consulted, as urgent or emergent surgery may be indicated. Chest radiographs should be obtained as they may reveal other complications, such as pulmonic emboli in patients with right-sided valvular involvement or congestive heart failure in those with left-sided IE.

There are no definitive laboratory tests that can be used to make the diagnosis of IE in the acute care setting. Laboratory abnormalities that are strongly associated with IE but are relatively nonspecific include anemia (70 to 90 percent of cases), elevated erythrocyte sedimentation rate, (>90 percent of cases), and hematuria.

Echocardiography

Echocardiography should be performed on all patients in whom the diagnosis of IE is under consideration for the following reasons: (1) echocardiographic abnormalities comprise one of the two major criteria required for definitive diagnosis of IE; (2) evaluation of the cardiac valve and its surrounding structures provides critical information regarding valvular function and associated complications, data which

are important for guiding management decisions. Most hospitals defer imaging to the inpatient unit since all patients with suspected IE should be admitted. However, for any patient with evidence of significant cardiovascular compromise, imaging should be obtained emergently.

Transthoracic two-dimensional (2-D) echocardiography (TTE) is rapid and noninvasive and should be the first choice of imaging for those with native valves in whom good quality images can be obtained. Specificity for vegetations is excellent (98 percent). However, sensitivity varies according to population. It is highest among IDUs (88 to 94 percent), who more often have larger vegetations, a preponderance of right-sided lesions, and a favorable acoustic precordial window characteristic of younger patients. For those with chest wall deformities, obesity, or chronic obstructive pulmonary disease (COPD), sensitivity is diminished. Transesophageal echocardiography (TEE) is invasive, requiring more time and skill than TTE. Sensitivity and specificity (for any valvular abnormalities) are significantly higher than for TTE, due to improved image resolution. TEE is recommended in the following patient populations with suspected IE: (1) patients with prosthetic valves; (2) those in whom inadequate images are likely to be obtained with TTE as described above; and (3) those with intermediate or high clinical probability of IE (an assessment which is difficult to make and usually not feasible in the ED). While rarely indicated in the ED, TEE is of particular value for assessment of the complications associated with IE, such as myocardial abscess and perivalvular extension.

TREATMENT AND PROPHYLAXIS**Initial Stabilization**

Patients with endocarditis may present with respiratory compromise due to decreased cardiac output (secondary to valvular defects), diminished pulmonary capacity (due to pulmonary emboli), altered mental status, or acidosis (related to CNS emboli and/or sepsis). In such cases rapid airway stabilization, including endotracheal intubation, is indicated.

Valvular rupture may present with acute cardiac decompensation. Rupture of left-sided valves more commonly results in cardiac decompensation, and should be managed with afterload reduction. Intraaortic balloon counterpulsation (IABP) may be indicated for the emergent management of unstable mitral valve rupture. However, the use of IABP is contraindicated for aortic valve rupture.

Neurologic complications, including stroke, should be managed with standard protocols, in addition to definitive therapy for endocarditis.

Empiric Treatment of Suspected Endocarditis of Native Valves

Empiric antibiotic therapy should be initiated promptly for suspected acute endocarditis. There is not complete agreement in the literature

TABLE 145-5 Empiric Therapy of Suspected Bacteria] Endocarditis*

Patient Characteristics	Recommended Agents	Initial Dose
Uncomplicated history	Ceftriaxone or nafcillin plus gentamycin	1–2 g IV 2 g IV 1–3 mg/kg IV
Injection drug use, congenital heart disease, hospital-acquired, suspected MRSA, or already on oral antibiotics	Nafcillin plus gentamycin plus vancomycin	2 g IV 1–3 mg/kg IV 15 mg/kg IV
Prosthetic heart valve	Vancomycin plus gentamycin plus rifampin	15 mg/kg IV 1–3 mg/kg IV 300 mg PO

*Because of controversy in the literature regarding the optimal regimen for empiric treatment, antibiotic selection should be based on patient characteristics, local resistance patterns, and current authoritative recommendations.

regarding specific antibiotic selection. Antibiotic selection should be based on patient characteristics and local resistance patterns. Table 145-5 lists some sample empiric treatment regimens based on current recommendations.^{24,26} Although some authors recommend awaiting culture results prior to antibiotic therapy for patients with subacute bacterial endocarditis,²⁷ we recommend prompt ED initiation of antibiotic therapy for all patients suspected of endocarditis. For patients with suspected native valve infection, empiric antibiotic therapy may include a penicillinase-resistant penicillin or a cephalosporin and an aminoglycoside. For patients with complications (including injection drug use, congenital heart disease, those who develop endocarditis while taking oral antibiotics, nosocomial infections, or those with suspected methicillin-resistant *S. aureus*), vancomycin should be added to the treatment regimen.

Empiric Treatment of Suspected Endocarditis of Artificial Valves

For patients with suspected artificial valve endocarditis, empiric therapy should include vancomycin, an aminoglycoside, and rifampin.

Definitive Antibiotic Treatment of Endocarditis

Definitive antibiotic treatment should be based on culture and sensitivity results. Selection of the most appropriate antibiotics and treatment duration should be undertaken in consultation with the primary care physician, and if appropriate, an infectious disease consultant. Most patients will require 4 to 6 weeks of antibiotic therapy. Certain

patients may be managed successfully with outpatient parenteral antibiotic therapy following definitive diagnosis of certain pathogens.²⁸

Surgical Treatment

Surgical management of endocarditis may be indicated in patients with severe valvular dysfunction, such as acute congestive heart failure or impaired hemodynamic status. The presence of large vegetations does not necessarily indicate a need for surgical intervention. Surgical intervention may also be indicated in patients with relapsing prosthetic valve endocarditis, major embolic complications, fungal endocarditis, new conduction defects or arrhythmias resultant from infection, or persistent bacteremia after appropriate antibiotic therapy. Prompt surgical consultation is indicated in patients who may be surgical candidates.^{29,30}

Anticoagulation

Anticoagulation for native valve endocarditis has not been shown to be beneficial.⁹ Additionally, anticoagulation may significantly increase the risk of intracranial hemorrhage. Patients with prosthetic valves who are treated at baseline with anticoagulants may be cautiously maintained on established regimens, with particular caution for central nervous system complications.

Prophylaxis

Antibiotic prophylaxis against endocarditis should be administered for patients with risk factors for endocarditis, including prosthetic heart valves, congenital cardiac malformations, acquired valvular dysfunction, hypertrophic cardiomyopathy, mitral valve prolapse with documented regurgitation, or a history of endocarditis. Prophylaxis is not routinely indicated for patients with mitral valve prolapse without regurgitation, pacemakers, physiologic murmurs, prior coronary artery bypass surgery or angioplasty, or previous surgical repair of atrial septal defect, ventricular septal defect, or patent ductus arteriosus.

Although there is some controversy regarding which procedures warrant endocarditis prophylaxis, current recommendations include dental work (including cleaning), bronchoscopy, cystoscopy, urethral instrumentation, and endoscopic retrograde cholangiopancreatography. Prophylaxis is not indicated for local injections, laceration suturing, intravenous line placement, blood drawing, endotracheal intubation, endoscopy, vaginal delivery, urethral catheterization, or uterine dilation and curettage.

Current recommendations for endocarditis prophylaxis include stratification into high-, moderate-, and low-risk populations.^{31,33} A simplified strategy is listed in Table 145-6.

TABLE 145-6 Prophylaxis Against Endocarditis for High-Risk Patients

Procedure	Antibiotic Agent	Dose
Dental/oral/respiratory/esophageal procedures	Amoxicillin or Ampicillin or Clindamycin or Azithromycin	2 g PO, 1 h before procedure 2 g IM or IV, 30 min before procedure 600 mg PO, 1 h before procedure, or 600 mg IV, 30 min before procedure 500 mg PO, 1 h before procedure
Genitourinary/gastrointestinal procedures	Ampicillin plus Gentamycin plus Ampicillin or Amoxicillin Alternative regimen: Vancomycin plus Gentamycin	2 g IM or IV, 30 min before procedure 1.5 mg/kg IM or IV, 30 min before procedure 1 g IV or IV, 6 h after procedure 1 g PO, 6 h after procedure 1 g IV over 1–2 h, completed 30 min before procedure 1.5 mg/kg IV or IM, within 30 min of procedure

TETANUS Donna L.

Garden

EPIDEMIOLOGY

Tetanus is an uncommon disease in the United States but continues to have a substantial global health impact. The worldwide incidence of tetanus approaches 1 million cases per year. Tetanus is associated with a mortality rate of 20 to 50 percent and at least half of these deaths occur in neonates. The prevalence of tetanus is highest in developing countries where it is among the ten most frequent causes of death and an important cause of infant mortality.¹

The institution of widespread immunization programs for children, routine boosters in adults, mechanization of agriculture, and use of chemical fertilizers rather than animal manure has resulted in a decline in the average annual incidence of tetanus in the United States to fewer than 50 cases per year.² In the United States, the majority of tetanus occurs in temperate areas, such as Texas, California, and Florida,² and is associated with a mortality rate of approximately 11 percent. Most patients who develop tetanus have an inadequate immunization history.² Only 27 percent of Americans older than age 70 years have adequate immunity to tetanus.³

The majority of patients diagnosed with tetanus who sought medical care for their initial injury did not receive adequate tetanus prophylaxis.² Heroin abusers, especially those who inject themselves subcutaneously, are at increased risk of contracting tetanus.⁴

PATHOPHYSIOLOGY

Tetanus is an acute, often fatal disease caused by wound contamination with *Clostridium tetani*, a motile, nonencapsulated anaerobic gram-positive rod. *C. tetani* exists in either a vegetative or a spore-forming state. The spores are ubiquitous in soil and in animal feces and are extremely resistant to destruction, surviving on environmental surfaces for years. *C. tetani* is usually introduced into a wound in the spore-forming, noninvasive state but can germinate into a toxin-producing, vegetative form if tissue oxygen tension is reduced. Factors such as the presence of crushed, devitalized tissue, a foreign body, or the development of infection, favor the growth of the vegetative, toxin-producing form of *C. tetani*.⁵

Once converted into the vegetative form, *C. tetani* produces two exotoxins: tetanolysin, which appears to be clinically insignificant, and tetanospasmin, a powerful neurotoxin that is responsible for the clinical manifestations of tetanus. Although the infection caused by *C. tetani* remains localized to the site of injury, tetanospasmin reaches the nervous system by hematogenous spread of the exotoxin to peripheral nerves and by retrograde intraneuronal transport. Blood-borne tetanospasmin does not cross the blood-brain barrier, but retrograde intraneuronal transport of the exotoxin enables tetanospasmin to gain access to the central nervous system.¹

Tetanospasmin acts on the motor end plates of skeletal muscle, in the spinal cord, in the brain, and in the sympathetic nervous system.

This extremely potent exotoxin prevents the release of the inhibitory neurotransmitters glycine and 7-aminobutyric acid (GABA) from presynaptic nerve terminals, releasing the nervous system from its normal inhibitory control. Loss of inhibition may also affect the pre-ganglionic sympathetic neurons resulting in sympathetic overactivity and high circulating catecholamine levels.⁶

CLINICAL FEATURES

The exotoxin tetanospasmin is responsible for the clinical manifestations of generalized muscular rigidity, violent muscular contractions, and instability of the autonomic nervous system. Wounds that become infected with toxin-producing *C. tetani* are most often puncture wounds,² but vary widely in severity from deep lacerations to minor abrasions.^{2,5} However, a wound cannot be identified in up to 10 percent of patients with tetanus. Tetanus can also develop after surgical procedures, otitis media, and abortion, and can develop in neonates through infection of the umbilical stump and in drug abusers.

The incubation period ranges from less than 24 h to more than 1 month. The shorter the incubation period, the more severe the disease and the worse the prognosis for recovery.¹

Clinical tetanus can be categorized into four forms: local, generalized, cephalic, and neonatal. The different categories of clinical tetanus depend on what population of neurons are involved.

Local tetanus is manifested by rigidity of muscles in proximity to the site of injury and usually resolves completely after weeks to months. Local tetanus may progress to the generalized form of the disease.

Generalized tetanus is the most common form of the disease.² The most frequent presenting complaints of patients with generalized tetanus are pain and stiffness in the masseter muscles (lockjaw).⁷ Nerves with short axons are affected initially; therefore, symptoms appear first in the facial muscles, with progression to the neck, trunk, and extremities.⁷ The transition from muscle stiffness to rigidity leads to the development of trismus and the resultant characteristic facial expression: risus sardonicus (sardonic smile) (Figure 146-1). Reflex convulsive spasms and tonic muscle contractions are responsible for the development of dysphasia, opisthotonos (Figure 146-2), flexing of the arms, clenching of the fists, and extension of the lower extremities. Patients are conscious and alert unless laryngospasm or contraction of respiratory muscles results in respiratory compromise.

Disturbances of the autonomic nervous system, generally a hyper-sympathetic state, occur during the second week of clinical tetanus and

FIG. 146-1. *Risus sardonicus* (sardonic smile) of tetanus. (Photograph reproduced with permission from the Immunization Action Coalition, St. Paul, MN.)

FIG. 146-2. *Opisthotonos* of tetanus. (Photograph reproduced with permission from the Immunization Action Coalition, St. Paul, MN.)

present as tachycardia, labile hypertension, profuse sweating, hyperpyrexia, and increased urinary excretion of catecholamines.⁸ The autonomic complications of generalized tetanus are difficult to manage and contribute significantly to morbidity and mortality.

Cephalic tetanus follows injuries to the head or occasionally otitis media and results in dysfunction of the cranial nerves, most commonly the seventh. It has a poor prognosis.

Neonatal tetanus is responsible for more than 400,000 deaths worldwide per year. It develops in children born to inadequately immunized mothers, frequently after unsterile treatment of the umbilical cord stump. Infants with neonatal tetanus present with weakness, irritability, and an inability to suck during the second week of life.¹

DIAGNOSIS

Tetanus is diagnosed solely on the basis of clinical evidence. Most patients who develop the disease have an unknown or inadequate immunization history.² There are no laboratory tests to diagnose tetanus, although serum antitoxin titers of >0.01 IU/mL are usually protective and may be helpful retrospectively. Wound culture is of limited value, because *C. tetani* may be cultured from wounds in the absence of clinical disease and may not be recovered in patients with documented tetanus.⁵ Table 146-1 presents the differential diagnosis of tetanus. Strychnine poisoning most closely mimics the clinical picture of generalized tetanus.

TREATMENT

Patients with tetanus should be managed in an intensive care unit. Respiratory compromise requires immediate neuromuscular blockade and orotracheal intubation. Environmental stimuli must be minimized to prevent the precipitation of reflex convulsive spasms.

The initial wound should be identified and debrided to improve the oxidation-reduction potential of the infected tissue and to prevent further toxin production.

TABLE 146-1 Differential Diagnosis of Tetanus

Strychnine poisoning
Dystonic reaction (phenothiazines, metoclopramide)
Hypocalcemic tetany
Peritonsillar abscess
Peritonitis
Meningeal irritation (bacterial meningitis, subarachnoid hemorrhage)
Rabies
Temporomandibular joint disease

Tetanus Immunoglobulin

Human tetanus immunoglobulin (TIG) neutralizes circulating tetanospasmin and toxin in the wound but not toxin that is already fixed in the nervous system. Even though TIG does not ameliorate the clinical symptoms of tetanus, it significantly reduces mortality.⁹ Although the optimal dose of TIG is unknown, 3000 to 6000 units is the usual recommended dose, administered IM opposite the site of tetanus toxoid administration. **It should be given before wound debridement, because exotoxin may be released during wound manipulation.** Repeated doses of TIG are unnecessary, because the half-life of the antitoxin is 28 days.⁷

Antibiotics

Antibiotics are of questionable utility but are traditionally administered. Parenterally administered metronidazole is the antibiotic of choice.¹⁰ Penicillin, a centrally acting GABAA antagonist may potentiate the effects of tetanospasmin, thus its use should be avoided.¹

Muscle Relaxants

Tetanospasmin prevents neurotransmitter release at inhibitory interneurons, and therapy of tetanus is aimed at restoring normal inhibition. The benzodiazepines are centrally acting inhibitory agents that have been used extensively for this purpose. However, the large intravenous doses of benzodiazepines required in tetanus may result in metabolic acidosis secondary to the propylene glycol vehicle. Thus, the water-soluble agent, midazolam, is the preferred agent for producing muscle relaxation in patients with tetanus.⁷ Other drugs, such as baclofen, a specific GABAB agonist, have been used to treat tetanus-induced muscle spasms.¹¹

Neuromuscular Blockade

To control ventilation and muscular spasms as well as to prevent fractures and rhabdomyolysis, prolonged neuromuscular blockade may be required in the treatment of tetanus. Succinylcholine is recommended for emergency airway control, while vecuronium is the neuromuscular blocking agent of choice for prolonged blockade because of minimal cardiovascular side effects.¹² Concomitant sedation with narcotics, barbiturates, or benzodiazepines is mandatory.

Treatment of Autonomic Dysfunction

Labetalol, the combined α - and β -adrenergic blocking agent, is useful in treating the manifestations of sympathetic hyperactivity of tetanus.

Short-acting (β -blockers such as esmolol may be advantageous in cases where (β -blockade alone is associated with severe hypertension from unopposed α -adrenergic stimulation. Adrenergic-blocking drugs, although effective in the treatment of the autonomic dysfunction of tetanus, may precipitate myocardial depression or sudden death if sympathetic activity transiently diminishes.^{13,14}

Magnesium sulfate inhibits the release of epinephrine and norepinephrine from the adrenal glands and adrenergic nerve terminals, eliminating the source of catecholamine excess in tetanus.¹⁵ Morphine sulfate reduces sympathetic α -adrenergic tone and central sympathetic efferent discharge and produces peripheral arteriolar and venous dilatation.⁷

Clonidine, a central α -receptor agonist, has also been used to manage tetanus-induced cardiovascular instability.--Continuous epidural block with bupivacaine has been suggested but may be difficult to administer and manage.

Active Immunization

Patients who recover from tetanus must undergo active immunization, because the disease does not confer immunity. Adsorbed tetanus toxoid (0.5 mL) should be administered IM at the time of presentation and at 6 weeks and 6 months after injury. Tetanus-diphtheria (Td) should be administered to patients older than 7 years of age,¹⁶ and diphtheria-pertussis-tetanus (DPT) should be administered to patients younger than 7 years of age.¹⁷ Tetanus immunization should be administered to unimmunized or inadequately immunized pregnant women. Table 146-2 summarizes the guidelines for active tetanus immunization and Table 146-3 summarizes the management of tetanus.

Adverse reactions following tetanus immunization include local adverse events such as erythema, induration, and pain at the injection site. Local reactions are common and usually self-limited. Exaggerated local reactions occur occasionally following tetanus toxoid and involve extensive pain and swelling of the entire extremity. Exaggerated local reactions occur most often in adults with high serum tetanus antitoxin levels who have received frequent doses of tetanus toxoid. These patients should not receive tetanus toxoid more frequently than every 10 years. Severe systemic reactions to tetanus immunization include generalized urticaria, anaphylaxis, or neurologic complications, including peripheral neuropathy and Guillain-Barre syndrome. A severe allergic reaction including acute respiratory distress or cardiovascular collapse following a previous dose of tetanus toxoid is a contraindication to further immunization. A moderate or severe acute illness is also a reason to defer routine immunization although a minor illness is not. If tetanus toxoid is contraindicated, passive immunization with TIG against tetanus should be considered.¹⁸

TABLE 146-2 Summary Guide to Tetanus Prophylaxis in Wound Management

History of Adsorbed Tetanus Toxoid (Doses)	CLEAN, MINOR WOUNDS		ALL OTHER WOUNDS*	
	Td† 0.5 mL IM	TIG, 250 U IM	Td† 0.5 mL IM	TIG, 250 U IM
Unknown or less than three	Yes‡	No	Yes	Yes
Three or more§	No¶	No	Yes**	No

*For example, wounds >6 h old, contaminated with soil, saliva, feces, or dirt; puncture or crush wounds; avulsions; wounds from missiles, burns, or frostbite. tDPT for children <7 years of age (DT if pertussis vaccine is contraindicated); Td for persons >7 years of age.
‡The primary immunization series should be completed. Three doses total are required, with the second dose given at least 4 weeks after the first and the third dose 6 months later.
§If only three doses of fluid toxoid have been received, then a fourth dose of *adsorbed* toxoid should be given.
¶Yes, if routine immunization schedule has lapsed in a child <7 years of age or if > 10 years since last dose.
**Yes, if routine immunization schedule has lapsed in a child <7 years of age or if >5 years since last dose. Boosters more frequent than every 5 years may predispose to side effects.
Abbreviations: DPT = diphtheria-pertussis-tetanus; DT = diphtheria-tetanus toxoids; Td = tetanus-diphtheria; TIG = tetanus immunoglobulin.

TABLE 146-3 Treatment of Tetanus

Respiratory management	Succinylcholine for emergency intubation; vecuronium for prolonged neuromuscular blockade
Immunotherapy	TIG \geq 500 U IM as a single dose and Tetanus toxoid (DPT or Td depending on age), 0.5 mL IM at presentation, and 6 weeks and 6 months after presentation
Antibiotic therapy	Metronidazole, 500 mg IV every 6 h
Muscle relaxation	Midazolam, 5–15 mg/h continuous IV infusion or Lorazepam, 2 mg IV to effect or Diazepam, 5 mg IV every 1–3 h to effect
Neuromuscular blockade	Vecuronium, 6–8 mg per h IV
Management of autonomic dysfunction	Labetalol, 0.25–1.0 mg per min continuous IV infusion or Magnesium sulfate, 70 mg/kg IV loading, then 1–4 g per h continuous infusion to maintain blood level of 2.5–4 mmol/L Morphine sulfate, 0.5–1.0 mg/kg per h Clonidine, 300 μ g every 8 h by nasogastric tube

**RABIES David J.****Weber David A. Wohl****William A. Rutala**

More than 2.5 billion people are at risk of rabies in over 100 countries.¹ Rabies ranks number 10 worldwide as a cause of mortality and causes an estimated 50,000 to 60,000 deaths annually, despite the availability of effective vaccines for postexposure treatment.¹ In addition, millions of persons, primarily in developing countries, undergo costly postexposure treatment.² In the United States, rabies continues to be endemic in many wild animals. Although human rabies is rare in the United States, postexposure rabies prophylaxis is likely provided to more than 35,000 persons per year.² Prevention efforts in the United States are estimated to cost between \$230 million and \$1 billion.²

This chapter briefly reviews the microbiology, epidemiology, clinical presentation, and treatment of rabies. Because animal bites and scratches are commonly seen by primary care and emergency medical physicians, the postexposure management of persons potentially exposed to a rabid animal is reviewed in detail. Comprehensive reviews of rabies have been published in the medical literature.^{3–6} Current information is available on the rabies homepage produced by the Centers for Disease Control and Prevention (www.cdc.gov).⁷

MICROBIOLOGY

Rabies virus is the prototype member of the genus *Lyssavirus*, of the family *Rhabdoviridae*, order *Mononegavirales*.⁶ Members of this order have a single-stranded, negative-sense, nonsegmented RNA genome that is tightly encapsulated into ribonucleocapsid structures. Members of the family *Rhabdoviridae* are grouped on the basis of their conical or bullet shape as visualized by electron microscopy. Their host range includes vertebrates (primarily mammals and fish), invertebrates (primarily arthropods), and plants. The *Rhabdoviridae* that infect animals and humans are divided into two genera, the *Lyssavirus* (Greek *Lyssa*, frenzy) and *Vesiculovirus* (Latin *vesicula*, little bladder).³ *Vesiculoviruses* (e.g., vesicular stomatitis virus) cause disease in cattle, swine, horses, and a variety of other vertebrates.³ Humans occasionally develop infection, which is most commonly characterized by a nonfatal, nonspecific influenza-like viral syndrome.

The rabies group of lyssaviruses is comprised of at least seven serotypes or genotypes: classic rabies virus, Lagos bat virus, Mokola virus, Duvenhage virus, European bat lyssavirus 1, European bat lyssavirus 2, and Australian bat virus.^{4–6} Rarely lyssaviruses other than rabies cause human disease (<10 total cases described worldwide).

PATHOPHYSIOLOGY

Once introduced, the initial infection and multiplication occur within local monocytes for the first 48 to 96 h. Subsequently, the virus spreads across the motor end-plate, and ascends and replicates along peripheral nervous axoplasm to the dorsal root ganglia, the spinal cord, and the central nervous system (CNS). Following CNS replication in the gray matter, the virus spreads outward by peripheral nerves to virtually all tissues and organ systems. Viral infection of the salivary glands engenders infectivity of saliva; the infectivity of other body fluids is less well established.

Histologically, rabies is similar to other forms of encephalitis: diffuse and extensive monocellular infiltration with focal hemorrhage and demyelination, predominantly in perivascular areas in the gray matter of the CNS, basal ganglia, and the spinal cord. Negri bodies, where CNS viral replication occurs, are the characteristic histologic finding for rabies. They are eosinophilic intracellular lesions found within cerebral neurons and are highly specific for rabies. Negri bod-

ies are encountered in about 75 percent of proven animal rabies; thus although their presence is pathognomonic for rabies, their absence does not exclude rabies as a diagnostic possibility.

EPIDEMIOLOGY

Rabies is primarily a disease of animals.³ The epidemiology of human rabies is a reflection of both the distribution of the disease in animals and the degree of human contact with these animals.³ In those parts of the world where canine rabies has been controlled [i.e., the United States (Table 147-1), Canada, and Europe], dogs account for less than 5 percent of the cases in animals. Where canine rabies has not been controlled (i.e., most developing countries of Asia, Africa, Latin America, and South America), dogs account for 90 percent or more of reported cases in animals. The major wildlife vectors of rabies are: dogs (major vector of rabies throughout the world, particularly Asia, Latin America, and Africa); foxes (Europe, the Arctic, and North America); raccoons (eastern United States); skunks (midwestern United States, western Canada); coyotes (Asia, Africa, and North America); mongooses (yellow mongoose in Asia and Africa; Indian mongoose in the Caribbean islands); and bats (vampire bats from northern Mexico to Argentina, insectivorous bats in North America and Europe). In 2000, 49 states, the District of Columbia, and Puerto Rico reported 7369 cases of rabies in animals, a 4.3 percent increase from the number of cases reported in 1999.⁸ Wild animals accounted for 93 percent of the reported cases: raccoons (37.7 percent); skunks (30.2 percent); bats (16.8 percent); foxes (6.2 percent); and other wild animals including beavers, otters, bobcats, rodents, and lagomorphs (rabbits, hares, and picas) (2.2 percent). Rabid domestic animals included cats (3.4 percent); cattle (1.1 percent); dogs (1.6 percent); horses, donkeys, and mules (0.71 percent); sheep, goats, and camels (0.15 percent); and other animals such as ferrets (0.06 percent). **The following animals very rarely have been found to be rabid and hence their bite almost never requires postexposure prophylaxis for rabies: squirrels, hamsters, guinea pigs, gerbils, chipmunks, rats, mice, domesticated rabbits, and other small rodents.**

Animal reservoirs for rabies are found worldwide with the exception of some islands (e.g., Hawaii, Great Britain), Australia, and Antarctica. Rabies infections of mammalian species occur in geographically discrete outbreaks. Disease transmission within an outbreak is primarily intraspecific and involves a single, distinctive rabies variant.

Transmission of rabies virus usually begins when the contaminated saliva of an infected host is passed to a susceptible host. The most common mode of rabies viral transmission is through the bite of a rabid animal. Other routes of documented transmission have included contamination of mucous membranes (i.e., eyes, nose, mouth), aerosol transmission during spelunking in bat-infested caves or while working in the laboratory with rabies virus, corneal transplants, and iatrogenic infection through improperly inactivated vaccine.

TABLE 147-1 Geographic Boundaries of North American Reservoirs for Rabies

1. An expanding reservoir of raccoon rabies that now encompasses the entire East coast from Maine to Florida.
2. A longstanding reservoir in red and arctic foxes in Alaska, that has spread to include foxes across Canada as far east as Ontario, Quebec, and the upper parts of the northern New England states.
3. Three separate variants that infect striped skunks in longstanding reservoirs in California, the north central states, and the south central states.
4. Two different variants in gray foxes in small but longstanding reservoirs in Arizona and Texas.
5. A small reservoir of coyotes in southern Texas.

The risk of developing rabies following an animal bite or scratch by a rabid animal depends on whether a bite or scratch occurred, the number of bites, the depth of the bites, and the location of the wounds (Table 147-2).

The epidemiology of human rabies in the United States between 1946 and 2000 has been well described in a series of reports from the CDC.^{8,11} In the United States, deaths in humans caused by rabies totaled 99 in the 1950s, 15 in the 1960s, 23 in the 1970s, 10 in the 1980s, and 32 from 1990 through 2000. The median age of patients reported from 1980 through 1996 was 27 (range: 4 to 82 years of age) and 20 (63 percent) were male. Cases were reported from 20 states; 7 cases (22 percent) were reported from California and 6 from Texas. Eleven patients were exposed to rabies in eight foreign countries. The onset of illness occurred in all months and with no apparent seasonal pattern.

Of the 32 patients that died of rabies between 1980 and 1996, a definite history of animal exposure was identified in only 7 (22 percent); 6 resulted from a dog bite received in a foreign country and 1 was from a bat bite received in the United States. Contact with an animal was identified in 12 persons; 8 with a bat, 2 with a dog, 1 with a cow, and 1 with a cat. For the remaining 13 patients, a potential source of animal exposure was not identified. Of the 10 deaths from 1997 through 2000, 9 persons had a bat variant isolated (only 1 had a history of a bite by a bat) and 1 person acquired disease from a dog bite in Ghana.

Current epidemiologic patterns of rabies in the United States have been summarized as follows:¹⁰ The annual reports of rabies in wildlife far exceed those of rabies in domestic animals; rabies variants in bats are associated with a disproportionate number of infections in humans (—90 percent), although bats constitute only about 15 percent of all reported rabies cases in animals annually; most other cases of human rabies diagnosed in the United States are attributable to infections acquired in areas of enzootic canine rabies outside the United States; most persons with a case of rabies that originated in the United States have no history of an animal bite; and rabies is diagnosed after death in more than one-third of the latter group. During the past half century, the number of humans dying of rabies has dramatically decreased to an average of 2 to 3 per year. Although the number of deaths is low, most deaths occur because individuals are unaware that they have been exposed to and infected with rabies virus, and therefore they do not seek effective postexposure prophylaxis.¹² Molecular epidemiologic studies have linked most of these cryptic rabies exposures to rabies virus variants associated with insectivorous bats. As a result of this data, the Centers for Disease Control has altered its recommendations for postexposure prophylaxis (see below).

PREEXPOSURE PROPHYLAXIS

Preexposure prophylaxis with rabies vaccine is highly recommended for persons whose recreational or occupational activities place them at risk for acquiring rabies (Tables 147-3 and 147-4).¹³ Although the initial rabies preexposure vaccine regimen is similar, the need for booster doses, the timing of booster doses, and the need and timing of serologic tests to confirm immunity differ based on the degree of individual risk for exposure to rabies. Emergency medicine health care providers should refer persons at risk for rabies who have not received

TABLE 147-2 Risk of Rabies in Absence of Postexposure Prophylaxis Following Exposure to a Rabid Animal

Multiple severe bites around the face: 80-100%
Single bite: 15-40%
Superficial bite(s) on the extremity: 5-10%
Contamination of open wound by saliva: —0.1%
Transmission via fomites (e.g., tree branch): theoretical (no cases reported)
Indirect transmission (e.g., raccoon saliva on a dog): theoretical (no cases reported)

TABLE 147-3 Rabies Preexposure Prophylaxis Schedule—United States, 1999

Type of Immunization	Route	Regimen
Primary	Intramuscular	HDCy PCEC, or RVA; 1.0 mL (deltoid area), one each on days 0,* 7, and 21 or 28
	Intradermal	HDCV; 0.1 mL, one each on days 0,* 7, and 21 or 28
Booster	Intramuscular	HDCY PCEC or RVA; 1.0 mL (deltoid area), one each on day 0* only
	Intradermal	HDCV, 0.1 mL, day 0* only

* Day 0 is the day the first dose of vaccine is administered.

preexposure prophylaxis to their local physician or health department for appropriate immunization.

Preexposure vaccination does not eliminate the need for additional therapy after a rabies exposure, but simplifies postexposure prophylaxis by eliminating the need for human rabies immune globulin (HRIG) and by decreasing the number of doses of vaccine required (see below).

POSTEXPOSURE PROPHYLAXIS

Postexposure prophylaxis is indicated for persons possibly exposed to a rabid animal (Figure 147-1). All persons presenting with an animal bite or scratch should be evaluated for the presence of a life-threatening condition, such as arterial laceration, pneumothorax, or respiratory compromise.¹⁴ Appropriate emergency care for animal bites should be provided.¹⁴ Key aspects include tetanus prophylaxis, wound cleansing, measures to prevent bacterial infection, and evaluation for rabies prophylaxis. Cleansing of the wound with a 20 percent solution of soap and water is an essential first step in rabies prevention. In experimental animals, simple wound cleansing has been shown to markedly reduce the likelihood of rabies.

All persons bitten or scratched by an animal, whether domestic or wild, should be evaluated for the need to initiate rabies postexposure prophylaxis. The decision to initiate rabies postexposure prophylaxis should be based on the following:⁷ geographic location of the incident; the type of animal that was involved; and how the exposure occurred (i.e., provoked or unprovoked), the vaccination status of the animal, and whether the animal can be safely captured and tested for rabies (Table 147-5). Excellent guidelines are often available from the local health department. For the purpose of rabies postexposure prophylaxis, a bite exposure is defined as any penetration of the skin by the teeth of an animal. Bites to the face and hands carry the highest risk, but the site of the bite should not influence the decision to begin therapy.¹³ Scratches, abrasions, open wounds, or mucous membranes contaminated with saliva or other potentially infectious material (such as brain tissue) from a rabid animal constitute nonbite exposures. If the material containing the virus is dry, the virus can be considered non-infectious. A fully vaccinated dog or cat is unlikely to become infected with rabies, although rare cases have been reported among animals that had received only a single dose of vaccine. No documented vaccine failures have occurred among dogs or cats that had received two vaccinations.

Other contact by itself, such as petting a rabid animal and contact with blood, urine, or feces (e.g., guano) of a rabid animal, does not constitute an exposure and is not an indication for prophylaxis.¹³ However, local health departments may vary in their recommendations for salivary exposure.

Bats are increasingly implicated as an important wildlife reservoir for variants of rabies virus transmitted to humans. Minor bites by bats and awakening in a room with a bat have been associated with the development of rabies. For this reason, the CDC recommends the following actions where bat-human contact has occurred.¹⁵ In all cases in which bat-human contact has occurred or is suspected, the bat should be collected and tested for rabies. If the bat is unavailable, the need for postexposure prophylaxis should be assessed by public health officials. Postexposure prophylaxis should be considered after direct contact between a human and a bat, unless the exposed person is certain a bite, scratch, or mucous membrane exposure did not occur. Postexposure prophylaxis may be considered for persons who were in the same room as a bat and who might be unaware that a bite or direct contact had occurred (e.g., when a sleeping person awakens to find a bat in the

TABLE 147-4 Rabies Preexposure Prophylaxis Guide

Risk Category	Nature of Risk	Typical Population	Preexposure Recommendations
Continuous	Virus present continuously, often in high concentrations; specific exposures likely to go unrecognized; bite, nonbite, or aerosol exposure	Rabies research laboratory workers,* rabies biologics production workers	Primary course Serologic testing every 6 months; booster immunization if antibody titer is below acceptable level
Frequent	Exposure usually episodic with source recognized, but exposure also might be unrecognized; bite, nonbite, or aerosol exposure	Rabies diagnostic lab workers,* spelunkers, veterinarians and staff, and animal-control and wildlife workers in rabies-enzootic areas.	Primary course Serologic testing every 2 years; booster immunization if antibody titer is below acceptable level
Infrequent (greater than population at large)	Exposure nearly always episodic with source recognized; bite or nonbite exposure	Veterinarians and animal-control and wildlife workers in areas with low rabies rates, veterinary students, travelers visiting areas where rabies is enzootic and immediate access to appropriate medical care including biologics is limited	Primary course; no serologic testing or booster immunization
Rare (population at large)	Exposure always episodic with source recognized; bite or nonbite exposure	U.S. population at large, including persons in rabies-enzootic areas	No immunization necessary

*Judgment of relative risk and extra monitoring of immunization status of laboratory workers is the responsibility of the laboratory supervisor.

fMinimum acceptable antibody level is complete virus neutralization at 1:5 serum dilution by the rapid fluorescent focus inhibition test. A booster dose should be administered if the titer falls below this level.

room or an adult witnesses a bat in a room with an unattended child, mentally disabled person, or intoxicated person). Seeing a bat does not constitute an exposure.

The CDC recommends that a healthy dog, cat, or ferret that bites a person should be confined and observed for 10 days.¹³ Such animals should be evaluated by a veterinarian at the first sign of illness during confinement. Any illness in the animal should be immediately reported to the local health department. If signs suggestive of rabies develop, the animal should be euthanized, its head removed, and the head shipped under refrigeration (not frozen) for examination of the brain by a qualified laboratory designated by the local or state health department. Any stray or unwanted dog, cat, or ferret that bites a person may be euthanized immediately and the head submitted for rabies examination. Animals other than dogs, cats, or ferrets that might have exposed a person to rabies should be immediately reported to the local health department. Prior vaccination of an animal does not preclude the necessity of euthanasia and testing if the period of virus shedding is unknown for that species.

There are anecdotal reports of person-to-person transmission of rabies.¹⁶ Fluids from the upper and lower respiratory tracts of humans frequently test positive for rabies virus. Despite the lack of proven health care-associated transmission, ~30 percent of health care workers who have had contact with a human case of rabies have received postexposure prophylaxis. Given the mechanism of disease transmis-

sion and concern among health care workers, contact isolation precautions should be used for patients with known or suspected rabies, and health care workers who care for such patients should wear either masks and eye protection or face shields.¹⁶ Health care workers with nonintact skin or mucous membrane exposure to infective saliva should receive postexposure prophylaxis.

In the United States, postexposure prophylaxis consists of a regimen of one dose of HRIG and five doses of rabies vaccine over a 28-day period (Table 147-6). Human rabies immune globulin and the first dose of rabies vaccine should be given as soon as possible after exposure, preferably within 24 h. Four formulations of three inactivated rabies vaccines are available in the United States, including human diploid cell vaccine (HDCV) (produced in human diploid cells; Imovax, Pasteur Merieux Connaught), rabies vaccine adsorbed (RVA) (produced in fetal rhesus diploid lung cells; Rabies Vaccine Adsorbed, SmithKline Beecham), and purified chick embryo cell culture vaccine (PCEC) (produced in chick embryo cells; RabAvert, Chiron). All currently used vaccines are produced in cell culture and are significantly less toxic than older vaccines that were produced in neural tissue. Side effects, including mild erythema, swelling, and pain at the injection site, have been reported among 30 to 74 percent of vaccine recipients. Systemic reactions, such as headache, nausea, abdominal pain, muscle aches, and dizziness, have been reported among 5 to 40 percent of recipients. Serum-sickness-like reactions (type III hypersensitivity) have

TABLE 147-5 Rabies Postexposure Prophylaxis Guide

Animal Type	Evaluation and Disposition of Animal	Postexposure Prophylaxis Recommendations
Dogs, cats, and ferrets	Healthy and available for 10 days of observations Rabid or suspected rabid Unknown (e.g., escaped)	Persons should not begin prophylaxis unless animal develops clinical signs of rabies* Immediate immunization Consult public health officials
Skunks, raccoons, foxes, and most other carnivores; bats	Regard as rabid unless animal proven negative by laboratory tests ^f	Consider immediate immunization
Livestock, small rodents, lagomorphs (rabbits and hares), large rodents, (woodchucks and beavers), and other mammals	Consider individually	Consult public health officials; bites of squirrels, hamsters, guinea pigs, gerbils, chipmunks, mice, rats, domesticated rabbits, and other small rodents, almost never require antirabies postexposure prophylaxis

*During the 10-day observation period, begin postexposure prophylaxis at the first sign of rabies in a dog, cat, or ferret that has bitten someone. If the animal exhibits clinical signs of rabies, it should be euthanized immediately and tested.

■(The animal should be euthanized and tested as soon as possible. Holding for observation is not recommended. Discontinue vaccine if immunofluorescence test results of the animal are negative. Source: Adapted from Centers for Disease Control and Prevention.¹³

been noted among approximately 6 percent of persons receiving booster doses of HDCV 2 to 21 days after administration of the booster dose. Such reactions have not been life threatening and have not been reported with the RVA or PCEC vaccines. Anaphylaxis and neurologic symptoms have only rarely been associated with the current rabies vaccines. Severe egg allergy is a contraindication to the use of the PCEC vaccine. Once initiated, rabies prophylaxis should not be interrupted or discontinued because of local or mild systemic adverse reactions to rabies vaccine.¹¹ Usually such reactions can be successfully managed with anti-inflammatory and antipyretic agents. When a person with a history of serious hypersensitivity to rabies vaccine must be revaccinated, antihistamines may be given. Epinephrine should be readily available to counteract anaphylactic reactions, and the person should be observed carefully immediately after vaccination.

HRIG is administered only once (i.e., at the beginning of antirabies prophylaxis) to provide immediate antibodies until the patient responds to rabies vaccine by producing antibodies. Failure to use HRIG has led to rabies, despite appropriate postexposure prophylaxis with HDCV. If HRIG was not given when vaccination was begun, it can be given through the seventh day after administration of the vaccine.¹³ Beyond the seventh day, HRIG is not indicated because an antibody response is presumed to have occurred. The CDC recommends that as much as possible of the full dose be infiltrated around the wound. HRIG should never be administered in the same syringe or into the same anatomical site as the vaccine. Even if the wound has to be sutured, it should be infiltrated locally with HRIG. This practice is safe and does not create an additional risk of infection. However, caution is needed when injecting into a tissue compartment, such as the finger pulp, because excessive HRIG can increase compartment pressure and lead to necrosis.¹⁷

The CDC recommendations for postexposure prophylaxis should be followed *EXACTLY*. Although no postexposure prophylaxis vaccine failures have been reported in the United States since the licensing of HDCV in 1980, 13 persons outside the United States have contracted rabies after postexposure prophylaxis with tissue culture-derived vaccine. Each of these cases involved deviation from the recommended protocol; wounds were not cleansed, passive immunization with HRIG was not provided, or rabies vaccine was injected into the gluteal rather than the deltoid area.

In order to reduce costs and because HRIG may not be available in other countries, postexposure regimens using intradermal administration of vaccine have been studied and approved by the World Health Organization and HRIG is advised only for the highest risk exposures.

However, in the United States, only regimens recommended by the CDC should be used because of their proven efficacy.

POSTEXPOSURE PROPHYLAXIS IN SPECIAL CIRCUMSTANCES

Prior Rabies Immunization

If exposed to rabies, persons previously vaccinated should receive two intramuscular doses (1 mL each) of vaccine, one immediately and one 3 days later.¹³ "Previously vaccinated" refers to persons who have received one of the recommended preexposure or postexposure prophylaxis regimens of HDCV, RVA, or PCEC, or those who have received another vaccine and had a documented rabies antibody titer. HRIG is unnecessary and should not be given in these cases because an anamnestic antibody response will follow the administration of a booster regardless of the prebooster antibody titer.

Immunocompromised Persons

Immunization of immunocompromised persons presents special challenges. First, vaccines may represent a danger to the immunocompromised person. Second, the immune response of immunocompromised persons to vaccination may not be as good as that of immunocompetent persons; higher doses or additional immunizations may be required, although even with these modifications, the immune response may be suboptimal. The Advisory Committee on Immunization Practices (ACIP) considers these persons severely immunocompromised: congenital immunodeficiency; human immunodeficiency virus (HIV) infection; leukemia or lymphoma; aplastic anemia; generalized malignancy; or therapy with alkylating agents, antimetabolites, radiation, or large amounts of corticosteroids.¹⁸

Because rabies vaccine is formulated with inactivated virus, it does not represent a danger to immunocompromised persons and may be administered to such persons using the standard recommended doses and schedule (see Table 147-6). Furthermore, the recommendations for the use of HRIG are the same in immunocompromised and immunocompetent persons. However, corticosteroids, other immunosuppressive agents, and immunosuppressive illnesses can interfere with the development of active immunity and predispose the patient to developing rabies if exposed. Immunosuppressive agents should not be administered during postexposure prophylaxis, unless essential for the

TABLE 147-6 Rabie Postexposure Prophylaxis Schedule—United States, 1999

Immunization Status	Treatment	aimen
Not previously immunized	Wound cleansing	All postexposure prophylaxis should begin with immediate thorough cleansing of all wounds with soap and water; if available, a virucidal agent such as povidone-iodine solution should be used to irrigate the wounds
	HRIG	Administer 20 IU/kg body weight. If anatomically feasible, <i>the full dose</i> should be infiltrated around the wound(s) and any remaining volume should be administered IM at an anatomical site distant from vaccine administration; also, HRIG should not be administered in the same syringe as vaccine; because HRIG might partially suppress active production of antibody, no more than the recommended dose should be given
	Vaccine	HDCV, RVA, or PCEC 1.0 mL (deltoid area*), one each on days 0,* 3, 7, 14, and 28
Previously immunized	Wound cleansing	All postexposure treatment should begin with immediate thorough cleansing of all wounds with soap and water; if available, a virucidal agent such as a povidone-iodine solution should be used to irrigate the wounds
	HRIG	HRIG should <i>not</i> be administered
	Vaccine	HDCV, RVA, or PCEC 1.0 mL (deltoid area ^f), one each on days 0 ^f and 3

*These regimens are appropriate to all age groups, including children.

^fThe deltoid area is the only acceptable site of vaccination for adults and older children. For younger children, the outer aspect of the thigh may be used. Vaccine should never be administered in the gluteal area. JDay 0 is the day the first dose of vaccine is administered.

#Any persons with a history of preexposure prophylaxis with HDCV, RVA, or PCEC; prior postexposure prophylaxis with HDCV, RVA, or PCEC; or previous immunization with any other type of rabies vaccine and a documented history of antibody response to the prior immunization.

Abbreviations: HDCV = human diploid cell vaccine; HRIG = human rabies immunoglobulin; PCEC = purified chick embryo cell vaccine; RVA = rabies vaccine adsorbed. Source: Adapted from Centers for Disease Control and Prevention.¹³

treatment of other conditions. When rabies postexposure prophylaxis is administered to persons receiving steroids or other immunosuppressive therapy, it is especially important that serum be tested for rabies antibody to ensure that an adequate response has developed.¹³ To test the adequacy of the immune response, serum collected 2 to 4 weeks after the postexposure prophylaxis should completely neutralize challenge virus at a 1:5 serum dilution by rapid fluorescent focus inhibition test (RFFIT).¹³

Travelers

Preexposure prophylaxis is recommended for international travelers based on the local incidence of rabies in the countries to be visited, the availability of appropriate antirabies biologics, and the intended activity.¹⁹ Such persons include veterinarians, animal handlers, field biologists, spelunkers, and certain laboratory workers. Chloroquine phosphate (and possibly other structurally-related antimalarials such as mefloquine, which is administered for malaria chemoprophylaxis) may interfere with the antibody response to HDCV. Always immunize persons receiving antimalarial chemoprophylaxis by the intramuscular route.

Between 1980 and 2000, seven persons died in the United States from rabies after having been bitten by a dog while visiting a foreign country. In that same period, three U.S. citizens died in foreign countries from exposure that occurred in the foreign country. For this reason, all persons who have returned from abroad should be questioned regarding whether they received an animal bite or scratch in an area with endemic rabies. Persons bitten or scratched by an animal in an area with endemic rabies should receive appropriate postexposure prophylaxis if the injury has occurred within the known incubation period (which may extend up to 5 years).

U.S. citizens and residents who are exposed to rabies while traveling in countries where rabies is endemic may sometimes receive postexposure prophylaxis with regimens or biologics that are not used in the United States. If postexposure prophylaxis is begun outside the United States using a non-FDA-approved regimen or biologic of nerve tissue origin, it may be necessary to provide additional treatment when the patient reaches the United States.¹³ State and local health departments should be contacted for specific advice in such cases. The ma-

jor modification used abroad, usually in an attempt to reduce cost, is the substitution of various schedules for intradermal injection or the use of non-FDA-approved vaccines.

Pregnancy

Adverse pregnancy outcomes or fetal abnormalities have not been associated with rabies vaccination. Because of the potential consequences of inadequately treated rabies exposure, and because adverse events have not been associated with rabies postexposure prophylaxis during pregnancy, pregnancy is not considered a contraindication to rabies postexposure prophylaxis or HRIG.¹³ If there is substantial risk of exposure to rabies, preexposure prophylaxis may also be indicated during pregnancy.

Children

The risk of rabies and the management of postexposure prophylaxis in children have been reviewed.¹⁷ In infants and children, the dose of rabies vaccine for preexposure and postexposure prophylaxis is the same as that recommended for adults (see Table 147-6). The dose of HRIG for postexposure prophylaxis is based on body weight. For small children with multiple bites, the calculated dosage of HRIG may be insufficient to infiltrate all wounds. However, sterile saline can be used to dilute the volume twofold or threefold to permit thorough infiltration.¹⁷

CLINICAL DISEASE

Rabies virus causes acute encephalitis in all warm-blooded hosts, including humans, and the outcome is almost always fatal. While patients with rabies may manifest a variety of clinical symptoms and signs, the disease tends to follow a characteristic course (Table 147-7). Rabies infection is most commonly initiated by the bite of a rabid animal. Most commonly, the incubation period ranges from 20 to 90 days.³ However, incubation periods have been reported as short as 4 days and as long as 19 years. Incubation periods exceeding 1 year have been well documented in the literature. For patients who died from rabies in the United States between 1980 and 1996 and for whom a definite animal bite occurred, the median incubation period was 85 days

TABLE 147-7 Natural History of Clinical Rabies in Humans

Clinical Stage	Defining Event	Usual Duration	Common Symptoms and Signs*
Incubation period	Exposure	20 to 90 days	None
Prodrome	First symptom	2 to 10 days	Pain or paresthesia at site of bite Malaise, lethargy Headache Fever Nausea, vomiting, anorexia Anxiety, agitation, depression
Acute neurologic phase	First neurologic sign	2 to 7 days	Anxiety, agitation, depression Hyperventilation, hypoxia Aphasia, incoordination Paresis, paralysis Hydrophobia, pharyngeal spasms Confusion, delirium, hallucinations Marked hyperactivity
Coma	Onset of coma	0 to 14 days	Coma Hypotension, hypoventilation, apnea Pituitary dysfunction Cardiac arrhythmia, cardiac arrest
Recovery	Death or initiation of recovery	Months	Pneumothorax Intravascular thrombosis Secondary infections

*Not every symptom or sign may be present in each case.

(range: 53 to 150 days).¹⁰ The incubation period has been reported to be shorter when the site of bite is on the head than when it is on an extremity.³

During the prodromal period, the symptoms and signs of rabies are often nonspecific. They include fever, sore throat, chills, malaise, anorexia, headache, nausea, vomiting, dyspnea, cough, and weakness. Early in the course some patients may report symptoms suggestive of rabies such as limb pain, limb weakness, and paresthesias at or near the presumed exposure site. Nonspecific neurologic symptoms may be reported including apprehension, anxiety, agitation, irritability, depression, and psychiatric disturbances.

The prodrome merges into the acute neurologic phase, which begins when the patient develops objective signs of central nervous system disease. Two major forms of acute neurologic disorder have been described: furious and paralytic. Furious rabies is noted in about 80 percent of patients and is characterized by hyperactivity, disorientation, hallucinations, and bizarre behavior. Periods of hyperactivity may alternate with periods of calm. Signs of autonomic dysfunction are frequently present and include hyperthermia, tachycardia, hypertension, and excessive salivation. About 50 percent of patients have classic hydrophobia in which attempts at drinking fluids result in severe spasms of the pharynx, larynx, and diaphragm. Paralytic rabies is noted in about 20 percent of patients and is characterized by paralysis, which may be maximal in the extremity that was bitten, diffuse, and symmetrical, or it may ascend in a pattern similar to Guillain-Barre syndrome. Accompanying signs may include fever and nuchal rigidity.

Coma almost always occurs within 10 days of the onset of symptoms. In the series reported by Noah and colleagues, the median duration of illness was 19 days (range: 7 to 28 days).¹⁰ All patients in the series died. Death occurs from a variety of complications including pituitary dysfunction, seizures, respiratory dysfunction with progressive hypoxia, cardiac dysfunction with dysrhythmias and arrest, autonomic dysfunction, renal failure, and secondary bacterial infections.

Rarely have patients recovered from rabies, but in all such cases the patient had received either postexposure or preexposure prophylaxis with duck embryo vaccine or suckling mouse brain vaccine before the onset of symptoms. Despite intensive therapy, no persons without post-exposure prophylaxis have survived in the United States since 1980.

DIAGNOSIS AND TREATMENT

Rabies should be included in the differential diagnosis of any acute encephalitis. The diagnosis of rabies is frequently made postmortem. This occurs because of the rarity of the disease, the increasing number of persons without an obvious exposure, and clinical confusion with other disorders. Important clues to diagnosis include a history of an animal bite and the development of the pathognomonic signs of hydrophobia and aerophobia. Tetanus should not be confused with rabies, because in tetanus the mental status is usually normal and the cerebrospinal fluid is normal. Other diseases that may be confused with rabies include poliomyelitis, Guillain-Barre syndrome, transverse myelitis, postvaccinal encephalomyelitis, intracranial mass lesions, cerebrovascular accidents, poisoning with atropine-like compounds, and other forms of viral encephalitis.²⁰

During the incubation period of rabies, no diagnostic test is available for animals or humans that will indicate infection. Routine laboratory tests are of limited value for the diagnosis of rabies. Specific tests are required to diagnose rabies. Because no single test is uniformly informative, a battery of tests is commonly recommended. Useful laboratory specimens include serum, cerebrospinal fluid, saliva, and tissue, such as skin from highly innervated locations (e.g., nuchal skin biopsy).⁴ The appearance of antibodies to specific viral antigens, either via serum binding or neutralization tests, is diagnostic in a patient with encephalitis and no history of previous immunization. Rabies virus has been isolated antemortem by animal inoculation or cell-culture passage from human saliva, brain tissue, cerebrospinal fluid, urine, and tracheal secretions. These samples can be probed for viral nucleic acid. Viral antigen can be detected by the direct fluorescent antibody (DFA) test on brain biopsy material, corneal touch impressions, or a full-thickness nuchal skin biopsy from the hairy nape of the neck. Early in the course of illness, the most reliable diagnostic test is a nuchal skin biopsy with immunofluorescent rabies antibody staining. Once clinical symptoms develop, a brain biopsy is universally positive when properly stained, but the invasive nature of this test precludes routine use. Tests to detect serum antibodies are useful, but while serum antibody may be present as early as day 5 of clinical illness, it may be absent after 10 to 14 days or more. Recently, nested polymerase chain reaction of RNA (RT-PCR) extracted from saliva has

been shown to be a useful adjunct in rabies diagnosis, especially as a confirmatory test.

No specific therapy exists to treat rabies. Treatment is directed at the clinical complications of the disease. Although rabies is not treatable, every attempt should be made at rapid diagnosis as it justifies public health measures to limit contacts with the patient and permits reconstruction of a history in which others may have been exposed to the same infective source.⁴

remains one of the most significant of these. Four species of the genus *Plasmodium* infect humans: *P. vivax*, *P. ovale*, *P. malariae*, and *P. falciparum*. Annually, over 250 million persons develop malaria, and more than 2.5 million persons die.¹ The incidence of malaria has been increasing in recent years despite aggressive worldwide attempts at control. Not only is the mosquito vector becoming less susceptible to a variety of insecticides, but *P. falciparum*—the parasite responsible for the most deadly form of malaria—is becoming increasingly resistant to antimalarial medications.

Malaria, especially disease due to *P. falciparum*, represents a medical emergency in any nonimmune host. Its early manifestations are largely nonspecific and can mimic other infectious diseases. Failure to diagnose infection rapidly can be disastrous. Likewise, failure to use specific antimalarial agents to which the individual strain is susceptible can result in early death. A diagnosis of malaria must be considered in any person returning from the tropics with an unexplained febrile illness. Questions regarding recent travel should become routine in emergency departments.

EPIDEMIOLOGY

Malaria transmission occurs in large areas of Central and South America, the Caribbean, sub-Saharan Africa, the Indian subcontinent, Southeast Asia, the Middle East, and Oceania. Certain species may predominate in a given geographic area.² For example, *P. vivax* is more common in the Indian subcontinent and in Central America, whereas *P. falciparum* is the most prevalent form in Africa, Haiti, and New Guinea.

The risk of contracting malaria, which varies considerably between regions, is largely dependent on the intensity of transmission in both urban and rural areas and, for travelers, on the itinerary and time and type of travel. In 1999 and 2000, the Centers for Disease Control and Prevention (CDC) reported 2942 cases of malaria, including 1660 cases among U.S. civilians, 735 cases among foreign civilians, and 101 cases occurring in U.S. military personnel. Cases occurring among U.S. citizens traveling abroad have increased to the highest levels observed in more than 30 years.³ Of the more than 1402 total cases in 2000, 783 (56 percent) were acquired in Africa (two-thirds from countries in sub-Saharan or West Africa), 238 (17 percent) in Asia (primarily from the Indian subcontinent), 230 (16 percent) in the Caribbean and Central America, 22 (2 percent) in Oceania, and only 57 (4 percent) in South America. *P. vivax* accounted for 42 percent of all cases, and *P. falciparum* accounted for another 49 percent. Mixed infections were uncommon, representing less than 1 percent of all cases. Thus more than half of all cases of malaria, including the majority of cases due to *P. falciparum*, were acquired from travels in sub-Saharan Africa. Yet, for every traveler to sub-Saharan Africa, at least 10 travelers visit potential malarious areas of Asia and South America each year. Clearly, the intensity of exposure appears to be much higher in sub-Saharan Africa. Four patients became infected in the United States in 2000; two through congenital transmission and two through locally acquired transmission via possible needle-stick injuries while caring for infected patients. Six deaths attributable to malaria were reported during 2000.

Resistance of *P. falciparum* to chloroquine continues to spread⁴ (Table 148-1). In addition, strains of *P. falciparum* are resistant to other chemotherapeutic agents, including pyrimethamine-sulfadoxine, quinine, mefloquine, doxycycline, and new agents such as halofantrine and artesunate (the latter two agents are not available in the United States). Recently, strains of *P. vivax* have been isolated from patients who have failed chloroquine therapy.⁵ Prior to 1990, no strains of *P. vivax*, *P. ovale*, or *P. malariae* were resistant to chloroquine.

PATHOPHYSIOLOGY

The organism is transmitted primarily by the bite of an infected female anopheline mosquito. This vector is found most frequently in tropical and subtropical regions below 2500 m (8200 ft) above sea level. Plasmodial

MALARIA Jeffrey D. Band

With the increase in international travel and the continued shift of travel to tropical locales, it is not surprising that physicians are seeing more patients with infectious diseases acquired in the tropics. Malaria, a protozoan disease transmitted by the bite of the *Anopheles* mosquito,

SECTION 13 • INFECTIOUS DISEASES

TABLE 148-1 Geographic Distribution of Malaria, Including Resistant Strains

Geographic Region	Areas with Malaria	Countries with Chloroquine-Resistant <i>P. falciparum</i> (CRPF)	Countries with Fansidar-Resistant <i>P. falciparum</i>
Central America	All countries	None	None
Caribbean	Dominican Republic and Haiti	None	None
South America Temperate Tropical	Argentina All countries	None All countries except Paraguay	None Interior Amazon Basin
East Asia	China	China	South China
Eastern South Asia	All countries except Brunei and Singapore	All infected areas	Infected areas except Philippines
Middle South Asia	All countries	All countries	Afghanistan and Bhutan
Western South Asia and Middle East	Iraq, Oman, Saudi Arabia, Syria, Turkey, and United Arab Emirates	All countries except Syria and Turkey	None
Northern Africa	All countries except Tunisia	None	None

Southern Africa	All countries except Lesotho and Saint Helena	Widespread	Occasional
Oceania	Limited to Papua New Guinea, Solomon Islands, and Vanuatu (small foci elsewhere)	Widespread	Widespread

sporozoites are injected into the host's bloodstream during the mosquito's blood meal and are carried via the bloodstream to the liver. The hepatic parenchymal cells are invaded, and asexual reproduction of the parasite begins (pre-erythrocytic schizogony or exoerythrocytic stage). As thousands of daughter merozoites are formed (amplification cycle), the parenchymal liver cell ruptures, releasing daughter merozoites back into the circulation, where they rapidly invade erythrocytes (erythrocytic stage). In *P. vivax* and *P. ovale* infection, a portion of the intrahepatic forms are not released, remain dormant for months, and can later activate and cause clinical relapses.

The clinical manifestations of malaria first appear during the erythrocytic stage. Once merozoites enter this stage, they never reinvest the liver. Merozoites mature within the erythrocyte and take on various morphologic forms, including the early ring forms, trophozoites, and schizonts (which represent a mass of new merozoites). Eventually, the target erythrocyte lyses, and new merozoites invade uninfected red blood cells, continuing the infection and causing clinical manifestations. Lysogeny may become regular, occurring at 2- to 3-day intervals

in established and untreated infections, producing the classic periodicity of symptoms.

After several cycles, a proportion of the merozoites develop into sexual forms (gametocytes). On ingestion by another feeding anopheline mosquito, male and female gametocytes undergo sexual reproduction and become infective sporozoites ready for their next host.

Each species of *Plasmodium* has specific characteristics, including typical morphologic forms and selective red blood cell tropism (Table 148-2). Many of these characteristics are responsible for important pathophysiologic consequences.

Malaria also may be transmitted by direct transfusion of infected blood or passed transplacentally from mother to fetus. In these cases, an exoerythrocytic phase is absent.

Disease ensues after an incubation period ranging from 8 days in the nonimmune and unprotected host to several weeks or more. Both incomplete suppression by partially active chemoprophylaxis and incomplete immunity can markedly prolong the incubation period to months or even years. For U.S. residents who developed malaria asso-

TABLE 148-2 Characteristics of Malaria-Causing *Plasmodium* Species

	<i>P. falciparum</i>	<i>P. vivax</i>	<i>P. ovale</i>	<i>P. malariae</i>
Incubation period	8-25 d	8-27 d	9-17 d	15-30 d
Asexual erythrocytic cycle	48 h	48 h	48 h	72 h
Relapse	No	Yes	Yes	No
Red blood cell (RBC) preference	Reticulocytes (but can infect RBCs of all ages)	Reticulocytes	Reticulocytes	Older cells
Morphologic characteristics Degree of parasitemia Ring forms and early trophozoites	High (multiple rings per RBC) Ring forms predominate; threadlike cytoplasm with double-chromatic dots	Low Ameboid cytoplasm	Low Compact cytoplasm	Low Compact cytoplasm
Mature trophozoites	Rarely seen	Observed	Observed	Observed
Schizonts	Rarely seen	Observed	Observed	Observed
Gametocytes	Banana shaped	Round	Round	Round

ciated with travels abroad during 2000, disease became evident within 1 month after arrival home in 80 percent of *P. falciparum* cases but in only 40 percent of *P. vivax* cases. Only 1 percent of persons became ill more than 1 year after returning to the United States.³ Only the asexual intraerythrocytic parasite is responsible for the symptoms and pathophysiologic consequences. The hallmark of malaria is the recurring febrile paroxysm that corresponds to hemolysis of infected erythrocytes and release of antigenic products with activation of macrophages and production of proinflammatory cytokines.

Hemolysis can be high with *P. falciparum* infection because parasitemia can be overwhelming and erythrocytes of all ages are susceptible. Parasitized erythrocytes lose flexibility and are removed in the microcirculation, with resulting obstruction and tissue anoxia of the lungs, kidneys, brain, and other vital organs. Noncardiac pulmonary edema, renal failure, and cerebral malaria may result. Sequestration accounts for the paucity of observed mature parasites in the peripheral smear of patients infected with *P. falciparum*.

In addition to prolonged high fever, hemolysis, and in the case of infection with *P. falciparum*, obstruction to capillary flow, immunologic sequelae also may occur, resulting in glomerulonephritis, nephrotic syndrome, thrombocytopenia, and polyclonal antibody stimulation. Lastly, hypersplenism with resulting pancytopenia may occur, especially in cases of prolonged, untreated malaria.

CLINICAL FEATURES

Typically, patients develop a prodrome of malaise, myalgia, headache, and low-grade fevers, often accompanied by chills.⁶ In some patients, headache, chest pains, cough, abdominal pain, arthralgias, or diarrhea may be prominent. The early manifestations are quite nonspecific and can be confused easily with a viral syndrome, influenza, hepatitis, and other less severe self-limited clinical entities. Illness usually progresses to severe chills followed by high-grade fevers accompanied by tachycardia, nausea, orthostatic dizziness, and extreme weakness. After several hours, the fever abates, and the patient becomes diaphoretic and exhausted. Over time, the paroxysms of malaria—chills and fever followed by diaphoresis—may occur at nearly regular intervals that correspond to the length of the asexual erythrocytic cycles (see Table 148-2). The classic paroxysms of malaria are often lacking in malaria due to *P. falciparum* or in persons who received some form of chemoprophylaxis.

The findings on physical examination are also not specific for malaria. Most patients appear acutely ill with high fevers, tachycardia, and tachypnea. Splenomegaly and tender abdomen are present commonly in advanced infection. The liver may or may not be enlarged. Features quite atypical for malaria include lymphadenopathy and a maculopapular skin rash.

Laboratory features include normochromic normocytic anemia with findings suggestive of hemolysis, a normal or mildly depressed total leukocyte count, thrombocytopenia, an elevated erythrocyte sedimentation rate, elevated lactate dehydrogenase, and mild abnormalities in liver and renal functions. Other laboratory abnormalities include hyponatremia, hypoglycemia, and a biologic false-positive VDRL.

Complications of malaria can occur rapidly in untreated infection, especially when the agent is *P. falciparum*.¹ Infections caused by any species of *Plasmodium* can result in hemolysis, splenic enlargement, and occasionally, splenic rupture. An immune-mediated glomerulonephritis is also common to all forms but tends to occur most often in *P. malariae* infection. With the ability to cause high parasitemia levels and sequestration with capillary sludging, *P. falciparum* infection can be fatal. Cerebral malaria—characterized by somnolence, coma, delirium, and seizures—is associated with mortality rates in excess of 20 percent. Reversible causes of encephalopathy must be excluded. The cerebrospinal fluid is usually normal, except for a slightly elevated opening pressure and protein concentration. A mild pleocytosis also may be present. Other life-threatening complications associated

with *P. falciparum* infection include respiratory failure due to noncardiogenic acute pulmonary edema (similar to adult respiratory distress syndrome), renal failure (acute tubular necrosis), and severe metabolic abnormalities, including lactic acidosis and profound hypoglycemia. Any target organ is susceptible to the effects of severe tissue hypoxia from the cytoadherence between the parasitized erythrocyte and the vascular endothelium of the host.

The very young, the elderly, and pregnant women are at greatest risk for complications due to *P. falciparum*. In addition to these host factors, additional risk factors for fatal malaria include an immunocompromised state, asplenia, failure to take appropriate chemoprophylaxis, refusal of or delay in seeking medical care, and misdiagnosis.⁸

DIAGNOSIS

The definitive diagnosis is established by the visualization of parasites on Giemsa-stained thick and thin blood smears. In early infection, especially infection due to *P. falciparum*, in which parasitized erythrocytes are sequestered from the bloodstream, parasitemia may be undetectable. Also, parasitemia fluctuates over time; it generally is highest during chills and as the fever is on the rise. High fevers are schizonticidal. In highly suspicious cases, failure to detect parasitemia is not an indication to withhold therapy. Delay in the diagnosis and treatment of malaria can have disastrous results. If parasitemia is not seen in the stained thin smear, a thick smear that concentrates blood cells may provide the diagnosis (Table 148-3). Extreme care in the preparation of slides is important because debris may result in false-positive smears. If parasites are not visualized, repeated smears should be obtained at least twice daily for 2 to 3 days to exclude malaria completely, although the first smear is positive in greater than 90 percent of cases.⁹ Newer molecular probes for rapid diagnosis and speciation of the invading pathogen are available or in development, but each of these tests has major limitations when compared with an experienced light microscopist.¹⁰ The two major questions to be answered by the blood smear are the degree of parasitemia present (correlates with prognosis) and whether *P. falciparum* is responsible for infection. Most patients with *P. falciparum* infection should be managed in the hospital setting, as should any patient with more than 3 percent parasitemia. Clues to the diagnosis of *P. falciparum* infection include the presence of small ring forms with double-chromatin knobs within the erythrocyte, multiply infected rings in individual red blood cells, a paucity of trophozoites and schizonts on smear, the pathognomonic crescent-shaped (banana-shaped) gametocyte, and parasitemia exceeding 4 percent. Repeated smears should be obtained daily to assess the efficacy of drug treatment.

TREATMENT

Therapeutic decisions are based on the severity of the illness, the agent, and whether the patient may be infected with chloroquine-resistant *P. falciparum*.²⁰ If *P. falciparum* infection can be excluded,

TABLE 148-3 Guidelines for Preparing Malaria Smears

Use scrupulously clean slides; manufacturers' precleaned slides may have residual debris.
Obtain a large drop of blood from the patient's finger by using a blood lancet. Place the cleaned surface of the slide against the drop of blood; with a quick circular motion, make a film the size of a dime. Do not mix excessively or distortion will result. The thick smear should be of such depth that newsprint would be barely legible. (Let the smear air dry for 30 to 60 min.)
Obtain a small drop of blood from the patient's finger, and with a second clean slide, spread the blood gently over the slide. Air dry the thin film, fix it with methyl alcohol, and stain it with Giemsa stain.
If the thin smear is negative, examine the thick smear. Once air dried, the thick film should not be fixed prior to staining with Giemsa.

most persons can be managed in the ambulatory setting. Close follow-up, including repeated smears, is necessary. Patients with significant hemolysis or those who have underlying severe chronic medical problems that can be aggravated by high fevers or hemolysis are best hospitalized. Infected infants and pregnant women are also best managed in the hospital.

Chloroquine is the drug of choice for treatment of infection due to *P. vivax*, *P. ovale*, and *P. malariae*. Table 148-4 summarizes the treatment regimens for malaria. With treatment, the parasite load should decrease significantly within the first 24 to 48 h. No asexual forms of the parasite should be detectable 3 to 4 days after treatment is completed. Gametocytes, the sexual forms that do not cause disease in the human host, may persist for several weeks after treatment and are not an indicator of treatment failure. Chloroquine has no effect on the exoerythrocytic parasites, which may be dormant in the liver with infection due to *P. vivax* and *P. ovale*. Unless terminal treatment is administered with primaquine, clinical relapses commonly occur. Primaquine should not be used in patients with glucose-6-phosphate dehydrogenase deficiency because primaquine may induce massive hemolysis of erythrocytes. Table 148-5 summarizes the commonly described adverse effects and precautions or contraindications of the an-

timalarial medications. Despite treatment with both chloroquine and primaquine, infection or relapse may persist.

Treatment of *P. falciparum* infection is generally best managed in a hospital setting, particularly if the level of parasitemia exceeds 3 percent. Unless one is certain that the patient could not have chloroquine-resistant *falciparum* infection (based on geographic exposure; see Table 148-1), it is best to assume that the infecting strain is resistant to chloroquine and to initiate treatment with a combination of quinine and doxycycline with or without pyrimethamine-sulfadoxine. Clindamycin can be substituted for doxycycline in patients in whom doxycycline is contraindicated. Mefloquine is also a very effective therapy for chloroquine-resistant *P. falciparum* (and the asexual erythrocyte stages of the other *Plasmodium* species) either alone or combined with doxycycline. It should not be used if it had been prescribed for chemoprophylaxis. Atovaquone-proguanil, a recently approved fixed-dose medication (Malarone) agent, is also highly effective, with cure rates exceeding 95 percent.¹¹ It is generally well tolerated and offers another excellent option in treatment. It should not be prescribed for therapy if used as chemoprophylaxis with suspected failure. It may be more effective than mefloquine.

Persons presenting with complications caused by *P. falciparum* or with high parasitemia but unable to tolerate oral medications due to

TABLE 148-4 Treatment Regimens for Malaria

Clinical Setting	Drug	Adults	Children
Uncomplicated infection with <i>P. vivax</i> , <i>P. ovale</i> , <i>P. malariae</i> , and chloroquine-sensitive <i>P. falciparum</i>	Chloroquine phosphate	1-g load (600-mg base), then 500 mg (300-mg base) in 6 h, then 500 mg (300-mg base) per day for 2 d (total dose 2.5 g)	10-mg/kg base to maximum of 600 mg load, then 5-mg/kg base in 6 h and 5-mg/kg base per day for 2 d
	plus Primaquine phosphate*	26.3-mg load (15-mg base) per day for 14 d on completion of chloroquine therapy	0.3-mg/kg base for 14 d on completion of chloroquine therapy
Uncomplicated infection with chloroquine-resistant <i>P. falciparum</i>	(a) Quinine sulfate	650 mg PO tid for 3–7 d	8.3 mg/kg PO tid for 3–7 d
	plus Doxycycline†	100 mg PO bid for 7 d	Contraindicated in children < 8 years of age†
	Plus or minus Pyrimethamine-sulfadoxine (fansidar)‡	3 tablets (75 mg/1500 mg) PO × 1 dose	Over 2 months old >50 kg 3 tabs 30–50 kg 2 tabs 15–29 kg 1 tab 10–14 kg ½ tab 4–9 kg ¼ tab
	or (b) Mefloquine	750 mg PO initially followed by 500 mg in 6–8 h	10–15 mg/kg base followed by 5–10 mg/kg base in 6–8 h
	plus doxycycline§	See above	See above
	or (c) Atovaquone-proguanil (Malarone)	4 adult-strength (250/100) tabs daily × 3 d	>40 kg, adult dose 31–40 kg, 3 adult tablets × 3 d 21–30 kg, 2 adult tablets × 3 d 11–20 kg, 1 adult tablet × 3 d
Complicated infection with chloroquine-resistant <i>P. falciparum</i>	Quinidine gluconate	10-mg/kg load over 2 h (maximum 600 mg), then 0.02 mg/kg per min continuous infusion until patient is stabilized and able to tolerate PO therapy (see above)	Same as adults¶
	plus Doxycycline†	100 mg IV q12h until tolerating PO therapy (see above)	Contraindicated in children < 8 years of age†

*Terminal treatment for *P. vivax* and *P. ovale* only.

†Clindamycin is an alternate to doxycycline at dose of 10 mg/kg (max 900 mg) every 8 h for 3–7 days.

‡Optional; of unlikely value if acquisition is with fansidar resistance.

§Optional; many experts feel comfortable with mefloquine alone.

¶Consult an expert in pediatric infectious disease immediately for guidance.

TABLE 148-5 Adverse Effects, Precautions, and Contraindications of Antimalarial Drugs

Drug	Minor Toxicity	Major Toxicity	Precautions/Contraindications
Chloroquine	Nausea/vomiting, diarrhea, pruritus, postural hypotension, rash, fever, headache, dizziness	Rare; hypotension and shock after parenteral therapy; retinopathy after prolonged use	Avoid in patients with severe psoriasis and some types of porphyria
Quinine or quinidine	Cinchonism (nausea and vomiting, headache, tinnitus, dizziness, visual disturbance)	Hypotension, cardiac dysrhythmias, hypoglycemia, Coombs-positive hemolysis, abortions, neuromuscular paralysis (myasthenia)	Contraindicated in cardiac disease; cautiously in pregnancy, myasthenia gravis
Fansidar (pyrimethamine-sulfadoxine)	GI disturbances, phototoxicity, headaches, dizziness, skin rash	Fatal cutaneous eruptions reported, agranulocytosis	Contraindicated during pregnancy and in infants or if the patient is allergic to sulfonamides or pyrimethamine
Mefloquine	Nausea/vomiting, cramps, diarrhea, anorexia; dizziness, headaches, nightmares, and bradycardia	Rare unless underlying heart disease with bradycardia or the patient is on selected cardiotoxic medications (dysrhythmias, arrest); acute toxic confusional states may occur, as can seizures	Precaution during pregnancy and in children weighing < 10 kg; avoid if the patient is receiving quinidine; avoid if the patient has heart conduction disturbance or if underlying seizure or major neuropsychiatric disorders.
Doxycycline	GI disturbances, phototoxicity, vaginal candidiasis	Rare; esophageal ulcerations if not taken with fluids	Contraindicated during pregnancy, in children < 8 years of age; may depress prothrombin time in patients receiving anticoagulants
Atovaquone-proguanil (Malarone)	Nausea, vomiting, cramps, oral ulcers, headaches, dizziness	Rare serious allergic reactions and alopecia reported.	Contraindicated in pregnancy and in children < 11 kg (no safety data).
Primaquine*	Nausea, vomiting, diarrhea, cramps, methemoglobinemia	Massive hemolysis in patients with G6PD deficiency, exacerbation of systemic lupus erythematosus or rheumatoid arthritis	Contraindicated in G6PD deficiency, pregnancy

*Terminal treatment for *P. vivax* and *P. ovale* infections only.

Abbreviations: G6PD = glucose-6-phosphate dehydrogenase; GI = gastrointestinal.

vomiting should receive intravenous medications. Supportive care is critical for these patients and includes close hemodynamic monitoring, use of judicious fluid replacement, correction of significant metabolic abnormalities, and additional support as needed (e.g., dialysis, mechanical ventilation, and so on). Exchange transfusions have been life-saving in some patients with parasitemia in excess of 10 percent,¹² although a recent meta-analysis suggested that exchange transfusion showed no significant benefit in survival when compared with antimalarial chemotherapy alone.¹³ Glucocorticoids have not been shown to be of benefit in the treatment of cerebral malaria and should not be used.¹⁴ Quinidine is the intravenous drug of choice due not only to its widespread availability but also to its enhanced activity against *P. falciparum*. Parenteral quinine is available only from the CDC. Its use should be reserved for individuals developing significant cardiotoxicity while receiving intravenous quinidine.

Quinine and quinidine are potent inducers of insulin release and may cause severe hypoglycemia. Sudden changes in orientation, sweating, tremor, tachycardia, or anxiety should prompt measurement of plasma glucose concentration. Cinchona alkaloids are myocardial depressants, so cardiac monitoring is needed during administration. Terminal treatment with primaquine is not needed in patients with *P. falciparum* malaria due to the absence of dormant asexual forms in the liver. Newer artemisinin compounds (e.g., artemisinin, artemether, and artesunate) are active against quinine-resistant strains of *P. falciparum*.¹⁵ These agents are not yet available in the United States and have been used either alone or in combination with mefloquine or benflumetol in a fixed-dose tablet (coartemether).

PREVENTION

Malaria is largely preventable through the use of personal protective measures and appropriate chemoprophylaxis. Recent studies confirmed that travelers to malarious areas frequently do not use anti-

mosquito measures or take antimalarial drugs.^{8,16} Of the 825 U.S. civilians who acquired malaria abroad during 2000, 635 (77 percent) reported that they had not followed a chemoprophylactic drug regimen recommended by CDC for the area to which they had traveled.³ Between dusk and dawn, travelers should remain in well-screened areas, use mosquito nets if needed, and wear long-sleeved, light-colored clothing. A pyrethrum-containing insect spray should be used during evening hours and before retiring to bed. Permethrin can be sprayed on clothing for additional protection, and an insect repellent containing A[^]TY-diethyl-m-toluamide (DEET) in concentrations no higher than 35 percent should be applied to exposed skin. Newer formulations of DEET exist with polymer encapsulation and sustained-release properties that provide long-acting protection at lower concentrations. These are especially useful for children, in whom lower concentrations of DEET are recommended, and for persons with intense, prolonged exposures.¹⁷

Appropriate chemoprophylaxis depends on where one will be traveling. If potential exposure to infected mosquitoes is likely, prophylaxis is warranted even if such exposure will be brief. Table 148-6 summarizes the chemotherapeutic agents of choice.^{2-4,18} Recommendations can be obtained by calling the CDC 24-h malaria hotline (888-232-3228) or by accessing the CDC's Internet site at <http://www.cdc.gov/travel>, which provides up-to-date information on resistance patterns in countries. Failure to take appropriate chemoprophylaxis has been identified as a significant risk factor for fatal infection.¹⁹ Studies exploring other chemoprophylactic options, such as proguanil combined with dapsone, primaquine and related newer analogues (tafenoquine), and monotherapy with daily azithromycin, appear promising.

Last, even with the religious use of antimosquito measures and chemoprophylaxis, malaria can be contracted or can recur. For reasons discussed earlier, malaria must be considered whenever fever occurs in someone who has traveled to a malarious area or who has received

TABLE 148-6 Recommendations for Chemoprophylactic Regimens for Prevention of Malaria*

Drug	Adult Dose	Pediatric Dose
TRAVEL TO AREA WHERE CRPF HAS NOT BEEN REPORTED		
Primary drugs		
Chloroquine phosphate	500 mg (300-mg base) PO, 1 per week (before, during, and for 4 weeks after last exposure)	8.3 mg/kg (5-mg/kg base) PO, 1 per week up to adult dose
Hydroxychloroquine	400 mg (300-mg base) PO, 1 per week (before, during, and for 4 weeks after last exposure)	6.6 mg/kg (4-mg/kg base) PO, every day up to adult dose
Second-line drugs		
Doxycycline	100 mg PO every day (2 days before, during, and for 4 weeks after last exposure)	>8 years of age: 2 mg/kg PO every day up to adult dose
Atovaquone-proguanil (Malarone)	250 mg/100 mg PO every day (2 days before, during, and for 1 week after last exposure)	62.5 mg/25 mg >40 kg 1 adult tab/d 31–40 kg 3 ped tabs/d 21–30 kg 2 ped tabs/d 11–20 kg 1 ped tab/d

*For prolonged exposure in areas with *P. vivax* or *P. ovale*, primaquine (see Table 148-5) should be added at completion of prophylaxis.

†Doxycycline is the preferred first-line agent for travels to rural Thailand (border areas along Cambodia and Burma) due to prevalence of mefloquine resistance.

Atovaquone-proguanil (Malarone) recently has demonstrated comparable efficacy in this area and is an alternative to doxycycline.

Abbreviations: CRPF = chloroquine-resistant *P. falciparum*; MDRPF = multiple-drug-resistant *P. falciparum*.

"successful" therapy in the past. Vaccines directed against various antigens of the malaria parasite are currently in trials, but the findings thus far have not been overwhelmingly encouraging and quite preliminary.²⁰

INFECTIONS FROM HELMINTHS

Harold H. Osborn

Parasitic diseases outrank cancer as a leading cause of death globally.¹ Parasitic infections can be acquired by consuming infected food or water, walking barefoot on contaminated soil, and from insect bites. Parasitic diseases are becoming increasingly encountered in industrialized nations. Immigration and travel are major factors in this recent trend. Tourism has replaced agriculture as the biggest industry in the world, with over 50 million people traveling from the developed to the underdeveloped world each year.² Over 650 million people crossed international borders in 1999, and that number will rise to over 1 billion annually by the year 2010.³

According to the World Health Organization (WHO), worldwide 3.5 billion people harbor intestinal parasites, of which 450 million are symptomatic, and the number of those infected is increasing in all WHO regions.⁴ There are 1.3 billion cases (24 percent prevalence) of *Ascaris* and 902 million cases (17 percent prevalence) of *Trichuris* around the globe (Table 149-1). Malaria is by far the most important parasite in the world today, infecting 270 million people annually with between 1.5 and 2.7 million deaths per year.⁵

Parasitic disease is an important cause of morbidity and mortality in the U.S. due to several factors: the persistence of endemic parasites; immigration to the U.S. of infected individuals from Asia, Africa, and Latin America; increased travel by Americans, particularly to the underdeveloped parts of the world; and the rise of parasitic infections among immunosuppressed patients, especially those afflicted with HIV.⁶

Cryptosporidium and *Giardia* are important pathogens causing traveler's diarrhea, and have also become major causes of diarrhea in immunocompetent individuals in the U.S.⁷ Person-to-person spread of these parasites has led to diarrheal illness in day-care centers and other institutions, and contamination of municipal water supplies has led to major outbreaks. In 1993, over 400,000 people in Milwaukee, Wisconsin became ill after *Cryptosporidium* contaminated the drinking water, and 54 people died as a result.⁸ About 10 to 15 percent of the chronic diarrhea and wasting in AIDS patients is due to infection with *Cryptosporidium parvum*. Recently, surveys of water throughout the United States indicated that 50 percent of rivers and lakes may be contaminated with *Cryptosporidium*.⁹ This parasite cannot be contained by chlorination, iodination, or ozonation of the water; it must be eliminated by filtration. Outbreaks of diarrhea in the summer of 1996 due to the consumption of strawberries contaminated with *Cyclospora*, a coccidian, further highlight the challenge of emerging parasitic diseases in the United States.

TABLE 149-1 Prevalence of Specific Parasitic Diseases Worldwide

Organism	No. of Cases
<i>Ascaris</i>	1.3 billion
<i>Filaria</i>	120 million
<i>Leishmania</i>	12 million
<i>Onchocerca</i>	18 million
<i>Paragonimus</i>	20 million
<i>Schistosoma</i>	200 million
<i>Taenia saginata</i>	45 million
<i>Taenia solium</i>	3 million
<i>Trichuris</i>	902 million
<i>Trypanosoma brucei</i>	(African trypanosomiasis) 55 million
<i>Trypanosoma cruzi</i>	(American trypanosomiasis) 18 million

The agents that cause parasitic diseases belong to three major groups: helminths (worms), protozoa, and arthropods. The multicellular helminths include nematodes (roundworms), cestodes (flatworms), and trematodes (flukes). There are about 20 species of helminths that are natural parasites of man, but many others cause zoonoses (infections of animals which also infect man). The protozoa are single-celled organisms that cause a variety of diseases ranging from malaria to amebiasis. Arthropods are classified as ectoparasites, and are medically important as obligate intermediate hosts and as mechanical vectors in many diseases. This chapter concentrates on diseases caused by helminths. Malaria is discussed in Chap. 148, and parasitic diseases organized by syndromes are also discussed in Chap. 206. Diseases in immunocompromised hosts (e.g., HIV patients) are discussed in Chap. 144.

HISTORY

The recognition of parasitic disease begins with the elicitation of a careful history. Specifically, the clinician should inquire about travel to or immigration from high-risk areas. Parasites flourish in warm, moist climates, in locations where sanitation is poor, and in places where many people have low socioeconomic status and inadequate nutrition. Children are infected with parasites more frequently than adults because of their oral behavior, poor hygiene, and limited ability to ward off arthropod vectors.

Parasitic disease should be considered in any patient with unexplained fever, abdominal pain, diarrhea, skin ulcers, rash, or eosinophilia. The history should include dates of travel or immigration, destination or country of origin, living conditions, and activities. Travel to or from certain specific areas of the world may implicate particular parasitic agents. Among tribesmen, who came to this country from Indochina in large numbers after the Vietnam War, often harbor *Paragonimus westermani* (lung fluke), whereas visitors to Russia or the Rocky Mountains may return with *Giardia*. The history should also include questions about sexual orientation and contacts, drug use, and past illnesses, as well as a complete review of systems. The use of pretravel medications, including antimalarial and antidiarrheal agents, should also be elicited.

The presence of risk factors can provide a clue to specific parasitic diseases (Table 149-2). Cases of acute Chagas disease (trypanosomiasis) and babesiosis following blood transfusions have been described in the United States and Canada. Institutionalized patients may suffer from amebiasis and can become infected with *Hymenolepis nana* (the most common tapeworm in the United States) or *Giardia*. Immunocompromised hosts (including those on steroids or antineoplastic agents) are susceptible to infection by *Strongyloides*, *Toxoplasma*, *Cryptosporidium*, and *Pneumocystis carinii* and can develop a life-threatening hyperinfection syndrome with *Strongyloides stercoralis*. It is interesting to note that patients with AIDS, while susceptible to *Toxoplasma*, *Cryptosporidium*, *Pneumocystis*, *Isospora*, *Microsporidium*, and *Cyclospora*, are not any more susceptible to *Amoeba* and *Strongyloides* than immunocompetent individuals. Finally, the consumption of raw food has been associated with a variety of parasitic diseases, including fish, pork, and beef tapeworm.

PATHOPHYSIOLOGY

Parasites differ in their pathogenicity and in their capacity to produce invasive or systemic disease. The subclass Coccidia, for example, includes both *Toxoplasma* and *Isospora*. However, *Isospora* is unable to invade the intestinal mucosa and thus produces only enterocolitis, whereas *Toxoplasma* crosses the intestine and produces severe systemic illness.

Sometimes various forms of the same parasite differ in their ability to cause illness. The adult form of *Trichinella spiralis* remains in the intestine, while the larval form crosses and migrates to striated and cardiac muscle. Amebiasis can be manifested as both an intestinal and

TABLE 149-2 Risk Factors for Parasitic Disease

Risk Factor	Parasite
Blood transfusion	<i>Plasmodium</i> species, <i>Trypanosoma</i> , <i>Babesia</i> , <i>Toxoplasma</i>
Intravenous drug use	<i>Plasmodium</i> species
Homosexuality	<i>Entamoeba</i> (also seen after colonic irrigation therapy), <i>Giardia</i> , <i>Cryptosporidium</i>
Immunocompromised host	<i>Toxoplasma</i> , <i>Pneumocystis</i> , <i>Strongyloides</i> , <i>Cryptosporidium</i> , <i>Microsporidium</i> , <i>Isospora</i> , and <i>Cyclospora</i>
Hypogammaglobulinemia	<i>Giardia</i> , <i>Cryptosporidium</i>
Institutionalization	<i>Hymenolepis nana</i> , <i>Entamoeba histolytica</i> , <i>Giardia</i>
Day-care centers	<i>Giardia</i> , <i>Cryptosporidium</i>
Livestock workers	<i>Cryptosporidium</i>
Pica	<i>Toxocara</i> (visceral larva migrans), hookworm (<i>Necator americanus</i>)
Consumption of raw food	
Sushi, sashimi, gefilte fish	<i>Diphyllobothrium</i> , <i>Anisakis</i>
Pork	<i>Taenia solium</i> , <i>Trichinella</i> , <i>Sarcocystis</i>
Beef	<i>Taenia saginata</i> , <i>Toxoplasma</i> , <i>Sarcocystis</i>

visceral infection. Pathogenicity may vary among strains within a genus. Infection with *Entamoeba* can result in an asymptomatic cyst carrier state or hepatic abscesses, depending on the strain involved.

Finally, organisms differ in their virulence. The infectious dose of *Giardia* and *Cryptosporidium* is on the order of 10^1 to 10^3 organisms. By contrast, the infectious dose of *Vibrio cholerae* and *Salmonella* is 10^5 to 10^8 organisms. This may be an important factor in the genesis of outbreaks in institutions and day-care centers.

CLINICAL FEATURES

Unfortunately, symptoms may be nonspecific, and the latency period between exposure and symptom appearance may be years. Symptoms can be acute or chronic, specific or vague. Parasitic disease can present with relatively common complaints, such as headache, fever, cough, and malaise, or with acute, life-threatening complications, such as seizures, hemoptysis, melena, and intestinal obstruction. A differential diagnosis can be attempted on the basis of history and knowledge of typical symptoms associated with various parasitic agents (Table 149-3).

DIAGNOSIS

Although viruses and bacteria are generally the most common causes of infectious diarrhea, parasites constitute a significant cause as well.

The majority of diarrhea-inducing infections are noninflammatory, usually arising in the upper small bowel from the action of an enterotoxin (e.g., *V. cholerae* or enterotoxigenic *Escherichia coli*) or other processes that alter the absorptive function of the villous tip (e.g., *Cryptosporidium*, *Giardia*, rotaviruses, and Norwalk-like virus). In contrast, inflammatory diarrhea, which often presents as dysentery (bloody stools), arises in the colon from an invasive process, sometimes mediated by a cytotoxin (e.g., *Salmonella*, *Shigella*, *Campylobacter*, *Clostridium difficile*, and *Amoeba*).

If diarrhea has persisted for more than a few days, is bloody in nature, or is accompanied by substantial fever, dehydration, or weight loss, the patient should be evaluated more closely. Diarrheal illness that lasts 10 days or longer, occurs in those with risk factors (see Table 149-2), or persists in those without evidence of a bacterial infection should prompt a vigorous search for parasites.

TABLE 149-3 Symptoms of Parasitic Disease

Symptom	Possible Cause
Abdominal pain	<i>Ascaris</i> , <i>Clonorchis</i> , <i>Diphyllobothrium</i> , <i>Entamoeba</i> , <i>Fasciola</i> , <i>Giardia</i> , hookworm, <i>Hymenolepis</i> , <i>Schistosoma</i> , <i>Taenia</i> , <i>Trichuris</i>
Anemia	<i>Babesia</i> , <i>Diphyllobothrium</i> , hookworm, <i>Leishmania donovani</i> , <i>Plasmodium</i> species, <i>Trichuris</i>
Asthma	<i>Ascaris</i> , <i>Strongyloides</i> , <i>Toxocara</i>
Conjunctivitis and keratitis	Filariæ (<i>Onchocerca volvulus</i>), <i>Taenia</i> , <i>Trichinella</i> , <i>Trypanosoma</i>
Diarrhea	<i>Dientamoeba</i> , <i>Entamoeba</i> , <i>Fasciola</i> , <i>Fasciolopsis</i> , <i>Giardia</i> , hookworm, <i>Hymenolepis</i> , <i>L. donovani</i> , <i>Palantidium</i> , <i>Schistosoma</i> , <i>Strongyloides</i> , <i>Taenia</i> , <i>Trichinella</i> , <i>Trichuris</i>
Edema	<i>Fasciolopsis</i> , filariæ (<i>Wuchereria bancrofti</i>), <i>Trichinella</i> , <i>Trypanosoma</i>
Eosinophilia	<i>Ascaris</i> , <i>Dracunculus</i> , <i>Fasciola</i> , filariæ (<i>W. bancrofti</i> , <i>Brugia malayi</i>), fluke (<i>Paragonimus westermani</i> , <i>Chlonorchis sinensis</i> , <i>Fasciolopsis leuski</i>), <i>Hymenolepis</i> , hookworm, <i>Schistosoma</i> , <i>Strongyloides</i> , <i>Taenia</i> , <i>Toxocara</i> , <i>Trichinella</i> , <i>Trichuris</i>
Fever	<i>Ascaris</i> , <i>Babesia</i> , <i>Entamoeba</i> , <i>Fasciola</i> , filariæ (<i>W. bancrofti</i>), fluke (<i>C. sinensis</i>), <i>Giardia</i> , <i>L. donovani</i> , <i>Plasmodium</i> species, <i>Toxocara</i> , <i>Trichi</i> , <i>Trichuris</i> , <i>Trypanosoma</i>
Hematuria	<i>Schistosoma</i>
Hemoptysis	<i>Ascaris</i> , <i>Echinococcus</i> , <i>Paragonimus</i>
Hepatomegaly	Fluke (<i>C. sinensis</i> , <i>Opisthorchis viverrini</i> , <i>Fasciola</i>), <i>L. donovani</i> , <i>Plasmodium</i> species, tapeworm (<i>Echinococcus</i>), <i>Schistosoma</i> , <i>Toxocara</i> , <i>Trypanosoma</i>
Intestinal obstruction	<i>Ascaris</i> , <i>Diphyllobothrium</i> , fluke (<i>Fasciolopsis buski</i>), <i>Strongyloides</i> , <i>Taenia</i>
Jaundice	Fluke (<i>C. sinensis</i> , <i>O. viverrini</i>), <i>Plasmodium</i> species
Meningitis	<i>Acanthamoeba</i> , malaria (<i>Plasmodium falciparum</i>), <i>Naegleria</i> , primary amebic meningoencephalitis, <i>Toxocara</i> , <i>Trichinella</i> , <i>Trypanosoma</i>
Myocardial disease	<i>Taenia</i> , <i>Trichinella</i> , <i>Trypanosoma</i> (<i>T. cruzi</i>)
Nausea and vomiting	<i>Ascaris</i> , <i>Entamoeba</i> , <i>Giardia</i> , <i>Leishmania</i> , <i>Taenia</i> , <i>Trichinella</i> , <i>Trichuris</i>
Pneumonia	<i>Ascaris</i> , filariæ (<i>W. bancrofti</i> , <i>B. malayi</i>), fluke (<i>P. westermani</i>), <i>Strongyloides</i> , <i>Trichinella</i>
Pruritus	<i>Dientamoeba</i> , <i>Enterobius</i> , filariæ (<i>O. volvulus</i>), <i>Trichuris</i>
Seizures	<i>Hymenolepis</i> , <i>Trichinella</i> , <i>Paragonimus</i> , tapeworm (<i>Echinococcus</i> , <i>Cysticercus</i>)
Skin ulcers	<i>Dracunculus</i> , hookworm, <i>L. donovani</i> , <i>Trypanosoma</i>
Splenomegaly	<i>Babesia</i> , <i>Toxoplasma</i> , <i>Plasmodium</i>
Urticaria	<i>Ascaris</i> , <i>Dracunculus</i> , <i>Fasciola</i> , <i>Strongyloides</i> , <i>Trichinella</i>

Examination of a stool sample for fecal leukocytes is neither sensitive nor specific for inflammatory causes.¹⁰

Examination of a stool specimen for ova and parasites has traditionally been the method of choice for detecting intestinal parasites, including the cysts and trophozoites of protozoa and the larvae, eggs, and adults of helminths. Three specimens collected on different days are examined. The stool must be free of substances such as bismuth, barium, nonabsorbable antidiarrheal agents, and mineral oil.¹¹ Antimicrobial agents should be stopped at least 1 week prior to the stool collection. Fresh specimens are best, and specimens over an hour old should be preserved with formalin or polyvinyl alcohol. Multiple stool examinations are particu-

larly important when dealing with formed stool, which usually contains fewer parasites than do diarrheal specimens.

Occasionally *Giardia*, *Cryptosporidium*, and the larvae of *Strongyloides* may be detected by examining a duodenal aspirate or by having the patient swallow a string attached to a gelatin capsule (Entero-test). However, detection of *Giardia* by examination of several stool specimens is just as effective as examination of duodenal contents.

Special procedures for removing parasites include the following: warm water concentration through a filter for *Strongyloides* (Baermann test), sticky tape swab of the perianal area for *Enterobius*, and passage of urine through a nucleopore filter for *Schistosoma haematobium*. Use of special stains such as an acid-fast stain to detect *Cryptosporidium*, *Isospora*, and *Cyclospora*, and a modified trichrome stain for microsporidia may be helpful.

The enzyme-linked immunosorbent assay (ELISA) technique can be used to make a serologic diagnosis of parasitic infection. Immunoassay tests have been used to detect antigens of *Giardia* and *Cryptosporidia* in particular in the stool. Immunodiagnostic assays are more sensitive and cost effective than the standard examination for ova and parasites.¹² The increased accuracy and availability of these tests have obviated the need for the standard examination for ova and parasites and the invasive duodenal fluid examination in the diagnosis of *Giardia* and *Cryptosporidium parvum*. Many experts now recommend immunoassay screening for these two most common parasitic pathogens first if parasitic disease is suspected. Microscopic examinations of the stool that are costly, time-consuming, and require a skilled technician should be reserved for patients with persistent symptoms and laboratory exclusion of the common enteric pathogens.

Malaria-causing plasmodia, *Babesia*, microfilaria of *Wuchereria* and *Brugia*, and the trypanosomes that cause Chagas disease can be detected by Giemsa-stained thick and thin films of peripheral blood.

Finally, organisms that affect the central nervous system (e.g., *P. falciparum*, which causes cerebral malaria, and *Acanthamoeba* or *Naegleria*, which cause amoebic meningoencephalitis) can be detected by culture or microscopic examination of centrifuged cerebrospinal fluid. *Pneumocystis* is detected by characteristic findings on chest x-ray, elevated lactate dehydrogenase (LDH) levels, and evidence of hypoxemia, and is confirmed by lung biopsy with special stains, while *Toxoplasma* is detected by characteristic findings on computed tomography (CT) scan in association with elevated serum antibody levels, and is rarely confirmed by brain biopsy.

HELMINTHS

Nematodes (Roundworms)

Nematodes are cylindrical, unsegmented, elongated white worms. Their mode of entry into the human host varies from ingestion of eggs (*Ascaris* and *Enterobius*) to penetration of the skin (*Necator*, *Ancylostoma*, and *Strongyloides*) to inoculation by insect bite (*Wuchereria*).

ASCARIS *Ascaris lumbricoides* has a worldwide distribution, and its lifespan if left untreated is 2 to 7 years. Larval invasion follows the ingestion of *Ascaris* eggs, and during this stage the parasite migrates through the lungs. Clinical disease is due to pulmonary hypersensitivity or intestinal complications. Patients may have fever, cough, dyspnea, hemoptysis, and eosinophilia. Obstruction of the common bile duct and the intestine have been described. The chest x-ray may reveal eosinophilic pneumonitis (Loeffler syndrome). The diagnosis is made by finding eggs, or occasionally an adult worm, in the stool. Serologic tests, including bentonite flocculation, ELISA, and indirect hemagglutination, may be helpful. Treatment is with mebendazole, albendazole, or pyrantel pamoate. Intestinal obstruction may necessitate surgery, especially in children.

ENTEROBIUS (PINWORM) Adult *Enterobius* (pinworm) resides in the cecum, appendix, ileum, and ascending colon after its eggs are in-

gested. The gravid female migrates to the anus, especially at night, where it causes intense pruritus. Autoinfection with hand-to-mouth transmission is possible after scratching. A host of problems from vaginitis to enuresis have been attributed to *Enterobius* infection, without good evidence. It is most prevalent in temperate climates during the winter and fall. The diagnosis is confirmed with a cellophane tape swab of the anus. All family members should be examined. Treatment is with pyrantel pamoate, albendazole, or mebendazole, and should be repeated after 2 weeks.

NECATOR (HOOKWORM) *Necator americanus* prevails in the southern United States and is often seen in immigrants from warmer climates. Infection is associated with the use of human feces as fertilizer and the lack of shoes and latrines. Because each worm can withdraw 0.03 to 0.2 mL of blood a day, infection often leads to chronic anemia. Pica and geophagy are often seen in infected children. Patients may have cough, low-grade fever, abdominal pain, diarrhea, weakness, weight loss, heme-positive stools, and eosinophilia. The diagnosis is made by finding ova in the stool. In mild infections, multiple stool specimens or concentration techniques may be necessary. The parasite burden may be estimated using the Beaver stool or Kato slide smear method. Infections with less than 2100 eggs per gram of feces (<50 adult worms) are usually not hematologically significant, whereas infections with over 11,000 eggs per gram results in significant anemia. Hookworm is best treated with mebendazole, albendazole, or pyrantel pamoate.

STRONGYLOIDES (TH READ WORMS) Adult threadworms reside in the mucosa of the small intestine. Because entry of the parasite is through the skin, penetration can lead to allergic manifestations, pruritus, and an erythematous rash. Migration throughout the lungs can produce cough, dyspnea, and pneumonia. The intestinal phase is manifested by abdominal pain, diarrhea with mucus and blood, and eosinophilia. Autoinfection can occur due to internal production of infective larvae. Larval migration in the skin produces larva currens. Fatalities may occur due to hyperinfection in elderly and immunocompromised patients (e.g., patients with leprosy, nephrotic syndrome, hepatic disease, or lymphoproliferative disorders and those on steroids). The diagnosis is confirmed by finding larvae in the stool. Occasionally, use of a formalin ether concentration method or duodenal aspiration may be necessary. Various stages of the parasite may be found in the sputum. An ELISA test is also available. An upper gastrointestinal series may reveal a deformed duodenal bulb, and *Strongyloides* may be confused with ulcer disease. Treatment is with thiabendazole or ivermectin.

TRICHURIS TRICHIURA (WHIPWORM) Like *Ascaris*, *Trichuris trichiura* is found in rural communities in the southern United States. The infection is most often acquired in childhood because the ova are deposited in the soil where children play and defecate freely. The adult worm resides in the cecum. Patients complain of anorexia, insomnia, abdominal pain (including pain in the right upper quadrant), fever, flatulence, bloody diarrhea, weight loss, and pruritus, and may have eosinophilia and microcytic hypochromic anemia. *Trichuris* can result in colitis or rectal prolapse in children. The diagnosis is made with the finding of ova in the stool. Mebendazole or albendazole are the drugs of choice for treatment.

TRICHINELLA SPIRAUS Trichinosis is common in Mexico and the United States and results from the consumption of infected pork, and less commonly, bear and walrus meat. In the early stages of infection with *Trichinella spiralis*, the patient may present with acute myocarditis, nonsuppurative meningitis, bronchopneumonia, or catarrhal enteritis. The primary lesions are in striated muscle. Clinical symptoms depend on the site of invasion. Patients may present with nausea and vomiting, diarrhea, fever, urticaria, periorbital edema, (pathognomonic) splinter hemorrhages, myalgia, muscle spasm, stiff neck, headache, and psychiatric disturbances. Laboratory manifestations of trichinosis include leukocytosis, eosinophilia, elevated creatine phosphokinase, and

electrocardiographic changes. The diagnosis can be confirmed with latex agglutination, skin test, and a bentonite flocculation test. Biopsy of tender muscle may be helpful after the fourth week. Since *T. spiralis* encysts in striated muscle, stool examination is not helpful after the initial gastrointestinal phase in making the diagnosis. The differential diagnosis includes staphylococcal and *Salmonella* food poisoning, shigellosis, and amebiasis. Albendazole or mebendazole are indicated for treatment of the intestinal phase, but may be ineffective after encystment. Steroids are indicated for severe infections, such as CNS disease and myocarditis, but are not advocated routinely because their use can increase the number of circulating larvae. Most cases are mild and never come to medical attention.

Trematodes (Flukes)

Trematodes are leaflike, symmetrical flatworms lacking a body cavity but possessing a ventral sucker to hold their position. They live in intermediate hosts such as snails, crabs, and fish, and shed their eggs from the human host in the feces (*Schistosoma*, *Clonorchis*, and *Fasciola*), urine (*Schistosoma haematobium*), or sputum (*Paragonimus*).

SCHISTOSOMA Schistosomes penetrate the skin, creating a papular pruritic rash. The adult form resides in the venous system. Symptoms of acute disease—fever, lymphadenopathy, and hepatosplenomegaly (so-called Katayama fever)—are rarely seen. More typically, patients present in the chronic stage with granulomas in the liver (portal hypertension) and bladder (obstructive hydronephrosis). Patients may present with diarrhea, abdominal pain, melena, hepatosplenomegaly, hematemesis, and in the late stages, ascites and liver failure. With *S. haematobium*, dysuria and hematuria may be found. The diagnosis is suggested by a positive immunofluorescent antibody test result and confirmed by finding eggs in the feces or on rectal biopsy. Treatment is with praziquantel.

Cestodes (Flatworms)

The cestodes are flatworms commonly referred to as tapeworms. They have a scolex, or head, equipped with suckers, or hooks. Cestodes grow by segmentation, extending proglottids from the neck.

TAENIA *Taenia solium* (pork tapeworm) is occasionally encountered in the United States in immigrants or visitors from Central America and the Middle East. *Taenia saginata* (beef tapeworm) is seen more often, especially in those who consume raw beef (e.g., steak tartare). Adult worms live in the small intestine. Infected patients can be

asymptomatic or present with nausea and vomiting, headache, abdominal pain, pruritus, constipation, diarrhea, and intestinal obstruction. The larval stage of *T. solium* can cause clinical disease (cysticercosis), which can be serious and sometimes fatal. *Taenia* cysts may be found in subcutaneous tissue, the eye, the brain, and the heart, and cause seizures and hydrocephalus. Radiographs of the soft tissues may reveal curvilinear calcifications indicative of cysts, and cysts can be seen in the meninges and brain parenchyma on CT scanning. The diagnosis is made by finding gravid proglottids in the stool. An ELISA or hemagglutination reaction may be helpful, but results of both can be falsely negative if the cysts are calcified. Treatment of the adult (intestinal) stage is with praziquantel. The larval (tissue) stage is treated with albendazole.

DIPHYLLOBOTHRIUM *Diphyllobothrium* (fish tapeworm) has been reported in the Pacific northwest, Minnesota, Michigan, and other areas where raw fish (e.g., sushi and sashimi) and gefilte fish are consumed. *Diphyllobothrium* can compete with the host for vitamin B₁₂, and thus patients can present with pernicious anemia. Treatment is the same as for *Taenia*.

TREATMENT

The geographic spread and emerging drug resistance of parasites have created challenges for successful treatment. A number of reports have recently highlighted persistent shedding of schistosome eggs despite multiple treatments with praziquantel, the drug of choice.¹³ Successful treatment of malaria has been compromised by strains of *P. falciparum* that are resistant to chloroquine which now have a global distribution. Pockets of malaria resistant to sulfadoxine-pyrimethamine have been found throughout Africa. Mefloquine, a fluoroquinolone, has historically been available for the treatment of multidrug resistant *P. falciparum*. Now, however, monotherapy with mefloquine is associated with over 50 percent failure rates in some areas.¹⁴ Strains of *Leishmania* resistant to antimonial compounds have also been reported.

In many cases international pharmaceutical companies have stopped manufacturing drugs of proven efficacy and have curtailed the research and development of new drugs and vaccines due to financial considerations. Eflornithine, a medication used for trypanosomiasis, is prohibitively expensive and is no longer manufactured. Drugs for schistosomiasis (oxaminiquine and metrifonate) are expensive and in very short supply.

The treatment of parasites is complex and constantly changing¹⁵ (Table 149-4). Patients with potentially life-threatening infections

TABLE 149-4 Commonly Used Antiparasitic Drugs

Drug	First-Line Agent	Alternative Agent	Side Effects
Albendazole (Zentel)	<i>Trichinella</i> , <i>Echinococcus granulosus</i> , <i>Cysticercus</i> , <i>Ascaris</i> , cutaneous larva migrans, <i>Enterobius</i> , <i>Gnathostoma</i> , <i>Trichuris</i> , hookworm (<i>Ascaris duodenale</i> , <i>Necator americanus</i>), <i>Microsporidium</i>	<i>Capillaria</i> , <i>Trichostrongylus</i> , visceral larva migrans	Diarrhea, abdominal pain
Amphotericin B (Fungizone)	Amebic meningoencephalitis (<i>Naegleria</i>)	<i>Leishmania</i> (<i>L. braziliensis</i> , <i>L. mexicana</i>)	Fever, headache, anorexia, nausea, diarrhea, muscle and joint pain, azotemia, anemia, renal tubular acidosis (RTA), leukopenia
Atovaquone (Mepron)	<i>Babesia</i>		Headache, dizziness, nausea, vomiting, anemia, neutropenia, hyperglycemia
Bithionol (Bithin)	Fluke (<i>Fasciola hepatica</i>)		Photosensitivity, nausea and vomiting, urticaria
Chloroquine	<i>Plasmodium</i> species (except resistant <i>P. falciparum</i>)		Pruritus, vomiting, headache, confusion, skin eruptions, myalgias, blurred vision
Clindamycin (Cleocin)	<i>Babesia</i> , chloroquine-resistant <i>P. falciparum</i>		C. difficile diarrhea

(continued)

TABLE 149-4 Commonly Used Antiparasitic Drugs (Continued)

Drug	First-Line Agent	Alternative Agent	Side Effects
Diethylcarbamazine (Hetrazan)	Filariae (<i>Wuchereria bancrofti</i> , <i>Loa loa</i> , tropical pulmonary eosinophilia), visceral larva migrans		Allergic reactions, GI symptoms
Fumagillin	<i>Microsporidia</i>		Thrombocytopenia
Iodoquinol (Yodoxin)	<i>Entamoeba</i> (<i>Entamoeba histolytica</i>), <i>Dientamoeba</i>	<i>Balantidium</i>	Rash, acne, enlarged thyroid, nausea, diarrhea, anal pruritus; rarely: optic atrophy, peripheral neuropathy
Ivermectin (Mectizan)	Filariae (<i>Onchocerca volvulus</i>), <i>Strongyloides</i> , cutaneous larva migrans		Fever, pruritus, tender nodes, bone and joint pain, headache
Lindane (Kwell)		Lice, scabies	Eczema, conjunctivitis, aplastic anemia
Mebendazole (Vermox)	<i>Angiostrongylus</i> , <i>Ascaris</i> , <i>Capillaria</i> , <i>Enterobius</i> , filariae (<i>Mansonella perstans</i>) <i>Trichuris</i> , hookworm, <i>Trichinella</i>	<i>Leishmania</i> , visceral larva migrans	Diarrhea, abdominal pain, agranulocytosis
Mefloquine (Lariam)		Chloroquine-resistant <i>P. falciparum</i>	Vertigo, nausea, nightmares, headache
Meglumine (Glucantime)	<i>Leishmania</i>		Joint and muscle pain, nausea
Metronidazole (Flagyl)	<i>Entamoeba</i> (<i>E. histolytica</i> , <i>E. polecki</i>), <i>Dracunculus</i> , <i>Trichomonas</i> , <i>Blastocystis</i> , <i>Giardia</i>	<i>Balantidium</i>	Nausea, headache, dry mouth, reaction with alcohol; rarely: seizures, ataxia, leukopenia, pancreatitis
Niclosamide (Niclocide)	Fluke (<i>Fasciolopsis buski</i>), tapeworm (<i>Diphyllobothrium</i> , <i>Taenia</i> , <i>Dipylidium</i>)	Tapeworm (<i>Hymenolepsis</i>)	Nausea, abdominal pain
Nifurtimox (Lampit)	<i>Trypanosoma</i> (<i>T. cruzi</i>)		Anorexia, vomiting, sleep disorder, tremors
Nitazoxanide (Cryptaz ¹⁶ , Alinia)	<i>Cryptosporidia</i>		Hypertension, headache, abdominal pain
Paromomycin (Humatin)	<i>Entamoeba</i> , <i>Dientamoeba</i> , <i>Cryptosporidium</i>	<i>E. histolytica</i> , <i>Giardia</i> , <i>Leishmania</i>	GI disturbance; rarely: eighth nerve and renal damage
Pentamidine isethionate (Pentam)	<i>P. carinii</i>	<i>Trypanosoma</i> (<i>T. brucei</i>), <i>Leishmania</i>	Hypotension, hypoglycemia, vomiting, blood dyscrasia, renal damage, GI disturbance
Praziquantel (Biltricide)	Fluke, <i>Schistosoma</i> , tapeworm (<i>Hymenolepsis</i> , <i>Cysticercus</i>); tapeworm (<i>Diphyllobothrium latum</i> , <i>Taenia</i> , <i>Dipylidium</i> , <i>Hymenolepsis nana</i> , <i>Cysticercus cellulosae</i>)		Malaise, headache, dizziness, abdominal upset, fever, eosinophilia
Primaquine phosphate	<i>P. vivax</i> , <i>P. ovale</i> (prevention of relapse only)		G6PD hemolysis, neutropenia, GI disturbances
Pyrantel pamoate (Antiminth)	<i>Ascaris</i> , <i>Enterobius</i> , hookworm, <i>Trichostrongylus</i> , <i>Moniliformis</i>		GI disturbances, headache, dizziness, rash, fever
Pyrimethamine (Daraprim)	Chloroquine-resistant <i>P. falciparum</i> , <i>Toxoplasma</i>		Blood dyscrasias, folate deficiency; rarely: rash, vomiting, seizures, shock
Quinacrine (Atabrine)		<i>Giardia</i>	Dizziness, headache, vomiting, diarrhea, yellow skin, toxic psychosis, insomnia, rash, blood dyscrasias
Quinine sulfate (Quinamm)	<i>Babesia</i> , chloroquine-resistant <i>P. falciparum</i>		Cinchonism, hemolytic, anemia, blood dyscrasias, photosensitivity, hypoglycemia, arrhythmias, hypotension
Sodium stibogluconate (Pentostam)	<i>Leishmania</i>		Muscle pain, joint stiffness, nausea, diarrhea, rash, pruritus, liver and heart damage, bradycardia; rarely: hemolytic anemia, sudden death
Spiramycin (Rovamycin)		<i>Toxoplasma</i>	GI symptoms
Suramin sodium (Germanin)	<i>Trypanosoma</i> (African)		Vomiting, pruritus, urticaria, paresthesias, neuropathy
Tetracycline (Achromycin)	<i>Dientamoeba</i>		Nausea, vomiting, metallic taste, discolored teeth in children

(continued)

TABLE 149-4 Commonly Used Antiparasitic Drugs (Continued)

Drug	First-Line Agent	Alternative Agent	Side Effects
Thiabendazole (Mintezol)	<i>Angiostrongylus</i> , <i>Strongyloides</i> , visceral larva migrans, cutaneous larva migrans	<i>Capillaria</i> , <i>Dracunculus</i> , <i>Trichostrongylus</i>	Nausea, vertigo, rash, leukopenia, hallucinations, erythema multiforme, Stevens-Johnson syndrome, rarely: shock, seizures
Tinidazole (Fasigyn)	<i>Amoeba</i> (<i>E. histolytica</i>), <i>Trichomonas</i>	<i>Giardia</i>	Colitis
Trimethoprim-sulfamethoxazole (Septra, Bactrim)	<i>Isospora</i> , <i>Pneumocystis carinii</i> , <i>Cyclospora</i>		Allergic reactions

Source: Adapted from Drugs for parasitic infections, *Med Lett* April 1, 2002, p. 1, with permission. Available at: www.medletter.com.

(e.g., cerebral malaria, *Pneumocystis* pneumonia, amebic meningoencephalitis, or CNS toxoplasmosis) should be started on antiparasitic treatment immediately in the emergency department and rapidly admitted to the hospital. Patients who are dehydrated from gastrointestinal losses or fever should receive intravenous hydration. Those who can take fluids orally can be rehydrated by mouth.

Patients with diarrhea who appear severely ill, toxic, or dehydrated; those who cannot tolerate anything by mouth; and those with organ system involvement (e.g., lung, blood, or CNS) should be admitted for intravenous hydration, further diagnostic evaluation, and antiparasitic drug treatment as indicated. Patients who do not require hospitalization can be treated with antiparasitic agents if a specific diagnosis has been made and should be referred for follow-up. Those who can tolerate oral fluids can be reliably rehydrated with the WHO oral rehydration solution. Such a solution can be prepared by adding 3.5 g sodium chloride (or three-quarters teaspoon of table salt), 2.5 g sodium bicarbonate (or 2.9 g sodium citrate or 1 teaspoon of baking soda), 1.5 g potassium chloride (or 1 cup of orange juice or two bananas), and 20 g glucose (or 40 g sucrose or 4 tablespoons of sugar) to a liter (1.05 quart) of clean water. This makes a solution of approximately 90 mmol sodium, 20 mmol potassium, 80 mmol chloride, 30 mmol bicarbonate, and 111 mmol glucose per liter.

FOOD-BORNE AND WATER-BORNE DISEASES William T. Anderson

The spectrum of food-borne and water-borne disease is changing with the emergence of new pathogens, reemergence of old pathogens and the increase in antibiotic resistance among these agents. The globalization of the food economy and explosion in international travel have facilitated the transmission of disease between continents.¹ Single outbreaks of food-borne or water-borne illnesses are capable of causing sickness in hundreds of thousands of people. Food or water may act as a vehicle for transmission of actively growing organisms or as a transfer medium for nonreplicating viruses, toxins, protozoa, bacteria, or chemical agents.

Food-borne illness is the occurrence of two or more cases of a similar illness resulting from the ingestion of a common food.²

Water-borne illness is defined by the Centers for Disease Control and Prevention (CDC) as an illness that occurs after consumption or use of water intended for drinking or as illness associated with recreational water such as swimming pools, whirlpools, hot tubs, spas, water parks, and naturally occurring fresh and marine surface waters.³

EPIDEMIOLOGY: FOOD-BORNE DISEASE

Food-borne diseases are estimated to cause approximately 76 million illnesses, 325,000 hospitalizations, and 5000 deaths in the United States each year. The majority of these illnesses are caused by unknown or unidentified pathogens.⁴ Three pathogens, *Salmonella*, *Listeria*, and *Toxoplasma* cause 1500 deaths each year, more than 75 percent of all deaths caused by known pathogens.⁴ Newly recognized pathogens include *Campylobacter jejuni*, *Escherichia coli* O157:H7, *Listeria monocytogenes*, and *Cyclospora cayentanensis*.⁴ A growing list of foods previously thought to be safe have been identified as new vehicles for transmission. *E. coli* O157:H7, generally associated with undercooked beef or unpasteurized dairy products, is now linked with items such as fruits, salad vegetables, yogurt, water, and acidic foods. International trade has allowed people to come into contact with previously unfamiliar pathogens that are native to remote parts of the world.⁵ Bacteria, viruses, parasites, and chemical contamination at the site of processing can be disseminated to a multitude of locations thousands of miles away. Low-dose contamination at a central processing site can cause widespread outbreaks.⁵ Consolidation of the food industry has led to a larger market share and greater geographic distribution of products from a single supplier or distributor.⁵ This increases the risk of larger outbreaks of disease. In 1994, a nationwide outbreak of over 224,000 cases

of *Salmonella enteritidis* from one distributor occurred when ice cream premix was transported in tanker trucks that had not been completely sanitized after transporting nonpasteurized liquid eggs.⁶

The eating habits of the U.S. population have changed, with a greater emphasis on incorporating fruits and vegetables into the diet.¹ To meet this increased demand, the volume of imported fresh fruits and vegetables has escalated. Imports can account for more than 75 percent of fruits and vegetables available at local grocery stores.¹ Outbreaks of food-borne illness have occurred recently in produce such as fresh squeezed orange juice, raspberries, frozen strawberries, sliced tomatoes, and lettuce.⁵

Also, a larger percentage of meals are consumed outside the home.³ Nearly 44 percent of food-borne outbreaks in the United States from 1993 to 1997 occurred in cafeterias, restaurants, or delicatessens.² Many restaurants rely on transient personnel who have inadequate knowledge of safe food-handling techniques.⁷ In the home, there has been a decline in basic food preparation skills. Many adults who prepare meals do not routinely wash their hands after handling raw meat or poultry.⁷

The number and the percentage of people with increased vulnerability to illness have changed. A demographic shift to an older population base⁸ and patients with compromised immunity secondary to AIDS, immunosuppressants, chemotherapy, or chronic illnesses also represent an expanding segment of the population with heightened susceptibility to food-borne illness.^{5,8}

Travelers are at an increased risk of food-borne illnesses secondary to exposure to new, previously unseen pathogens, increased exposure through meals at hotels and restaurants, and unpredictable standards for public health cleanliness and water-supply systems.⁹ The relative risk of food-borne infection with viruses, bacteria, or parasites varies by country, but ranges from 20 to 50 percent for all travelers.¹ Enterotoxigenic *E. coli* is recognized as the major cause of traveler's diarrhea, but other strains of *E. coli* are also associated with travel, including enterohemorrhagic and enteroinvasive *E. coli*.⁹ The prevalence of *Salmonella typhi* necessitates typhoid immunization for travelers to many countries.⁹ *Salmonella enteritidis* outbreaks have occurred due to contaminated meals on airlines and railways.⁹ Other pathogens associated with international travel include *Brucella*, hepatitis A,⁹ *Vibrio*, *Shigella*, *Campylobacter*, *Giardia lamblia*, and *Cryptosporidium*.¹⁰

Food industry influences have contributed to the emergence of new pathogens in food-borne disease. The routine use of antibiotics to promote growth in food animals in North America and Europe for more than 50 years has facilitated an increase in antibiotic-resistant strains of *Salmonella* and *Campylobacter jejuni*. *Salmonella* contamination was found in 20 percent of supermarket ground meat samples. Of these isolates, 84 percent were resistant to at least one antimicrobial, including ceftriaxone, the drug of choice in treating *Salmonella* infection in children.^{4,11} The disposal of the more than 1 billion tons of manure and associated pathogens that are an annual by-product of the farming industry can contribute to the contamination of fruits and vegetables at harvest.⁵

National and international surveillance systems provide only rough estimates of the incidence of disease. Cholera is the only food-borne disease that must be reported internationally.¹² Many governments are reluctant to provide information on food-borne diseases, particularly if a country's economy is based on tourism or food exports.¹² International surveillance systems and laboratories have insufficient resources for accurate reporting.¹² Globally, only 1 to 10 percent of incidents of food-borne illnesses are reported.¹² Some countries have estimated that food-borne illnesses may be 300 to 350 times more common than reported.¹²

EPIDEMIOLOGY: WATER-BORNE DISEASE

United States public water systems are regulated under the Safe Water Drinking Act and the Surface Water Treatment Rule.³ These regulations require water utilities to disinfect surface water and groundwater,

and use parameters such as turbidity, coliform counts, and the presence of human enteric viruses, *Cryptosporidium parvum* and *Giardia lamblia* cysts as target organisms to assess efficacy of treatment.³

The CDC identified 39 outbreaks of water-borne disease in the United States associated with drinking water that caused illness in 2068 people from 1999 to 2000.³ Most outbreaks of water-borne illness remain unrecognized when they do not cause an acute serious illness, involve few people, have long incubation periods, or involve private, noncommunity water systems.³ A 1994 outbreak of cryptosporidiosis, the largest water-borne disease outbreak ever reported in the United States, accounted for 403,000 total cases of which 4400 people were hospitalized. The outbreak was traced to a community water system. Surface water from Lake Michigan had been filtered and chlorinated, but a deterioration in the water quality and the decreased effectiveness of the coagulation-filtration process led to inadequate removal of *Cryptosporidium parvum* oocysts. The treated water had met all state and federal quality standards that were then in effect. The outbreak was recognized by widespread absenteeism among employees of hospitals, students, and schoolteachers; a shortage of antidiarrheal drugs citywide; and a marked increase in the number of emergency department visits.¹³

PATHOPHYSIOLOGY

Normal physiologic defense mechanisms that exist to prevent disease from food- and water-borne pathogens include gastric acid, the normal flora of the gastrointestinal tract, intestinal motility, and mucous glycoproteins of the intestinal mucus. The effectiveness of each of these barriers can be altered by age, concomitant infections, chronic illnesses, medications, and the pathogen itself.

A gastric pH of 3 or less is generally found in most healthy adults and can effectively kill most food-borne pathogens.¹⁴ A reduction in acidity can occur secondary to antacids, H₂ blockers, and proton-pump inhibitors. Chronic underlying medical conditions such as diabetes mellitus, pernicious anemia, and gastric surgery also reduce gastric pH. Hypochlorhydria has also been demonstrated in *Helicobacter pylori* infections.¹⁴

Nonpathogenic indigenous intestinal bacteria inhibit colonization of pathogens by direct competition for nutrients and by the production of fatty acids or chemicals that are bactericidal. Alterations of intestinal flora commonly occur after antibiotic use, as well as secondary to radiation therapy, chemotherapy, and abdominal surgery.¹⁴ Recent antibiotic use lowers resistance to *Salmonella* infections and has been implicated as a risk factor for infection with *E. coli* O157:H7.¹⁴

The normal motility of the intestinal tract provides an important defense mechanism by minimizing the contact between the mucosal surface and potential pathogens. Bowel stasis permits multiplication and overgrowth of food-borne or water-borne pathogens and contributes to retrograde migration from the colon to the small intestine. Antiperistaltic agents, narcotics, and previous radiation therapy theoretically can prolong gut transit time and increase pathogen infectivity.¹⁴

The most common cause of bacterial food-borne illnesses in the United States is *Campylobacter* followed in order by *Salmonella*, *Shigella*, and *E. coli*.¹⁵ Infectivity of bacteria occurs by a variety of methods. Protein toxins are produced by *Vibrio cholerae* and enterotoxigenic *E. coli*. These toxins alter fluid and electrolyte movement across the mucosal surface, producing large volumes of fluid in excess of the absorptive capacity of the colon, causing excessive diarrhea and rapid dehydration. *E. coli* can adhere to the mucosal surface via surface pili or fimbria that bind to intestinal epithelial cell receptors. *Shigella*, *Salmonella*, enteroinvasive *E. coli*, *Campylobacter*, and *Vibrio parahaemolyticus* can invade the mucosal cells directly, causing cellular death. Cytotoxins, such as the Shiga toxin of *Shigella dysenteriae* or Shiga-like toxins produced by enterohemorrhagic *E. coli* O157:H7, enteropathogenic *E. coli*, and *V. parahaemolyticus* cause cellular membrane disruption and cell lysis.¹⁶

Food-borne viruses are usually transmitted person to person by the fecal-oral route and are infectious in very low doses. Viruses do not multiply or produce toxins, and food items simply act as transfer media. Testing for viral etiologies of diarrheal disease is rarely done, leading to underreporting of viral food-borne outbreaks. Viral gastroenteritis, caused by Norwalk viruses, astroviruses, rotaviruses, and enteric adenoviruses are the most common form of food-borne disease with an estimated annual incidence in the United States of 23,000,000 illnesses.^{4,10}

Simultaneous infection with more than one viral pathogen is common. Viral contamination can occur at the source, after harvesting, or during food preparation. Bivalve mollusk (oysters, clams, and mussels) contamination usually occurs at the source in polluted shallow coastal waters. The application of raw sewage or sludge to fruit and vegetable crops is another source of primary viral contamination. Viral contaminants remain active when they are inadequately cooked or consumed raw, particularly in oysters.¹⁷

Viral contamination from infected food handlers is largely associated with cold food items that require much handling during preparation, such as salads and sandwiches, ice, or ready-to-eat foods.¹⁰

Water-borne transmission of virus is an effective mechanism of infectivity. Outbreaks have been associated with contamination of private wells, small water systems, and community water systems.³ Seasonal outbreaks of Norwalk gastroenteritis have been associated with swimming in lakes and pools.

Hepatitis A is the only reportable food-borne viral disease, and the true incidence of illness is underreported. Hepatitis A outbreaks are likely to be recognized weeks after contaminated food has been consumed and samples are unavailable for testing. Most infections are the result of consumption of infected bivalves, but outbreaks associated with infected raw produce have occurred.¹⁰

Viruses can be eliminated at any step along the food-handling process. Heating is an effective means of inactivating hepatitis A virus particles in mollusks, and their exposure to temperatures of 85° to 90°C for at least 90 s is recommended.¹⁷ Viruses are a small target for ionizing radiation. Enteric viruses are often acid resistant, and hepatitis A virus is quite resistant to drying. Viruses in water or on surfaces can be inactivated by chlorine, ozone, or ultraviolet light.¹⁷

DIAGNOSIS AND TREATMENT

Symptoms associated with food-borne illness are very common and often nonspecific except for syndromes associated with particular chemical agents such as ciguatera toxin, organophosphates, or histamine (scombroid). Obtaining a complete history of an acute diarrheal illness is important. In a presumed food-borne illness, determining the exact time of exposure can help direct the evaluation to particular causative agents, although significant overlap exists between syndromes of food-borne illness (Table 150-1).¹⁰ Extending a history beyond 3 or 4 days will provide only limited benefit in identifying pathogens such as hepatitis A, *Cryptosporidium*, and *Salmonella* with prolonged incubation periods.

A history of two or more people within a household becoming ill simultaneously may indicate a food-borne etiology. If additional cases occur within 24 to 36 h, non-food-borne sources such as viruses are more likely. Patients should be questioned about inadequate food-handling practices at home, such as preparation of food several hours prior to consumption, insufficient cooking or reheating of food, cross contamination between raw and cooked foods on common preparation surfaces, or people with poor personal hygiene handling the food.¹⁸

Patients should be questioned about other activities associated with an increased risk of food-borne disease, such as frequent restaurant meals, exposure to day care centers, consumption of street-vended food or raw seafood, overseas travel, and camping with the ingestion of lake or stream water.

Host factors that reduce resistance and immunocompetence should be identified. The recent use of antibiotics and medications that reduce gastric acidity, such as H₂ blockers, proton-pump inhibitors, and

antacids, should be identified. Identify patients with AIDS or other immunocompromised conditions.

Children younger than age 5 and adults older than age 65 have the highest attack rate for infection with *E. coli* and are at the greatest risk for hemolytic-uremic syndrome.¹⁴ Residents of chronic care facilities are at increased risk for illness and death because of their close proximity, increased frequency of fecal incontinence, and a general debilitated state with multiple concurrent illnesses.¹⁴

A recent history of swimming in pools, water parks, lakes, and other recreational water facilities is important and should raise suspicion for cryptosporidiosis, although other pathogens such as enterohemorrhagic *E. coli* have been linked to water park outbreaks.³

Physical examination should be directed at identifying toxic or dehydrated patients, identifying the presence of blood in the stool, and excluding other diarrheal illnesses.

A variety of diagnostic tests are available for confirmation of pathogens in suspected outbreaks. The majority of patients will have a self-limited illness that resolves by the time culture results are available. Stool cultures are indicated if the patient is febrile, has bloody diarrhea, has severe abdominal pain, if the illness is clinically severe or persistent, or if the patient has significant historical risk factors for food-borne illness.¹⁰ Routine testing of all patients with infectious diarrhea for ova and parasites and stool cultures is not cost effective. Stool cultures should minimally include the more frequent causes of

TABLE 155-10 Antiviral Agents for Systemic Herpes, Varicella, CMV, and Influenza Virus Infections

Drug	Mechanism of Action	Activity Against
Acyclovir (Zovirax), valacyclovir (Valtrex) Penciclovir, famciclovir (Famvir)	Purine nucleoside analogues; triphosphate form inhibits HSV DNA polymerase and viral DNA replication	HSV I and II, VZV
Ganciclovir (Cytovene), valganciclovir (Valcyte)	Nucleoside analogue (guanine); when phosphorylated, inhibits viral DNA polymerase	HSV I and II, VZV, CMV
Foscarnet (Foscavir)	Inorganic pyrophosphate analogue that inhibits DNA polymerase	HSV I and II, VZV, CMV
Cidofovir (Vistide)	Nucleotide analogue that inhibits viral DNA polymerase	HSV I and II, VZV, CMV
Amantadine (Symmetrel), rimantadine (Flumadine)	Inhibits uncoating of virus and uptake of nucleic acid by host cells	Influenza A
Oseltamivir (Tamiflu), zanamivir (Relenza)	Inhibitor of influenza virus neuraminidase with possible alteration in viral aggregation and release	Influenza A and B

Source: From Hardman et al.

Several important comments are necessary regarding the adverse effects of the antiretroviral agents. Certain reactions may be life-threatening and thus may be important circumstances that could arise in the emergency department. First, lactic acidosis is being recognized increasingly as a significant adverse effect of therapy. The onset of the acidosis may be subacute, so patients will complain of several weeks of fatigue, anorexia, weight loss, confusion, and loss of energy. Arterial lactic acid levels may be increased two to three times, and resolution of the acidosis typically is slow, even after discontinuation of the antiretroviral drugs. Lactate levels should be checked in patients with the preceding symptoms who have been receiving antiretroviral agents, especially stavudine (d4T, Zerit) or didanosine (ddl, Videx). Second, the hypersensitivity syndrome secondary to abacavir (Ziagen) must be noted. As briefly described in Table 155-11, the syndrome is characterized by rash and other systemic complaints. The reaction is reversible with discontinuation of abacavir. However, if the patient then takes abacavir again, cardiovascular and respiratory insufficiency has been observed that can be life-threatening. Rechallenge should be done only under the supervision of a clinician very experienced in HIV care. Finally, it should be noted that there are multiple and important drug interactions between the antiretroviral drugs themselves and with drugs used for other indications. A comprehensive summary of these interactions is beyond the scope of this chapter. Excellent resources, such as the references for this chapter, can help with a listing of these drug interactions. Multiple online sources are also available and are updated frequently. These sources, in particular, include www.hivatis.org and www.pedhivaid.org.²⁻⁵

TABLE 155-11 Antiviral Agents for HIV Infection

Drug	Usual Dose	Adverse Events and Administration Issues
Nucleoside reverse-transcriptase inhibitors		
Zidovudine (Retrovir) (AZT, ZDV)	300 mg PO bid	Bone marrow suppression with anemia, macrocytosis; headache, nausea, vomiting; can be given with or between meals Peripheral neuropathy; pancreatitis, nausea diarrhea; lactic acidosis (myalgia, fatigue, anorexia); give between meals
Didanosine (Videx) (ddl)	200 mg PO bid or 400 mg qd (>60 kg) 250 mg qd (<60 kg)	
Zalcitabine (Hivid) (ddC)	0.75 mg PO q8h	
Stavudine (Zerit) (d4T)	40 mg bid (>60 kg) 20 mg bid (<60 kg) 150mgPObid	Peripheral neuropathy, stomatitis; give between meals Peripheral neuropathy, hepatitis; lactic acidosis; can be given with or between meals Few adverse events: headache, nausea, pancreatitis; can give with or between meals Hypersensitivity reaction (fever, rash, nausea, abdominal pain, malaise); do not readminister abacavir; headache, lactic acidosis; can give with or between meals Nausea, diarrhea, vomiting; take with food
Lamivudine (Epivir) (3TC) Abacavir (Ziagen)	300 mg PO q12h	
Tenofovir (Viread)	300 mg qd	
Nonnucleoside reverse-transcriptase inhibitors		
Nevirapine (Viramune)	200 mg PO qd X 7 d; then 200 mg bid	Rash (can be severe), hepatitis, nausea, vomiting, diarrhea; give with/without food Rash, nausea, headache; give with or without food Vivid dreams, headache, rash (can be severe), dizziness, light-headedness; avoid taking with high-fat meals—increases toxicity
Delavirdine (Rescriptor)	400 mg PO q8h	
Efavirenz (Sustiva)	600 mg PO hs	
Protease inhibitors		
Indinavir (Crixivan)	800 mg q8h or 400 mg bid with 400 mg bid ritonavir	Kidney stones; hyperbilirubinemia (indirect), nausea, vomiting, hepatitis, increased glucose and lipids; lipodystrophy; must be taken between meals Nausea, vomiting, diarrhea, hepatitis; increase in glucose and lipids; lipodystrophy; take with food As above
Lopinavir (Kaletra) (fixed combination with ritonavir)	3 capsules bid	
Ritonavir (Norvir)	400 mg bid in combination with other protease inhibitors	
Nelfinavir (Viracept)	1250 mg bid	Diarrhea (~20%); increase in lipids; lipodystrophy; take with meal or snack Nausea, diarrhea, abdominal pain, headache; hepatitis, increases in glucose and lipids Lipodystrophy; take with food Rash, nausea, vomiting, diarrhea, circumoral paresthesias; lipodystrophy; can be taken with or between meals
Saquinavir (Fortovase)	1200 mg tid or 400 mg bid with ritonavir	
Amprenavir (Agenerase)	1200 mg bid, or 450 mg bid with 100 mg bid ritonavir

TABLE 150-2 Bacterial Food-Borne Illnesses (Continued)

Organism	Incubation Period	Signs and Symptoms	Illness Duration	Food Source	Lab Testing	Treatment*
Enterotoxigenic <i>E. coli</i>	1–3 d	Watery diarrhea, vomiting, cramps	3–10 d	Fecal contamination of water or food	Specific stool culture	Ciprofloxacin* or TMP-SMX*
<i>Listeria monocytogenes</i>	9–48 h for GI, 2–6 weeks for invasive disease	Fever, myalgias, nausea, diarrhea in pregnant women, flu-like illness Can lead to premature delivery Elderly or immunocompromised can have sepsis or meningitis	Variable	Soft cheese, unpasteurized milk, deli meats, and hot dogs	Blood or CSF culture	IV ampicillin, or TMP-SMX
<i>Salmonella</i> spp.	1–3 d	Diarrhea, fever, cramps, vomiting <i>S. typhi</i> and <i>paratyphi</i> cause chills, myalgias, headache, with rare diarrhea	4–7 d	Eggs, poultry, unpasteurized milk or juice, cheese, raw fruits and vegetables, street vendors, fecal water contamination	Stool cultures	Ciprofloxacin* or TMP-SMX*
<i>Shigella</i> spp.	24–48 h	Bloody diarrhea, fever, cramps	4–7 d	Fecal food or water contamination person-person spread by fecal-oral contamination	Stool culture	TMP-SMX if susceptible
<i>S. aureus</i>	1–6 h	Sudden severe nausea, vomiting, diarrhea	24–48 h	Unrefrigerated meats, potato and egg salad, cream pastries	None	Supportive only
<i>Vibrio cholerae</i>	24–72 h	Severe watery diarrhea and vomiting	3–7 d, death from dehydration	Contaminated water, fish, shellfish, street vendors	Specific stool culture	Ciprofloxacin in adults, TMP-SMX in children
<i>Vibrio vulnificus</i>	1–7 d	Vomiting, diarrhea, abdominal pain, sepsis, wound infections, liver disease and elderly can have skin bullae	2–8 d, death can result	Raw shellfish and fish, open wounds exposed to seawater	Specific wound or blood cultures	Doxycycline or ceftazidime
<i>Yersinia</i> spp.	24–48 h	Mimics appendicitis, can have rash	1–3 weeks	Undercooked pork, unpasteurized milk, contaminated water	Specific stool or blood culture	Ciprofloxacin,* doxycycline,* ceftriaxone,* or gentamycin*

*Antibiotics for severe cases only.

Abbreviation: TMP-SMX = trimethoprim-sulfamethoxazole.

CHRONIC SEQUELAE

Chronic secondary complications of food-borne illness occur in about 2 to 3 percent of patients.²⁰ If the host and pathogen have common surface antigens, host recognition of the foreign antigen can initiate an autoimmune response. A low but consistent incidence (0.2 to 2.4 percent) of seronegative reactive arthritis has been noted following outbreaks of *Salmonella typhimurium*, *Shigella flexneri*, and *Campylobacter jejuni*.^{20,21} Superantigens—protein virulence factors that can elicit extreme immune responses in the host—have been isolated from several food-borne bacteria. These are thought to be associated with multiple autoimmune disorders, such as rheumatoid arthritis, multiple sclerosis, Graves disease, and psoriasis.²⁰ A link between *Campylobacter* and Guillain-Barre syndrome has been suspected for over a decade. It is estimated that possibly 40 percent of Guillain-Barre cases are secondary to primary infection, with *Campylobacter* usually developing 7 to 21 days after resolution of gastrointestinal symptoms.^{20,21} Hemolytic-uremic syndrome (HUS), characterized by acute renal failure, thrombocytopenia, and microangiopathic hemolytic anemia, develops in some patients, particularly children, following acute colitis with *E. coli* O157:H7. HUS is caused by toxin-mediated damage to the glomerular epithelial cells and possibly the tubular epithelial cells and is the leading cause of acute renal failure in children.^{20,21} Other organisms that have been linked to HUS include other strains of *E. coli*, *Citrobacter*,

Campylobacter, *Shigella*, *Salmonella*, and *Yersinia*.²¹ Adults with *E. coli* O157:H7 infection may develop HUS or thrombotic thrombocytopenic purpura (TTP), a microangiopathic disorder that resembles HUS but is accompanied by neurologic abnormalities.¹⁰ Many of the acute symptoms of ciguatera poisoning can persist as a waxing and waning chronic symptom complex that is often misdiagnosed as chronic fatigue syndrome, brain tumor, or multiple sclerosis.²¹

PREVENTION AND SURVEILLANCE

Traditional Surveillance

Effective food-borne disease surveillance is critical to determine the frequency of cases, identify newly emerging pathogens, and isolate factors that contribute to disease transmission.⁸ Traditional surveillance systems for food-borne illnesses rely on clinical microbiology laboratories reporting identified pathogens or suspected outbreaks to state health departments, which then report them to the CDC.²² This type of passive surveillance requires a person with a diarrheal illness to seek care from a physician who then in turn obtains a stool culture. The current underreporting of food-borne illnesses is a direct consequence of this interdependent chain of events in which elimination of even one step results in a case not being identified.²²

FoodNet

FoodNet is a collaborative project of participating data collection sites in the CDC, U.S. Department of Agriculture, and the Food and Drug Administration (FDA) that became operational in 1995. It employs an active surveillance strategy for diarrheal illnesses and food-borne illnesses in sentinel populations monitored at over 300 clinical laboratories throughout the United States with a surveillance population of approximately 33.1 million people.¹⁵ FoodNet investigators actively contact these laboratories for confirmed cases of *Salmonella*, *Shigella*, *Campylobacter*, *E. coli* O157:H7, *Listeria*, *Yersinia*, *Vibrio*, *Cyclospora*, and *Cryptosporidium*. They have built a comprehensive database of food-borne illness in these regions.²³ Physician practice patterns for ordering stool specimens have also been monitored. Population surveys allow an approximation of the number of patients with diarrheal illness who seek medical care.²³ This information is centrally based at the CDC and facilitates timely recognition and response to food-borne outbreaks.

PulseNet

PulseNet, completed in May 1998, is a national computer network of public health laboratories that perform DNA fingerprinting on two bacteria: *E. coli* O157:H7 and *Salmonella typhimurium*. Using a standardized methodology for pulsed-field gel electrophoresis (PFGE), designated network laboratories in the United States can rapidly determine whether food-borne illnesses in multiple locations are linked to a common pathogen and food source. The state or local health department enters bacterial PFGE patterns into a centralized national electronic database. Matching patterns from different locations during a defined time period will trigger an alert to a possible multilocation food-borne-illness outbreak.²³

Prevention

The current system for ensuring food safety is complex, with authority divided between federal, state, and local governments. Currently in the United States, the FDA inspects food-processing plants, and along with the U.S. Department of Agriculture, regulates the interstate commerce of these foods. Final delivery destinations, such as restaurants, supermarkets, and cafeterias, are regulated by local health departments. The movement of food from the farm or water sources follows a predictable process-specific pathway. Contamination can occur at one or more points in the process.

Hazard Analysis and Critical Control Points (HACCP) is an applied methodology mandated for the meat and poultry industries in 1998. HACCP identifies vulnerable points in food production, such as sensitive ingredients, human interactions, and critical processing steps that are at high risk of contamination. It requires cooperation between government regulatory agencies and the food industry and replaces simple inspection of a final product. Industry-wide solutions can be implemented once contamination points are identified.^{1-7,8,24} HACCP directives do not extend to the home, food service, or retail establishments.

Emergency physicians should advise infected patients of the potential risks they pose to family members or others, particularly if they are food handlers or health care workers.¹⁷ A small number of factors in food handling are responsible for a large percentage of food-borne disease.¹⁸ The most important steps that can be taken in the home to prevent food-borne disease are thorough cooking and eating cooked food promptly. Educate patients that food from animal sources such as meat, dairy, and eggs should be either pasteurized or completely cooked and not eaten undercooked or raw. Cross contamination from the juices or drippings from raw meat, poultry, eggs, or shellfish with other foods must be avoided by washing hands or common preparation surfaces with soap and water. Prepared food should not be left for extended periods of time at temperatures that will promote bacterial growth.¹⁸ The World Health Organization has established rules for the preparation of safe food in the home that can be accessed via the Internet at <http://www.who.int/fsf/gldnrls.htm>.¹⁸

ZOO NOTIC INFECTIONS

John T. Meredith

The World Health Organization classifies zoonotic infections as those diseases and infections that are naturally transmitted between vertebrate animals and humans.¹ This broad class of diseases includes more than 200 specific diseases and syndromes covering an extremely variable range of clinical syndromes and medical therapy.² Zoonotic infections can be transmitted to humans by direct contact with an infected animal or infected animal product, by ingestion of contaminated water or food products, by inhalation, and through arthropod vectors.

In North America, an estimated 4 million people are infected annually.³ Zoonotic infections represent a significant public health problem in underdeveloped regions dependent economically on agricultural animals. The growth and mobility of the world's population has resulted in the appearance of new zoonotic infections and the reemergence of previously eliminated ones. More than 50 percent of the newly identified infectious agents since 1976 are associated with animals.⁴ Thus diversity of presentation, human mobility, and zoonotic reemergence make the diagnosis and management of zoonotic infections a challenge for emergency physicians.

RISK ASSESSMENT

A zoonotic infection should be considered part of the differential diagnosis of any undifferentiated infectious syndrome: fever, headache, myalgias, malaise, and weakness. However, diagnosis is difficult. Determining risk factors for acquiring a zoonotic infection can help focus the differential diagnosis.

Specific avocations and occupations that involve animal contact⁵ and certain medical comorbidities carry an increased risk (Table 151-1).⁶ The type of animal exposure is an important factor. Dressing, skinning, or handling an animal's skin; a history of animal bite or scratch; and ingestion of animal or dairy products all carry an associated risk of zoonotic infection. Recent travel and history of habitation, particularly in an underdeveloped country or rural area, are additional risk factors. Zoonoses can occur at any time of the year, but in the United States, most zoonoses show an increased incidence in the spring and summer.

Zoonoses that can present as an undifferentiated febrile illness or sepsis are listed in Table 151-2. The table lists only some of the more common zoonotic diseases.

TICK-BORNE ZOOONOTIC INFECTIONS

More zoonotic diseases are transmitted by ticks than by any other vector.⁷ In the United States more than 15,000 cases are diagnosed each year.^{8,9} Tick-borne diseases should be considered in the differential diagnosis of nonspecific febrile illnesses, especially if there is associated rash. Many patients do not recall a history of a tick bite.⁸ Tick-borne zoonoses have a geographic distribution (Table 151-3) and seasonal variation, with the highest U.S. incidence in spring and summer.

Tick Removal

The most effective way to remove an embedded tick is a three-step approach. First, viscous lidocaine is applied to kill the tick and anesthetize the bite site. Second, careful and gentle traction is applied to the tick's head with fine forceps. Third, all parts of the tick need to be removed. Residual tick body parts can stimulate a granulomatous reaction and persistent infection.

Techniques to avoid include the use of a burning match or any action resulting in crushing the tick. These attempts can cause infection by tick regurgitation into the wound site, and often result in incomplete tick removal.

Rocky Mountain Spotted Fever

The causative organism of Rocky Mountain spotted fever (RMSF) is *Rickettsia rickettsii*, a pleomorphic, obligate intracellular organism, and the vector is the *Dermacentor* tick. Deer, rodents, horses, cattle, cats, and dogs are zoonotic hosts.¹⁰ The classic clinical picture of RMSF is the triad of fever, rash, and tick exposure, but only about half of the patients can recall a tick bite. Other signs and symptoms include malaise, myalgias, lymphadenopathy, abdominal pain, nausea, vomiting, diarrhea, hepatosplenomegaly, headache, conjunctivitis, confusion, meningismus, renal failure, respiratory failure, and myocarditis. The rash of RMSF occurs on days 1 to 15 of the illness but is absent in about 20 percent of patients.^{11,12} The characteristic maculopapular rash begins on the hands, feet, wrists, and ankles, and then spreads centripetally up the trunk (see Chap. 248 for more detailed discussion). Laboratory abnormalities are usually nonspecific, but the combination of neutropenia, thrombocytopenia, elevated liver function studies, and hyponatremia suggests RMSF, especially in advanced disease. Diagnosis can be confirmed with a rise in antibody titer between acute and convalescent serum, skin biopsy with immunofluorescent testing,^{12,13} or culture, although none of these are useful for ED diagnosis. Preferred treatment is doxycycline 100 mg PO bid for 7 days, or for 2 days after temperature normalizes. While chloramphenicol is still an alternative, it can cause serious toxicity, including myelosuppression. It is contraindicated in children <2 years of age, pregnancy and breast-feeding, G6PD deficiency, porphyria, and those with hepatic or renal disease.

Lyme Disease

Lyme disease is the most common vector-borne zoonotic infection in the United States, with approximately 15,000 cases reported annually.¹⁴ The responsible organism is *Borrelia burgdorferi*, a spirochete, and the vector is the *Ixodes* deer tick. Lyme disease is most prevalent in the Northeast, but all continental 48 states have reported it.¹⁴ The overall risk of Lyme disease after a deer tick bite is relatively low, approximately 3 percent in highly endemic areas. However, the risk of infection is proportional to the length of time the tick feeds on the host. There is almost no risk if duration of attachment is <72 h, and about 25 percent risk of infection if the tick has been attached for 72 h or more.¹⁵

The disease has three stages. The initial stage of illness is often characterized by erythema migrans. Erythema migrans is an erythematous plaque with central clearing. It is the most common clinical manifestation associated with *B. burgdorferi* infection, occurring in about 60 to 80 percent of cases.⁸ It develops within 2 to 20 days at the site of the tick bite and is a result of a vasculitis. It may persist for

TABLE 151-1 Risk for Zoonotic Infection

Risk Category	Examples
Agricultural workers	Farmers, cattle ranchers, sheep ranchers, and migrant workers
Animal processing workers	Slaughterhouse workers, animal-hide processors, and workers in any manufacturing plant that deals with animal products or by-products
Outdoor enthusiasts	Forestry workers, lumbermen, surveyors, park rangers, hunters, spelunkers, fishermen, and those who regularly engage in outdoor recreational activities
Pet owners	Those with a dog, cat, bird, rodent, rabbit, reptile, or fish
Professionals	Veterinarians, animal researchers, and animal handlers
Immunocompromised patients	Those with congenital immunodeficiencies, diabetes mellitus, alcoholism, renal failure, liver failure, cancer, splenectomy, or HIV

TABLE 151-2 Systemic Zoonotic Infections

Agent	Animal Reservoir	Physical Findings	Diagnostic Tests	Treatment
<i>Aeromonas</i> spp.	Fish, reptiles	Nonspecific fever, severe crepitant cellulitis with systemic toxicity		Fluoroquinolones, TMP-SMX, cephalosporin (third or fourth generation), or Amox/Clav
<i>Brucella canis</i>	Dog	Nonspecific fever	Serologic testing, blood culture	Doxycycline plus gentamicin or rifampin
<i>Capnocytophaga</i>	Dogs and cats	Fever, sepsis, and endocarditis from infected bite	Culture of bite wound	Amoxicillin-clavulanate, or clindamycin plus either a fluoroquinolone or TMP-SMX
<i>Chlamydia psittaci</i>	Birds	Fever, pneumonia, endocarditis, sepsis	Serologic testing and sputum culture	Tetracycline or erythromycin
<i>Coxiella burnetii</i> (Q fever)	Cats, livestock animals, ticks	Fever, pneumonia, hepatitis, meningitis, endocarditis	Serologic testing	Azithromycin, doxycycline, or a fluoroquinolone
<i>Ehrlichia</i> spp.	Tick	Nonspecific fever, sepsis, meningitis, hepatitis	Serologic testing, peripheral blood smear, immunocytologic testing, PCR testing	Doxycycline
<i>Leptospira</i> spp.	Birds, dogs, rodents	Fever, pneumonia, conjunctivitis, lymphadenopathy	Darkfield microscopic examination of body fluids serologic testing	Penicillin G IV; doxycycline IV or PO, or ampicillin IV
<i>Francisella</i> spp. (tularemia)	Rabbits, cats, wild animals	Fever, sepsis, meningitis, pneumonia, hepatitis, rash	Serologic testing	Tobramycin or gentamicin plus chloramphenicol for meningitis
<i>Rickettsia rickettsii</i>	Ticks	Fever, diarrhea	Stool culture	Doxycycline or chloramphenicol
<i>Salmonella enterica</i>	Dogs, cats (rarely), reptiles (turtles)	Fever, sepsis, cellulitis, meningitis, endocarditis, septic arthritis	Blood culture	Ciprofloxacin or ceftriaxone
<i>Streptococcus inae</i> cellulitis	Livestock	Fever, pneumonia, meningitis, lymphadenopathy	Blood culture	Erythromycin, vancomycin, or TMP-SMX
<i>Yersinia pestis</i>	Dogs, cats, rodents		Blood culture, culture of suspected sites	Gentamicin, streptomycin, doxycycline, or chloramphenicol

Abbreviations: Amox/Clav = amoxicillin clavulanate; TMP-SMX = trimethoprim-sulfamethoxazole.

up to 1 month and recur in the secondary stage of Lyme disease.¹⁵ Untreated erythema migrans resolves spontaneously in 3 to 4 weeks.

The secondary stage of illness develops with the dissemination of the *Borrelia* spirochete and occurs within a few days to 6 months of the initial infection. This stage is characterized by fever, adenopathy, neuropathies, cardiac abnormalities, arthritic problems, and multiple annular dermatologic lesions. The multiple annular lesions occur in up to 50 percent of the patients infected, and are the most characteristic component of the secondary stage of illness.

The most common neurologic symptom in the secondary stage of illness is the development of cranial neuritis, most often unilateral or bilateral facial nerve palsy. This palsy can also occur concomitantly with the initial rash of erythema migrans. Neuroborreliosis occurs in 15 percent of the untreated cases, and can consist of periodic headache, neck stiffness, difficulty in mentation, cerebellar ataxia, myelitis, encephalitis, motor or sensory radiculoneuritis, mononeuritis multiplex, and facial palsy.¹⁴ Asymmetric oligoarticular arthritis of the large joints, with a particular predilection for the knees, is another complication. Brief attacks of asymmetrical oligoarticular arthritis are commonplace in the untreated patient in the secondary stage of illness. These attacks are characteristically separated by months of remission.¹⁶ Cardiac abnormalities occur in up to 8 percent of patients and present as varying degrees of atrioventricular block, sometimes requiring the insertion of a temporary pacemaker for stabilization. Additionally, myopericarditis may also be a manifestation on initial presentation.

The tertiary stage of illness occurs years after the initial infection and can be characterized by chronic arthritis, myocarditis, subacute encephalopathy, axonal polyneuropathy, and leukoencephalopathy.¹⁴

Diagnosis is principally clinical, though confirmation may be obtained by either polymerase chain reaction testing, polyvalent fluorescence immunoassay, or Western immunoblot testing.¹⁴ *Borrelia burgdorferi* has been cultured with difficulty. Of special note, the advanced, chronic neurologic forms of Lyme disease can persist for more than 10 years.¹⁶

Treatment of primary stage and to some degree the secondary stage of Lyme disease can be accomplished with several antimicrobial agents: doxycycline, amoxicillin, cefuroxime, ceftriaxone, or erythromycin. When only the initial rash of erythema migrans is present, the response to therapy is excellent. The duration of antimicrobial therapy in the primary stage of illness is 14 to 21 days. The more advanced secondary stage of illness requires longer duration of therapy, up to 28 days. However, there is a controversy in the treatment of the tertiary stage of illness.^{14,16} Intravenous antibiotics, ceftriaxone or penicillin, are recommended for the tertiary stage of Lyme disease, with duration of therapy extending from 28 to 60 days. But this late phase of illness may not respond to aggressive antimicrobial therapy.

A vaccine was commercially available, but was withdrawn from the market in February 2002.¹⁷ Vaccination was felt to be the best prevention against Lyme disease. As the tick feeds on an immunized host, antibodies are ingested, destroying spirochetes in the gut of the engorging tick prior to transmission to the host.

However, there was little demand for the vaccine, and it was expensive. Optimal protection required immunization at 0, 1, and 12 months, one booster immunization every 1 to 3 years. There was concern that immunization would lead recipients to disregard physical precautions against tick-borne diseases in general.

TABLE 151-3 Tick-Borne Zoonotic Infections

Disease	Vector	Animal Reservoir	Clinical Features	Antibiotic Treatment	Geographic Distribution
Babesiosis	<i>Ixodes dammini</i> , <i>I. scapularis</i> , and <i>I. pacificus</i>	Cattle, horses, dogs, cats, rodents, deer	Fatigue, malaise, anorexia, nausea, headache, sweats, rigors, abdominal pain, emotional lability, depression, dark urine, hepatomegaly, fever, petechiae, ecchymosis, occasional rash, and occasionally pulmonary edema	For the seriously ill, atovaquone and azithromycin, or quinine plus clindamycin	Coastal areas of MA, RI, and NY; also in MD, VA, MN, WI, GA, WA, and Mexico
Colorado tick fever	<i>Dermacentor andersoni</i>	Deer, marmots, porcupines	Fever, chills, headache, myalgias, nausea, vomiting photophobia, abdominal pain, and occasional sore throat; also may have conjunctivitis, lymphadenopathy, hepatosplenomegaly, stiff neck, retroorbital pain, weakness, and lethargy	Supportive care	Western and northwestern US and southwestern Canada
Human granulocytic ehrlichiosis	<i>Ixodes scapularis</i>	Dogs, deer, other mammals	Fevers, chills, malaise, headache, nausea, muscle aches, cough, sore throat, and pulmonary infiltrates (especially in children)	Doxycycline or tetracycline	Japan, Malaysia, and the Eastern, northeastern, and northcentral US
Human monocytic ehrlichiosis	<i>Amblyomma americanum</i> (Lone Star tick) and <i>D. variabilis</i>	Dogs, deer, other mammals	Fevers, chills, malaise, headache, nausea, muscle aches, cough, sore throat, and pulmonary infiltrates (especially in children)	Doxycycline or tetracycline	Japan, Malaysia, and southern US
Lyme disease (<i>Borrelia burgdorferi</i>)	<i>Ixodes dammini</i>	Deer, sheep, deer mice	Erythema migrans, meningitis, encephalitis, neuropathy, and joint and heart symptoms	Doxycycline, amoxicillin, cefuroxime, erythromycin, ceftriaxone, or cefotaxime	Atlantic central and northcentral US
Rocky Mountain spotted fever (<i>Rickettsia rickettsii</i>)	<i>Dermacentor andersoni</i> (wood tick) and <i>D. variabilis</i> (dog tick)	North American mammals	Petechiae, purpura, pulmonary infiltrates, jaundice, myocarditis, hepatosplenomegaly, meningitis, encephalitis, and lymphadenopathy	Doxycycline or chloramphenicol	Most of the continental US, although more prevalent in the southeast and southcentral US
Relapsing fever (<i>Borrelia</i> spp.)	<i>Ornithodoros</i> spp.	Human body lice, wild rodents, humans	Fever, chills, headache, myalgias, and arthralgias; pain, nausea, vomiting, and hypotension	Erythromycin or doxycycline	Worldwide
Tularemia (<i>Francisella tularensis</i>)	<i>Dermacentor</i> spp. and <i>Amblyomma</i> spp.	Rabbits, deer, dogs	Pneumonia, regional lymphadenopathy and headache, cough, myalgias, arthralgias, nausea, vomiting, ulceration at inoculation site, and ocular findings	Tobramycin or gentamycin, and chloramphenicol for meningitis	US (except Hawaii) and Canada

Routine prophylactic treatment is not recommended, since only approximately 3 percent of the bites transmit the disease, and because prophylactic antibiotic administration may depress the immune response to the disease.¹⁸ Recommended considerations for prophylactic treatment include treating patients bitten by deer ticks in areas where Lyme disease is highly endemic, the nymphal deer tick is at least partially engorged with blood, and/or when the deer tick has been feeding for more than 72 h.¹⁸

A single 200-mg dose of doxycycline given within 72 h of the deer tick bite is effective in preventing Lyme disease.¹⁹ It is important to note that nearly one-third of those treated with single dose doxycycline will develop nausea and vomiting.¹⁹

Relapsing Fever

Relapsing fever is caused by *Borrelia* spirochetes. *Ornithodoros* ticks are the vectors, and the principal zoonotic reservoirs are wild rodents.^{20,21} Often the initial presentation is that of a rash or pruritic eschar at the site of a tick bite. An average incubation period of 7 days precedes the onset of fever, chills, cephalgia, myalgia, arthralgia, abdominal pain, and general malaise. Characteristically, the febrile episodes are interspersed with afebrile periods. Leukocytosis, thrombocytopenia, and an elevated erythrocyte sedimentation rate are the typical laboratory findings. Diagnosis is confirmed with the appearance of spirochetes on Wright- or Giemsa-stained peripheral blood smears. Treatment is with doxycycline or erythromycin (doxycycline 100 mg PO bid for 10 days or erythromycin 500 mg qid for 10 days).^{20,22}

Colorado Tick Fever

Colorado tick fever is caused by an RNA virus. The principal vector is the tick of the species *Dermacentor*, and the zoonotic reservoirs are deer, marmots, and porcupines. The disease is endemic to the western mountainous regions of the United States, but only about 300 cases are reported annually. The incubation period is 3 to 7 days, and the onset of illness is characterized by fever, chills, headache, myalgias, and photophobia. There may be a macular or petechial rash. Complications are rare. Diagnosis is most often based on clinical findings and geography. The virus can be isolated from blood or cerebrospinal fluid (CSF) by inoculating suckling mice.²³ Treatment is supportive.

Tularemia

Tularemia, which has been characterized as "a plague-like disease of rodents,"²⁴ is caused by a gram-negative, nonmotile coccobacillus, *Francisella tularensis*. The zoonotic vectors are ticks of the *Dermacentor* spp. and the *Amblyomma* spp., and the principal zoonotic reservoirs are rabbits, hares, and deer.⁹ Tularemia can be contracted through tick bites or through open wounds while dressing an infected zoonotic host. The clinical presentation depends on the method of inoculation, and the clinical forms are called ulceroglandular, glandular, typhoidal, pneumonic, and oropharyngeal. The ulceroglandular form is the most common. It is characterized by an ulcer at the site of the tick bite, and painful regional adenopathy. The glandular form consists of painful adenopathy without ulcerations. The typhoidal form consists of fever, chills, cephalgia, and abdominal pain. The ocular-oropharyngeal form and pneumonic form are the result of deposition into the eyes or inhalation of the *F. tularensis* bacterium. Laboratory findings are nonspecific, and the diagnosis can be determined by culture and enzyme-linked immunosorbent assay (ELISA).^{24,25}

Treatment is with tobramycin (5 mg/kg IV divided in 3 doses for 7-14 d) or gentamicin (5 mg/kg per d in three divided doses for 7 to 14 d). Chloramphenicol and ciprofloxacin are also effective in treating tularemia. A live attenuated vaccine is available for research workers and laboratory personnel.²⁴

Babesiosis

Babesiosis is a malaria-like disease transmitted by ticks with the etiologic agents being protozoan parasites: *Babesia microti* and *Babesia equi*.²⁶ The major zoonotic reservoirs are domesticated mammals, rodents, and deer. *Ixodes* ticks function as the principal vector. Blood transfusions have been implicated in the transmission of babesiosis.²⁶ Clinically, the presentation is generalized malaise, anorexia, fever, and chills that can progress to intermittent sweats, myalgia, headache, and hemolytic anemia. Splenectomy and immunosuppression are risk factors. Laboratory tests can provide evidence of hemolysis, liver dysfunction, anemia, thrombocytopenia, and renal failure. Interestingly, approximately 20 percent of patients with babesiosis have a concurrent infection with Lyme disease.⁹ Diagnosis is made by finding intraerythrocytic ring forms on a Giemsa-stained peripheral blood smear, though false-negative results can occur when the level of parasitism is low.

Treatment is with atovaquone (750 mg PO q12h) plus azithromycin (500 mg PO on day 1, then 250 mg/d) both for 7 days. Clindamycin plus quinine is an alternative regimen.

Ehrlichiosis

Ehrlichiosis is a zoonotic disease with two principal presentations: *human granulocytic ehrlichiosis* and *human monocytic ehrlichiosis*. The etiologic agent, *Ehrlichia chaffeensis*, that is responsible for the granulocytic form is similar in ribosomal RNA gene-sequence to *Ehrlichia phagocytophila* and *Ehrlichia equi*.^{9,27,28} The predominant form in the United States is the monocytic form caused by *Ehrlichia chaffeensis*. The *Ehrlichia* bacteria are gram-negative pleomorphic coccobacilli that infect circulating leukocytes.²⁷ The zoonotic reservoirs are thought to be deer, dogs, and other mammals, with the vectors being *Ixodes* spp. and *Amblyomma* spp. ticks. Approximately 90 percent of patients have a tick bite history in the 3 weeks prior to the onset of symptoms.^{9,27} Characteristic clinical presentation is that of a febrile illness with cephalgia, malaise, nausea, vomiting, abdominal pain, anorexia, and myalgia. In 20 percent of the cases, a maculopapular or petechial rash is present that only infrequently involves the soles and palms occurs during the initial phase of illness. In contrast, over 80 percent of patients infected with Rocky Mountain spotted fever develop a maculopapular rash.⁹ With disease progression, a minority of patients go on to develop severe complications of renal failure, respiratory failure, and encephalitis. The acute phase of illness lasts less than 4 weeks, with the majority of patients recovering and preceding on to a convalescent phase. Laboratory studies can demonstrate leukocytopenia, thrombocytopenia, and liver dysfunction at 1 week from the onset of acute symptoms. Diagnosis is based on seroprevalence studies using an indirect immunofluorescent antibody test.^{9,27} The diagnosis is made by either a fourfold rise or a decrease in antibody titer between the acute phase and convalescent phase of illness. Treatment is with doxycycline, 100 mg PO bid for 7 to 14 days.²⁷

ZOO NOTIC ENCEPHALITIS

Zoonotic encephalitis is most often an arboviral infection transmitted hematologically by an arthropod vector and animal host. Often the vector is a mosquito or tick and the animal host is a small animal or bird. The one exception is rabies (see Chap. 147), which follows peripheral nerve tracts after inoculation from an infected animal's bite. Additionally, encephalitis may be seen in the nonviral zoonotic infections of *Bartonella henselae*, *Brucella canis*, borreliosis, *Coxiella burnetii*, *Ehrlichia* spp., listeriosis, leptospirosis, Lyme disease, RMSF, psittacosis, and toxoplasmosis.^{9,29,30}

The clinical presentation is a prodromal illness with malaise, myalgia, fever, and occasionally parotitis. This prodromal phase advances to a sudden decline in mental status associated with headache and

SECTION 13 • INFECTIOUS DISEASES

fever. However, there are no specific signs and symptoms that determine the exact etiology and causative organism of encephalitis. The CSF is often abnormal, showing a slightly elevated opening pressure, normal to slightly elevated protein concentration, normal glucose levels, and predominance of lymphocytes. The electroencephalogram is abnormal with diffuse bilateral slowing interrupted by occasional spike activity. CSF viral cultures are frequently sterile, and the infectious agent is rarely isolated from the CSF.^{29,32} ELISA of serum can be used to detect most arboviral infections causing encephalitis. Computed axial tomography is often negative with no evidence of focal findings or abnormalities. Magnetic resonance imaging often does reveal evidence of encephalitis by the imaging of cerebral swelling. If the CT scan were negative, following up with an MRI scan would be the prudent course of investigation. Treatment is supportive and directed toward decreasing elevated intracranial pressure.

West Nile Virus Encephalitis

The West Nile virus was first isolated in the West Nile District of Uganda in 1937, and since then was commonly found in vertebrates in Africa, Eastern Europe, West Asia, and the Middle East.³³ It is a member of the Japanese encephalitis serocomplex of the Flaviviridae family of viruses.³⁴ In 1999 it was detected in the western hemisphere.

The mode of transmission involves mosquitoes, primarily of the *Culex* species, that feed on infected birds, which serve as the natural reservoir for the virus. Over 110 species of birds have been identified as being infected by the West Nile virus in the United States. Most of these birds are crows, ravens, and jays.³⁴

Infected mosquitoes transmit the virus to humans and other animals when taking a blood meal.

There is an incubation period of 3 to 15 days after an infected bite. About 20 percent of those bitten develop fever and a flu-like illness, "West Nile fever." The classic presentation for West Nile fever is that of a mild dengue-like illness of sudden onset with fever, lymphadenopathy, headache, abdominal pain, vomiting, rash, conjunctivitis, eye pain, and anorexia. Duration is typically 3 to 6 days.³⁴

Meningoencephalitis occurs in approximately 1 in 150 patients that become infected and is more common than meningitis. Risk factors for the development of meningoencephalitis are immunocompromised host (HIV TB, or malaria), or advanced age. Complaints of weakness out of proportion to physical examination findings are common and myoclonus is nearly a universal finding. Interestingly, complete flaccid paralysis may occur and can be confused with Guillain-Barre syndrome. Other neurologic findings include parkinsonian-like signs, ataxia, extrapyramidal signs, cranial nerve abnormalities, myelitis, optic neuritis, and seizures. Treatment for West Nile virus is supportive.³⁴

Laboratory findings for West Nile virus infection are limited to a total leukocyte count that is either normal or slightly elevated. Hyponatremia has been occasionally associated with patients with encephalitis. Cerebrospinal fluid demonstrates mostly lymphocytes, protein elevation, and a normal glucose. Computed tomography of the brain shows no evidence of acute disease, though with progressive meningoencephalitis cerebral edema may be noted.

Diagnosis is made by identifying West Nile virus (WNV)-specific IgM antibody in serum or CSF specimens. IgM-specific antibody is an acute-phase identifier that can persist in serum for up to 12 months postinfection. IgG WNV-specific antibody is found in the convalescent phase in both serum and CSF. As of this writing, PCR testing is still in an experimental stage.³⁴

Methods to reduce the exposure risk for West Nile virus include use of mosquito repellents, clothing with long sleeves and long pants, and avoiding the outdoors during dawn and dusk. The insect repellent recommended is DEET (N,N-diethyl-m-toluamide and related compounds). Personal insect repellents should not be used on infants under 6 months of age. Use of mesh covers on strollers is recommended for this age group, along with protective clothing.³⁴

ZOONOTIC MENINGITIS

Zoonotic meningitis can be caused by brucellosis, listeriosis, plague, salmonellosis, tularemia, leptospirosis, Lyme disease, ehrlichiosis, Q fever, RMSF, and psittacosis. CSF is almost always abnormal, showing a slightly elevated opening pressure, normal to slightly elevated protein concentration, normal glucose levels, and predominance of lymphocytes. Treatment is directed toward the specific organism cultured from the CSF. However, empiric antibiotic coverage should be administered immediately in any presumptive case of meningitis in an effort to reduce mortality and morbidity.³¹ See Chap. 235 for specific empiric recommendations.

RESPIRATORY ZOONOTIC INFECTIONS

Respiratory zoonotic infections can be divided into upper (pharyngitis) and lower respiratory infections (pneumonia).

Upper Respiratory Zoonotic Infections

Recurrent culture-proven streptococcal pharyngitis in a household member can have a zoonotic source—often the household pet.^{35,36} For complete eradication of this form of streptococcal pharyngitis from a family, the family pet, in addition to family members, may require a course of antistreptococcal antimicrobial therapy. Prolonged exudative pharyngitis raises the suspicion of a zoonotic origin or atypical pharyngitis, particularly if the exudative pharyngitis includes systemic symptoms and leukocytosis, and is refractory to standard antistreptococcal therapy. In this case, it is pertinent to inquire about animal exposure. Dogs and domesticated farm animals can be the source of *Streptococcus* spp., *Corynebacterium ulcerans*, *Yersinia* spp., and viral vesicular stomatitis. All of these zoonoses can present as an exudative pharyngitis.⁵ Nondomesticated animals can be a source of exudative pharyngitis as a result of *Bordetella* spp., *Francisella tularensis*, *Streptobacillus moniliformis*, and *Yersinia pestis*.⁵ Both pet birds and wild birds carry *Chlamydia psittaci*, which can cause an atypical exudative pharyngitis in humans.

Lower Respiratory Zoonotic Infections

Zoonotic pneumonia presents as an atypical, community-acquired pneumonia with systemic symptoms. Most often the presentation consists of productive or nonproductive cough, fever, chills, headache, myalgias, and a nonspecific rash. Symptoms can progress very rapidly. Zoonotic pneumonia should be considered in any case of gram-negative community-acquired pneumonia and in any case of atypical pneumonia with systemic symptoms (Table 151-4).³⁶

A detailed history provides the data necessary for the consideration of zoonotic pneumonia. Inquiries about animal exposure, occupation, and recent travel are warranted for patients with an atypical pneumonia. Particular attention should be paid to slaughterhouse workers and those individuals exposed to ticks, birds, and other fowl. Additionally, a history of outdoor activity, recreational history, and food-contact history should be obtained.³⁷

Inhalation anthrax (*Bacillus anthracis*) is acquired most often from handling unsterilized, imported animal hides or imported raw wool, and is generally fatal. Inhalation anthrax is a mediastinitis without alveolar involvement, and is not a true pneumonia. Initial symptoms are flulike in character and progress to respiratory failure in 3 to 4 days, with marked mediastinal and hilar edema. Treatment is with either ciprofloxacin (400 mg IV q12h) or with doxycycline (100 mg IV q12h), plus elindamyacin (900 mg IV q8h) and/or rifampin (300 mg IV q12h). Treatment may be needed for 60 days.

Brucellosis (*Brucella* spp.) occurs most often in slaughterhouse workers exposed to aerosols containing *Brucella* bacteria. The con-

TABLE 151-4 Zoonotic Pneumonias

Disease	Organism	Reservoirs	Treatment
Inhalation anthrax	<i>B. anthracis</i>	Imported animal hides, raw wool, sick domestic animals	Ciprofloxacin, clindamycin, and rifampin
Brucellosis	<i>Brucella</i> spp.	Food animals and product handling, ingestion, inhalation	Doxycycline plus rifampin or gentamicin, or TMP-SMX plus gentamicin
Psittacosis, ornithosis	<i>C. psittaci</i>	Bird exposure—pet and pet shop, veterinarians, turkey farms	Macrolides, or a fluoroquinolone, or doxycycline
Q fever	<i>C. burnetii</i>	Inhaled endospores from animal-contaminated soil; cat afterbirth, ticks	Tobramycin, doxycycline, erythromycin, or a fluoroquinolone
Tularemia	<i>F. tularensis</i>	Aerosol from dead birds, animals; bacteremic spread from bubo; ticks and biting flies	Gentamicin, or chloramphenicol for meningitis
Leptospirosis	<i>L. interrogans</i>	Domestic and wild animals, contaminated water, veterinarians, farmers	Doxycycline, ampicillin, amoxicillin, or penicillin
Pasteurellosis	<i>P. multocida</i>	Underlying respiratory disease; contact with cat, dog in home	Doxycycline, penicillin, third-generation cephalosporin, or Amox/Clav
Melioidosis	<i>P. pseudomallei</i>	Penetrating injury in endemic area in rodent-contaminated soil or water	Ceftazidime plus TMP-SMX; chloramphenicol or doxycycline
Rocky Mountain spotted fever	<i>R. rickettsii</i>	Tick-associated, typical rash	Doxycycline or chloramphenicol
Toxoplasmosis	<i>T. gondii</i>	Contact with domestic food animals and pets, ingestion of cysts, pneumonia in immunocompromised persons	Pyrimethamine plus sulfadiazine and folinic acid
Plague	<i>Y. pestis</i>	Contact with mammals and fleas; veterinarians; outdoor activities in endemic area; cats	Gentamicin, streptomycin, doxycycline, or ciprofloxacin
Viral pneumonias			
Hantavirus pulmonary syndrome	Bunyaviridae	Rodent feces, urine, and saliva	Ventilator oxygenation or ribavirin
Influenza pneumonia	Influenza A	Aquatic fowl, pigs, horses, marine mammals	Supportive care; amantadine or rimantadine

Abbreviations: Amox/Clav = amoxicillin clavulanate; TMP-SMX = trimethoprim-sulfamethoxazole.

sumption of unpasteurized dairy products is another way of acquiring brucellosis. Often the presentation is one of an upper respiratory infection with a cough, hoarseness of voice, and wheezing. Typically, peritracheal and hilar lymph node enlargement is seen on x-ray. Pulmonary infiltrates or consolidation are uncommon. With longstanding resolution, calcified granulomas and lymph nodes are characteristic findings.³⁸ Doxycycline (100 mg PO bid for up to 6 weeks) combined with gentamicin (2 mg/kg IV q8h) or rifampin (10 mg/kg per d up to 600 mg/d) is effective therapy.^{38,39}

Psittacosis is also known as parrot fever, parrot disease, or ornithosis, and is caused by *Chlamydia psittaci*, an organism common to most birds and domesticated fowl. Human acquisition is from the inhalation of dust from dried bird feces, feather dust, or aerosolized avian respiratory secretions. Psittacosis is characterized by an incubation period of 5 to 14 days followed by abrupt onset of fever, chills, cephalgia, myalgia, and generalized malaise. Pneumonia is atypical, with a nonproductive cough and lobar or interstitial infiltrates on chest radiograph. Extrapulmonary manifestations involving the heart, central nervous system, liver, and kidney are common.^{40,41} Macrolides (azithromycin, clarithromycin, or erythromycin for 7-14 d) are the drugs of choice for treatment, with doxycycline (100 mg PO bid for 7-14 d) as an alternative.

Q fever (*Coxiella burnetii*) is the only rickettsial infection acquired by aerosol inhalation rather than by an arthropod vector. Q fever is common among domesticated farm animals in the United States and is shed in urine, afterbirth products, and feces. Feedlots are often contaminated with *C. burnetii*, which is highly resistant to environmental degradation. The disease is often self-limiting, with variable pulmonary manifestations and extrapulmonary findings. In addition to pulmonary infiltrates, pericarditis, myocarditis, and endocarditis, granulomatous hepatitis can occur.⁴² Treatment is with doxycycline

(100 mg PO bid for 10 to 14 d), with erythromycin (250 mg PO qid for 10 to 14 d) as an alternative.

Pasteurellosis (*Pasteurella multocida*) is endemic to the normal oral flora of cats and most dogs. Often associated with necrotizing cellulitis from bite wounds, bronchitis, bronchopneumonia, and suppurative pleural effusion can occur as a result of pulmonary infection.⁴³ Treatment is with amoxicillin-clavulanate (500 mg/125 mg PO tid for 10 to 14 d), tetracycline (doxycycline 100 mg PO bid for 10 to 14 d), penicillin (penicillin V 500 mg PO qid for 10 d), or a third-generation cephalosporin.

Rocky Mountain spotted fever (*Rickettsia rickettsii*), a rickettsial infection carried by an arthropod vector, can result in a pulmonary capillary vasculitis with associated bronchiolitis.⁹ Often a nonproductive cough is present. The chest radiographic findings vary from a normal radiograph to one that shows diffuse interstitial infiltrates and pleural effusions. A secondary bacterial pneumonia is commonly associated with this rickettsial pneumonia. Recommended treatment is with doxycycline.⁴⁴

Plague (*Yersinia pestis*) is endemic to the United States and is most often found in rock squirrels and ground rodents of the Southwest. Cats can also be carriers of plague. The principal vector is the rodent flea. Humans and household pets can become infected when bitten by an infected flea. Often an eschar is found at the site of the flea bite, followed by the development of a bubo, an enlarged, suppurative, proximal lymph node. Sepsis and pneumonia from hematologic spread then follow the bubo formation. The pneumonic form is highly contagious and rapidly fatal if not aggressively treated. Additionally, the pulmonary plague can be disseminated from one person to another through aerosolization of respiratory secretions.⁴⁵ Treatment is with gentamicin (2 mg/kg IV loading dose followed by 1.7 mg/kg IV tid for 10-14 d), streptomycin (1 g IM bid for 10-14 d), or doxycycline or ciprofloxacin.

Influenza viruses cause zoonotic pneumonia. Influenza types A, B, and C infect humans, but zoonotic infections are limited to influenza type A.⁴⁶ Migrating aquatic fowl are thought to be the natural animal reservoir for influenza type A. Horses and marine mammals can also serve as reservoirs for this zoonotic virus. Influenza can be transmitted between certain species, such as between pigs and humans.⁴⁶ Antigenic drift of the viral surface proteins hemagglutinin and neuraminidase in conjunction with a zoonotic reservoir accounts for the frequent human pandemics of influenza. Treatment and prevention of influenza and influenza pneumonia are discussed in Chap. 143.

Hantavirus, identified in 1977, is a viral zoonosis. The recognized etiologic agent in North America is the Sin Nombre virus, which belongs to the Bunyaviridae family of viruses. To date, at least 10 distinctive serotypes have been identified, each with a specific rodent vector, geographic distribution, and clinical manifestation.^{47,48} The deer mouse (*Peromyscus maniculatus*) is the primary vector in the United States.^{47,48} Infected rodents excrete hantavirus in feces, urine, and saliva. Human infection occurs with the inhalation of dried, particulate feces, contact with urine, or by a rodent bite. The majority of hantavirus serotypes have a predilection for the kidney, and the most common worldwide presentation is that of acute renal failure with concurrent thrombocytopenia, ocular abnormalities, and flulike symptoms. In the United States, the presentation of this zoonosis is that of hantavirus pulmonary syndrome,^{47,48} which consists of an initial flu-like prodromal illness of 3 to 4 days' duration, rapidly followed by pulmonary edema, hypoxia, hypotension, tachycardia, and metabolic acidosis. Dizziness, nausea, vomiting, absence of cough, and thrombocytopenia are common and may help to differentiate hantavirus pulmonary syndrome from acute respiratory distress syndrome, bacterial pneumonia, and influenza pneumonia.² Hantavirus pulmonary syndrome carries a very high mortality rate of 50 to 70 percent. Diagnosis is with an immunofluorescent or immunoblot assay. Treatment consists of supportive care with attention to adequate oxygenation and possibly the use of an inhalation solution of ribavirin.^{47,48}

GASTROINTESTINAL ZOO NOTIC INFECTIONS

Many of the parasitic, bacterial, and viral organisms responsible for gastroenteritis share a zoonotic source in addition to a human source. In the evaluation of patients with suspected gastroenteritis, information regarding travel history and animal exposure is extremely important. Occupational exposure to cattle, horses, poultry, sheep, swine, or reptiles, and even exposure to a household pet can be significant in determining a zoonotic origin. Dogs in particular are well known to have a 40 percent carriage rate for *Giardia lamblia* and a 30 percent carriage rate for the bacterial enteropathogens *Salmonella* spp. and *Yersinia* spp.⁴⁹

Zoonotic gastroenteritis often presents with fever, headache, and abdominal pain, often localizing to the right lower quadrant. Patients may have diarrhea or constipation. Laboratory findings may consist of electrolyte and acid-base abnormalities if diarrhea is severe. Leukocytosis may be seen if an interstitial invasion has occurred, and eosinophilia is often a finding with intestinal parasitic infestation. Most cases of zoonotic gastroenteritis are self-limiting and require only fluid hydration. However, specific pathogens may require specific therapy (Table 151-5).

TABLE 151-5 Gastrointestinal Zoonotic Infections

Zoonoses	Animal Reservoir	Antibiotic Therapy
Brucellosis	Dogs and farm animals	ifampin plus doxycycline, or TMP-SMX plus gentamicin
<i>Campylobacter</i> spp.	Dogs, cats, farm animals, poultry, unpasteurized milk	rythromycin, fluoroquinolones
<i>Giardia lamblia</i>	Beavers, dogs, cats, farm animals	Metronidazole, tinidazole, quinacrine
<i>Salmonella</i> spp.	Reptiles (turtles), aquatic animals, dogs, cats, and humans (<i>S. typhi</i>)	luoroquinolones or TMP-SMX
Tularemia	Rabbits, cats, wild animals	obramycin, gentamicin, or doxycycline
<i>Yersinia enterocolitica</i>	Dogs and cats	luoroquinolone, TMP-SMX, or third-generation cephalosporin
<i>Vibrio cholerae</i>	Shellfish	oxycycline, ciprofloxacin, TMP-SMX (strain 0139 resistant to TMP-SMX)

Abbreviation: TMP-SMX = trimethoprim-sulfamethoxazole.

toses.⁵⁰ Chancriform lesions (ulcerations at the site of inoculation) can result from zoonotic infection of bacterial, mycobacterial, fungal, or viral etiology.

The most significant bacterial chancriform zoonotic lesions are *Bacillus anthracis* (anthrax), *Bartonella henselae* (cat-scratch disease), *Erysipelothrix rhusiopathiae* (erysipeloid), *Francisella tularensis* (tularemia), *Listeria monocytogenes* (listeriosis), *Mycobacterium marinum*, and *Pseudomonas mallei* (glanders).^{50,51} The vast majority of these chancriform zoonotic infections occur in livestock workers, cattle ranchers, veterinarians, stable workers, horse trainers, slaughterhouse workers, poultry workers, and farmers. Significant zoonotic fungal chancriform infection is principally from *Blastomyces dermatitidis* (cutaneous blastomycosis) and *Sporothrix schenckii* (sporotrichosis). Dog and cat owners, along with veterinarians, are most at risk of contracting these two fungal zoonoses.^{50,51} All of the chancriform zoonotic infections most commonly appear at the site of inoculation, often the hands or forearms.

Zoonotic dermatoses of viral etiology include *Vaccinia* spp. (cowpox), *Paravaccinia* spp. (pseudocowpox), and bovine papular stomatitis. These cutaneous viral zoonoses often occur on the hands and forearms of patients who work closely with cattle, sheep, goats, or horses.

Systemic zoonoses can be accompanied by dermatologic findings, usually a generalized maculopapular rash, which is common in bartonellosis, lymphocytic choriomeningitis, Colorado tick fever, leptospirosis, psittacosis, and rickettsial infections. However, the maculopapular rash associated with most zoonotic infections is nonspecific and does not facilitate the diagnosis. Those zoonotic infections with specific dermatologic findings that can aid in diagnosis are infections from *Aeromonas* spp., Lyme disease, RJVISF, *Vibrio* spp., and viral hemorrhagic fevers (Table 151-6).⁵⁹

Of special note is cutaneous anthrax (Figure 135-7), also known as woolsorter's disease. Cutaneous anthrax accounts for 95 percent of all anthrax infections seen by physicians. This variant is most common in Third World nations dependent on livestock, and agriculture-based societies. With disruption of the dermal layer of the skin, anthrax spores are deposited, and within 1 to 5 days a pruritic macule becomes visible at the inoculum site. The hands and fingers are the most commonly infected areas of the body, but arms, lower legs, and feet can also be involved. The macule evolves into an ulcerative site with multiple

TABLE 151-6 Specific Zoonotic Dermatologic Findings

Zoonoses	Characteristic Rash
<i>Aeromonas</i> spp.	Crepitant cellulitis with systemic toxicity
Lyme disease	Erythema migrans at the focus of the tick bite
Rocky Mountain spotted fever	Maculopapular rash on soles and palms with centripetal spread, advance characteristic of petechial hemorrhage and necrosis
Viral hemorrhagic fever	Petechial and purpuric rash

vesicles. These vesicles are serosanguineous and contain the anthrax bacillus. Gram stain or culture of the vesicular fluid is often diagnostic. The ulcer eventually progresses to a painless black eschar and falls off within 2 weeks. Antibiotic coverage is the same as for pulmonary or systemic anthrax, but it does not alter the progression of cutaneous anthrax. But antibiotic therapy does inhibit the progression from cutaneous to systemic anthrax.

ZOONOSES ACQUIRED FROM HOUSEHOLD PETS

There are more than 30 significant human diseases acquired from household pets.⁵² Dogs and cats are the two most common household pets in North America and account for the majority of these zoonotic infections. Small rodents, pet birds, reptiles, and aquarium fish account for only a fraction of the zoonotic infections in the United States (Table 151-7).^{51,53} Although pet owners often have close contact with their pets, pet-acquired zoonoses are rare and not often recognized. Yet these infections have a very diverse etiology and encompass parasitic, bacterial, rickettsial, and fungal infections.

Up to 50 percent of dogs are infected with at least one intestinal parasite, and 15 percent of adult dogs actively excrete *Toxocara canis*, the source of *toxocariasis* and visceral larva migrans.⁴⁹ Despite its prevalence in dogs, human toxocariasis is infrequently diagnosed, probably because infection is often subclinical. Typically, the only indication of infection is eosinophilia. Children may display fever, cough, and nonspecific rash, as well as an inability to gain weight. Rarely, pulmonary infiltrates, hepatosplenomegaly, and seizures may occur. Diagnosis is by either biopsy of infected tissue or by ELISA. Treatment in the symptomatic patient consists of albendazole (400 mg bid for >5 d) or Mebendazole, (100-200 mg PO bid for >5 d). Corticosteroids can be used to control the allergic component.

Other intestinal parasites that may be transmitted to humans from household pets include *Ancylostoma caninum* (cutaneous larva migrans), *Echinococcus granulosus* (echinococcosis), and *Dipylidium*

caninum (dipylidiasis or dog and cat tapeworm).⁴⁹ Cutaneous larva migrans is often a self-limiting, pruritic, erythematous serpiginous rash caused as the larva migrates through the skin, and is often acquired from fecally contaminated soil. Topical or oral thiabendazole is effective therapy for shortening the disease course.^{50,51}

Though dogs and other carnivores are the definitive hosts for *E. granulosus*, *echinococcosis* is most common in areas of cattle and sheep ranching. This zoonosis involves multiple organ systems: liver, lung, muscle, bone, kidney, and brain. Typically, there is a unilocular cyst containing multiple larvae that enlarge over time. Diagnosis and treatment usually occur at the time of surgical resection. Aspiration of the cyst is contraindicated, because leakage of the cystic fluid can spread the infection and cause an anaphylactic reaction.

Dipylidiasis, caused by a tapeworm common to both dogs and cats, is found worldwide. Human infection is rare; however, when infection does occur, it is often in children and presents with the nonspecific symptoms of diarrhea and pruritus ani. Occasionally, the cucumber-shaped proglottides are seen moving in the child's stool. Treatment is with praziquantel (5-10 mg/kg PO single dose), or niclosamide (2 mg PO single dose).

Cats are the host of the intracellular protozoan *Toxoplasma gondii*, which causes *toxoplasmosis*. Human toxoplasmosis can occur in three ways: by ingestion of uncooked or raw meat, especially pork or mutton containing the *Toxoplasma* cysts; by ingestion of the oocysts from cat and wild-animal feces; and transplacentally.^{49,52} Transplacental transmission can result in congenital abnormalities of retinochoroiditis, hydrocephalus, hepatosplenomegaly, and thrombocytopenia in 10 percent of the children infected. The majority of children transplacentally infected with toxoplasmosis display no significant abnormalities. Nevertheless, pregnant women should limit their contact to only indoor cats and avoid contact with cat feces. The encysted trophozoite can become reactivated in a previously infected host if the host becomes immunocompromised.⁵⁴

Bacterial zoonoses from household pets include, but are not limited to, brucellosis, leptospirosis, salmonellosis, and campylobacteriosis. *Brucellosis* (*Brucella canis*) is an uncommon infection in humans and is most often acquired from dogs. Pigs, cattle, and goats are less frequent transmitters. The typical human course for brucellosis is self-limited, with fever, headache, myalgias, and nonspecific laboratory findings. Doxycycline plus rifampin or gentamycin is the standard therapy in treating human brucellosis, or alternatively, TMP/SMX plus gentamycin.

Leptospirosis (*Leptospira canicola*) infects almost all mammals, but dogs are the principal vector for humans. Humans become infected through exposure to body fluids, particularly urine, of an infected animal. The acute phase of leptospirosis is characterized by headache,

TABLE 151-7 Pet-Associated Zoonotic Infections

Dog	Cat	Bird	Rodent	Fish and Reptiles
Anthrax	Anthrax	Cryptococcosis	Leptospirosis	Erysipeloid
Brucellosis	Campylobacteriosis	Erysipeloid	Listeriosis	<i>Mycobacterium marinum</i>

SECTION 13 • INFECTIOUS DISEASES

malaise, myalgias, and fever. Nonspecific rash, meningitis, uveitis, myositis, and leptospiruria follow the acute phase. Doxycycline (100 mg PO bid for 10 to 14 d) or high-dose penicillin (penicillin G 20 to 24 million units IV qd for 10 to 14 d) are the mainstays of treatment for leptospirosis.^{35,51}

Campylobacteriosis (*Campylobacter jejuni*) is a major cause of infectious diarrhea in humans. This zoonotic infection also occurs in dogs, cats, pigs, poultry, cattle, and horses. Human infection from a pet is uncommon, but the presence of a puppy or kitten with a diarrheal illness in the house and human contacts experiencing diarrhea should raise the suspicion of pet-acquired campylobacteriosis. Though the disease is often self-limiting, treatment with erythromycin can facilitate resolution in protracted cases.⁴⁹

Nontyphoidal salmonellosis is typically a self-limiting gastrointestinal illness prevalent among dogs. Human transmission is rare. Diarrhea in any pet should alert the pet owner to use increased personal hygiene and to dispose of the pet's feces properly.^{35,52}

The ticks and fleas inhabiting dogs and cats can transmit the zoonotic infections of tularemia, plague, and Rocky Mountain spotted fever. Transmission is often by cat bite, tick bite, or scratch. Dogs do not directly transmit tularemia, but do serve as carriers of the ticks that can transmit this zoonosis.

Plague (*Yersinia pestis*) is endemic in the rodent population of the southwestern United States. Dogs and cats can also be sources of this zoonosis. Transmission occurs when bitten by fleas inhabiting an infected rodent, dog, or cat or by eating infected rodents. Plague has three forms: bubonic or suppurative lymphadenopathy (the most common), the pneumonic form, and the septicemic form. Because of the aggressive nature of *Y. pestis*, treatment should not be delayed.

Rocky Mountain spotted fever (*Rickettsia rickettsii*) is a tick-transmitted, systemic zoonosis, with the tick *Dermacentor* as principal vector and reservoir. Animal reservoirs consist of rodents, rabbits, and infrequently, dogs. Zoonotic fungal infections are occasionally ac-

quired by humans. The most common of these infections is a dermatophytosis from *Microsporum canis*. It is estimated that up to 30 percent of human dermatophytoses have a zoonotic origin.⁵⁰ Treatment is with topical ketconazole or other imidazole antifungals.

ZOONOTIC INFECTIONS AND IMMUNOCOMPROMISED PATIENTS

Immunocompromised patients deserve special consideration and encompass a very large group: patients with congenital immunodeficiencies, diabetes mellitus, chronic renal failure, or liver failure; splenectomized patients; chronic alcoholics; cancer patients; and HIV-positive patients. Of all of these patients, those undergoing chemotherapy and those with AIDS have the greatest risk of acquiring a zoonotic infection.⁵⁵ It is estimated that 30 to 40 percent of immunocompromised patients may own pets.⁵⁴ *Salmonella* and *Campylobacter* are the two most common infections acquired by immunocompromised patients from their pets,⁵⁵ but the overall risk of transmission of *Salmonella* and *Campylobacter* from contact with pets is low. Additionally, *Mycobacterium marinum* from aquatic pets, and *Bartonella* from cats, are also commonly acquired by immunocompromised patients. Other acquired zoonotic infections that immunocompromised patients are susceptible to include *Toxoplasma gondii*, *Cryptosporidium*, *Giardia*, *Rhodococcus equi*, and *Bordetella bronchiseptica* (Table 151-8). With the exception of *Bartonella* (cat-scratch disease), most of these zoonotic infections are acquired by immunocompromised patients from sources other than exposure to animals.⁵⁴ These sources are principally from contaminated food or water. Nevertheless, it is important for emergency physicians to inquire about animal exposure and zoonotic risk factors when evaluating immunocompromised patients. Consultation with an infectious disease specialist and a veterinarian may be warranted in evaluating immunocompromised patients in the ED.

TABLE 151-8 Zoonotic Infections Among Immunocompromised Patients

Infection		Clinical Findings	Antibiotic Treatment
Cat-scratch disease <i>Bartonella henselae</i>	Cats	Pyogenic granulomas, regional lymphadenopathy, and fever	Erythromycin or doxycycline
<i>Bordetella bronchiseptica</i>	Dogs	Fever, pharyngitis, and cough	Erythromycin or TMP/SMX
<i>Campylobacter</i> <i>Campylobacter</i> spp.	Dogs, cats	Gastroenteritis and diarrhea	Erythromycin, ciprofloxacin, or azithromycin
<i>Cryptococcus</i> <i>Cryptococcus neoformans</i>	Bird droppings and cats	Flulike symptoms early, photophobia, headache, cranial nerve symptoms, and meningeal irritation later	Amphotericin B, fluconazole
<i>Cryptosporidium</i>	Dogs	Diarrhea	Nitazoxanide ⁵⁶
<i>Giardia lamblia</i>	Dogs, cats	Gastroenteritis and diarrhea	Metronidazole, tinidazole, albendazole, quinacrine
<i>Listeria monocytogenes</i>	Livestock, and dairy products	Sepsis and meningitis	Ampicillin, high-dose penicillin, or TMP/SMX
<i>Mycobacterium</i> <i>M. avium</i> <i>M. marinum</i>	Pet birds Fish	Pneumonia and gastroenteritis Cutaneous granulomas, skin ulcerations at distal extremities	Clarithromycin plus ethambutol Clarithromycin, doxycycline, TMP/SMX, or rifampin and ethambutol
<i>Rhodococcus</i> <i>Rhodococcus equi</i>	Farm animals	Pneumonia and cavitating lung lesions	Vancomycin, erythromycin, or imipenem plus rifampin
<i>Salmonella</i> <i>Salmonella</i> spp.	Dogs, cats, reptiles, and farm animals	Gastroenteritis, diarrhea, and sepsis	Ciprofloxacin, ceftriaxone, azithromycin, or TMP/SMX
Toxoplasmosis <i>Toxoplasma gondii</i>	Cats	Pneumonia, brain abscesses, encephalitis, and ocular disease	Pyrimethamine, plus sulfadiazine and folinic acid

Abbreviation: TMP/SMX = trimethoprim-sulfamethoxazole.

SOFT TISSUE INFECTIONS

Steven G. Folstad

NECROTIZING SOFT TISSUE INFECTIONS

Although these individual infectious entities are often discussed separately, necrotizing soft tissue infections actually represent a spectrum of illness differentiated primarily by the depth of soft tissue involvement. The similar feature in all of these infections is, as the name implies, some extent of tissue necrosis. The spectrum of these illnesses extends from localized infection involving only the subcutaneous tissue, as is the case in necrotizing cellulitis, through extensive soft tissue fascial plane involvement and sepsis, as in necrotizing fasciitis, to the deep myonecrosis and sepsis seen with gas gangrene. These necrotizing

infections are most commonly polymicrobial in nature, and involve mixed aerobic and anaerobic organisms. There are a few specific bacteria, such as the *Clostridium* species and group A *Streptococcus* that can produce a single organism infection. With each of these infections soft tissue gas production may or may not be present.

Due to the rapid progression of illness and the high mortality rate associated with the more invasive of these infections, early recognition and aggressive treatment are essential. A keen eye for the early subtle signs and symptoms that differentiate these from the much less severe forms of cellulitis is required to lessen the high morbidity and mortality seen with these infections.

Gas Gangrene (Clostridial Myonecrosis)

Clostridial myonecrosis is a rapidly progressive and serious life- and limb-threatening deep subcutaneous tissue infection caused by several of the spore-forming clostridial species of organism. It is the deepest of the necrotizing soft tissue infections. Severe myonecrosis with gas production and sepsis are the hallmarks of this disease.

EPIDEMIOLOGY *Clostridium* species are ubiquitous organisms found throughout our environment. There are approximately 1000 cases of gas gangrene reported to the Centers for Disease Control and Prevention (CDC) each year in the United States.¹ The incidence of disease secondary to these organisms is decreasing, presumably due to better wound management and more effective antibiotic therapy. For example, the incidence of gas gangrene in battle-related injuries was 5 percent during World War I; this dropped to 0.2 percent during the Korean War, and to 0.01 percent during the war in Vietnam.

PATHOPHYSIOLOGY There have been seven *Clostridium* species identified as causing gas gangrene. *Clostridium perfringens* is attributed to 80 to 95 percent of cases, with *C. septicum* being the second most common etiology.² The clostridial organisms are large, gram-positive, spore-forming anaerobic bacilli normally found in the soil, gastrointestinal tract, and female genitourinary tract. They produce over ten exotoxins that are responsible for the cellular destruction as well as the rapid progression and systemic toxicity of the disease. The exotoxin that is considered to be the most significant is the α -toxin. This toxin has direct cardiodepressant activity. It also hydrolyzes cell membranes, causes tissue necrosis, inactivates leukocytes, and hemolyzes erythrocytes. Secondary toxic effects may be caused by the release of myoglobin, creatine phosphokinase (CPK), and potassium from tissue breakdown.

There are two potential mechanisms for infection with clostridial organisms. The most common is through direct inoculation from an open wound. Similarly to tetanus, clostridial species thrive best in contaminated wounds with crushed or ischemic edges that tend to offer a favorable anaerobic environment. Uterine myonecrosis due to clostridial infection has also been documented following cesarean section delivery. This is most likely due to the significant incidence of clostridial colonization in the female genitourinary tract. The second mechanism for infection is by hematogenous spread, particularly in the immunocompromised. Almost a third of cases of "spontaneous gas gangrene" are caused by *C. septicum*, with an even higher incidence in cases related to malignancies.

CLINICAL FEATURES The incubation period is usually less than 3 days. The most common presenting complaints in early gas gangrene are pain out of proportion to physical findings, as well as a sensation of "heaviness" of the affected part. On examination, the area may demonstrate a brawny edema with crepitance. Crepitance is a later finding, however, and its absence does not rule out the diagnosis. The skin will develop a bronze or brownish discoloration with a malodorous serosanguineous discharge, and bullae may be present. Systemic manifestations include a low-grade fever with tachycardia out of pro-

portion to the fever. The patient may be confused or irritable and have a rapid deterioration of the sensorium. Laboratory evaluation may reveal any or all of the following: metabolic acidosis, leukocytosis, anemia, thrombocytopenia, coagulopathy, myoglobinemia and myoglobinuria, and liver or kidney dysfunction. Gram stain of the bullae often shows pleomorphic gram-positive bacilli with or without spores, red blood cells, but very few white blood cells. Radiologic studies may demonstrate gas within the involved muscle and surrounding soft tissue, and when the infection involves the trunk, possibly gas within the peritoneal or retroperitoneal space.

Surgical exploration is also helpful in the diagnosis. In the early stages, the muscles are edematous and pale but still bleed when cut; in later stages, the muscles lose contractility and on dissection appear beefy red without bleeding and gas bubbles may be evident between the tissues.

The differential diagnosis of clostridial myonecrosis must encompass other gas-forming infections, including necrotizing fasciitis, streptococcal myositis, and clostridial or nonclostridial anaerobic cellulitis. The crepitance of infection should be differentiated from other causes of subcutaneous emphysema such as pneumothorax, pneumomediastinum, and fractured larynx or trachea. The edema and pallor, with loss of distal pulses, seen in an affected extremity should be differentiated from vascular thrombosis conditions such as phlegmasia cerulea dolens.

TREATMENT Treatment consists of four main phases:

1. *Resuscitation* should begin in the ED immediately upon making a presumptive diagnosis. Aggressive fluid resuscitation using crystalloid, plasma, and packed cells is usually needed to replace red blood cells lost due to hemolysis and to correct hypotension due to shock. Volume status should be closely monitored using urine output and central venous pressure readings. Avoid the use of vasoconstrictors when possible due to the possibility of decreasing perfusion to already ischemic muscle.
2. *Antibiotic therapy* using penicillin G, 24 million units IV per d in divided doses plus clindamycin, 900 mg q8h IV, is recommended. Ceftriaxone or erythromycin are alternative choices. Sodium penicillin is recommended over potassium penicillin to reduce the risk of worsening hyperkalemia in patients with hemolysis and tissue necrosis. Mixed infections with other anaerobes, gram-negative rods, and staphylococci are common. Therefore, multiple-antibiotic therapy using aminoglycosides, penicillinase-resistant penicillins, or vancomycin is recommended. Tetanus prophylaxis should be given as indicated.
3. *Surgical debridement* is a mainstay of therapy and may include fasciotomy, debridement, or amputation. Early removal of the infected tissue by surgical debridement is most important. The borders for debridement are guided by the appearance of the muscle.
4. *Hyperbaric oxygen (HBO) therapy* should be initiated as soon as possible after surgical debridement. Although there are no prospective human studies, retrospective data suggest a twofold reduction in mortality in patients receiving concomitant HBO therapy.³ Typical HBO therapy consists of 100 percent oxygen at 3 atm of pressure for 90 min immediately following surgery, with three dives in the first 24 h followed by two dives a day for 4 or 5 days.

Wound care at the time of initial evaluation and treatment is the most important factor in preventing clostridial infections. Debridement of crushed or dead tissue and copious irrigation prior to wound closure will help prevent the development of an environment favorable to clostridial growth. Amoxicillin/clavulanate, imipenem, meropenem, or ampicillin/sulbactam may be beneficial.

Gas Gangrene (Nonclostridial Myonecrosis)

Most cases of nonclostridial myonecrosis are caused by mixed infections involving both aerobic and anaerobic organisms. The clinical

presentation, evaluation, and treatment of nonclostridial myonecrosis is very similar to that caused by the clostridial species, and only the differences seen with the nonclostridial infections will be discussed here.

A recent Japanese study examined the treatment outcome of a small group of patients with nonclostridial myonecrosis.⁴ Each patient had a mixed infection with an average of 5.1 different species of organisms being isolated. The range of organisms per patient was 2 to 10. Both aerobic and anaerobic organisms were found in all cases. The most common bacteria were: *Enterococcus* (100 percent); *Staphylococcus* (71 percent); *ct-Streptococci* (57 percent); *E. coli*, *Klebsiella*, and *Proteus* (each at 43 percent); and *Bacteroides* (43 percent). Other less common bacteria included *Peptostreptococcus*, *Bacillus*, *Citrobacter*, *Enterobacter*, and *Morganella* (each at 14 percent). *Clostridium* was also isolated in 29 percent of these mixed infections.

The pain associated with the onset of infection was not as pronounced as with typical clostridial infection, and the authors felt that this led to a delay in presentation (2 to 10 days after symptom onset), and contributed to their significant mortality rate of 43 percent.

Broad-spectrum antibiotic coverage is of the utmost importance due to the mixed nature of the organisms involved with these infections. Coverage for aerobic gram-positive and gram-negative organisms as well as anaerobes is necessary. The most commonly recommended drugs are: ampicillin/sulbactam, ticarcillin/clavulanate, piperacillin/tazobactam, imipenem, or meropenem. Vancomycin, a fluoroquinolone, and clindamycin can be used in penicillin-allergic patients. Fluoroquinolones should be added for freshwater infections. Early surgical debridement and HBO therapy are recommended as for clostridial infections.

Streptococcal Myositis

This is an extremely rare muscle infection caused by an invasive form of group A *Streptococcus*. Clinically, it is difficult to distinguish from other forms of myonecrosis, except there is typically no gas production. It is a very virulent infection that has a high rate of bacteremia, and subsequent toxic shock syndrome (see Chap. 142). The case mortality rate is reported to be in the 80 to 100 percent range. There will be further discussion of group A streptococcal infections later in this chapter.

Necrotizing Fasciitis (Polymicrobial Infection)

Necrotizing fasciitis is characterized by widespread necrosis involving the subcutaneous tissue and fascia. The infection does not spread through the fascial layer into the underlying muscle, as it does with the clostridial and nonclostridial myonecrosis infections. It is an infectious process that has been recognized for centuries, but was brought to the world's attention in the mid-1990s when the tabloid press began reporting about an outbreak of "flesh-eating bacteria."

As with gas gangrene, there is a mixed-organism form of this infection, which is the most common, and a single-organism form, which is typically caused by group A *Streptococcus*. The presentation, evaluation, and treatment of these two forms of infection are very similar, and a discussion of the differences of the group A *Streptococcus* infection will follow in a separate section.

EPIDEMIOLOGY There are 10 to 20 cases of invasive group A streptococcal infection per 100,000 population, and about 27 cases per 10,000 hospital admissions.⁵

Those with underlying illnesses such as diabetes and peripheral vascular disease are at higher risk. Smoking and intravenous drug use are also significant predisposing factors.

A majority of cases involve the lower extremities, with the upper extremities, perineum, trunk, head and neck, and buttocks following in decreasing order of incidence.

PATHOPHYSIOLOGY The majority of cases of necrotizing fasciitis are mixed aerobic and anaerobic. Common pathogens include: the gram-positive α , (3, and γ streptococci, *Staphylococcus aureus*, the gram-negative *E. coli*, *Pseudomonas* spp., *Enterobacter*, *Klebsiella*, and *Proteus*, and the anaerobic bacteria *Bacteroides*, *Clostridium*, and *Peptostreptococcus*. Most patients are infected with several strains of bacteria. One study of 182 patients with positive cultures showed a mean of 4.4 organisms per patient, and up to 6 organisms per wound culture.⁶

The exact pathogenesis of this infection is not clear, but there seems to be a symbiotic relationship between the different bacteria that acts to promote the overall infection. The facultative gram-negative organisms lower the oxygen-reduction potential of the tissue, which promotes an environment for anaerobic organism growth. The anaerobic organisms impede phagocyte function in the host immune response, which favors aerobic bacterial growth.

The mechanism for the wide spread of fascial plane necrosis appears to be secondary to a vasculitis and thrombosis of regional blood vessels. Bacterial tissue toxins cause inflammation in the walls of larger regional blood vessels, which eventually leads to thrombosis in the vessel lumen, as well as ischemia of the skin, subcutaneous fat, and fascia that the vessel supplies. This ischemic tissue environment promotes the spread of bacterial growth, propagating the process occurring in regional blood vessels, resulting in rapid spread of the infection.

The most common mechanisms for infection are soft tissue trauma and surgery, with insults such as intravenous injection, surgical incision, abscess, insect bite, and ulcer. Diabetes and underlying malignancy are predetermining risk factors for spontaneous infection.

The overall mortality rate is usually reported in the 25 to 50 percent range. Bacteremia is reported in 25 to 30 percent of cases, and is a strong predictor of mortality. Other patient factors that have been shown to affect mortality are age less than 1 year or greater than 60; intravenous drug use; comorbid conditions, especially cancer, chronic renal disease, and congestive heart failure; certain characteristics of the clinical course such as positive blood culture, trunk or perineal involvement, infection related to peripheral vascular disease, and delayed time to diagnosis or treatment.

CLINICAL FEATURES The primary presenting complaint in patients with necrotizing fasciitis is pain well out of proportion to the physical findings. The skin appears erythematous and possibly edematous. Discoloration, vesicles, and crepitus are typically later findings. A low-grade fever and tachycardia are common. Early on, the sensorium is typically clear. Necrotizing fasciitis infections can progress with alarming rapidity, within hours.

DIAGNOSIS CBC with differential, and chemistry including liver enzymes, coagulation studies, arterial blood gas, and possibly serum lactate should be obtained. Aerobic and anaerobic culture specimens should be obtained of the blood, and if possible of the infected area. Bedside soft tissue biopsies sent for rapid frozen section can be helpful in making an early diagnosis.⁷ The tissue biopsy specimen needs to extend down to the level of the deep fascial plane.

The "finger test" is another bedside diagnostic aid that may help in making an early diagnosis. This test is performed in the following manner: After local anesthesia, a 2-cm incision is made in the suspected area of tissue down to the deep fascial plane. A lack of bleeding or the presence of a foul, cloudy fluid is a very suggestive sign. A finger is then placed in the incision, just superior to the deep fascia, and pushed forward. If the finger dissects the soft tissue away from the fascia without difficulty, the test is considered positive, and indicative of necrotizing fasciitis. In healthy tissue the subcutaneous fat adheres strongly to the deep fascia.

Very early surgical consultation is indicated in all suspected cases of necrotizing fasciitis.

TREATMENT The treatment of necrotizing fasciitis is similar to that of gas gangrene, and should be considered to consist of four phases: (1) *aggressive fluid and blood resuscitation, and avoidance of vasopressors*; (2) *antibiotic therapy* similar to that for nonclostridial myonecrosis should be empirically given—imipenem or meropenem, or vancomycin, clindamycin and a fluoroquinolone in penicillin-allergic patients; (3) *surgical debridement* is again the mainstay of therapy; (4) *hyperbaric oxygen (HBO)* therapy can be instituted following surgical debridement.

Necrotizing Fasciitis (Group A *Streptococcus*)

As with gas gangrene, the basic presentation, evaluation, and treatment for group A streptococcal (GAS) necrotizing fasciitis is very similar to that of the polymicrobial type, and only the differences will be discussed here.

The overall incidence is reportedly 10 to 20 cases per 100,000 population.⁸ Most series report an overall mortality rate of 20 to 60 percent for invasive GAS infections, supposedly due to more virulent strains of bacteria.

Concomitant *Varicella* infection, especially in children, and NSAID use increase the risk for invasive GAS infection. *Varicella* lesions are presumed to be a portal of entry for the GAS bacteria into the host. It is unclear if the use of NSAIDs predisposes certain patients to invasive GAS infection, or if it acts to mask the early symptoms of disease.

Clinically, patients with GAS necrotizing fasciitis present very similarly to those with the polymicrobial form of infection; however, there is usually no gas formation in the soft tissue. Patients tend to have a more rapid progression of illness and are more prone to bacteremia and subsequent development of toxic shock syndrome (TSS) (see Chap. 142). Necrotizing fasciitis secondary to GAS is a subsegment of the overall spectrum of invasive GAS infections. The most severe end of this spectrum is TSS, and it is estimated that 50 percent of patients with GAS TSS had necrotizing fasciitis as the initiating infection.

Treatment should initially begin with a broad-spectrum antibiotic regimen as discussed above, but it can be changed to a combination of penicillin and clindamycin when cultures identify an isolated GAS infection. Penicillin alone often fails in severe GAS infections. Clindamycin has a synergistic effect with penicillin and improves treatment success greatly. Some of the mechanisms of clindamycin efficacy include: suppression of bacterial toxin synthesis, promotion of phagocytosis of the bacterium by inhibiting M protein synthesis, suppression of synthesis of penicillin-binding proteins, and a prolonged postantibiotic effect in comparison to penicillin.

HBO therapy is of minimal benefit with infections involving aerobic organisms.

Necrotizing Cellulitis

Necrotizing cellulitis is the most superficial form of necrotizing soft tissue infection, with the involved tissue being limited to the skin and subcutaneous fat. This is often determined at the time of surgery, or from a superficial tissue biopsy sent for rapid frozen section. Other synonyms for the disorder are crepitant cellulitis and synergistic necrotizing cellulitis.

PATHOPHYSIOLOGY This infection is also typically associated with a preceding soft tissue trauma or surgery, but can occur spontaneously, usually in patients with an underlying malignancy or diabetes. The invading bacteria cause direct local tissue necrosis and vasculitis, which lead to edema and eventual thrombosis. This is similar to that seen with necrotizing fasciitis, but involves only the more superficial vessels.

Clostridial species are common pathogens, with *Clostridium perfringens* being the most commonly found in the setting of trauma or surgery, and *Clostridium septicum* more commonly found in the setting of malignancy and spontaneous infection. Clostridial infection is

typically associated with significant gas production in the subcutaneous tissue.

Nonclostridial necrotizing cellulitis is caused by a variety of other anaerobic bacteria, similar species as those previously discussed for the deeper soft tissue infections. Infection may be caused by a single organism, but is most commonly polymicrobial. There is usually less gas production than that seen with clostridial infection, and there may be no gas at all.

CLINICAL FEATURES Pain and erythema at the site of infection are the most common presenting complaints. The pain is often severe, but not typically to the degree of that seen with the deeper necrotizing infections. There may be an ecchymotic or frankly necrotic center to the infected area. Vesicles or blebs may also be present. The presence of crepitance is strongly suggestive of a necrotizing infection. Systemic symptoms are typically mild or absent due to the more localized nature of the infection.

TREATMENT Surgical debridement of the local skin and subcutaneous fat is required, but extensive soft tissue removal is not needed. Surgical debridement is typically curative; however, administration of broad-spectrum antibiotics, similar to those used in the deeper infections should be started early, and continued until significant improvement is seen in the patient's clinical condition.

CELLULITIS

Cellulitis is a local soft tissue inflammatory reaction secondary to bacterial invasion of the skin. The classic symptoms of cellulitis have been attributed previously to bacterial invasion and subsequent proliferation within the local tissues; however, there is some evidence that suggests that the majority of symptoms may instead be secondary to a complex set of immune and inflammatory reactions triggered by cells within the skin itself.⁹

Epidemiology

Cellulitis is presumed to selectively affect the elderly, the immunocompromised, and those with peripheral vascular disease. Epidemiologic data on prevalence and incidence of disease has typically been difficult to obtain and interpret. One study of over 300,000 patient visits over a 1-year period¹⁰ identified almost 4000 cases of cellulitis, or 1.3 percent of all patient visits. Patient characteristics demonstrated a slight male predominance (61 percent); a mean age of 46 years; a vast majority of infections involving either the lower or upper extremities (48 and 41 percent respectively); and interestingly, in this study predisposing medical conditions such as diabetes, peripheral vascular disease, cancer, and alcohol abuse were each seen in less than 5 percent of patients.

Pathophysiology

Cellulitis is a local inflammation of the skin characterized by pain, induration, warmth, and erythema. It is caused by invasion of the tissues by bacteria, most commonly staphylococci or streptococci in adults and *Haemophilus influenzae* in children. In diabetic patients, additional consideration needs to be given to Enterobacteriaceae and rarely clostridia. Lymphangitis and lymphadenopathy are seen occasionally in previously healthy patients, but purely local inflammation is much more common. Systemic involvement with fever, leukocytosis, and bacteremia is seen most typically in patients with underlying immunosuppressive disorders.

Efforts at isolating causative organisms from infected tissue have had a very poor yield. Needle aspiration of the leading edge of an area of cellulitis produces organisms in less than 10 percent of cultures, and even punch biopsy from the same area yields organisms in only about 20 percent of cultures. Only areas with suppuration or abscess forma-

tion have significantly higher yields. Although bacterial invasion is what triggers the inflammation, the organisms are largely cleared from the site within the first 12 h, and the infiltration of lymphoid and reticular cells and their products is what produces the majority of symptoms. Cells such as Langerhans cells and keratinocytes release the cytokines interleukin-1 and tumor necrosis factor that enhance infiltration of the skin by circulating lymphocytes and macrophages. The net effect of this is much more rapid clearing of bacteria, but at the price of a significantly greater inflammatory response.

Clinical Features

Patients with cellulitis typically present with localized tenderness, warmth, induration, and erythema. Specific note should be made on physical examination of evidence of lymphangitis or lymphadenitis; although uncommon, these may suggest more serious infection. The presence of high fever and chills suggests bacteremia, especially in patients with underlying medical disorders. Recurrent attacks can lead to impairment of lymphatic drainage, permanent swelling, dermal fibrosis, and epidermal thickening. These chronic changes are known as *elephantiasis nostra* and predispose patients to further attacks of cellulitis. In otherwise healthy patients, the clinical presentation is sufficient for diagnosing cellulitis. In patients with underlying disease or signs of bacteremia, blood cultures and leukocyte counts are indicated. Local means of isolating the organism are controversial, but in the case of a toxic-appearing patient, they may be worthwhile. Differentiating deep venous thrombosis from cellulitis in the lower extremities is often difficult and may require Doppler studies or venogram.

Treatment

Simple cellulitis in otherwise healthy adult patients can be treated on an outpatient basis with dicloxacillin (500 mg PO q6h), a macrolide (erythromycin ethylsuccinate 500 mg PO q6h, azithromycin 500 mg PO initial dose, then 250 mg PO qd X 4 d, clarithromycin 500 mg PO q12h), or amoxicillin-clavulanate (875/125 mg PO q12h), with all treatments lasting for 10 days except for azithromycin. The exception to this is cellulitis involving the head or neck, for which most patients should be admitted for intravenous antibiotics. Appropriate intravenous antibiotics include parenteral first-generation cephalosporins (cefazolin 1 g IV q6h) and penicillinase-resistant penicillins (nafcillin or oxacillin 2 g IV q4h). In diabetics, a parenteral second- or third-generation cephalosporin (ceftriaxone 1 to 2 g IV qd) should be used, or imipenem (500 mg IV q6h), meropenem (0.5 to 1 g IV q8h), or trovafloxacin (200 to 300 mg IV qd) in severe cases.¹¹ A once-daily treatment with cefazolin (2 g IV) plus probenacid (1 g PO) has recently been shown to be as efficacious as a once-daily dose of ceftriaxone (1 g IV), and much more cost effective.¹² This may be a viable option for patients who have access to home health services or an outpatient treatment center.

Disposition

Patients with evidence of bacteremia and those with underlying diseases such as diabetes mellitus, alcoholism, or other immunosuppressive disorders should be admitted for intravenous antibiotics. Empirical therapy may be started with the antibiotics listed earlier and changed as indicated by culture results.

Follow-up intervals depend on initial presentation, but generally within 2 or 3 days is sufficient to evaluate the success of treatment.

ERYSIPELAS

Epidemiology

Previously, erysipelas involved the face more frequently, but now it is primarily an infection of the lower extremities.

Pathophysiology

Erysipelas is a superficial cellulitis with lymphatic involvement that is caused primarily by group A *Streptococcus*. Atypical infections most commonly seen with other groups of streptococci are also noted. Infection is typically achieved through a portal of entry into the skin, with traumatic wounds, ulcers, and infected dermatoses of the lower extremities being the most common sites. Lymphedema and injury at the site of entry were the most common risk factors in one recent study (odds ratio 71.2 and 23.8 respectively).¹³ Toe-web intertrigo had the highest population attributable risk, and proper diagnosis and treatment of toe-web intertrigo could prevent up to 60 percent of cases of lower extremity erysipelas. Leg edema, venous insufficiency, and obesity were also risk factors for infection (odds ratio 2.5, 2.9, and 2). Most often erysipelas occurs proximal to the portal of entry into the skin.

Clinical Features

The onset of symptoms is usually abrupt, with a sudden onset of high fever, chills, malaise, and nausea representing the prodromal phase. Over the next 1 to 2 days a small area of erythema with a burning sensation develops. As the infection continues, a red, shiny, hot plaque forms. The plaque has a tense, painful induration that is sharply demarcated from the surrounding normal tissue. Lymphatic inflammatory changes, known as *toxic striations*, and local lymphadenopathy are common. Purpura, bullae, and small areas of necrosis also are seen. The presence of bullae suggests a more serious form of infection, often requiring longer treatment courses and hospital admissions.¹⁴ Systemic symptoms continue until antibiotic therapy is initiated. On resolution of the infection, desquamation of the site typically occurs.

The diagnosis is based primarily on physical findings. Leukocytosis with an increase in the neutrophil count is common. Performing a needle aspiration of the infection site is rarely successful at isolating an organism, but swabbing the portal of entry, when identifiable, may have a higher success rate. Blood cultures are positive in only around 5 percent of patients, and so are not helpful. Serologic testing to determine ASO and anti-DNase B titers may be more specific but is of little use in the ED.

The differential diagnosis includes other forms of local cellulitis. Some believe that necrotizing fasciitis is a complication of erysipelas infections and should be considered in all cases.

Treatment

Penicillin G (1 to 2 million units IV q6h) may be used in nondiabetic patients for initial treatment due to the high incidence of streptococcal infection. Penicillinase-resistant penicillins (nafcillin or oxacillin 2 g IV q4h), parenteral second- or third-generation cephalosporins (ceftriaxone 1 to 2 g IV qd), or amoxicillin-clavulanate (875/125 mg PO q12h) should be used in diabetic patients and those with facial disease. Imipenem (500 mg IV q6h) is recommended in severe cases. Erythromycin, cephalosporins, or a macrolide should be used in patients with penicillin allergy. Essentially all patients with erysipelas should be admitted to the hospital for intravenous antibiotics.

CUTANEOUS ABSCESES

The development of cutaneous abscesses most often is caused by a breakdown in the skin's normal protective barrier, followed by contamination with local resident bacterial flora. In most cases, involving otherwise immunocompetent patients, appropriate surgical incision and drainage are the only treatment required.

Epidemiology

Cutaneous abscesses are a common ED presentation, representing 1 to 2 percent of presenting complaints. There has been little recent

SECTION 13 • INFECTIOUS DISEASES

investigation into the bacteriology or recommended treatment of simple cutaneous abscesses. This is probably secondary to the excellent outcome with simple incision and drainage procedures regardless of the location or etiology.

Pathophysiology

Intact, healthy skin usually acts as an excellent barrier to bacterial invasion. Cutaneous factors such as constant desquamation of the epidermis, continually shedding bacteria, and the lower pH of 3 to 5 of the skin also contribute to the skin's protective function. Host cellular and humoral defenses further protect invading bacteria from developing subsequent infection. When favorable host factors are lacking, or in cases of overwhelming bacterial contamination, a break in the skin's integrity either superficially (abrasion, laceration, or thermal injury) or from deep inoculation (laceration, puncture, or bite) may lead to colonization and subsequent infection. Infection typically starts as a local superficial cellulitis. Many organisms that colonize normal skin can cause necrosis and liquefaction with subsequent accumulation of leukocytes and cellular debris. Loculation and subsequent walling off of these products of infection lead to abscess formation. As the infection progresses and the area of liquefaction increases, the abscess wall thins and ruptures spontaneously, draining either cutaneously or into an adjoining tissue compartment.

The bacterial etiology of soft tissue abscesses often can be predicted by knowledge of the normal flora colonizing specific areas of the body. Environmental factors such as temperature, humidity, and the general hygiene of a patient play a role in the likelihood of infection, but only by increasing the number of bacteria colonizing the skin. In abscesses involving the scalp, trunk, and extremities, staphylococcal species are the most common infecting organism. *Staphylococcus aureus*, the least common of the staphylococcal species isolated on normal skin, is the most common species causing infection. *S. epidermidis* and *S. hominis* are also seen frequently. Streptococci commonly colonize the oral and nasal mucosa and can be seen in abscesses involving the adjoining soft tissues. The intertriginous and perineal areas often are colonized by the gram-negative aerobes *Escherichia coli*, *Proteus mirabilis*, and *Klebsiella* species. Abscesses involving the axillae are most often infected with *P. mirabilis* for reasons that are not clear. Abscesses in the perirectal and genital areas are most commonly mixed anaerobic and aerobic in nature, with *Bacteroides* species being the most common anaerobe.

In abscesses secondary to foreign bodies, *S. aureus* is the most commonly isolated species. Bite injuries, especially by cats, are at risk for infection with *Pasteurella multocida*, but also can involve *S. aureus*, as well as *Streptococcus viridans* and *Eikenella corrodens*. Human bites are less likely to involve *P. multocida*, but have a high incidence of involvement with the anaerobe *Bacteroides fragilis* and the gram-positive *Corynebacterium jeikeium*, as well as the usual staphylococcal and streptococcal organisms. In infections associated with intravenous drug abuse, mixed infections prevail, with anaerobic bacteria predominating. The most common anaerobic organisms are *Peptostreptococcus* species, with *Staphylococcus* and *Streptococcus* species being the predominating aerobic organisms. Interestingly, a significantly higher percentage of anaerobic infections have been noted in patients injecting cocaine. This has been attributed to the relative anaerobic environment created by the vasoconstrictive effect of the cocaine.

Clinical Features

Patients present with an area of swelling, tenderness, and erythema. Inspection of the area may reveal fluctuance, induration, or active drainage. Lymphadenitis, localized lymphadenopathy, or fever may indicate systemic involvement of the infection, but in otherwise healthy

patients, cutaneous abscesses tend to remain localized. A careful history should be obtained, with special attention given to underlying immunocompromising illnesses, steroid or other immunosuppressive drug use, and alcoholism. Close inspection of the area for evidence of predisposing injury or foreign body is important. Radiography may be indicated to evaluate for certain radiopaque foreign bodies, and ultrasound may be useful in identifying nonradiopaque objects. Ultrasound can accurately identify many small foreign objects or at least a small fluid collection representing surrounding abscess. The limiting factor in the use of ultrasound is that because of the superficial location of most of these objects, a very high-frequency ultrasound transducer is required (7.5 to 10 MHz). Specific abscesses that may be encountered in the ED are discussed below.

BARTHOLIN GLAND ABSCESES Bartholin gland abscesses are discussed in Chap. 108.

PARONYCHIA AND FELONS Paronychia and felons are discussed in Chap. 285.

HIDRADENITIS SUPPURATIVA Hidradenitis suppurativa is a recurrent, chronic infection that is a disorder of the terminal follicular epithelium within apocrine gland-bearing skin.¹⁵ The blockage of the apocrine glands is secondary to an adjacent folliculitis. The folliculitis, and secondary blockage of the surrounding apocrine glands by keratinous material, leads to inflammation, local cellulitis, and subsequent abscess formation. Multiple areas of infection develop and coalesce to form chronic draining fistulous tracts. These tracts tend to occur in the axilla, groin, and perianal regions, where the apocrine sweat glands predominate. Hidradenitis suppurativa is more common in women and blacks, and there appears to be a genetic factor involved in its development. Obesity, shaving, and mechanical irritation have been considered risk factors, but study data have never supported this. The onset of symptoms almost universally occurs after the onset of puberty, and a relationship between androgens and hidradenitis suppurativa has been closely considered. Androgen administration has been shown to worsen symptoms; however, antiandrogen therapy has shown mixed results at best.

The causative organism is usually *Staphylococcus*, but *Streptococcus* also can be involved. In the groin, gram-negative organisms and anaerobes also may be seen. Patients often will present with multiple lesions in different stages of development and healing, but with an acute exacerbation in one or a few areas. ED treatment is directed primarily at incision and drainage of the acute infection with referral to a surgeon for further definitive treatment. Oral antibiotics should be considered in patients with significant areas of cellulitis or systemic symptoms.

Patients with longstanding disease are at risk of developing an aggressive form of squamous cell carcinoma that is associated with local invasion, recurrence after excision, distant metastasis, and high mortality.

INFECTED SEBACEOUS CYSTS Sebaceous glands occur diffusely throughout the body. Blockage of the duct of a sebaceous gland may lead to development of a glandular cyst that may exist for a long period of time without becoming infected. Once bacterial invasion occurs, abscess formation is common. Patients typically present with an erythematous, tender cutaneous nodule that is commonly fluctuant. Simple incision and drainage are the appropriate ED treatment. The cyst always contains a capsule that must be removed to prevent further infection. This is usually best done at a later follow-up visit when the initial inflammation has improved or resolved. Occasionally the wall of the sac can be grasped with a forceps and removed at the time of drainage.

PERSRECTAL ABSCESES These are discussed in Chap. 82.

PILONIDAL ABSCESES Pilonidal abscesses are located along the superior gluteal fold. It is thought that a pilonidal sinus forms along the gluteal fold possibly at the time of embryogenesis, although others believe it to be secondary to local soft tissue trauma. These sinuses are lined with squamous epithelium and hair. It is blockage of the sinus tract with hair and other keratinous material that leads to bacterial invasion and infection. The causative organisms typically are normal skin flora, with *Staphylococcus* species being the most common. Contamination with peritoneal and fecal organisms is also possible. Patients tend to develop symptoms in their late teens and early twenties, and without definitive surgical treatment, they tend to have recurrent infections, sometimes developing a chronic draining fistulous tract. Patients typically present to the ED with a tender, swollen, and fluctuant nodule located along the superior gluteal fold. Systemic symptoms are rare. The appropriate initial treatment includes incision and drainage using care to remove all excess hair and debris from the abscess cavity. The cavity should be packed with iodoform gauze, and the patient should return in 2 to 3 days for advancement of the packing. Antibiotics generally are not needed. Surgical referral is recommended for more definitive treatment. This now typically consists of wide surgical excision, and healing by secondary intention.

STAPHYLOCOCCAL SOFT TISSUE ABSCESES *Staphylococcus* species are ubiquitous throughout the skin and have a particular affinity for hair follicles, where infection is common. Inflammation of a hair follicle caused by bacterial invasion is known as *folliculitis* and is best treated noninvasively with warm soaks. A deeper invasion into the soft tissue surrounding a hair follicle can lead to a localized abscess formation called a *furuncle* (boil). These are most commonly found on the face, neck, back, axilla, inner thighs, and other areas exposed to friction. Unless severe, warm compresses usually are adequate to promote spontaneous drainage. In the thick skin on the back, neck, lateral thighs, and buttocks, several furuncles may coalesce to form a large area of infection containing many interconnected sinus tracts and abscesses. This is known as a *carbuncle* and often requires wide surgical excision for complete resolution. Carbuncles are seen much more commonly in diabetics and may demonstrate signs of systemic involvement.

Diagnosis Most simple cutaneous abscesses in otherwise healthy patients are local infections without need for further evaluation. Clinical presentation of a tender, swollen, often erythematous nodule strongly suggests infection. A palpable area of fluctuance is typically enough for the diagnosis of abscess. Notice should be made of the admitting vital signs, with particular attention to temperature and heart rate. Fever or tachycardia suggests systemic involvement of the infection and may indicate the need for further laboratory testing. In patients with diabetes, alcoholism, and other immunocompromising conditions, the threshold for further diagnostic studies should be lower. A complete blood count and in certain situations (such as possible osteomyelitis) an erythrocyte sedimentation rate usually are all that are needed to evaluate for possible systemic involvement. Diabetic patients routinely should have their blood glucose checked.

In simple abscesses involving otherwise healthy patients, a routine culture and sensitivity is not needed. If it is felt that antibiotic treatment is indicated, the causative organisms usually can be predicted by the general location of the abscess. If further certainty is required, a Gram stain of the abscess aspirate most often will lend the required information, and results can be obtained while the patient is still in the ED. Gram-positive cocci in clusters suggest infection with *S. aureus*, whereas many different organisms suggest a mixed anaerobic and aerobic infection. In patients in whom possible deep or chronic infection may complicate the course, early wound cultures with sensitivities may prove useful. Immunocompromised patients demonstrating systemic signs of infection also should have blood cultures drawn. In patients in whom foreign body involvement is a potential issue, plain radiographs or possibly ultrasound should be used to assist in identification.

Treatment Incision and drainage is the only treatment necessary in most cases of superficial and localized abscesses. Often it is difficult to determine clinically if an area of fluctuance is present within an area of induration and swelling. Needle aspiration of the most likely area of induration often can help in the diagnosis. When pus is encountered with aspiration, incision and drainage should be performed. When no pus is located, a trial of antibiotic therapy and warm compresses is appropriate initially. Patients should have a follow-up evaluation in 48 to 72 h to identify the need for incision and drainage.

Consideration must be given to the best location for abscess drainage. Abscesses well suited to ED treatment are those that are superficial, well localized, and not in close proximity to nerves or vascular structures. Fluctuant masses should be examined for pulsations or bruits if near vascular structures. Patient comfort is also an important consideration. Infiltration of a local anesthetic most often gives poor pain relief. The lower pH of infected tissue typically greatly reduces the effectiveness of a local anesthetic. Injecting additional fluid into an already swollen and tender area also increases pain. Regional or field blocks can be effective. Some may require systemic sedation and analgesia, and those in whom adequate analgesia cannot be obtained in the ED should be taken to the operating room for appropriate surgical drainage.

Before the procedure, consent should be obtained and complications explained. Complications are few with superficial abscesses, but include residual local numbness, the risk of injury to deeper nerves and blood vessels, and poor or delayed wound healing, especially in those with diabetes or peripheral vascular disease. Some estimate should be made of the residual scarring that may be anticipated, especially in areas of cosmetic significance.

The patient should be positioned to ensure appropriate access to the abscess and in the most comfortable position possible. The area should be prepared with povidone-iodine solution and draped in a sterile fashion. After appropriate anesthesia, the abscess should be opened widely over the area of greatest fluctuance, using a no. 11 or 15 scalpel blade to ensure adequate drainage. As much pus as possible should be expressed by gentle compression. Hemostats are then used to break up any loculated areas within the abscess cavity. The cavity is irrigated with saline and packed loosely with gauze tape to hold it open to promote drainage while the infection resolves. The packing should be left in place long enough for the cavity to heal from the inside out, preventing recollection of the abscess. Patients are discharged with instructions for warm compresses or soaks three to four times a day. A follow-up visit should be scheduled in 2 to 3 days for recheck and advancement or replacement of the packing. Wounds that continue to actively drain at the time of follow-up should have the packing replaced. Replacing the packing performs some degree of debridement of the abscess cavity, as well as providing fresh packing for absorption of pus and debris. Wounds that are not actively draining can have the packing replaced and advanced as needed to allow for internal healing while keeping the incision open to promote drainage.

The use of antibiotics in patients with cutaneous abscesses is somewhat controversial. The risk of systemic infection following local incision and drainage appears to be low. An ED study demonstrated that in 50 afebrile patients in whom blood cultures were drawn 2 and 10 min after incision and drainage of cutaneous abscesses, none of the cultures was found to be positive.¹⁶ There are no good data suggesting that antibiotic treatment following incision and drainage speeds infection resolution in otherwise healthy patients. Generally, it is felt that in patients without underlying immunocompromising conditions or signs of systemic infection, antibiotics are not indicated following incision and drainage of superficial cutaneous abscesses. With a lack of hard scientific data pointing to clear-cut guidelines for antibiotic therapy, clinical judgment needs to be exercised. In patients with diabetes, alcoholism, or other underlying immunocompromising illnesses, or in those on immunosuppressant medications such as steroids or chemotherapeutics, the threshold for antibiotic use should be much

lower. Furthermore, patients who present with signs of systemic disease such as fever and chills and those with cellulitis extending beyond the abscess borders also should be considered for antibiotic therapy. Abscesses involving the hands or face should be treated more aggressively with antibiotics because of the higher morbidity associated with prolonged infection or complications. The specific antibiotic used should be chosen according to the most likely pathogen involved. This can be somewhat predicted by the location of the infection. Duration of therapy should be directed to some degree by the severity of infection but typically should continue for 5 to 7 days.

Of separate concern are patients with underlying structural heart disease at risk for bacterial endocarditis. Certain structural cardiac conditions lead to a higher incidence of bacterial endocarditis. Furthermore, the severity of disease and morbidity are increased in patients with certain underlying cardiac diseases who develop bacterial endocarditis. The American Heart Association publishes guidelines for patients it considers at increased risk for developing bacterial endocarditis.¹⁷ Table 152-1 outlines the cardiac conditions considered to be at high and moderate risk based on predicted outcomes if endocarditis does occur. Note that several types of patients frequently encountered in the ED, namely patients after coronary artery bypass grafting, those with pacemakers, and those with mitral valve prolapse without valvular regurgitation, are not recommended for endocarditis prophylaxis. Despite the apparent low risk of transient bacteremia following incision and drainage of a simple cutaneous abscess, the American Heart Association recommends prophylactic antibiotics for those patients in the high- and moderate-risk categories prior to the procedure. No mention is made of postprocedure treatment. The antibiotic selected should be directed at the most likely organism causing the abscess. Suggested antibiotic treatment by organism for soft tissue infections is shown in Table 152-2,¹⁸ and should be used for preprocedure prophylaxis for endocarditis. An intravenous or intramuscular antistaphylococcal penicillin, clindamycin, or first-generation cephalosporin is appropriate for patients not able to take oral medications. In patients with known methicillin-resistant *S. aureus* infection, vancomycin is recommended for prophylaxis.

SPOROTRICHOSIS

Sporotrichosis is a mycotic infection caused by the fungus *Sporothrix schenckii*, commonly found on plants and vegetation and in soil. Infection is caused by traumatic inoculation and usually remains within the local soft tissues and lymphatics. Disseminated forms, although more rare, do occur.

TABLE 152-1 Cardiac Conditions at Risk for Endocarditis

Endocarditis prophylaxis recommended:
High-risk category:
Prosthetic cardiac valves
Previous bacterial endocarditis
Complex cyanotic heart disease (e.g., single ventricle, transposition of the great vessels, tetralogy of Fallot)
Surgically constructed systemic pulmonary stunts or conduits
Moderate-risk category:
Most other congenital cardiac malformations
Acquired valvular dysfunction (e.g., rheumatic heart disease)
Hypertrophic cardiomyopathy
Mitral valve prolapse with valvular regurgitation and/or thickened leaflets
Endocarditis prophylaxis not recommended:
Negligible-risk category (no greater risk than general population):
Isolated secundum atrial septal defect
Surgical repair of ASD, VSD, or PDA
Previous coronary artery bypass grafting
Mitral valve prolapse without valvular regurgitation
Physiologic, functional, or innocent heart murmur
Cardiac pacemakers

Abbreviations: ASD = atrial septal defect; VSD = ventricular septal defect; PDA = patent ductus arteriosus.

TABLE 152-2 Oral Antibiotic Recommendations for Common Skin Infections

Staphylococcus and *Streptococcus* Species

Common infections:

Cellulitis; erysipelas (typically *Streptococcus*); sebaceous cyst abscesses; abscesses secondary to foreign bodies; hidradenitis suppurativa; pilonidal abscesses; folliculitis, boils, and carbuncles (typically *Staphylococcus*)

Antibiotic recommendations:

Cloxacillin or dicloxacillin, 250-500 mg q6h
 Cephalexin 250—500 mg q6h (high resistance rate with *Staphylococcus*)
 Clindamycin 150-150 mg q6h
 Amoxicillin-clavulanate 875/125 mg q12h
 Erythromycin 250-500 mg q6h
 Clarithromycin 500 mg q12h
 Azithromycin 500 mg first day, then 250 mg qd X 4 d

Escherichia, *Proteus*, and *Klebsiella* Species

Common infections:

Cutaneous abscesses involving the axilla, perineum, and groin; Bartholin gland abscesses; perirectal abscesses, hidradenitis suppurativa involving the groin;

pilonidal abscesses Antibiotic recommendations:

Trimethoprim-sulfamethoxazole 160/800 mg q12h
 Amoxicillin-clavulanate 875/125 mg q12h
 Ciprofloxacin 500—750 mg q12h
 Ofloxacin 200-400 mg q12h
 Levofloxacin 250-500 mg qd

Bacteroides Species

Common infections:

Cutaneous abscesses involving the groin and perineum; human bites; abscesses secondary to IV cocaine use; Bartholin's gland abscesses; hidradenitis suppurativa involving the groin and perineum, perirectal abscesses, pilonidal abscesses Antibiotic recommendations: Clindamycin 150-450 mg q6h
 Metronidazole 500 mg q6h Amoxicillin-clavulanate 875/125 mg q12h

Pasturella multocida

Common infections:

Animal bites, especially cats

Antibiotic recommendations:

Penicillin V 250-500 mg q6h
 Doxycycline 100 mg q12h
 Amoxicillin-clavulanate 875/125 mg q12h
 Trimethoprim-sulfamethoxazole 160/800 mg q12h

Epidemiology

The organism responsible for sporotrichosis occurs worldwide and is found most commonly in soil, sphagnum moss, and decaying vegetable matter. Inoculation into the host most commonly occurs from a spine or barb on a plant puncturing the skin during handling. It is a common disease among florists, gardeners, and agricultural workers. Transmission from infected animals, especially cats, has been documented, and veterinarians and animal handlers are also at increased risk. The largest outbreak of sporotrichosis in the United States involved 15 states and 84 persons, all of whom handled conifer seedlings shipped in sphagnum moss contaminated with *S. schenckii*.⁶

Pathophysiology

S. schenckii is a thermally dimorphic fungus that changes from its mycelial form to its yeast form on entering a body-temperature environment. Local infection occurs in most cases, with disease limited to cutaneous or lymphocutaneous areas. Osteoarticular involvement including osteomyelitis, septic arthritis, bursitis, and tenosynovitis oc-

curs and may be related to a local cutaneous infection or secondary to hematogenous spread. Systemic forms, including pulmonary and meningial, are much more rare.

Clinical Features

The incubation period averages 3 weeks from the time of initial inoculation, but varies from a few days to several weeks. After the fungus enters the body through a break in the skin, three types of localized infections may occur. The *fixed cutaneous* type is characterized by lesions restricted to the site of inoculation and may appear as a crusted ulcer or verrucous plaque. *Local cutaneous* type infections also remain local but present as a subcutaneous nodule or pustule. The surrounding skin becomes erythematous and may ulcerate, resulting in a chancre. Local lymphadenitis is common. The *lymphocutaneous* type is the third and most common type. It is characterized by an initial painless nodule or papule at the site of inoculation that later develops subcutaneous nodules with clear skip areas along local lymphatic channels. The local reactions in all three types of infections tend to be relatively painless but show no signs of improvement without treatment.

Patients occasionally develop extracutaneous illness from what is most probably hematogenous spread. It is not clear what the exact pathogenesis of infection is since most cases do not involve the cutaneous form of the infection at the same time. Most cases of extracutaneous sporotrichosis involve the skeletal system. An indolent form of monarticular arthritis is the most common symptom. Osteomyelitis, tenosynovitis, and carpal tunnel syndrome are occasionally seen as well. Multiarticular arthritis is usually only seen in patients with underlying immunocompromising illness. Rarely patients will develop pulmonary involvement, which typically occurs in elderly alcoholic males, and clinically resembles tuberculosis. Chronic lymphocytic meningitis can be a delayed complication of sporotrichosis infection, and should be considered in patients with chronic meningial symptoms.

Diagnosis

History and physical findings are the keys to diagnosis. Histopathologic stains are of little help because the organisms are scarce in tissues. Fungal cultures are the best way to isolate the fungus, and tissue biopsy cultures often are diagnostic. Routine laboratory tests are non-specific, but an increased white blood cell count, eosinophil count, and erythrocyte sedimentation rate may be noted. The differential diagnosis includes tuberculosis, tularemia, cat-scratch disease, leishmaniasis, staphylococcal lymphangitis, and nocardiosis.

Treatment

Itraconazole (100 to 200 mg qd for 3 to 6 months) is the treatment of choice for localized and systemic infections.¹⁹ Fluconazole is less effective than itraconazole and should be reserved for those few patients not tolerating itraconazole. Ketoconazole has shown even poorer results than fluconazole. Intravenous amphotericin B is effective, but adverse reactions usually limit its use to disseminated forms.

REPORTABLE INFECTIOUS DISEASES Jane H. Brice J. Brent Myers

The Centers for Disease Control and Prevention (CDC) in Atlanta publishes a list of notifiable infectious diseases that is updated and revised routinely. The most recent update as of this writing (2002) includes 54 nationally notifiable diseases and is summarized in Table 153-1.¹ The requirement to report these diseases is mandated by state or territory laws and regulations, and therefore, the list differs for each state or territory.

The reliability of the national reporting system rests on health care providers, laboratories, and other public health personnel, as is emphasized by the CDC: "The usefulness of public health surveillance data depends on its uniformity, simplicity, and timeliness."² Without consistent and timely notification, it becomes very difficult to monitor trends in disease patterns, to detect unusual occurrences or pockets of disease, and to assess the effectiveness of public health interventions to eradicate or contain disease. In effort to improve the consistency and timeliness of notification, the CDC has established a nationwide, computerized system that collects and analyzes data on a weekly basis.³ Data reported by the 50 states, the District of Columbia, and the U.S. territories are summarized in the *Morbidity and Mortality Weekly Report*, which can be accessed online at www.cdc.gov/mmwr.

In an effort to ensure uniformity, the CDC maintains a revised case definition for all notifiable diseases. What follows is a summary of the

TABLE 153-1 Nationally Reportable Communicable Diseases

Acquired immunodeficiency syndrome (AIDS)	Malaria
Anthrax	Measles
Botulism	Meningococcal disease
Brucellosis	Mumps
Chancroid	Pertussis
<i>Chlamydia trachomatis</i> genital infections	Plague
Cholera	Poliomyelitis, paralytic
Coccidioidomycosis	Psittacosis
Cryptosporidiosis	Q fever
Cyclosporiasis	Rabies, animal
Diphtheria	Rabies, human
Ehrlichiosis	Rocky Mountain spotted fever
Encephalitis or meningitis, arboviral	Rubella
<i>Escherichia coli</i> O157:H7	Rubella, congenital syndrome
Giardiasis	Salmonellosis
Gonorrhea	Shigellosis
<i>Haemophilus influenzae</i> invasive disease	Streptococcal disease, invasive, group A
Hansen's disease (leprosy)	<i>Streptococcus pneumoniae</i> , drug-resistant invasive disease
Hantavirus pulmonary syndrome	Streptococcal toxic shock syndrome
Hemolytic-uremic syndrome, post-diarrheal	Syphilis
Hepatitis A	Syphilis, congenital
Hepatitis B	Tetanus
Hepatitis C/non-A, non-B	Toxic shock syndrome
HIV infection, pediatric	Trichinosis
Legionellosis	Tuberculosis
Listeriosis	Tularemia
Lyme disease	Typhoid fever
	Varicella (deaths only)
	Yellow fever

case definitions for each of the specified nationally notifiable diseases. Unless otherwise noted, these case definitions were obtained from the 1997 *Morbidity and Mortality Weekly Report (MMWR)* update on reportable diseases.² These case definitions establish uniform notification criteria and are subject to revision. For the most up-to-date information, go to <http://www.cdc.gov/epo/dphsi/casedef/index.htm>.

ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS)

AIDS is a chronic illness with varying manifestations; for patients 13 years of age or older, reporting is required if the patient demonstrates (1) a CD4⁺ T-cell count of less than 200/fj.L, (2) a CD4⁺ T-cell percentage of total lymphocyte of less than 14 percent, or (3) any of the following: pulmonary tuberculosis, recurrent pneumonia, invasive cervical cancer, or 23 other clinical conditions discussed elsewhere in this text (Chap. 144) and via the *Morbidity and Mortality Weekly Reports*.⁴⁻⁶ For patients less than 13 years of age, a revised system has been developed to include a child's infection status, immunologic status, and clinical status. Infection status is discussed in the HIV section (below). The immunologic status is based on age-appropriate CD4⁺ T-cell counts. The clinical status includes the asymptomatic, the moderately symptomatic, and the severely symptomatic, with this latter category including the majority of the traditional AIDS-defining illnesses.⁵

ANTHRAX

Anthrax is an acute illness with one of several distinct clinical presentations. The cutaneous form is characterized by a skin lesion evolving over 2 to 6 days from a papule to a vesicle to a depressed black eschar. The inhalation form presents with a brief upper respiratory infection followed by hypoxia and dyspnea. On chest radiography, there will be evidence of mediastinal widening from adenopathy. The intestinal

form is distinguished by severe abdominal pain and cramping followed by fever and sepsis. Finally, in the oropharyngeal form, a mucosal lesion in the oral cavity develops along with cervical adenopathy, edema, and fever.

The laboratory diagnosis is made by (1) isolation of *Bacillus anthracis* from a clinical specimen, (2) anthrax electrophoretic immunoblot (EITB) reaction to the protective antigen and/or lethal factor bands in at least one serum specimen obtained after onset of symptoms, or (3) demonstration of *B. anthracis* through immunofluorescence.

BOTULISM

Foodborne An acute illness of varying severity, foodborne botulism is manifested by diplopia, blurred vision, bulbar weakness, or symmetric paralysis that may be of rapid onset. Laboratory confirmation of this illness consists of demonstration of botulinum toxin in serum or stool or in food the subject recently consumed. A positive *Clostridium botulinum* culture from stool also serves as confirmation of the diagnosis.

Infant A constellation of symptoms in an infant under 1 year of age including constipation, poor feeding, and failure to thrive followed by progressive weakness, impaired respiration, and death should suggest infant botulism. Laboratory confirmation of the diagnosis is made in the same manner as described for foodborne botulism.

Wound The symptoms for wound botulism mirror those found in the foodborne form. The laboratory diagnosis is made by finding botulinum toxin in serum or obtaining a positive culture from the wound.

BRUCELLOSIS

Infection with *Brucella* may be either of acute or insidious onset. Brucellosis is characterized by fever, night sweats, undue fatigue, anorexia, weight loss, headache, and arthralgias. The laboratory diagnosis may be made in several ways: (1) culture positive from a clinical specimen, (2) at least a fourfold increase in *Brucella* agglutination titers between the acute and convalescent phases in serum taken at least 2 weeks apart and studied in the same laboratory, or (3) positive immunofluorescence of *Brucella* in a clinical specimen.

CHANCROID

Chancroid is a sexually transmitted disease caused by the organism *Haemophilus ducreyi*. It is manifested by a painful genital ulcer with inflamed inguinal lymph nodes. Isolation of the organism from a clinical specimen confirms the diagnosis.

CHLAMYDIA TRACHOMATIS GENITAL INFECTIONS

Genital infection with *Chlamydia trachomatis* is sexually transmitted and may present in several different manners. There may be evidence of urethritis, epididymitis, cervicitis, or acute salpingitis, or the infection may be completely asymptomatic. It is therefore essential to test for *Chlamydia* whenever there is a suspicion of infection or when there is evidence of other sexually transmitted infection. *Chlamydia* also may cause conjunctivitis or pneumonia in newborns through perinatal transmission. Finally, *Chlamydia* causes lymphogranuloma venereum, which is discussed below. The diagnosis of *Chlamydia* is confirmed through either a positive culture or detection of the antigen or nucleic acid on immunofluorescence.

CHOLERA

Cholera infection is manifested by a diarrheal illness of varying severity. The presence of vomiting does not exclude the diagnosis. Isolation

of the toxigenic *Vibrio cholerae* O1 or O139 from stool or emesis confirms the diagnosis. Serologic evidence of recent infection also may confirm a recent illness caused by cholera. The CDC requests notification for cholera only if the one of the two *Vibrio* serotypes listed above is isolated; there is no need to notify the CDC for other serotypes.

COCCIDIOIDOMYCOSIS

Infection with the fungus *Coccidioides immitis* may manifest in an acute or chronic illness and may, in some persons, be maintained in an asymptomatic state. This fungus is endemic in the southwestern United States. Those demonstrating symptoms usually complain of an influenza-like febrile respiratory illness. The disease may disseminate in approximately 0.5 percent of patients.

Coccidioidomycosis should be considered in those with one or more of the following: (1) influenza-like signs and symptoms (i.e., fever, cough, chest pain, myalgia, arthralgia, and headache), (2) pneumonia or other pulmonary lesion on chest radiograph, (3) erythema nodosum or erythema multiforme rash, (4) involvement of bones, joints, or skin by dissemination, (5) meningitis, and/or (6) involvement of viscera or lymph nodes.

Laboratory confirmation is made through (1) culture, histopathology, or molecular evidence of *C. immitis*, (2) serologic tests including detection of IgM by immunodiffusion, enzyme immunoassay, latex agglutination, or tube precipitation or detection of rising titer of IgG by immunodiffusion, enzyme immunoassay, or complement fixation, or (3) coccidioidal skin-test conversion after onset of symptoms.

CRYPTOSPORIDIOSIS

Diarrhea, abdominal cramps, loss of appetite, low-grade fever, and nausea and vomiting are the cluster of signs and symptoms associated with cryptosporidiosis. The infection may be asymptomatic in some persons. The illness also can be prolonged and life-threatening in immunocompromised patients. It is caused by the protozoa *Cryptosporidium parvum*.

In the laboratory, the diagnosis is confirmed by detection of oocysts in stool, demonstration of *Cryptosporidium* in intestinal fluid or small bowel biopsy specimens, detection of *Cryptosporidium* antigen in stool by specific immunodiagnostic testing, use of polymerase chain reaction (PCR) techniques where routinely available, or demonstration of reproductive stages in tissue preparations.¹

CYCLOSPORASIS

Cyclosporiasis is an intestinal illness caused by the protozoa *Cyclospora cayetanensis*. Symptoms include watery diarrhea, weight loss, increased flatus, nausea, fatigue, and perhaps vomiting. Other symptoms may include anorexia, abdominal bloating/cramping, and low-grade fever. Asymptomatic and relapsing infections can occur. Laboratory confirmation is accomplished by one of four methods: (1) detection of oocysts in stool by microscopic examination, (2) detection of *Cyclospora* in intestinal fluid or bowel biopsy specimens, (3) demonstration of sporulation, or (4) detection of DNA by PCR in stool, duodenal/jejunal aspirates, or small bowel biopsy specimens.¹

DIPHThERIA

Diphtheria is characterized by upper respiratory symptoms, including sore throat, low-grade fever, and an adherent membrane to tonsils, pharynx, and/or the nose. There is a cutaneous form of diphtheria that does not need to be reported to the CDC. Isolation of *Corynebacterium diphtheriae* from clinical specimens or a histopathologic diagnosis of diphtheria confirms the illness.

EHRLICHIOSIS

Ehrlichiosis is a tick-borne illness characterized by acute onset of a flulike illness with fever, headache, myalgias, and malaise. In addition, some cases may demonstrate nausea, vomiting, or rash. Laboratory abnormalities may include thrombocytopenia, leukopenia, and/or elevated liver enzymes. Intracytoplasmic bacterial aggregates (morulae) may be visible in the leukocytes of some patients. Three categories of ehrlichiosis should be reported and are described below.

HME A variant of the disease caused by *Ehrlichia chaffeensis*. Laboratory confirmation is achieved by demonstration of a fourfold increase in antibody titer to *E. chaffeensis* by immunofluorescence assay (IFA) in paired serum samples, positive PCR with demonstration of *E. chaffeensis* DNA, identification of morulae in leukocytes with a positive IFA titer to *E. chaffeensis* antigen, immunostaining of *E. chaffeensis* antigen in biopsy or autopsy specimen, or culture of *E. chaffeensis* from a clinical specimen.

HGE A variant of the disease caused by *E. phagocytophila*. The laboratory mechanisms described for *E. chaffeensis* detection and confirmation are the same procedures used for *E. phagocytophila*.

Ehrlichiosis, Human, Other, or Unspecified Agent This variant of the disease is confirmed in the laboratory by either a fourfold change in antibody titer to more than one *Ehrlichia* species by IFA in paired samples in which a dominant reactivity cannot be established or by the identification of an *Ehrlichia* species other than *E. chaffeensis* or *E. phagocytophila* by PCR, immunostaining, or culture.¹

ENCEPHALITIS OR MENINGITIS, ARBOVIRAL

Arboviral central nervous system (CNS) infections range in severity from febrile headache to encephalitis; these illnesses are often indistinguishable from other viral CNS infections. Arboviral meningitis is characterized by fever, headache, stiff neck, and pleocytosis. Arboviral encephalitis is characterized by a febrile illness associated with any of the following neurologic signs and symptoms: headache, confusion, altered sensorium, nausea and vomiting, meningismus, cranial nerve palsy, paresis or paralysis, sensory deficit, altered reflexes, seizures, abnormal movements, or coma. The diagnosis is made based on laboratory detection of (1) a fourfold or greater rise in serum antibody titer, (2) isolation of virus or finding of viral antigen or genomic sequences in tissue, blood, cerebral spinal fluid (CSF), or other bodily fluids, (3) IgM antibody detected on enzyme immunoassay from serum or CSF, or (4) virus specific IgM antibodies demonstrated in serum by antibody-capture EIA and confirmed by demonstration of virus-specific IgG antibodies in the same or later specimen by another serologic assay. Eastern equine encephalitis/meningitis, western equine encephalitis/meningitis, California serogroup encephalitis/meningitis, St. Louis encephalitis/meningitis, Powassan encephalitis/meningitis, and West Nile meningitis/encephalitis are reportable to the CDC.¹

ENTEROHEMORRHAGIC *ESCHERICHIA* CO Σ /(EHEC)

A diarrheal disease of variable severity, *E. coli* infections have gained national prominence through several foodborne outbreaks. A recently revised CDC case definition includes not only the well-recognized *E. coli* O157:H7 but also other subtypes of *E. coli* capable of producing enterohemorrhagic illness. The diarrhea of this disease is often bloody and associated with abdominal cramping. It may be complicated by hemolytic-uremic syndrome (HUS) or thrombotic thrombocytopenic purpura (TTP). It also may be asymptomatic.

In the laboratory, isolation of *E. coli* O157:H7 or a Shiga toxin producing *E. coli* is confirmatory. A probable case is defined as one in

SECTION 13 • INFECTIOUS DISEASES

which (1) there is isolation of *E. coli* O157 from a clinical specimen pending H7 or Shiga toxin production, (2) there is an epidemiologic link with a confirmed or probable case, (3) there is identification of a Shiga toxin from a clinically compatible case, or (4) there is definitive evidence of an elevated antibody titer to a known EHEC serotype from a clinically compatible case. The CDC should be notified concerning both confirmed and probable cases.'

GIARDIASIS

Caused by the protozoan *Giardia lamblia*, this intestinal illness is characterized by diarrhea, abdominal cramps, weight loss, malabsorption, and bloating. Some individuals may remain as asymptomatic carriers. Diagnosis is confirmed by demonstration of *G. lamblia* cysts in stool; *G. lamblia* trophozoites in stool, duodenal fluid, or small bowel biopsy; or *G. lamblia* antigen in stool by specific immunodiagnostic test.'

GONORRHEA

This sexually transmitted disease is characterized by varying manifestations, including urethritis, cervicitis, or salpingitis. It may be asymptomatic in some persons or may become disseminated. Laboratory detection of *Neisseria gonorrhoeae* in clinical specimens confirms the diagnosis. Other methods of laboratory confirmation include detection of antigen or nucleic acid in specimens or observation of gram-negative intracellular diplococci in a urethral smear obtained from a male patient.

HAEMOPHILUS INFLUENZAE INVASIVE DISEASE

Invasive diseases caused by *H. influenzae* include meningitis, bacteremia, epiglottitis, or pneumonia. Laboratory isolation of *H. influenzae* from a normally sterile site such as blood, CSF, or joint fluid is necessary to confirm the diagnosis.

HANSEN DISEASE (LEPROSY)

Hansen disease is a chronic infection with *Mycobacterium leprae* involving the skin predominantly but which can include peripheral nerves and the mucosa of the upper airway as well. There are four clinical forms of Hansen disease. Tuberculoid leprosy is characterized by one or a few well-demarcated, hypopigmented, and anesthetic skin lesions. Often these lesions have active, spreading edges and a clearing center. Peripheral nerve swelling or thickening also may be present. In the lepromatous form, a number of erythematous papules and nodules may be present or an infiltration of face, hands, and feet with lesions in a bilateral and symmetric pattern that progresses to thickening of the skin. The borderline or dimorphous form presents with skin lesions characteristic of both the tuberculoid and lepromatous forms. Finally, in the indeterminate form, early lesions, usually hypopigmented macules, are present that do not develop the more characteristic features of the tuberculoid or lepromatous forms.

Demonstration of acid-fast bacilli in skin or dermal nerves makes the diagnosis. Specimens should be obtained from a full-thickness skin biopsy of a lepromatous lesion, if possible.

HANTAVIRUS PULMONARY SYNDROME

Hantavirus pulmonary syndrome is a febrile illness characterized by bilateral interstitial pulmonary infiltrates and respiratory compromise resembling adult respiratory distress syndrome. There is typically a prodrome of fever, chills, myalgias, headache, and gastrointestinal distress. Common laboratory findings include one or more of the following: hemoconcentration, left shift in white blood cell count, neutrophilic leukocytosis, thrombocytopenia, or circulating immunoblasts.

Hantavirus should be considered in the setting of one or more of the following: (1) febrile illness [temperature greater than 38.3°C

(101°F)] in a previously healthy individual with bilateral interstitial edema that may resemble adult respiratory distress syndrome radiographically and respiratory compromise requiring oxygen support developing within 72 h of hospitalization or (2) unexplained respiratory illness resulting in death and autopsy examination demonstrating non-cardiogenic pulmonary edema without identifiable cause.

Detection of hantavirus-specific IgM or rising titers of IgG, detection of hantavirus-specific ribonucleic acid sequences by PCR techniques in clinical specimens, and detection of hantavirus antigen by immunohistochemistry are all acceptable laboratory methods for confirming the diagnosis.

HEMOLYTIC-UREMIC SYNDROME, POSTDIARRHEAL

HUS presents as acute onset of microangiopathic hemolytic anemia, renal injury, and low platelet count. Most cases occur within 3 weeks of an acute diarrheal illness. A low platelet count is typical early in the illness (within the first 7 days) but may have normalized by the time the patient seeks care. If the platelet count is not less than 150,000/xL within 7 days of the onset of the gastrointestinal illness, consider another diagnosis. TTP has similar features and is distinguished from HUS by the presence of fever and CNS involvement. Additionally, it may have a more gradual onset. Few cases of TTP are associated with a diarrheal illness.

In the laboratory, both of the following findings will be present: (1) anemia of acute onset with microangiopathic changes (schistocytes, burr cells, or helmet cells on smear) and (2) acute renal failure with hematuria, proteinuria, or increased creatinine levels (50 percent over the patient's baseline values, or greater than 1.0 mg/dL for a child under 13 years of age, or greater than 1.5 mg/dL for persons over 13 years of age with previously normal renal function).

HEPATITIS

Hepatitis is characterized by acute and discrete onset of symptoms and jaundice or elevated serum aminotransferase levels. At present, hepatitis A, B, C, and non-A and non-B are reportable. The laboratory diagnosis of each of the hepatitis viruses is listed below.

Hepatitis A. Detection of IgM to the hepatitis A virus (anti-HAV).

Hepatitis B. (1) Detection of IgM to hepatitis B core antigen (anti-HBc) or hepatitis B surface antigen (HBsAg) and (2) anti-HAV negative, if done.

Hepatitis C. (1) Detection of antibody against hepatitis C antigen (anti-HCV) with verification by an additional, more specific assay, (2) serum aminotransferase levels greater than 7 times the upper limit of normal, (3) anti-HAV negative, (4) anti-HBc negative (if done), and (5) HBsAg negative.

Non-A, non-B hepatitis. (1) Serum aminotransferase levels greater than 2.5 times the upper limit of normal, (2) anti-HAV negative, and (3) anti-HBc (if done) and/or HBsAg negative.

Delta hepatitis. (1) HBsAg or anti-HBc positive and (2) detection of antibodies to hepatitis delta virus (not a reportable disease).

Persons with chronic hepatitis, those who are hepatitis B surface antigen positive, or those who are anti-hepatitis C virus positive should not be reported unless they have acute illness compatible with viral hepatitis at the time of the laboratory finding.'

PERINATAL HEPATITIS B

In infants aged 1 to 24 months, infection with hepatitis B may range from an asymptomatic state to fulminant hepatitis. On laboratory investigation, the infant will be HBsAg positive.

HIV INFECTION

Adults, Adolescents, and Children 18 Months of Age and Older HIV cases are reportable if they meet the following criteria: (1) Positive result on a screening test for HIV antibody (e.g., repeatedly positive enzyme immunoassay) followed by a positive result on a confirmatory test for HIV antibody (e.g., Western blot), (2) positive report on any one of the virologic tests: HIV nucleic acid detection (e.g., ⁵CR), HIV p24 antigen test (including neutralization), or HIV isolation in viral culture), or (3) clinical criteria meeting the definition of AIDS (see AIDS section above). If the actual laboratory results are not available, a signed note from the patient's physician documenting the laboratory results used to fulfill the preceding criteria is acceptable.

Children Less than 18 Months of Age A definitive diagnosis is confirmed if two of the virologic tests mentioned above are positive. The diagnosis is reported as presumptive if only one of the virologic tests is positive. These virologic tests must be obtained at two different times; cord blood may not be used for testing. As with adults, adequate physician documentation of laboratory results is acceptable if the actual laboratory results are not available.⁷

LEGIONELLOSIS

Infection with *Legionella* causes two distinct illnesses: (1) legionnaires' disease, manifested by fever, myalgia, cough, and pneumonia, and (2) Pontiac fever, which is a milder illness without pneumonia. Laboratory confirmation of *Legionella* infection can be made by any of the following methods: (1) isolation of *Legionella* from respiratory secretions, lung tissue, pleural fluid, or other normally sterile site, (2) demonstration of fourfold or greater rise in reciprocal immunofluorescence antibody titer to greater than or equal to 128 against *L. pneumophila* serogroup 1 between paired acute and convalescent serum specimens, (3) detection of *L. pneumophila* serogroup 1 in respiratory secretions, lung tissue, or pleural fluid by direct fluorescent antibody testing, or (4) detection of *L. pneumophila* serogroup 1 antigen in urine by radioimmunoassay or enzyme-linked immunosorbent assay.

LISTERIOSIS

Invasive disease associated with *Listeria monocytogenes* is characterized by meningitis and/or bacteremia. In pregnant females, infection may result in miscarriage or stillbirth. Confirmation is achieved by isolation of *L. monocytogenes* from a normally sterile site or, in the setting of childbirth, from fetal or placental tissue.¹

LYME DISEASE

This tick-borne illness presents with systemic manifestations, including those of the dermatologic, rheumatologic, neurologic, and cardiac systems. The best clinical marker is erythema migrans, the initial skin lesion that occurs in 60 to 80 percent of patients. Other acute symptoms include fatigue, fever, headache, mildly stiff neck, arthralgias, and myalgias. Late manifestations are variable and are best discussed by system:

Musculoskeletal. Recurrent brief and intermittent episodes (over weeks or months) of objective joint swelling in one or several joints, sometimes followed by chronic arthritis.

Central nervous system. Any of the following (alone or in combination): lymphocytic meningitis, cranial neuritis (particularly facial palsy that occasionally is bilateral), radiculopathy, or rarely, encephalomyelitis.

Cardiovascular. Acute onset of high-grade (second- or third-degree) atrioventricular (AV) block that resolves in days to weeks and sometimes is associated with myocarditis (note that palpitations, bradycardia, bundle-branch block, or myocarditis alone is not enough).

Isolation of the organism *Borrelia burgdorferi* from a clinical specimen or demonstration of antibody (IgM or IgG) against *B. burgdorferi* in serum or CSF confirms the diagnosis. A two-test approach (enzyme-linked immunosorbent assay followed by Western blot) is recommended.

MALARIA

Malaria is caused by infection with one of the *Plasmodium* species. Most patients have fever. Other complaints include headache, chills, sweats, myalgias, nausea, vomiting, diarrhea, or cough. Untreated infection by *P. falciparum* can lead to coma, renal failure, pulmonary edema, and death. In the laboratory, malaria parasites can be seen on blood smear.

MEASLES (RUBEOLA)

Measles is an illness characterized by all the following (1) generalized rash lasting more than 3 days, (2) temperature greater than or equal to 38.3°C (101°F), and (3) cough, coryza, or conjunctivitis. The laboratory diagnosis can be made by any of the following: (1) positive serologic tests for measles IgM, (2) significant rise in measles antibody levels by any standard serologic assay, or (3) isolation of measles virus from clinical specimens.

MENINGOCOCCAL DISEASE

Meningococcal disease is most commonly evident as meningitis and/or meningococcemia. It may progress rapidly to purpura fulminans, shock, and death. Isolation of *Neisseria meningitidis* from a normally sterile site such as blood or CSF confirms the diagnosis.

MUMPS

An illness with acute onset, mumps is characterized by unilateral or bilateral tender, self-limited swelling of parotid or other salivary gland for 2 or more days without other cause. The laboratory diagnosis is evident by (1) isolating mumps virus from a clinical specimen, (2) a significant rise between acute and convalescent titers in serum mumps IgG, or (3) finding mumps IgM in serum.

PERTUSSIS

Pertussis is an illness with cough lasting for 2 weeks or longer without other cause and with one of the following: (1) paroxysms of cough, (2) inspiratory whoop, or (3) posttussive vomiting. The laboratory confirmation is found in isolation of *Bordetella pertussis* from clinical specimens or a positive PCR for *B. pertussis*.

PLAGUE

An illness characterized by fever, chills, headache, malaise, prostration, and leukocytosis, plague manifests predominantly in one of the following clinical forms: (1) bubonic plague, manifested by regional lymphadenitis, (2) septicemic plague, in which there is septicemia without evident bubo, (3) pneumonic plague, where pneumonia results from either inhalation of infectious droplets (primary pneumonic plague) or hematologic spread from bubonic or septicemic cases (secondary pneumonic plague), or (4) pharyngeal plague, in which there is pharyngitis and cervical lymphadenitis resulting from exposure to larger infectious droplets or ingestion of infected tissues.

Presumptive laboratory diagnosis is made by (1) an increase in serum antibody titers to *Yersinia pestis* fraction 1 antigen without plague vaccination or (2) detection of fraction 1 antigen by fluorescent assay. Confirmatory laboratory diagnosis is produced by (1) isolation of *Y. pestis* in clinical specimens or (2) a fourfold or greater rise in serum antibody titer to *Y. pestis* fraction 1 antigen.

POLIOMYELITIS, PARALYTIC

Paralytic poliomyelitis is an illness of acute onset characterized by flaccid paralysis of one or more limbs. Deep tendon reflexes are absent or diminished. There are no accompanying sensory or cognitive losses; there should be no other apparent cause for the findings. Laboratory testing only serves to classify the case into categories set up by the CDC. The clinical case definition is sufficient for reporting.

PSITTACOSIS

Psittacosis is a disease found among bird handlers that presents with fever, chills, headache, photophobia, cough, and myalgia. In the laboratory, any of the following methods will confirm the diagnosis: (1) isolation of *Chlamydia psittaci* from respiratory secretions, (2) a fourfold or greater increase in antibodies against *C. psittaci* by complement fixation or microimmunofluorescence (MIF) to a reciprocal titer of at least 32 between paired acute and convalescent serum samples, or (3) detection of serum IgM to *C. psittaci* by MIF to a reciprocal titer of at least 16.

Q FEVER

The acute infection with *Coxiella burnetii* is characterized by fever, myalgias, malaise, and retrobulbar headache. More severe cases may result in hepatitis, pneumonia, and meningoencephalitis. Chronic infections may result in potentially fatal endocarditis (especially in those with preexisting valvular disease) and the chronic fatigue syndrome. In addition, asymptomatic infections have been reported. Diagnosis is confirmed by (1) at least a fourfold change in antibody titer to *C. burnetii* phase II or phase I antibody titer in paired serum specimens, ideally taken 3 to 6 weeks apart, (2) isolation of *C. burnetii* from a specimen by culture, or (3) demonstration of *C. burnetii* in a clinical specimen by antigen or nucleic acid testing.¹

RABIES, ANIMAL

The laboratory diagnosis of animal rabies is the only necessary item for reporting. The diagnosis usually is made by a positive direct fluorescent antibody test (preferably performed on CNS tissue) or by isolation of rabies virus in cell culture or in a laboratory animal.

RABIES, HUMAN

In humans, rabies is an acute encephalomyelitis that almost always progresses to coma and death within 10 days of the first symptom. Laboratory confirmation of the illness can be made in any of the following manners (although the CDC strongly recommends confirming the diagnosis by *all* the suggested methods): (1) direct fluorescent antibody of viral antigen in clinical specimen (preferably the brain or the nerves surrounding hair follicles in the nape of the neck), (2) isolation in cell culture or in a laboratory animal of rabies virus from saliva, CSF, or CNS tissue, or (3) identification of a rabies neutralizing antibody titer of greater than 5 in the serum or CSF of an unvaccinated person.

ROCKY MOUNTAIN SPOTTED FEVER

This is a tick-borne illness of acute onset characterized by headache, myalgia, fever, and petechial rash that appears on the palms and soles in two-thirds of patients. Laboratory diagnosis may be made by one of several methods: (1) a fourfold or greater rise in antibody titer to *Rickettsia rickettsii* antigen by immunofluorescence antibody, complement fixation, latex agglutination, microagglutination, or indirect hemagglutination antibody test in acute and convalescent specimens taken 4 weeks apart, (2) positive PCR to *R. rickettsii*, (3) positive immunofluorescence of skin lesion (biopsy) or organ tissue (autopsy), or (4) isolation of *R. rickettsii* from a clinical specimen.

RUBELLA (GERMAN MEASLES)

Rubella is characterized by all of the following: (1) acute onset of generalized maculopapular rash, (2) temperature greater than 37.2°C (99°F), if measured, and (3) arthralgia/arthritis, lymphadenopathy, or conjunctivitis. Laboratory confirmation is obtained by (1) isolation of rubella virus, (2) significant rise in serum rubella IgG titers between the acute and convalescent phases by any standard serologic assay, or (3) positive serologic test for rubella IgM. It should be noted that rubella IgM tests are occasionally falsely positive in persons with other viral illnesses such as Epstein-Barr virus, cytomegalovirus, or parvovirus infection or in the presence of rheumatoid factor.

RUBELLA, CONGENITAL SYNDROME

The congenital syndrome of rubella is an illness of infancy resulting from rubella virus infection in utero. Infants present with signs and symptoms from the following categories: (1) cataracts/congenital glaucoma, congenital heart disease, hearing loss, and pigmentary retinopathy or (2) purpura, splenomegaly, jaundice, microcephaly, mental retardation, meningoencephalitis, and radiolucent bone disease. Deafness is the most common deficit. Laboratory detection is undertaken by any of the following methods: (1) isolation of rubella virus, (2) demonstration of rubella-specific IgM, (3) infant rubella antibody levels persistently high for longer than expected from passive maternal antibody transfer (infant antibodies should decrease by a twofold dilution each month of life), or (4) a positive PCR for rubella.

SALMONELLOSIS

Infection with *Salmonella* causes diarrhea, abdominal pain, and occasionally, nausea and vomiting of variable severity. Infections may be asymptomatic or may cause extraintestinal disease. Isolation of *Salmonella* from a clinical specimen confirms the diagnosis.

SHIGELLOSIS

Shigellosis presents with diarrhea, nausea, abdominal cramping, and tenesmus of varying severity; alternatively, asymptomatic infections may occur. Isolation of *Shigella* from a clinical specimen confirms the diagnosis.

STREPTOCOCCAL DISEASE, INVASIVE, GROUP A

Invasive group A streptococcal disease is associated with any of several clinical syndromes, including (1) pneumonia, (2) bacteremia associated with cutaneous infection (cellulitis, erysipelas, or infection of a surgical or nonsurgical wound), (3) deep soft tissue infection (myositis or necrotizing fasciitis), (4) meningitis, (5) peritonitis, (6) osteomyelitis, (7) septic arthritis, (8) postpartum sepsis (puerperal fever), (9) neonatal sepsis, or (10) nonfocal bacteremia. Laboratory isolation of group A streptococci (*Streptococcus pyogenes*) by culture from a normally sterile site makes the diagnosis.

STREPTOCOCCAL TOXIC SHOCK SYNDROME

Streptococcal toxic shock syndrome (STSS) is a severe, rapidly progressive illness associated with either invasive or noninvasive group A streptococcal infection. This syndrome may occur with infection at any site but is associated most often with a cutaneous lesion. To be considered as STSS, all the following manifestations must be present within 48 h of hospitalization:

1. *Hypotension*. Systolic blood pressure less than 90 mm Hg for adults or less than the fifth percentile by age for children under 16 years of age.

2. *Multiorgan involvement* with two or more of the following:

- a. *Renal*. Creatinine greater than 2 mg/dL for adults, or twice the upper limit of normal for age, or twice the baseline value for persons with underlying renal dysfunction.
- b. *Coagulopathy*. Platelets less than 100,000/ \times L or disseminated intravascular coagulopathy.
- c. *Hepatic*. Total bilirubin, alanine aminotransferase, or aspartate aminotransferase twice the upper limit of normal for age or twice normal baseline values for those persons with underlying liver disease.
- d. *Respiratory*. Adult respiratory distress syndrome.
- e. *Dermatologic*. Generalized erythematous macular rash that may desquamate.
- f. *Musculoskeletal*. Soft tissue necrosis including necrotizing fasciitis, myositis, or gangrene.

The laboratory diagnosis is made by isolating group A *Streptococcus* in a normally sterile site.

STREPTOCOCCUS PNEUMONIAE DRUG-RESISTANT INVASIVE DISEASE

Drug-resistant, invasive *S. pneumoniae* is associated with many clinical syndromes depending on the site of infection. Isolation of the organism from a normally sterile site and finding a "nonsusceptible" isolate form the crux of the diagnosis.¹

STREPTOCOCCUS PNEUMONIAE, INVASIVE, CHILDREN < 5 YEARS OF AGE

Invasive *S. pneumoniae* is associated with many clinical syndromes depending on the site of infection. Isolation of the organism from a normally sterile site confirms the diagnosis.¹

SYPHILIS

The manifestations of syphilitic illness vary with the time period between infection and detection. Primary syphilis is recognized by the one or more chancres, usually on the genitalia. Secondary syphilis is identified by the presence of localized or diffuse mucocutaneous lesions. The primary chancre may still be present. Laboratory diagnosis for primary or secondary syphilis rests on demonstrating *Treponema pallidum* by dark-field microscopy, direct fluorescent antibody (DFA-TP), or equivalent method.

Latent syphilis has no clinical symptoms. The early latent period occurs in those infected within the previous 12 months, and the late latent period occurs in those infected for greater than 1 year. Persons in whom the period of infection cannot be documented and in whom there are no clinical symptoms are referred to as being latent of unknown duration. Laboratory diagnosis of latent syphilis can be made in one of the following ways: (1) no past diagnosis of syphilis and a reactive nontreponemal test (VDRL or RPR) and a reactive treponemal test (FTA-ABS or MHA-TP) or (2) history of syphilis therapy and current test titer with fourfold increase from last nontreponemal test titer.

Neurosyphilis is evident by the presence of CNS findings in the setting of a reactive serologic test for syphilis and a reactive VDRL in CSF. Late syphilis with clinical manifestations other than neurosyphilis is manifested by inflammatory lesions of the cardiovascular system, bone, and skin. Rarely, lesions of the upper or lower respiratory tracts, mouth, eye, abdominal organs, reproductive organs, lymph nodes, or skeletal muscles occur. Evidence of late syphilis is seen after more than 15 years of untreated infection.

Syphilitic stillbirth is fetal death after at least a 20-week gestation or in a fetus weighing greater than 500 g in which the mother had untreated or inadequately treated syphilis at delivery. This should be reported as congenital SVDIIIIIS.

SYPHILIS, CONGENITAL

Infection in utero with *T. pallidum* causes an illness of varying severity in children. Those under 2 years of age may present with hepatosplenomegaly, rash, condyloma lata, snuffles, jaundice (nonviral hepatitis), pseudoparalysis, anemia, or edema from nephrotic syndrome and/or malnutrition. Older children may have the stigmata of syphilis: interstitial keratitis, nerve deafness, anterior bowing of the shins, frontal bossing, mulberry molars, Hutchinson teeth, saddle nose, rhagades, or Clutton joints.

Identification of *T. pallidum* by dark-field microscopy, fluorescent antibody, or other specific stains in specimens from lesions, placenta, cord blood, or autopsy material confirms the diagnosis.

TETANUS

Tetanus has an acute onset and is characterized by hypertonia and/or painful muscular contractions typically of the muscles of the neck and jaw without other cause. Since there are no serologic tests available to confirm the suspicion of tetanus, a clinically compatible case is sufficient for diagnosis.

TOXIC SHOCK SYNDROME

Toxic shock syndrome is an illness manifested by:

1. Temperature greater than or equal to 38.8°C (102°F)
2. Diffuse macular erythroderma
3. Desquamation, particularly affecting the palms and soles, 1 to 2 weeks following onset of illness
4. Hypotension, as defined by:
 - a. Systolic blood pressure less than or equal to 90 mm Hg for adults or less than the fifth percentile by age for those persons under 16 years of age
 - b. Orthostatic decrease in diastolic blood pressure greater than or equal to 15 mm Hg from lying to sitting
 - c. Orthostatic syncope or dizziness
5. Multisystem involvement (three or more):
 - a. *Gastrointestinal*. Vomiting or diarrhea at outset
 - b. *Muscular*. Severe myalgia or creatinine phosphokinase twice the upper limit of normal
 - c. *Mucous membranes*. Vaginal, oropharyngeal, or conjunctival hyperemia
 - d. *Renal*. Blood urea nitrogen or creatinine twice the upper limit of normal or urinary sediment with pyuria in the absence of urinary tract infection
 - e. *Hepatic*. Total bilirubin, alanine transferase, or aspartate transferase twice the upper limit of normal
 - f. *Hematologic*. Platelets less than 100,000/ \times L
 - g. *Central nervous system*. Disorientation or alteration in consciousness without focal neurologic signs when fever and hypotension are absent

Although the diagnosis is primarily a clinical one, laboratory evaluation should include no rise in Rocky Mountain spotted fever, leptospirosis, or measles titers, if obtained, and negative blood, throat, and CSF cultures. Blood culture positive for *S. aureus* is not inconsistent with the diagnosis of toxic shock syndrome.

TRICHINOSIS

Trichinosis presents with variable manifestations. Most commonly a person will complain of fever, myalgia, and periorbital edema. Eosinophilia may be present on white blood cell differential. Trichinosis is caused by ingestion of *Trichinella* larvae in meat most commonly. On laboratory evaluation, *Trichinella* larvae may be found in tissue obtained by muscle biopsy, or the serologic test for *Trichinella* will be positive.

TUBERCULOSIS

Tuberculosis is a chronic infection characterized pathologically by formation of granulomas. Caused by *Mycobacterium tuberculosis*, the most common site of infection is the lungs, although other organs may be involved. The following criteria must be met for a reportable case of tuberculosis: (1) a positive tuberculin skin test, (2) other signs and symptoms compatible with tuberculosis (abnormal chest radiograph or clinical evidence of current disease), (3) treatment with two or more antituberculosis medications, and (4) completed diagnostic evaluation. Laboratory confirmation can be made by any of the following methods: (1) isolation of *M. tuberculosis* from a clinical specimen, (2) detection of *M. tuberculosis* from a clinical specimen by nucleic acid amplification test, or (3) acid-fast bacilli in a clinical specimen when culture has not or cannot be obtained.

TULAREMIA

Seven clinical forms characterize infection with *Francisella tularensis*: (1) ulceroglandular: cutaneous ulcer with regional lymphadenopathy; (2) glandular: regional lymphadenopathy without an ulcer; (3) ocularglandular: conjunctivitis with preauricular lymphadenopathy; (4) oropharyngeal: tonsillitis, stomatitis, or pharyngitis and cervical lymphadenopathy, (5) intestinal: intestinal pain, vomiting, and diarrhea; (6) pneumonic: primary pleuropulmonary disease; or (7) typhoidal: febrile illness without early localizing signs and symptoms. The presumptive laboratory diagnosis is made by detection of serum antibody titers to the organism in an individual with no history of *F. tularensis* vaccination or by detection of *F. tularensis* in a clinical specimen by fluorescent assay. Confirmatory laboratory testing is accomplished by the isolation of *F. tularensis* in a clinical specimen or by detection of a fourfold or greater change in serum antibody titer to *F. tularensis* antigen.¹

TYPHOID FEVER

The insidious onset of fever, headache, malaise, anorexia, relative bradycardia, constipation or diarrhea, and cough are characteristic of typhoid fever. Caused by the bacteria *Salmonella typhi*, typhoid fever may be relatively mild or even asymptomatic. Isolation of *S. typhi* in blood, stool, or other clinical specimen seals the diagnosis.

VARICELLA (CHICKENPOX, DEATHS ONLY)

Varicella is an illness characterized by the acute onset of diffuse maculopapulovesicular rash with no other apparent cause. Laboratory confirmation is achieved by (1) isolation of varicella virus from a clinical specimen, (2) positive direct fluorescent antibody (DFA) for the virus, (3) detection of nucleic acid by PCR, or (4) significant rise in serum IgG antibody level as detected by any standard serology. Laboratory confirmation is only recommended in the event of fatal cases or other special circumstances.

A case is considered probable if the clinical criteria are met in the absence of laboratory confirmation or epidemiologic linkage. Two epidemiologically linked probable cases are considered confirmed, as is any case meeting the laboratory confirmation requirements above.

Any case in which varicella infection contributes directly or indirectly to the patient's death should be reported. A fatal case is reported as probable if it meets the probable criteria above and as confirmed if the case meets confirmed criteria above. Nonfatal cases need not be reported.¹

YELLOW FEVER

This mosquito-borne viral illness presents with acute onset of fever, headache, myalgias, and conjunctival injection. This is followed by brief remission and recurrence of the preceding symptoms along with hepati-

tis, albuminuria, jaundice, and in some cases, renal failure, shock, and generalized hemorrhages. Laboratory diagnosis of yellow fever is made on finding (1) a fourfold or greater rise in yellow fever titer in patients with no recent history of yellow fever vaccination and in whom cross-reaction to other flaviviruses has been excluded or (2) yellow fever virus antigen or genome in tissue, blood, or other body fluids.

OCCUPATIONAL EXPOSURES, INFECTION CONTROL, AND STANDARD PRECAUTIONS Kathy J. Rinnert

This chapter examines standard precautions, routes of infectious disease exposure, and infection control practices. This discussion includes an overview of exposure management and commonly encountered occupational exposures in the ED.

OCCUPATIONAL EXPOSURES

The Centers for Disease Control and Prevention (CDC) estimates that 8 million health care workers are at risk of acquiring infections in the course of providing care for their patients.

An additional 1.2 million non-health care workers are also at risk for infectious exposure, and include those engaged in law enforcement; fire, rescue, and emergency medical services; correctional facilities; research laboratories; and the funeral industry.

The Occupational Safety and Health Administration (OSHA) defines *occupational exposure* as a "reasonably anticipated skin, eye, mucous membrane, or parenteral contact with blood or other potentially infectious materials that may result from the performance of the employee's duties."¹ Blood is defined as "human blood, blood products, or blood components."¹ *Other potentially infectious materials* (OPIM) are defined as "human body fluids, such as saliva, semen, and vaginal secretions; cerebrospinal, synovial, pleural, pericardial, peritoneal, and amniotic fluids; any body fluids visibly contaminated with blood; unfixed human tissue or organs; HIV (human immunodeficiency virus) or HBV (hepatitis B virus) containing cell or tissue cultures, culture mediums, or other solutions; and all body fluids where it is difficult or impossible to differentiate between body fluids."¹ Health care workers should treat all bodily secretions, fluids, and tissues as potentially infectious substances.

Sources of exposure for blood-borne, airborne or droplet, and contact-related pathogens are multiple and varied. Health care activities

that expose medical personnel to blood-borne diseases include placement of venous access, phlebotomy, needle recapping, specimen handling, administration of injected medications, lumbar puncture, chest tube insertion, airway suctioning, placement of nasogastric and orogastric tubes, intubation, placement of urinary catheters, and hemorrhage control. Health care activities that bring workers into close physical proximity to patients or their environment expose workers to airborne or droplet-dispersed organisms. Dressing changes, wound debridement, and wound irrigation may expose health care workers to contaminated materials or infectious agents. Workplace activities that may expose health care personnel to contact-dispersed organisms or parasites include cleaning patient care areas or equipment, changing linens, caring for incontinent and diapered patients, and physical examination. A seemingly innocuous physical examination (including integument, scalp, eyes, oropharynx, respiratory tract, and wounds) is not an activity without risk, depending on the nature of the infectious agent or exposure source.

The Hospital Infection Control Practices Advisory Committee (HICPAC) of the Centers for Disease Control and Prevention has developed a listing of selected infections and conditions that may be encountered in the ED, along with recommended occupational exposure precautions.^{2,3} While the geographic distribution and population incidence of most infectious diseases are well known, this does not imply that infectivity is limited to specific ethnic groups, races, or subsets of the population. As the world population becomes increasingly mobile, patients with geographically isolated diseases may migrate to regions where the disease incidence may be low or nonexistent. In addition, many infectious diseases display heterogeneous and varying symptom complexes, including prolonged latent or asymptomatic stages. Therefore providing care to an apparently healthy, asymptomatic patient does not preclude the possibility of disease infectivity and exposure. Since health care workers cannot readily identify those who are infected or risky, it is prudent to employ infection control practices and utilize personal protective equipment (PPE) during all patient care activities. It is on this premise that the concept of standard precautions is based.

Portals for infectious disease entry are percutaneous, mucous membrane (oral, ocular, nasal, or rectal), respiratory, and dermal.

Percutaneous exposures are the most commonly reported and pose the highest risk for the contraction of blood-borne disease. Needle sticks or cuts by sharp objects account for the majority of percutaneous injuries. Workplace activities that put personnel at risk for percutaneous injuries include phlebotomy, initiation of intravenous access, manipulation of access devices, suturing, and medication injection. Since the majority of these activities are nursing functions, it is not surprising that nurses are the most likely recipients of needle-stick injury.

Mucous membrane exposures are the second most commonly reported occupational exposure, and result from splatters, splashes, and sprays of blood and body fluids. Risk is entailed by such health care tasks as wound management (hemorrhage control, exploration, cleansing, irrigation, and debridement), airway suctioning, nasogastric or orogastric tube placement, intubation, and handling specimen containers of blood or body fluids.

Respiratory exposures result from the inhalation of airborne or droplet particulate materials. Health care workers risk respiratory exposure when they are confined with an expectorating, coughing, or sneezing patient for prolonged periods or in a poorly ventilated environment.

Dermal exposure involves skin contact with patients (direct contact) or environmental surfaces or objects that are contaminated with infectious materials (indirect contact). The risk of infection is increased if worker contact involves a large surface area or if the dermis is not intact (abraded, chapped, or excoriated). Drug-resistant organisms, such as methicillin-resistant *S. aureus* and vancomycin-resistant enterococci, pose additional dermal exposure risk. Transmission of these diseases may be related to contact with infected patients, medical equipment used on them, or both. Workplace activities that place the health care worker at risk include patient examination, turning or moving patients, and changing linens or wound dressings. Parasites of

the integument (e.g., scabies, lice, etc.) are also agents of dermal exposure. Other dermal exposures include hypersensitivity reactions of health care workers that may occur with prolonged or repeated exposure to specific inert substances (e.g., latex).

The risk of infection in an exposed health care provider depends on the route (portal) of exposure, the concentration (number of organisms) of pathogen in the infectious material, the infectious characteristics (virility) of the pathogen, the volume (dose) of infectious material, and the immunocompetence (susceptibility) of the exposed individual. Infectious characteristics may vary as the pathogen mutates, becoming resistant to treatment agents (e.g., antibiotics, antivirals, antifungals, etc.) or the host's immune defenses. The potential for infection may be incrementally higher as the route of exposure changes; that is, percutaneous exposures have greater potential for infection than do mucous membrane exposures, respiratory exposures, or dermal exposures.

LEGISLATIVE REGULATIONS

OSHA has drafted federal regulations that prescribe safeguards to protect workers and reduce risk of exposure to blood and body fluids.⁴ Updated and more detailed standards (known as the Blood Borne Pathogens Standard) were then published in Title 29 of the Code of Federal Regulations in December 1991 and amended in September 2000 by the Needlestick Safety and Prevention Act.⁵⁻⁶

The standards require health care facilities to develop programs involving five major initiatives for the mitigation of blood-borne disease transmission. These are (1) to develop a written exposure control plan, (2) to utilize engineering controls to reduce risk by removing the hazard or isolating the worker from exposure, (3) to utilize work practice controls to standardize and maximize the safety with which work tasks are performed, (4) to identify mechanisms for compliance with Title 29 standards, and (5) to communicate workplace hazards to those with potential for blood-borne disease exposures. CDC and OSHA websites should be accessed to keep abreast of future amendments and revisions of these regulations and standards.

INFECTION CONTROL

Infection control practices are designed to prevent transmission of microbial agents and to provide a wide margin of safety for health care workers. These practices include hand washing; use of PPE; cleaning, disinfecting, and sterilizing patient care equipment and environmental surfaces; decontamination and laundering of soiled uniforms, clothing, and patients' linens; disposal of needles, sharps, and infectious waste; and patient location. Infection control measures that are simple, part of the routine work environment, and uniform across all situations have the greatest likelihood of compliance.

A complete infection control program includes administrative controls, equipment engineering, work practice controls, education of the work force, and medical management.

Administrative controls are designed to organize, define, and direct infection control activities. The most important of these is the development of a written infection control (exposure) plan. This plan defines all policies, procedures, and activities related to the education, prevention, and management of infectious diseases in the work force. Jobs and specific work tasks are identified and evaluated for potential exposure to infectious diseases. Initial and recurrent training in infectious disease hazards and risk activities must be provided to all health care workers.

Equipment engineering serves to reduce employee exposure by removing the hazard or isolating the health care provider from exposure. Examples include self-sheathing needles, needleless drug administration devices, sharps containers, disposable airway equipment, syringe splash guards, and PPE. Medical safety devices may significantly mitigate occupational exposures experienced by health care personnel, and recommendations for task-specific use of these devices are shown in Table 154-1.⁷

SECTION 13 • INFECTIOUS DISEASES

TABLE 154-1 Task-Specific Recommendations for Use of Medical Safety Devices

Patient Care Activity	Self-Sheathing Needles	Needless Administration Devices	Splash Guards	Sharps Containers
Wound care, lavage	No	No	Yes	No
Venipuncture	Yes	No	No	Yes
Intravenous line placement	Yes	No	No	Yes

PPE is "specialized clothing or equipment which does not permit blood or potentially infectious substances to pass through or reach worker clothing, skin, eyes, mouth, or other mucous membranes under normal conditions of use."¹ PPE includes such items as examination gloves, face masks, eye protection, face shields, and impervious gowns, leggings, and shoe covers. PPE may significantly mitigate occupational exposures experienced by health care personnel, and recommendations for task-specific use of PPE are shown in Table 154-2.⁷

Work practice controls modify the performance of a task to minimize exposure to blood and blood-containing body fluids and infectious materials. Work practice controls necessitate the development of policies concerning disposal of needles and sharps containers (i.e., avoid shearing, bending, recapping, or breaking); disposal of contaminated linens, clothing, and infectious waste; disinfection techniques for reusable equipment; and restriction of employee activities (e.g., avoidance of eating,

drinking, smoking, and application of cosmetics) while in work areas that have a reasonable likelihood of exposure to blood and body fluids. Education of the work force should include information about the agents of infectious disease, epidemiology, methods of disease transmission, disease signs and symptoms, risky work activities, risk reduction strategies, and postexposure management. Such education must occur at initial employment, with recurrent training provided at specified intervals. Health care providers must also be aware that utilization of PPE and engineering controls does not totally eliminate infection risk. Medical management practices include preexposure preventive vaccinations, acute postexposure medical evaluation, infectious disease counseling, disease prophylaxis, and medical testing and referral. OSHA mandates preexposure vaccines at initial employee training and within 10 days of employment for all personnel at risk of exposure.⁹ The Advisory Committee on Immunization Practices (ACIP) and the

Hospital Infection Control Practices Advisory Committee (HICPAC) make specific recommendations concerning the use of certain immunizing agents in health care personnel.⁸

MANAGEMENT OF HEALTH CARE PERSONNEL POTENTIALLY EXPOSED TO HBV, HCV, OR HIV

Once an infectious exposure has occurred, a plan for postexposure prophylaxis (PEP) medical management should be available to health care providers 24 h a day. This plan should include immediate medical assessment, risk analysis, counseling, treatment and prophylaxis, and follow-up appropriate to the type and source of the exposure.^{8,11} The emergency physician, often the first to examine the exposed person and make an assessment of the relative risk of the transmission, serves an important role in managing occupational exposures.

A standardized approach to the management of exposures to blood or body fluids will ensure efficient and efficacious treatment of these incidents. An outline for general management has been developed and is shown in Table 154-3.¹⁰

The exposed person's medical record (the occupational exposure report) should contain specific information relative to the exposure incident. Key elements include the circumstances of exposure, medical history of the source person, and medical history of the exposed person. The CDC recommends specific data elements be included in the occupational exposure report (Table 154-4).⁹

Treatment of the exposure site is similar to standard wound care. Wounds and skin sites that have been exposed to potentially infectious materials should be washed with soap and water; mucous membranes should be flushed with water. The application of caustics (bleach), antiseptics, or disinfectants directly into the wound is not recommended.

The exposure event should be evaluated for the potential to transmit HBV, HCV, and HIV, based on the type of body substance involved and the route and severity of the exposure (Table 154-5).⁹ Blood, fluid containing visible blood, or OPIM (including semen, vaginal secretions, and cerebrospinal, synovial, pleural, peritoneal, pericardial, and amniotic fluids) or tissue may transmit blood-borne viruses. Exposures to these fluids through a percutaneous injury or mucous membrane contact are situations that pose a risk for virus transmission and require further evaluation. For dermal exposure, follow-up is indicated only if it involves exposure to blood or OPIM and the skin is not intact (abraded, chapped, excoriated, open wound).

Testing to determine the HBV, HCV, and HIV infection status of an exposure source should be performed as soon as possible (Table 154-6).⁹ An FDA-approved rapid HIV-antibody test should be considered. Direct viral assays (HIV p24 antigen enzyme immunoassay, HIV RNA, HCV RNA) are not recommended. If the exposure source is not

TABLE 154-3 Outline for Management of Exposures to Blood or Body Fluids

Expedite triage
Irrigate exposed areas
Obtain history regarding exposure circumstances, source patient, and vaccination history of exposed (see Table 154-4)
Obtain blood samples for laboratory studies (using consents when required)
from exposed person; obtain urine pregnancy test for women of childbearing potential
Order laboratory studies from source patient, if known
Determine need for tetanus immunization
Determine need for hepatitis B PEP (see Table 154-7)
Determine need for HIV PEP (Tables 154-8 and 154-9)
Counsel exposed person regarding risk of specific blood-borne pathogens and discuss risks/benefits of available treatment options
Review dosing and side effects of recommended treatments (see Tables 154-10, 154-11, and 154-12)
Arrange follow-up through employee health clinic or other resource

Source: Moran,¹⁰ with permission.

TABLE 154-4 Recommendations for the Contents of the Occupational Exposure Report

Date and time of exposure
Details of the procedure being performed, including where and how the exposure occurred; if related to a sharp device, the type and brand of device and how and when in the course of handling the device the exposure occurred
Details of the exposure, including the type and amount of fluid or material and the severity of the exposure (e.g., for a percutaneous exposure, depth of injury and whether fluid was injected; for a skin or mucous membrane exposure, the estimated volume of material and the condition of the skin [e.g., chapped, abraded, intact])
Details about the exposure source (e.g., whether the source material contained HBV, HCV, or HIV; if the source is HIV-infected, the stage of disease, history of antiretroviral therapy, viral load, and antiretroviral resistance information, if known)
Details about the exposed person (e.g., hepatitis B vaccination and vaccine-response status)
Details about counseling, postexposure management, and follow-up

Source: From CDC.⁹

known, epidemiologic data should be used to determine the exposure risk. Testing of needles or sharps instruments is not recommended as reliability is suspect. If the source is known to have HIV information about the state of the infection (CD4⁺ T-cell count, and viral load, current and previous antiretroviral therapy) may guide the choice of an appropriate PEP regimen. If this information is not immediately known, the initiation of PEP should not be delayed, as changes in the regimen may be made on follow-up (within 72 h postexposure).⁹

Factors to consider in the management of HBV exposure include the hepatitis B surface antigen (HBsAg) status of the source and the hepatitis B vaccination and vaccine response status of the exposed person. Every unvaccinated health care worker who has been exposed to blood or body fluids should receive the hepatitis B vaccine series. Summary recommendations for the percutaneous or mucosal exposure to blood according to the HBsAg status of the exposure source and the vaccination/vaccine-response status of the exposed person is shown in Table 154-7.⁹ Hepatitis B immune globulin (HBIG), when indicated, should be administered as soon as possible after the exposure (ideally within 24 h). After a period of 7 days, the effectiveness of HBIG is unknown. When hepatitis B vaccine is indicated, it should be given as soon as possible.

For occupational HCV exposures the CDC recommends anti-HCV testing of the source patient. The exposed person should be tested for

TABLE 154-5 Factors to Consider in Assessing the Need for Follow-Up of Occupational Exposures

Type of exposure
Percutaneous injury
Mucous membrane exposure
Nonintact skin exposure
Bites resulting in blood exposure to either person involved
Type and amount of fluid/tissue
Blood
Fluids containing blood
Potentially infectious fluid or tissue (semen; vaginal secretions; and cerebrospinal, synovial, pleural, peritoneal, pericardial, and amniotic fluids)
Direct contact with concentrated virus
Infectious status of source
Presence of HBsAg
Presence of HCV antibody
Presence of HIV antibody
Susceptibility of exposed person
Hepatitis B vaccine and vaccine response status
HBV, HCV and HIV immune status

TABLE 154-6 Evaluation of Occupational Exposure Sources**Known sources**

Test known sources for HBsAg, anti-HCV, and HIV antibody

- Direct virus assays for routine screening of source patients are *not* recommended
- Consider using a rapid HIV-antibody test
- If the source person is *not* infected with a blood-borne pathogen, baseline testing or further follow-up of the exposed person is *not* necessary

For sources whose infection status remains unknown (e.g., the source person refuses testing), consider medical diagnoses, clinical symptoms, and history of risk behaviors

Do not test discarded needles for blood-borne pathogens

Unknown sources

For unknown sources, evaluate the likelihood of exposure to a source at high risk for infection

- Consider likelihood of blood-borne pathogen infection among patients in the exposure setting

Source: From CDC.⁹

anti-HCV and alanine aminotransferase (ALT) at baseline and follow-up (at 4 to 6 months). Testing for HCV RNA may also be performed at 4 to 6 weeks if earlier diagnosis of HCV is desired. All positive anti-HCV tests by enzyme immunoassay (EIA) should be confirmed by supplemental testing (i.e., recombinant immunoblot assay [RIBA]). Immunoglobulin (IG) and antivirals are not recommended for PEP after exposure to HCV-positive blood. Medical personnel exposed to HBV- or HCV-infected blood do not need to take any precautions to prevent secondary transmission during the follow-up period; however, they should not donate blood, plasma, organs, tissue, or semen.

Health care personnel potentially exposed to HIV should receive expedited evaluation (ideally in less than 1 h) and should be tested for HIV at baseline. If the source patient is HIV-negative, baseline testing or further follow-up for the exposed person is not normally necessary. Factors to consider in the management of HIV exposure include the type of exposure (percutaneous, mucous membrane, or dermal),

the volume of the exposure (small or large), and the HIV status of the source patient. The CDC provides detailed recommendations concerning PEP for percutaneous, mucous membrane, and nonintact skin exposures (Tables 154-8 and 154-9).⁹ These recommendations apply to situations when a person has been exposed to a source person with HIV infection or when information suggests the likelihood that the source is HIV-infected. PEP should be initiated as soon as possible; if later testing determines the source patient to be HIV-negative, PEP should be discontinued. PEP is substantially less effective if started more than 24 to 36 h postexposure, although the interval after which no benefit is gained is not known. Therefore, PEP should be started even when the postexposure interval exceeds 36 h. In addition, the optimal duration of PEP is unknown; the CDC recommends 4 weeks.

In an effort to balance the substantial risk of PEP toxicity (over 50 percent of those who initiate PEP discontinue treatment due to side effects), and with the negligible risk of HIV infection even when exposed to HIV-positive blood, the CDC has developed two drug regimens for PEP. The basic two-drug regimen is appropriate for most HIV exposures. The expanded three-drug regimen is used for those exposures determined to be an increased risk for transmission. Recommended drug regimens and dosing information for the basic and expanded HIV PEP regimens are shown in Tables 154-10 and 154-11.¹² Since HIV PEP may cause a number of side effects (Table 154-12),¹⁰ patients should be closely monitored at baseline and at 2 weeks with blood cell counts and renal and hepatic tests. HIV-antibody testing should be performed for at least 6 months postexposure. Exposed health care personnel should be advised to use the following measures to prevent secondary transmission during the follow-up period (6 to 12 months): exercise sexual abstinence or use condoms; refrain from donating blood, plasma, organs, tissue, or semen; and avoid breastfeeding. Exposed workers should be advised to seek medical evaluation for any acute illness which occurs during the follow-up period, as this may signal the onset of acute retroviral syndrome.

The postexposure management for occupational exposures is complex due to the variable circumstances of the exposure (route, body

TABLE 154-7 Recommended PEP for Percutaneous and Mucous Membrane Exposure to HBV

Vaccination and Antibody Response Status of Exposed Workers*	TREATMENT		
	Source HBsAg Positive	Source HBsAg Negative	Source Unknown or Not Available for Testing
Unvaccinated	HBIG ^J X 1 and initiate HB vaccine series [#]	Initiate HB vaccine series	Initiate HB vaccine series
Previously vaccinated Known responder [§] Known nonresponder*	No treatment HBIG X 1 and initiate revaccination or HBIG X 2 ^{tt}	No treatment No treatment	No treatment If known high-risk source, treat as if source were HBsAg positive Test exposed person for anti-HBs
Antibody response unknown	Test exposed person for anti-HBsH 1. If adequate, § no treatment is necessary 2. If inadequate,** administer HBIG X 1 and vaccine booster	No treatment	1. If adequate,§ no treatment is necessary 2. If inadequate,** administer vaccine booster and recheck titer in 1-2 months

*Persons who have previously been infected with HBV are immune to reinfection and do not require postexposure prophylaxis.

tHepatitis B surface antigen.

JHepatitis B immune globulin; dose is 0.06 mL/kg IM.

#Hepatitis B vaccine.

§A responder is a person with adequate levels of serum antibody to HBsAg (i.e., anti-HBs 2:10 mIU/mL).

**A nonresponder is a person with inadequate response to vaccination (i.e., serum anti-HBs <10 mIU/mL).

ttThe option of giving one dose of HBIG and reinitiating the vaccine series is preferred for nonresponders who have not completed a second 3-dose vaccine series. For persons who previously completed a second vaccine series but failed to respond, two doses of HBIG are preferred.

substance involved, volume of infectious material, etc.), health status of the exposed person (previous immunizations, comorbid conditions, immunocompetence, nature of the exposure site), health status of the source person (previous immunizations, comorbid conditions, immunocompetence, current and past therapies for infectious diseases, etc.), and recommendations for treatment and prophylaxis given the current understanding of the optimal therapies (immunomodulators, vaccinations, antibiotics/antivirals, etc.). Since CDC guidelines for managing these complex cases are constantly evolving, optimal case management can be extremely difficult.

To address these issues and facilitate care, the CDC offers three resources. The National Clinician's Post-Exposure Prophylaxis Hotline (PEpline) offers 24-h telephone consultation for physicians managing occupational exposures to blood-borne pathogens. Expert clinicians from the University of California-San Francisco and San Francisco General Hospital provide immediate, confidential, and free consultation (1-888-448-4911, www.ucsf.edu/hivcntr). The service is intended primarily for cases that represent a management challenge, such as delayed (over 24 to 36 h) reporting of exposure, unknown source, pregnancy in the exposed patient, suspected resistance of the source virus, and toxicity of the initial PEP regimen.⁹ A second source of information developed and maintained by the University of California-Los Angeles, is Needlestick! (www.needlestick.mednet.ucla.edu). This interactive, Web-based, electronic medical record is intended to assist emergency physicians with the management of occupational exposures. The physician anonymously and confidentially enters relevant data and the program uses contingency tables and current CDC guidelines to provide advice regarding testing and treatment. The Hepatitis Hotline provides guidance to clinicians in regard to the acute and chronic management of hepatitis (1-888-443-7232, www.cdc.gov/hepatitis).

INFECTION PRECAUTIONS

In 1985, the CDC first introduced the concept of universal blood and body fluid precautions. The focus of these "universal" precautions centered on blood and blood-containing fluids (substances implicated in the transmission of blood-borne pathogens) with inadequate attention to infections transmitted by airborne/respiratory droplet or direct/indirect contact.

In 1996, the CDC's Hospital Infection Control Practices Advisory Committee (HICPAC) devised a new system of isolation precautions.

TABLE 154-11 Expanded HIV Postexposure Prophylaxis (PEP) Regimens

<i>Expanded Regimen</i>
Basic two-drug regimen plus <i>ONE</i> of following:
Indinavir (800 mg every 8 h on an empty stomach)
Nelfinavir (750 mg tid with food or 1250 mg bid with food)
Efavirenz (600 mg daily, at bedtime)
Abacavir (300 mg bid)

The new guidelines contain two tiers of precautions: standard and transmission-based. Standard precautions assume a broad approach to health care and patient protection, by including agents transmitted by routes other than blood. Transmission-based precautions are designed for patients with documented or suspected transmissible pathogens for which additional protection beyond standard precautions is required. Transmission-based precautions are of three types: airborne, droplet, and contact. These precautions are to be utilized in addition to, not in place of, standard precautions.^{2,3}

Standard Precautions

Standard precautions are exercised when caring for *all* patients, and include hand washing, gloves, mask and eye protection or face shield, gowns, handling of patient care equipment and linens, environmental controls, workplace controls, and patient location or placement.

Hand washing is performed after touching blood, body fluids, secretions, excretions, and contaminated items *even if gloves are worn*. Hands should be washed immediately after gloves are removed, between patient contacts, and when otherwise indicated to avoid the transfer of organisms to other patients or environments. It may be necessary to wash hands between procedures on the same patient to prevent cross-contamination of various body sites. Plain soap and water are recommended for routine use. Washing with an antimicrobial agent or waterless antiseptic may be utilized for control of outbreaks or hyperendemic infections.

Clean, nonsterile gloves are used when touching blood, body fluids, secretions, excretions, and contaminated items. Clean gloves should also be utilized when touching nonintact skin and mucous membranes. Gloves should be changed between tasks and procedures following contact with material that may contain a high concentration of microorganisms. Gloves should be removed and hands washed before touching noncontaminated items, environmental surfaces (phones, light switches, writing implements, etc.), or other patients.

Face masks, eye protection, and face shields that are fluid resistant are worn to protect mucous membranes of the eyes, nose, and mouth during patient care activities and the performance of procedures likely to generate splashes or sprays of blood, body fluids, secretions, excretions, and infectious materials. Masks that become significantly soiled, moistened by the user's exhaled vapor, or contaminated by fluids are immediately replaced, since loss of protective function occurs if the barrier device is completely saturated.

Clean, nonsterile gowns that are fluid resistant are used to protect the worker's skin and clothing during patient care activities and the performance of activities likely to generate splashes or sprays of blood, body fluids, secretions, and excretions. Soiled gowns should be replaced as soon as possible, since barrier protection is lost if the garment is saturated with contamination. Sleeve protectors, booties, and leggings should be used if a large volume of contamination or infectious material that is difficult to contain is anticipated.

Patient care equipment and linens soiled with blood, body fluids, secretions, and excretions should be handled so as to prevent skin and mucous membrane exposure, contamination of clothing, and transfer of microorganisms to other patients and environments. Reusable items should be cleaned and reprocessed to eliminate infectivity. Single-use items should be promptly discarded.

Environmental controls relate to hospital procedures for the decontamination of objects in patient care areas. Environmental surfaces, beds, bed rails, bedside equipment, and frequently touched surfaces should be cleaned and disinfected between patient uses.

Workplace controls (work practice controls) include proper disposal of needles, scalpels, and other sharp instruments. Workers should avoid recapping, excessive handling, and manipulation of sharp devices. Disposal should emphasize the use of self-sheathing devices, use of puncture-resistant containers, and replacement of sharps containers prior to overflowing. Patients who contaminate the environment or those who cannot assist in their own hygiene should be located in a private room if available.

Airborne Precautions

In addition to standard precautions, airborne precautions are utilized for patients known to be or suspected of being infected with microorganisms transmitted by airborne droplet nuclei. Airborne precautions also apply to small particle residue (5 μm or smaller) of evaporated droplets containing microorganisms that remain suspended in the air and can be dispersed widely by air currents over a long distance. Examples of infectious agents spread by this method are found in Table 154-13.

The placement of patients in the ED requires a room with (1) monitored negative air pressure in relation to surrounding areas, (2) 6 to 12 air changes per hour, and (3) discharge of the room air to the outdoors or high-efficiency filtration of the air before it is circulated to other areas in the hospital. The door to the patient's room must be kept closed, and the patient must remain in the room. Movement and transportation of the patient should be limited. If movement is unavoidable, the patient should wear respiratory protection to avoid contamination of other areas within the hospital. Health care providers entering the room must wear respiratory protection, such as a personalized, fitted mask with efficient filters (approved particulate respirator).

Droplet Precautions

In addition to standard precautions, droplet precautions are employed for patients known to have or suspected of having serious illnesses

TABLE 154-13 Airborne-Spread Infectious Diseases

Rubeola (measles)
Varicella (including disseminated zoster)
Tuberculosis

Source: Modified from CDC.²

transmitted by large particle droplets (>5 μm in size) that can be generated by the patient during talking, sneezing, or coughing or during the performance of procedures. Examples of infectious agents spread by this method are listed in Table 154-14.²

Patients should be placed in a private room. Special air handling and ventilation are not required, and the door may remain open. If a private room is not available, the patient may be placed in a room with other patients who have active infections with the same microorganism (i.e., cohorting). When this is not possible, maintain spatial separation of at least 3 ft between the infected patient and other patients and visitors. Patient transportation should be limited. Patients who must be moved for testing and procedures should don face masks to minimize the dispersal of droplets. Health care personnel should wear face masks when working within 3 ft of the patient.

Contact Precautions

In addition to standard precautions, contact precautions should be utilized with patients known to have or suspected of having serious illnesses easily transmitted by direct patient contact or by contact with items in the patient's environment. Examples of such infectious diseases are shown in Table 154-15.²

If the examination and care of a patient result in contact with infective materials and a high concentration of microorganisms (wound drainage or fecal material), changing of gloves is required. Hand washing with an antimicrobial agent or waterless antiseptic is required after removal of gloves. After glove removal and hand washing, workers should avoid contact with potentially contaminated environmental surfaces or items in the patient's room.

Upon entering the patient's room, a clean, nonsterile gown should be worn if one anticipates substantial contact with the patient or if the patient is incontinent or has diarrhea, a colostomy, an ileostomy, or wound drainage not contained by dressings. The gown should be removed prior to leaving the patient's room, and care should be taken to avoid contact with potentially contaminated environmental surfaces.

Transportation and movement should be limited. If the patient must be moved, one should ensure that contamination spread is minimized by large, bulky dressings. Bulky, adsorbent, leak-proof dressings are utilized to contain contaminated secretions and therefore limit spread of disease.

Durable, multiuse medical equipment (e.g., blood pressure cuffs, stethoscopes, bedside commodes, etc.) should be dedicated to a single patient (or cohort of similarly infected patients) to avoid sharing between noninfected patients. Personnel who use personal medical equipment (e.g., stethoscopes) should thoroughly clean these items between using them on different patients if the possibility of contamination exists.

COMMON OCCUPATIONAL EXPOSURES

Hepatitis

Viral hepatitis represents a group of infections that produce a large burden of disease in the United States, and is most commonly caused by one of five different viruses (known as hepatitis A, B, C, D, and E).

Hepatitis A and E are transmitted by the fecal-oral route and can cause extensive single-source outbreaks of disease. These viruses do not cause persistent infection, nor have they been identified as the causative agents of chronic viral hepatitis. In contrast, hepatitis B, C, and D are transmitted by several routes, including virus shed from mucous membranes or by percutaneous exposure. Each of these may cause persistent infection, and have been identified as etiologic agents in chronic viral hepatitis and cirrhosis. Persistent infections caused by HBV and HCV may ultimately result in the development of primary hepatocellular carcinoma. Hepatitis A and B can be prevented by vaccination.

Hepatitis A virus (HAV), a single-strand RNA picornavirus, is worldwide in its distribution, with the highest prevalence of infection in geographical regions with substandard water and sanitation. Occupationally acquired HAV is primarily contracted via the fecal-oral route, by either person-to-person contact or via ingestion of contaminated food or water. Rarely has HAV been transmitted by the transfusion of blood or blood products. Since HAV is associated with a substantial viremia that may persist for several weeks, percutaneous transmission of the virus is possible if health care workers receive a blood or body fluid exposure from a patient in the prodromal phase.

Passive immunity to HAV is conferred by intramuscular injection of immunoglobulin (IG). Preexposure administration of IG (0.02 mL/kg IM) confers protection for 1 to 2 months, while a higher dose (0.06 mL/kg IM) confers protection for 3 to 5 months. Postexposure use of IG (0.02 mL/kg IM) is more than 85 percent effective in preventing hepatitis, with greatest efficacy seen when it is administered early in the incubation period. Active immunity to HAV is conferred by two highly effective, formalin-inactivated vaccines currently licensed in the United States; Havrix (SmithKline Beecham) and Vaqta (Merck & Co., Inc.).¹³ Primary vaccination consists of two doses, given at 0 and 6 to 12 months. Dosage differs depending on the age of the recipient, as well as the type and formulation of the vaccine being

administered. Both Havrix and Vaqta are licensed in two formulations, pediatric and adult. Health care personnel should always follow the manufacturer's dosage recommendations. Protective antibody levels develop in 94 to 100 percent of adults 1 month after the initial dose. All healthy persons exhibit protective levels of antibodies following the second dose.¹³ Other preventive measures for health care providers include the use of standard precautions, with the addition of contact precautions when caring for patients who are incontinent or diapered. Acute postexposure medical examination, counseling, risk/benefit analysis, treatment (IG and HAV vaccine), and follow-up are required for exposed health care personnel.

HBV is a partially double-strand, circular DNA hepadnavirus with worldwide distribution. HBV is an established cause of acute and chronic hepatitis and cirrhosis, and is the cause of up to 80 percent of hepatocellular carcinomas. The virus is occupationally transmitted by parenteral or mucosal exposure to virus-containing blood or body fluids. The rate of HBV transmission to susceptible health care workers ranges from 6 to 30 percent after a single needlestick exposure to an HBV-positive patient.⁹

Passive immunity to HBV is available using HBIG, which is prepared from human plasma known to contain a high titer of antibody to the HBV surface antigen (anti-HBs). In the occupational setting, multiple doses of HBIG (0.06 mL/kg IM) initiated within 1 week following percutaneous exposure to HBsAg-positive blood provides an estimated 75 percent protection from HBV infection. Highest efficacy is found when HBIG is administered within 12 h of exposure. The efficacy of combination treatment with HBIG and the hepatitis B vaccine series has not been studied in the occupational setting. The combination of HBIG and HBV vaccine, as opposed to immunoglobulin or vaccine alone, conferred increased efficacy in the perinatal setting (70 to 75 percent vs. 85 to 95 percent), and is presumed to apply to occupational exposures as well.⁹ Active immunity to HBV is conferred by two highly effective, recombinant vaccines commercially available in the United States; Engerix-B (SmithKline Beecham) and Recombivax HB (Merck & Co., Inc.). Primary vaccination consists of three doses, given on a 0-, 1-, and 6-month schedule. Dosage differs depending on the age of the recipient, as well as the type and formulation of the vaccine being administered. Both Engerix-B and Recombivax HB are licensed in two formulations, pediatric and adult. Health care personnel should always follow the manufacturer's dosage recommendations. Protective antibody levels develop in over 90 percent of healthy adults. A combined hepatitis A and B vaccine, Twinrix (SmithKline Beecham) is made of the antigenic components used in Havrix and Engerix-B. Primary vaccination consists of three doses, given on a 0-, 1-, and 6-month schedule, similar to that used for single antigen hepatitis B vaccines. The utility of this combination vaccine in the setting of occupational exposures is unknown. Other HBV preventive measures for health care providers include the use of standard precautions. Acute postexposure medical examination, counseling, risk/benefit analysis, treatment (HBIG and HBV vaccine), and follow-up are required for exposed health care personnel.

Hepatitis C virus (HCV) is an enveloped, single-strand RNA flavivirus. HCV is the most common chronic blood-borne infection in the United States and a major cause of chronic liver disease worldwide. Chronic hepatitis develops in approximately 60 to 70 percent of HCV-infected patients and may progress to cirrhosis (10 to 20 percent) and hepatocellular carcinoma (1 to 5 percent).¹⁴ The most common and efficient route of HCV transmission is parenteral. The average incidence of anti-HCV seroconversion after unintentional needle sticks or sharps exposure from an HCV-positive source is 1.8 percent (range, 0 to 7 percent).¹⁴

Neither IG nor antiviral therapy (interferon or rifampin) is recommended as postexposure prophylaxis. No vaccine currently exists to prevent HCV. Preventive measures must focus on limiting exposure risk via standard precautions. Acute postexposure medical examina-

tion, counseling, and follow-up disease monitoring are required for exposed health care personnel.

Hepatitis D virus (HDV) is a single-strand, circular RNA virus. The genome of HDV is contained within an envelope provided by HBV and HBV surface proteins are required for HDV viral assembly. HDV infection can occur simultaneously with HBV infection (coinfection) or as a superinfection of patients with chronic HBV infection. Occupational transmission is primarily by parenteral contact with blood.

Prevention of HDV depends on prevention of HBV infection (immunization) and reducing exposure to blood and body fluids. No vaccine for HDV currently exists. Preventive measures for health care providers include the use of standard precautions. Acute postexposure medical examination, counseling, risk/benefit analysis, treatment (HBIG and HBV vaccine), and follow-up are required for exposed health care personnel.

Hepatitis E virus (HEV) is a nonenveloped, single-strand RNA calicivirus. HEV is the major etiologic agent of enterically transmitted non-A, non-B hepatitis worldwide. The virus is endemic and epidemic in developing countries that lack the infrastructure to ensure adequate sanitation and water purification. HEV is spread primarily by the fecal-oral route.

No vaccine for HEV currently exists. Preventive measures for health care providers include the use of standard precautions, with the addition of contact precautions when caring for patients who are incontinent. Acute postexposure medical examination, counseling, and follow-up are required for exposed health care personnel.

Human Immunodeficiency Virus

HIV is a lentivirus with an enveloped genome of two identical, single-strand RNA molecules. There are two types of human lentiviruses: HIV-1, the predominant HIV type in most parts of the world, and HIV-2, primarily found in West Africa. The capacity of HIV to recombine and generate mosaic genotypes confounds treatment efforts and vaccine development. The virus mutates at varying rates over time in various individuals, and data suggest that the host's ongoing immune response is a driving force for genetic variation.

Occupational exposure occurs with percutaneous, mucous membrane, or dermal exposure to HIV-infected blood or body fluids. The average risk of HIV transmission after a percutaneous exposure to HIV-infected blood is approximately 0.3 percent.⁹ Risk of infection after percutaneous injury is increased for deep injury, injury by a device previously placed in the source patient's artery or vein, visible blood on the device causing the injury, and death of the source patient as a result of AIDS within 60 days postexposure. The risks of acquiring HIV after mucous membrane and nonintact skin exposure to HIV-infected blood are approximately 0.09 percent and less than 0.09 percent respectively.⁹ Risk of infection after mucous membrane or dermal exposure is increased for large-volume exposures or those involving mucous membranes or skin which has lost its integrity. Chemoprophylaxis should be recommended to exposed workers after occupational exposures associated with highest risk for HIV transmission. The U.S. Public Health Service regularly updates and publishes guidelines relating to postexposure prophylaxis for health care workers exposed to blood-borne pathogens including HIV, HBV, and HCV. Detailed recommendations are discussed earlier in this chapter and in Tables 154-3 through 154-12.

If warranted, chemoprophylaxis should begin as soon as possible after the exposure, ideally within 1 to 2 h. Animal studies show that antivirals are less effective if initiated more than 24 to 36 h after the exposure event.⁹ No vaccine currently exists to prevent HIV infection. A large consortium of public health agencies and academic institutions including the World Health Organization (WHO), Joint United Nations Program on HIV/AIDS (UNAIDS), International AIDS Vaccine Initiative (IAVI), U. S. National Institutes of Health (NIH), and the Centers for Disease Control and Prevention (CDC) have been working

to develop an HIV vaccine. A number of experimental vaccines are currently undergoing phase II and III clinical trials.¹⁵

HIV preventive measures for health care providers include the use of standard precautions. Acute postexposure medical examination,⁹ counseling,¹¹ risk/benefit analysis, treatment (basic or expanded PEP regimen), and follow-up are required for exposed health care personnel.

Tuberculosis

Four subspecies of mycobacteria exist, each of which can cause tubercular disease: *Mycobacterium africanum*, *Mycobacterium bovis*, *Mycobacterium microti*, and *Mycobacterium tuberculosis*. *Mycobacterium tuberculosis* is the primary cause of TB in humans.

Transmission of TB occurs through inhalation of aerosolized bacilli. As few as 1 to 10 bacilli can cause infection, but only about 20 percent of exposed individuals become infected.

Preventive measures include environmental controls (rooms with negative-pressure ventilation and ultraviolet radiation) in health care settings, application of directly observed therapy, and vaccine development. Occupational exposures for health care providers can be mitigated through use of standard and airborne precautions. These measures include the routine use of National Institute for Occupational Safety and Health (NIOSH)-approved particulate filtration respirator (PFR) masks during patient encounters at risk for TB. The most effective control measure is curative treatment of patients with infectious pulmonary TB. While bacille Calmette-Guerin (BCG) vaccine is the most widely administered of all vaccines worldwide, questions regarding its efficacy and its tendency to cause a dermal hypersensitivity reaction to purified protein derivative (PPD) has precluded its use in the United States. The CDC has advocated preventive chemotherapy (antibiotics) and vaccine development for those at risk for developing active TB; however, research does not currently support these measures.¹⁶ Routine annual or semiannual PPD testing or chest x-rays may be warranted if personnel work in high-risk environments.

Measles

Rubeola, or measles, is an acute viral illness caused by a single-strand RNA paramyxovirus. Worldwide, measles is the most common vaccine-preventable cause of death among children. Obstacles to measles eradication in the United States include increasing numbers of susceptible children and infants who are not immunized, and circulation of measles virus from other geographic regions of the world.

Transmission of measles is primarily person-to-person via large respiratory droplets. Airborne transmission via aerosolized droplet nuclei has been documented in closed areas. While isolation of patients is the mainstay of outbreak control, this mechanism is not effective in preventing subsequent cases. Primary prevention by immunization is preferred.

Measles vaccine is available in monovalent form as Attenuvax (Merck & Co., Inc.). Combination vaccines include measles-mumps-rubella (MMR) (M-M-R-II, Merck & Co., Inc.) and measles-rubella (MR) (M-R-Vax, Merck & Co., Inc.). All vaccines are highly effective and are administered subcutaneously in a 2-dose schedule, with the second administration occurring at least 1 month after the initial dose. Health care personnel should always follow manufacturer's dosage recommendations. According to the ACIP, MMR is the vaccine of choice when protection against any of the three diseases is required, unless any of its component vaccines is contraindicated.

Adults who may be at increased risk for exposure to and transmission of measles (including persons who work in health care facilities) should be considered for vaccination. For postexposure prophylaxis, measles vaccine provides permanent protection and may prevent disease if given within 72 h of exposure. This route of prophylaxis is preferable to using immune globulin. Immunoglobulin (IG) may prevent or modify disease if given within 6 days of exposure. Any immunity conferred by IG is temporary.¹⁷ Preventive measures for health

care providers include use of standard and airborne precautions, as well as vaccination if immunization status is unclear.

Mumps

Mumps is an acute viral illness caused by a single-strand RNA paramyxovirus. Humans are the only known host.

Transmission of mumps occurs through airborne transmission or direct contact with infected droplet nuclei or saliva.

While isolation of patients is the mainstay of outbreak control, this mechanism is not effective in preventing subsequent cases. Primary prevention by immunization is preferred. Mumps vaccine is available in monovalent form as Mumpsax (Merck & Co., Inc.). Combination vaccines include measles-mumps-rubella (MMR) (M-M-R-II, Merck & Co., Inc.) and rubella-mumps (Biavax II, Merck Co., Inc.). All vaccines are highly effective and are administered subcutaneously in a 2-dose schedule, with the second administration occurring at least 1 month after the initial dose. Health care personnel should always follow the manufacturer's dosage recommendations. According to the ACIP, MMR is the vaccine of choice when protection against any of the three diseases is required, unless any of its component vaccines is contraindicated.

Adults who may be at increased risk for exposure to and transmission of mumps (including persons who work in health care facilities) should be considered for vaccination. For postexposure prophylaxis, neither mumps immune globulin nor IG is effective and they are not recommended for that use.¹⁷ Mumps vaccine after exposure is not harmful and may provide protection against subsequent exposures. Preventive measures for health care providers include use of standard and droplet precautions, as well as vaccination if immunization status is unclear.

Rubella

Rubella, or German measles, is an exanthematous viral illness caused by an enveloped RNA togavirus. Some of the most important consequences of rubella are miscarriages, stillbirths, fetal anomalies, and therapeutic abortions that result when rubella infection occurs during early pregnancy.

Transmission of rubella is due to person-to-person spread via airborne transmission or droplets shed from the respiratory secretions of infected persons. While isolation of patients is the mainstay of outbreak control, this mechanism is not effective in preventing subsequent cases. Primary prevention by immunization is preferred.

Rubella vaccine is available in monovalent form as Meruvax (Merck & Co., Inc.). Combination vaccines include measles-mumps-rubella (MMR) (M-M-R-II, Merck & Co., Inc.), measles-rubella (MR) (M-R-Vax, Merck & Co., Inc.), and rubella-mumps (Biavax, Merck & Co., Inc.). All vaccines are highly effective and are administered subcutaneously in a 2-dose schedule, with the second administration occurring at least 1 month after the initial dose. Health care personnel should always follow the manufacturer's dosage recommendations. According to the ACIP, MMR is the vaccine of choice when protection against any of the three diseases is required, unless any of its component vaccines is contraindicated.

Adults who may be at increased risk for exposure to and transmission of rubella (including persons who work in health care facilities) should be considered for vaccination. For postexposure prophylaxis, neither rubella vaccine nor IG is effective.¹⁷ Vaccination after exposure is not harmful and may possibly avert later disease. Preventive measures for health care providers include use of standard and droplet precautions, as well as vaccination if immunization status is unclear.

Varicella and Herpes Zoster

Varicella zoster virus (VZV) is a double-strand DNA herpes virus. Primary infection with VZV results in varicella (chickenpox). Herpes

zoster (shingles) is the result of recurrent VZV infection. Chickenpox is highly contagious and poses a serious nosocomial and occupational infection risk.

Transmission of VZV occurs person-to-person from infected respiratory tract secretions. Transmission may also occur by direct contact or inhalation of aerosols from vesicular fluid of skin lesions of acute varicella or zoster.

When administered within 96 h of exposure, varicella zoster immunoglobulin (VZIG) may modify or prevent clinical varicella and complications. VZIG is indicated for use in susceptible individuals at risk for complications who have had significant exposure (prolonged direct contact). Of note, VZIG provides temporary protection and should be given as soon as possible after the exposure. Susceptible workers with significant exposure should be furloughed from work from days 10 to 21 postexposure. Receipt of VZIG does not change this recommendation.

Active immunity is provided by the VZV vaccine Oka (Merck & Co., Inc.). The vaccine is administered subcutaneously in a 2-dose schedule, with the second dose given 4 to 8 weeks after the initial dose. Health care personnel should always follow the manufacturer's dosage recommendations. Postexposure use of varicella vaccine may prevent infection.¹⁸ Preventive measures for health care providers include use of standard, airborne, and contact precautions, as well as vaccination if immunization status is unclear. Medical providers who are susceptible to varicella should avoid infected patients if immune caregivers are available.

Influenza

Influenza is a highly infectious viral illness caused by a single-strand RNA orthomyxovirus. Influenza A and B are the two types of influenza virus that cause epidemic human disease. Peak influenza activity levels are found in temperate climates between late December and early March.

Influenza virus is transmitted via aerosolized or droplet transmission from the respiratory tract of infected persons. A less important mode of transmission of droplets is by direct contact.

Two measures are available to reduce the impact of influenza: immunoprophylaxis with inactivated (killed virus) vaccine, and chemoprophylaxis with influenza-specific antiviral agents. Antiviral agents for influenza are an adjunct to vaccine and are not a substitute for vaccine. A trivalent vaccine is prepared on an annual basis (typically two strains of influenza A, one strain of influenza B) representing the influenza viruses likely to circulate in the upcoming winter. Immunity following vaccination rarely exceeds 1 year. Vaccine efficacy varies depending on the age and immunocompetence of the vaccine recipient and the degree of similarity between the viruses in the vaccine and those in circulation. The vaccine is most effective if administration precedes exposure by no more than 2 to 4 months. Health care providers should receive annual vaccination, ideally in October. One dose of the vaccine is administered by the intramuscular route. Health care personnel should always follow the manufacturer's dosage recommendations. Intranasally administered, live, attenuated influenza virus vaccines (LAIVs) are under development in the United States. Monovalent, bivalent, and trivalent formulations have been studied. An application for FDA licensure is under review.

Four antiviral agents are approved for preventing or treating influenza. Dosage recommendations and duration of administration vary by age group and medical conditions. Amantadine and rimantadine are FDA approved for both prophylaxis and treatment of influenza type A in persons 1 year of age and older. Both agents come as oral formulations (tablets, capsules, and syrup). Zanamivir (available as an inhaled powder) is approved for treatment of influenza A or B in persons 7 years of age and older who have been symptomatic for no more than 2 days. Zanamivir is not approved for prophylaxis. Oseltamivir (available as a tablet), is approved for the treatment of influenza A and B in

persons 1 year of age and older who have been symptomatic for no more than 2 days. This agent is approved for prophylaxis of influenza infection among persons 13 years of age and older.¹⁹ Additional preventive measures include use of standard, airborne, and contact precautions.

Scabies

Scabies is a highly contagious, pruritic skin disorder caused by an arachnid, *Sarcoptes scabiei* var. *hominis*. The human scabies mite is endemic in many developing countries, where the prevalence ranges from 20 to 100 percent.

Human scabies is transmitted primarily by direct personal contact with infected individuals. Although less common, transmission may also occur by contact with contaminated bedding and clothing. The mite has been found to survive for 2 to 3 days on inanimate objects. The scabies mite is motionless at room temperature and lacks the ability to jump or fly from person to person.

The average person infected with scabies harbors 10 to 15 live adult female mites at any given time. Patients with crusted (Norwegian) scabies, an atypical form of scabies, harbor mite populations in the thousands to millions. This form is often seen in physically or mentally handicapped, immunocompromised, or institutionalized persons. Some sources advise testing patients who exhibit crusted scabies for HIV. Preventive measures for health care providers include use of standard and contact precautions in patients with pruritic eruptions.

Pediculosis

Pediculosis is a dermal infestation caused by a parasitic insect (louse). Infestations in various body regions (e.g., head, thorax, and groin) are caused by the head louse (*Pediculus humanus capitis*), the body louse (*Pediculus humanus corporis*), and the crab louse (*Phthirus pubis*). Adult lice are about the size of a sesame seed and can live for up to 30 days on an infested individual. Adult forms also feed on blood and may survive up to 2 days on inanimate objects.

Lice are transmitted by direct contact with infected individuals or common use of infected bedding, clothing, or combs, brushes, or headgear. Prevention of occupational exposures in health care providers includes use of standard and contact precautions.

Latex Allergy

Latex is a milky cytosol secreted by lactifer cells from the rubber tree, *Hevea brasiliensis*.²⁰ The cytosol contains as-1,4 polyisoprene, which is immunologically inert. The manufacturing process results in the cross-linking of chains of polyisoprene, yielding a polymer that exhibits excellent tensile strength, elasticity, and barrier capacity.²⁰ Such desirable characteristics have led to the use of rubber latex in the manufacture of many medical products, including gloves (for surgery, examination, and housekeeping and cleaning), intravascular devices (balloon catheters, intravenous tubing, and ports), airway devices (nasopharyngeal airways, endotracheal tubes, and oxygen masks), tourniquets, blood pressure cuffs, electrocardiogram leads, tape, and dressings.

Immune reactions to latex products may take three forms: irritant, contact dermatitis (type IV), and IgE (type I). Irritant reactions are nonimmune in nature and result in dry dermal erythema limited to the site of contact. Contact dermatitis occurs as a result of dermal exposure to chemicals used in the manufacturing of latex products. Thiurams and thiazoles are the most common chemicals to induce this type IV response. This reaction, which may extend beyond the site of contact, results in a dry dermal erythema, pruritus, weeping, and vesiculation. Such loss of skin integrity permits the access of latex proteins to the immune system and may result in an IgE-mediated response. IgE (type I) response is an immunologic reaction to protein allergens contained in latex. Clinical manifestations of such reactions include

urticaria, asthma, rhinitis, angioedema, laryngeal edema, and anaphylaxis. IgE reactions may occur as a result of mucosal, dermal, contact, or inhalational exposure. Cornstarch powder, which serves as a lubricant to ease the donning of latex gloves, binds and aerosolizes protein allergens, leading to inhalation exposure.

At highest risk of developing IgE-mediated latex allergy are individuals with high exposure to latex and those who are atopic. Workers in industries that make rubber products (e.g., tire manufacturers and doll makers) and those who use rubber products (e.g., housekeepers, hairdressers, and health care workers) are at high risk of developing this allergy. While anyone can develop latex allergy, specific populations are at higher risk. Individuals likely to develop latex allergy include those with a history of multiple allergies (including dermal, respiratory, oral, or facial reactions to latex or rubber products), asthma (reactive airways disease), eczema, multiple food allergies (especially to bananas, avocados, and other tropical fruit), frequent surgical or dental procedures, multiple urogenital procedures (e.g., bladder, vaginal, and rectal), spina bifida and related conditions of spinal dysraphism, congenital urinary anomalies, or sensitivity to ethylene oxide (a sterilizing agent).

Since September 1998, the U.S. Food and Drug Administration has promulgated uniform labeling for all medical products. Many latex-free medical products exist on the market and may be substituted for currently used products. Prevention of disease in health care workers is critical and requires the use of synthetic or low-allergen powder-free gloves.²⁰ NIOSH and the CDC have published several documents that describe the hazards of latex allergy and suggest steps health care providers may take to protect themselves.²¹ To protect themselves from latex exposure and allergy in the workplace, health care personnel may: use nonlatex gloves for workplace activities that do not involve contact with infectious materials; use synthetic or low-allergen powder-free gloves when handling infectious materials; avoid oil-based hand lotions or creams when wearing latex gloves (to prevent glove deterioration); wash hands with mild soap and dry thoroughly upon removal of latex gloves; frequently clean work areas and equipment contaminated with latex-containing dust; obtain education and training regarding latex allergy; and recognize the symptoms of latex allergy. Health care providers should be aware that hypoallergenic latex gloves do not reduce the risk of latex allergy, but do reduce reactions to chemical additives in latex.

SARS

As of this writing (May 2003), Severe Acute Respiratory Syndrome (SARS) is thought to be due to coronavirus, and is characterized as asymptomatic or mild, moderate, or severe. Clinical criteria of moderate disease are temperature of $>38^{\circ}\text{C}$ (100.4°F) and one or more findings of respiratory illness; additional criteria for severe disease include radiographic evidence of pneumonia, or respiratory distress syndrome, or autopsy findings consistent with pneumonia or respiratory distress syndrome without an identifiable cause. In addition, epidemiologic criteria for disease are travel within 10 days of onset of symptoms to an area with SARS, or close contact within 10 days of onset of symptoms of a person suspected to have SARS. As of this writing there is no diagnostic testing available outside of a research setting. Infection control guidelines consist of hand washing with soap and water or alcohol-based hand rubs for all possible contacts. Infection control of EMS vehicles with potential contamination includes the use of any EPA-registered detergent-disinfectant currently used by healthcare facilities for environmental sanitation. All surfaces and equipment should be cleaned. At ED triage, questions about SARS exposure should be asked. If positive, a surgical mask should be placed on the patient and the patient should be kept away from others in the waiting room. In the ED or EMS vehicles, full personal protective attire should be used. Health care personnel should use an N-95 filtering disposable respirator. Patients need admission for medical care, but not for infection

control, unless infection control is not possible outside of a hospital setting (prison, homeless shelter, dormitory, etc.). In April, 2003, SARS was added to the list of quarantinable communicable diseases in the US. Since SARS information is changing rapidly, the CDC should be consulted for the most recent case and epidemiologic definitions, laboratory testing, travel advisories, and infection control guidelines, (<http://www.cdc.gov/ncidod/sars>).

PHARMACOLOGY OF ANTIMICROBIALS, ANTIFUNGALS, AND ANTIVIRALS **Ralph H. Raasch**

This chapter reviews the basic pharmacology of commonly prescribed antimicrobial agents used in the emergency department. Topics discussed are mechanisms of action, indications for use in the emergency department, contraindications, adverse drug reactions, dosage adjustments for renal or hepatic insufficiency, use in pregnancy, and important drug interactions. Additional information regarding the treatment of specific infections will be found in other chapters of this text and Principles of Drug Interactions are discussed in Chap. 157.

ANTIBACTERIAL DRUGS

Effective antibacterial drugs have the ability to either inhibit the growth of (bacteriostatic effect) or kill (bactericidal effect) bacteria. These drugs have an antibacterial effect as a result of a variety of mechanisms, including the inhibition of cell wall synthesis, inhibition of intrabacterial protein synthesis, alteration in nucleic acid metabolism, or intrabacterial enzyme inhibition (Table 155-1). The mechanism of action does not necessarily correlate with bacteriostatic or bactericidal effects, which are also highly dependent on the concentration of antibiotic to which bacteria are exposed. Drugs of choice for most infections are not based on a bacteriostatic or bactericidal effect of an agent but rather on whether the drug reaches the site of infection in adequate quantities, the spectrum of the agent, its safety, and its cost.

Mechanisms of Action

CELL WALL-ACTIVE AGENTS Beta-lactam (penicillins, cephalosporins) and glycopeptide antibiotics (vancomycin, teicoplanin) must bind to receptors in the bacterial cell wall in order to cause an antibacterial effect. The target receptors (there are at least seven) for

penicillins and cephalosporins are collectively called *penicillin-binding proteins* (PBPs). With binding to the PBPs, autolytic enzymes within the cell wall are activated, resulting in the deterioration of the peptidoglycan component of the cell wall, cell wall weakening, and eventual cell lysis. Glycopeptide antibiotics bind to a terminal dipeptide (alanine-alanine) in the cell wall peptidoglycan and then by steric hindrance prevent the necessary cross-linking for a competent cell wall structure. At usual doses, (3-lactam and glycopeptide antibiotics are bactericidal. Resistance can arise to these antibiotics due to mutations in the PBPs, leading to markedly reduced beta-lactam binding (e.g., in oxacillin-resistant *Staphylococcus aureus* or penicillin-resistant *Streptococcus pneumoniae*), or when the terminal dipeptide mutates to a lactate-alanine (e.g., vancomycin-resistant *Enterococcus faecium*) that markedly reduces the level of vancomycin binding.

PROTEIN SYNTHESIS INHIBITORS Several classes of antibacterial drugs bind to ribosomes within bacteria, thereby blocking necessary protein synthesis. Aminoglycosides and tetracyclines bind to the 30S ribosomal subunit, whereas macrolide antibiotics and clindamycin bind to the 50S subunit. Ribosomal binding inhibits transfer RNA function, thereby decreasing the amount of protein synthesis. In order for these ribosomal binding drugs to work, they must enter the cell through the cell wall and bind in adequate concentrations to reversibly inhibit protein synthesis. Resistance mechanisms arise when there is reduced cell wall permeability, an active efflux pump that removes the antibiotic from the cell, or ribosomal binding-site mutations that decrease antibiotic affinity. All these mechanisms may result in resistance to each of the drug classes listed above.

NUCLEIC ACID INHIBITORS Fluoroquinolone antibiotics inhibit DNA gyrase, the enzyme responsible for DNA unwinding for transcription and then recoiling during bacterial replication. These agents must reach the nucleus of the bacterial cell in order to provoke these effects; hence resistance can arise when cell wall permeability is reduced, active efflux occurs, or a DNA gyrase mutation has arisen that reduces fluoroquinolone binding. Rifampin is a broad-spectrum antimicrobial agent active against many gram-positive and gram-negative bacteria and mycobacteria. Rifampin inhibits RNA synthesis by binding to DNA-dependent RNA polymerase, thereby blocking the initiation of RNA chain formation. Nitrofurantoin is modified by bacterial metabolism to a compound that damages DNA. Susceptible bacteria rarely become resistant to nitrofurantoin.

ENZYME INHIBITORS Sulfonamides and trimethoprim block sequential steps in the formation of folic acid. Sulfonamides inhibit dihydropteroate synthase, the enzyme that converts para-aminobenzoic acid (PABA) to dihydrofolic acid; then trimethoprim inhibits dihydrofolate reductase, the enzyme that converts dihydrofolic to tetrahydrofolic acid. Resistance to these drugs can arise by enzyme mutations that reduce the affinity of the sulfonamide or trimethoprim to their respective enzyme targets.¹

Table 155-2 summarizes the classification and names of most antibiotics within each antibiotic class referred to above. Available routes of administration are also listed.

Indications in the Emergency Department and Drugs of Choice

Drugs of choice for specific infections are based largely on clinical experience of effectiveness, supported by clinical trial reports and case series, with an acceptable level of adverse events. Successful effectiveness is based on the knowledge of the likely bacterial pathogen responsible for a specific infection type and the usual antimicrobial spectrum of antibiotics. Alternate drugs of choice are selected in cases of resistance to an initial drug, a history of intolerance or allergy to the drug of choice, or because of a higher risk of adverse events.

TABLE 155-2 Classification of Antibacterial Drugs with Common Trade Names

Penicillins

Natural penicillins Penicillin G—IV, PO* Penicillin V (Pen-Vee K)—PO

Aminopenicillins

Ampicillin (Omnipen)—IV, PO
Amoxicillin (Amoxcil)—PO

Penicillinase-resistant penicillins

Oxacillin (Bactocill)—IV, PO
Nafcillin (Unipen)—IV, PO
Dicloxacillin (Dynapen)—PO
Cloxacillin (Cloxapen)—PO

Antipseudomonal penicillins

Ticarcillin (Ticar)—IV
Piperacillin (Pipracil)—IV

P-lactam-fi-lactamase inhibitor

combination Amoxicillin-clavulanic acid

Taking into account those infections most likely to be present in emergency department patients and the most likely pathogens involved in these infections, Table 155-3 summarizes drugs of choice for these infections.²

Antibiotic Dosage and Dosage Adjustments

Providing an antibiotic in adequate dosage is one of the requirements for successful treatment. Drug dosage usually takes into account achievable serum and tissue levels and the concentrations necessary (determined in the laboratory) to inhibit the growth of susceptible bacteria. These empirical doses are then usually evaluated in clinical trials for various indications to ensure that positive treatment outcomes occur at one or more tested doses. Thus standard dosing guidelines are available that usually will result in successful treatment, assuming that a susceptible organism is present and issues regarding drug penetration to the site of infection (i.e., abscess) are not present. In cases

SECTION 13 • INFECTIOUS DISEASES

TABLE 155-3 Antibiotics of Choice for Treatment of Common Adult Infections in the ED

SITE/TYPE OF INFECTION	SUSPECTED ORGANISMS	DRUG OF CHOICE	ALTERNATIVE
Respiratory			
Pharyngitis	Group A streptococci	Penicillin V	Macrolide
Bronchitis, otitis, Acute sinusitis	<i>S. pneumoniae</i> <i>H. influenzae</i>	amoxicillin, amox/clav, or cefuroxime	Macrolide or doxycycline
Epiglottitis	<i>H. influenzae</i> , Group A streptococci	Ceftriaxone	Cefuroxime
Community-acquired pneumonia			
Normal host	<i>S. pneumoniae</i> , viral, Mycoplasma	Azithromycin	Levofloxacin
Aspiration Alcoholic	Aerobes and anaerobes <i>S. pneumoniae</i> , <i>Klebsiella</i>	Clindamycin Ceftriaxone	Cefoxitin Levofloxacin
Urinary tract infection	<i>E. coli</i> and other enteric Gram-negative rods	Amoxicillin or TMP/SMX	Ciprofloxacin, cephalexin, or nitrofurantoin
Sexually-transmitted infections			
Urethritis	<i>N. gonorrhea</i> , Chlamydia	Ceftriaxone	Ciprofloxacin
Genital ulcers	<i>Treponema pallidum</i> , Herpes simplex virus	Penicillin G Acyclovir	Doxycycline Valacyclovir
Skin/soft tissue			
Cellulitis	Group A streptococci, Cephalexin <i>S. aureus</i>	Dicloxacillin	
Necrotizing Fasciitis	Polymicrobial	Imipenem or meropenem Plus vancomycin	
Fresh/brackish water infections Cat bite	Mixed flora, <i>Aeromonas</i> <i>Pasteurella</i> , mixed flora	TMP/SMX Amox/clav	Fluoroquinolone Clindamycin and ciprofloxacin
Meningitis			
Normal host	<i>S. pneumoniae</i> , <i>N. meningitidis</i> , <i>S. aureus</i>	Ceftriaxone and vancomycin	
Immunocompromised or >50	<i>Listeria</i> , <i>H. influenzae</i>	add Ampicillin	
Acute Abdomen (perforation)	Gram-negative rods, anaerobes, Enterococci	AM/SB or Pip/TZ	Cefoxitin or cefotetan

Abbreviations: AM/SB = ampicillin/sulbactam; TMP/SMX = trimethoprim/sulfamethoxazole; Pip/TZ = piperacillin/tazobactam; amox/clav = amoxicillin/clavulanate.

where there may be antibiotic penetration issues, such as meningitis, endocarditis, or osteomyelitis, the highest doses recommended should be given. Dosage adjustments of many antibiotics are necessary for patients with renal disease to prevent adverse events that would occur with drug accumulation (if dosage reduction did not occur). Because the highest doses of drugs usually are given intravenously, dosage adjustments are most relevant for intravenous administration. Oral doses are typically at the "low end" of the dosage range, meaning that toxic drug accumulation is much less likely when oral doses are given in renal dysfunction. Hence little dose modification is necessary with oral dosing. Dosage modifications in liver disease are less clear because of a poorer understanding of how liver function tests measure a decrease in drug elimination characteristics or rate. Adverse events (dose-related and allergic) of antibacterial drugs will be discussed in the next section. Guidelines for dosing adjustment, primarily with intravenous therapy, are summarized in Table 155-4.²

Adverse Effects and Contraindications of Antibacterial Drugs

Allergic reactions and direct pharmacologic-based toxicity are the two general categories of adverse drug reactions to antibiotics. Allergic reactions are not dose-related, they are unpredictable, and they cannot be studied effectively in animal models. Reactions can vary from very mild skin rashes to life-threatening circumstances, such as toxic epi-

dermal necrolysis or anaphylactic reactions. Drug fever, hepatitis, and interstitial nephritis are also examples of allergic drug reactions. Direct dose-related toxicity is the result of the pharmacologic properties of the drug. These reactions are possible in any recipient (including animal models) if the dose or accumulated drug in the body is high enough. Dose-related adverse events typically are reversible if the antibiotic is discontinued. There is some predictability to these reactions, such as renal dysfunction caused by an aminoglycoside, if the blood level of drug is high enough for an extended period of time. It is these dose-related or pharmacologic side effects that are avoided if appropriate dose adjustments of antibiotics are made as in the dosing guidelines in Table 155-4. Certain adverse effects of antibiotics, such as pseudomembranous colitis, do not fall easily into either category; all antibiotics can cause this side effect. The common allergic and dose-related adverse effects of antibacterial drugs are summarized in Table 155-5. This table also includes the Food and Drug Administration (FDA) safety-in-pregnancy categories.^{1,15}

Contraindications and Drug Interactions

There are certain important contraindications to the use of several of the antibacterial drugs. In general, a contraindication exists if the patient has a previous history of allergy to the drug being considered for use. This circumstance is most pertinent for patients with a penicillin or cephalosporin allergy, but in particular, the nature of the allergy is

TABLE 155-4 Dosage Guidelines for Selected Antibacterial Drugs in Adults

Drug	Major Route of Elimination	Maximum Daily IV Dose (g)	Dose Adjustment for Creatinine Clearance (mL/min)		
			>50	10-50	<10
Ampicillin	Renal	12	1-2 g q4-8h	1 g q6h	1 g q12h
Aztreonam	Renal	8	1-2 g q6-8h	1-2 g q12h	1 g q12h
Cefazolin	Renal	8	1-2 g q8h	1 g q12h	1 g q24h
Cefotaxime	Renal	12	1-2 g q4-8h	1-2 g q12h	1 g q12h
Cefotetan	Renal	6	1-2 g q12h	1-2 g q24h	1 g q24h

important to understand when making decisions for alternate therapy. For example, a patient with a history of respiratory distress, wheezing, urticaria, or hives during a previous course of P-lactam treatment would be at significant risk for another potential life-threatening reaction upon reexposure to another (3-lactam. In this case, a penicillin or cephalosporin would be strongly contraindicated. (3-Lactam therapy could still be used if absolutely necessary but should be accomplished first in a desensitization protocol in the intensive care unit. On the other hand, if the patient history is a mild maculopapular rash while taking amoxicillin or other penicillin, the chances are very high that subsequent treatment with a cephalosporin would not provoke another allergic event.

Drug interactions with antibacterial drugs, fortunately, are infrequent, but several must be kept in mind. Two mechanisms for interactions predominate with these drugs. **The first mechanism is an inhibition of absorption of oral antibiotics. The best example of this interaction occurs when any of the tetracycline or fluoroquinolone antibiotics are given at the same time as divalent cations (Ca^{2+} , Mg^{2+} , Fe^{2+}).** If this occurs, the ions bind to the antibiotic and reduce markedly the amount of drug that is absorbed orally. Tetracyclines and fluoroquinolones should not be given with calcium or iron preparations or with antacids. **Second, certain antibiotics can slow the metabolism of other drugs by inhibiting several of the hepatic cytochrome P450 enzymes in the liver. In particular, ciprofloxacin, clarithromycin, and trimethoprim-sulfamethoxazole are drugs that are able to provoke this enzyme inhibition.** Summaries of these antibiotic contraindications and drug interactions are included as Tables 155-6 and 155-7, respectively.⁴

ANTIFUNGAL DRUGS

New antifungal agents for systemic infections have been developed over the last 5 years. These agents are effective for significant infec-

tions with a lower adverse-effect risk than traditional antifungal drugs (e.g., amphotericin B). The mechanism of action of antifungal agents is primarily based on actions that decrease cell wall integrity. Amphotericin B (and its lipid-based derivatives) binds to cell wall ergosterol, increasing cell wall permeability that eventually results in cell lysis. Triazole antifungals (e.g., fluconazole, itraconazole) block ergosterol synthesis by inhibition of a fungal cytochrome P450-dependent enzyme. Caspofungin is another enzyme inhibitor, in this case, the inhibition is of beta-glucan synthetase. Beta-glucan, like ergosterol, is another necessary component of the cell wall of several fungal species. Flucytosine is an antimetabolite that disrupts DNA function after conversion intracellularly to 5-fluorouracil. These agents for systemic fungal infections are summarized in Table 155-8. Multiple topical antifungal preparations are available, as summarized in Table 155-9, and are indicated for *Candida* or tinea infections.^{3,5}

Of the various lipid-based amphotericin B preparations, liposomal amphotericin B (Ambisome) is becoming the preferred product primarily because of a lower rate of infusion-related reactions and perhaps a lower frequency of renal dysfunction compared with the other lipid products. Because amphotericin B has the broadest antifungal spectrum of all these systemic agents, it is the preferred drug for empirical therapy, including ED use, until further diagnostic workup determines the likely pathogen involved. All amphotericin B infusions, whether conventional (infused over 4 h) or lipid-based (infused over 2 h) can be preceded by routine premedications to diminish the frequency of infusion-related fever and chills. Acetaminophen (650 mg PO) and diphenhydramine (Benadryl, 25-50 mg PO or IV) should be given 30 min prior to the infusion. If rigors occur, meperidine (Demerol, 25-50 mg IV) likely will promote resolution of the rigor. With these premedications, a "test dose" (1 mg) infused slowly is not necessary.

In addition to the preceding infusion-related reactions, amphotericin B toxicity is related to renal dysfunction. The lipid-based products

TABLE 155-5 Antibacterial Adverse Effects

Antibiotic Class	Allergic Reactions	Dose-Related Effects
β-lactams (penicillins, cephalosporins, monobactams, carbapenems) Pregnancy category* B	Anaphylaxis, urticaria, rash, fever, serum sickness; hepatitis, nephritis, anemia, thrombocytopenia Cross-reactivity between penicillins and cephalosporins is ~5%; little cross-reactivity between cephalosporin and aztreonam or imipenem	Diarrhea (Augmentin), biliary sludging (ceftriaxone); phlebitis; seizures (imipenem, penicillin G); anti-platelet effects and hemolytic anemia; decreased vitamin K synthesis and disulfiram reaction (cefotetan); nausea, hypotension (rapid infusion of imipenem).
Aminoglycosides Pregnancy category C	Rare	Nephrotoxicity: incidence 10–15%, usually reversible Ototoxicity: incidence 1–5%, causes deafness and/or dizziness; toxicity is both dose- and duration-related
Macrolides Pregnancy category B C (clarithromycin)	Cholestatic jaundice: associated with IV erythromycin	GI toxicity: nausea, vomiting diarrhea, cramping—mostly with erythromycin
Clindamycin Pregnancy category B	Rash	Diarrhea—most common adverse effect; pseudomembranous colitis
Tetracyclines Pregnancy category D	Rash, anaphylaxis, urticaria, fever, hepatitis	Nausea, diarrhea; increase in BUN; deposits and discolors teeth and bone (avoid in pediatrics); dizziness and vertigo (minocycline)
Vancomycin Pregnancy category C	Rash (rare)	Infusion-related reactions: phlebitis, “red-person syndrome” from rapid fusions—give 1 g over 60 min; oto- and nephrotoxicity is rare with current formulations
Fluoroquinolones Pregnancy category C Sulfonamides Pregnancy category X	Rare Rash, Stevens-Johnson syndrome, exfoliative dermatitis (more common in AIDS); hepatitis; bone marrow suppression	Nausea, vomiting, diarrhea; confusion, headache, seizures; tendonitis and tendon rupture; prolonged QT interval Nausea, vomiting, diarrhea; crystalluria (doses taken with insufficient fluids)

■"United States FDA Safety-in-Pregnancy Code: A: controlled human studies show no risk; B: no evidence of risk in humans; the chance of fetal harm is remote but remains a possibility; C: risk cannot be ruled out; well-controlled human studies are lacking, and animal studies have shown risk or are lacking; there is a chance of fetal harm if administered during pregnancy; D: positive evidence of risk; studies in humans have demonstrated fetal risk; X: contraindicated in pregnancy; the risk of fetal abnormalities outweighs the potential benefit of the drug. *Source:* From Cunha BA.³

TABLE 155-6 Antibiotic Contraindications

Antibiotic Class	Contraindications
Penicillins	History of hypersensitivity to penicillins, cephalosporins, imipenem (carbapenems)
Cephalosporins	Hypersensitivity to cephalosporins, imipenem (carbapenems), penicillins
Fluoroquinolones	Hypersensitivity to any of the fluoroquinolones; tendonitis or tendon rupture; use of QT interval-prolonging drugs (amiodarone, procainamide)
Tetracyclines	Hypersensitivity to any of the tetracyclines
Macrolides	Hypersensitivity to any of the macrolides; treatment of meningitis (inadequate CNS penetration)
Vancomycin	Hypersensitivity to vancomycin
Clindamycin	Hypersensitivity to clindamycin; treatment of meningitis (inadequate CNS penetration)
Aminoglycosides	Previous allergic or toxic reactions to any of the aminoglycosides
Metronidazole	Hypersensitivity to metronidazole; first trimester of pregnancy
Sulfonamides	Hypersensitivity to sulfonamides or related drugs (sulfonylureas, thiazides, loop diuretics), pregnancy at term, lactation

Source: From Burnham et al.

significantly reduce but do not totally eliminate the risk of renal toxicity. Consequences of the renal effects of amphotericin B are renal tubular acidosis and renal wasting of bicarbonate, potassium, and magnesium. Serum electrolyte levels should be followed closely, with aggressive supplementation of potassium and magnesium being frequently necessary. Amphotericin B is also responsible for causing frequent elevations of blood urea nitrogen (BUN) and serum creatinine, which, again, have been reduced with the use of the lipid-based products. Nevertheless, increases in creatinine are possible with any of these amphotericin products and, if present, should result in reduction of the daily dose or, preferably, infusion of the product every other day if the creatinine level rises to greater than 2.5 to 3.0 mg/dL.

Fluconazole, itraconazole, voriconazole, and caspofungin are very safe drugs and do not provoke the renal dysfunction associated with amphotericin B. Occasionally, liver function test elevations and hepatitis result from triazole therapy, so patients on prolonged courses of these drugs should be followed with liver function tests monthly. Triazoles (particularly itraconazole) can interact with other drugs metabolized by the cytochrome P450 system. In particular, warfarin, phenytoin, cyclosporine, and tacrolimus levels routinely increase in patients on these drugs who are then given itraconazole. Fluconazole is a less potent inhibitor of cytochrome P450, so significant interactions with fluconazole are less frequent. Flucytosine can cause reversible bone marrow suppression, with leukopenia and thrombocytopenia. The pregnancy category for the amphotericin products is category B, and for the triazoles, caspofungin, and flucytosine, it is category C. Finally, dose-modification issues are only relevant for fluconazole and flucytosine as follows: For creatinine clearance less than 50 mL/min, reduce

TABLE 155-7 Antibacterial Drug Interactions

Antibiotic Class	Drug Interactions
Penicillins	Oral contraceptives—failure (infrequent) Allopurinol—increased rash with ampicillin Aminoglycosides—when administered IV simultaneously, inactivation occurs Probenecid—reduced renal elimination of penicillin
Cephalosporins	Warfarin—cefotetan and cefoperazone enhance the anticoagulant effect of warfarin Antacids—may reduce the oral absorption of cefaclor, cefdinir, and cefpodoxime
Fluoroquinolones	Antacids, iron salts, sucralfate—absorption of the fluoroquinolone is reduced by chelation Theophylline—metabolism is slowed by ciprofloxacin, may cause theophylline toxicity; warfarin elimination is slowed by fluoroquinolones—follow clotting times carefully
Tetracyclines	Antacids, iron salts—bind to tetracycline and reduce oral absorption (occur least with doxycycline) Oral contraceptives—failure
Macrolides	Clarithromycin can increase levels of warfarin, cyclosporin, lovastatin, theophylline—monitor additive effects carefully
Vancomycin	Aminoglycosides—may increase risk of nephrotoxicity
Aminoglycosides	Neuromuscular blockers—may prolong respiratory depression; loop diuretics—may increase auditory toxicity
Trimethoprim-sulfamethoxazole	Warfarin—can prolong clotting times; phenytoin—increase in serum levels and possible toxicity

TABLE 155-9 Selected Topical Antifungal Agents

Class and Products	Dosage Forms	Comments
Allylamines/benzylamines		
Butenafine (Mentax)	1% cream,	Treatment for
Naftifine (Naftin)	gel, solution,	1–4 weeks for
Terbinafine (Lamisil)	spray	tinea
Imidazoles		
Clotrimazole (Lotrimin, Mycelex)	1% cream, lotion, vaginal tablets	Topical (<i>Candida</i> , tinea) apply bid; Vag. tab 100 mg × 7d or 500 mg hs × 1
Miconazole (Micatin, Monistat)	2% cream, ointment, vag. supp.	As above, except 200 mg vag. supp. × 3 d
Tioconazole (Vagistat-1)	6.5% vag. ointment	Application hs × 1
Miscellaneous (for tinea only)		
Haloprogin (Halotex)	1% cream, solution	Apply bid 2–4 weeks
Tolnaftate (Tinactin, Ting)	1% cream, solution, gel, powder, spray	Apply bid 2–6 weeks Less effective than Imidazoles

Source: From Anderson et al.⁵

fluconazole to 200 mg daily and flucytosine to 25 to 37.5 mg/kg every 12 h; for creatinine clearance less than 10 mg/min, flucytosine should be further reduced to 25 to 37.5 mg/kg every 24 h.

ANTIVIRAL AGENTS

Recent advances in the development of antiviral agents has increased our ability to treat infections caused by herpes simplex virus (HSV I and II), varicella-zoster virus (VZV), cytomegalovirus (CMV), influenza A and B, and human immunodeficiency virus (HIV). Table 155-10 summarizes the mechanism of action of the agents used for these viral infections, except for HIV, and the antiviral spectrum of each agent.¹ Table 155-11 summarizes the antiviral mechanisms of the antiretroviral (anti-HIV) drugs, their dosing regimens, and their common adverse effects. Uses for the non-HIV antiviral agents for patients in the emergency department are summarized in Table 155-12. Adverse effects of these drugs are compiled in Table 155-13.^{2,4}

Acyclovir (and penciclovir) and ganciclovir are excellent drugs for the treatment of HSV and CMV infections, respectively. When given orally, however, the absorption of these agents is less than optimal. As a result, large oral doses are necessary to achieve adequate blood and tissue levels to inhibit viral replication. Drug formulation and product development generated the three *prodrugs* valacyclovir, famciclovir, and valganciclovir. In the case of valacyclovir and valganciclovir, a valine ester has been added to acyclovir and ganciclovir, respectively, that produces enhanced absorption from the gastrointestinal tract. On reaching the liver, the valine is hydrolyzed and removed, resulting in the emergence of acyclovir or ganciclovir. Specifically, acyclovir oral absorption is about 16 percent of a dose, whereas for valacyclovir absorption increases to about 55 percent. Valganciclovir absorption is about 60 percent of an oral dose; for ganciclovir the percentage of dose absorbed in only 5 percent. This is why the dosage of the prodrugs is significantly less than the oral doses of the parent compounds.

As far an antiretroviral therapy is concerned, treatment is *always* a combination of at least three drugs using agents with different mechanisms of action. Current drugs either inhibit the enzyme responsible for the conversion of HIV RNA to a DNA copy (reverse transcriptase) for replication in human T cells or inhibit a viral protease that promotes the maturation of new HIV virions prior to their budding from host cells.

TABLE 155-10 Antiviral Agents for Systemic Herpes, Varicella, CMV, and Influenza Virus Infections

Drug	Mechanism of Action	Activity Against
Acyclovir (Zovirax), valacyclovir (Valtrex) Penciclovir, famciclovir (Famvir)	Purine nucleoside analogues; triphosphate form inhibits HSV DNA polymerase and viral DNA replication	HSV I and II, VZV
Ganciclovir (Cytovene), valganciclovir (Valcyte)	Nucleoside analogue (guanine); when phosphorylated, inhibits viral DNA polymerase	HSV I and II, VZV, CMV
Foscarnet (Foscavir)	Inorganic pyrophosphate analogue that inhibits DNA polymerase	HSV I and II, VZV, CMV
Cidofovir (Vistide)	Nucleotide analogue that inhibits viral DNA polymerase	HSV I and II, VZV, CMV
Amantadine (Symmetrel), rimantadine (Flumadine)	Inhibits uncoating of virus and uptake of nucleic acid by host cells	Influenza A
Oseltamivir (Tamiflu), zanamivir (Relenza)	Inhibitor of influenza virus neuraminidase with possible alteration in viral aggregation and release	Influenza A and B

Source: From Hardman et al.¹

Several important comments are necessary regarding the adverse effects of the antiretroviral agents. Certain reactions may be life-threatening and thus may be important circumstances that could arise in the emergency department. First, lactic acidosis is being recognized increasingly as a significant adverse effect of therapy. The onset of the acidosis may be subacute, so patients will complain of several weeks of fatigue, anorexia, weight loss, confusion, and loss of energy. Arterial lactic acid levels may be increased two to three times, and resolution of the acidosis typically is slow, even after discontinuation of the antiretroviral drugs. Lactate levels should be checked in patients with the preceding symptoms who have been receiving antiretroviral agents, especially stavudine (d4T, Zerit) or didanosine (ddl, Videx). Second, the hypersensitivity syndrome secondary to abacavir (Ziagen) must be noted. As briefly described in Table 155-11, the syndrome is characterized by rash and other systemic complaints. The reaction is reversible with discontinuation of abacavir. However, if the patient then takes abacavir again, cardiovascular and respiratory insufficiency has been observed that can be life-threatening. Rechallenge should be done only under the supervision of a clinician very experienced in HIV care. Finally, it should be noted that there are multiple and important drug interactions between the antiretroviral drugs themselves and with drugs used for other indications. A comprehensive summary of these interactions is beyond the scope of this chapter. Excellent resources, such as the references for this chapter, can help with a listing of these drug interactions. Multiple online sources are also available and are updated frequently. These sources, in particular, include www.hivatis.org and www.pedhivaid.org.^{2a5}

Drug	Usual Dose	Adverse Events and Administration Issues
Nucleoside reverse-transcriptase inhibitors		
Zidovudine (Retrovir) (AZT, ZDV)	300 mg PO bid	Bone marrow suppression with anemia, macrocytosis; headache, nausea, vomiting; can be given with or between meals
Didanosine (Videx) (ddl)	200 mg PO bid or 400 mg qd (>60 kg) 250 mg qd (<60 kg)	Peripheral neuropathy; pancreatitis, nausea diarrhea; lactic acidosis (myalgia, fatigue, anorexia); give between meals
Zalcitabine (Hivid) (ddC)	0.75 mg PO q8h	Peripheral neuropathy; stomatitis; give between meals
Stavudine (Zerit) (d4T)	40 mg bid (>60 kg) 20 mg bid (<60 kg)	Peripheral neuropathy, hepatitis; lactic acidosis; can be given with or between meals
Lamivudine (Epivir) (3TC)	150 mg PO bid	Few adverse events: headache, nausea, pancreatitis; can give with or between meals
Abacavir (Ziagen)	300 mg PO q12h	Hypersensitivity reaction (fever, rash, nausea, abdominal pain, malaise); do not readminister abacavir; headache, lactic acidosis; can give with or between meals
Tenofovir (Viread)	300 mg qd	Nausea, diarrhea, vomiting; take with food
Nonnucleoside reverse-transcriptase inhibitors		
Nevirapine (Viramune)	200 mg PO qd × 7 d; then 200 mg bid	Rash (can be severe), hepatitis, nausea, vomiting, diarrhea; give with/without food
Delavirdine (Rescriptor)	400 mg PO q8h	Rash, nausea, headache; give with or without food
Efavirenz (Sustiva)	600 mg PO hs	Vivid dreams, headache, rash (can be severe), dizziness, light-headedness; avoid taking with high-fat meals—increases toxicity
Protease inhibitors		
Indinavir (Crixivan)	800 mg q8h or 400 mg bid with 400 mg bid ritonavir	Kidney stones; hyperbilirubinemia (indirect), nausea, vomiting, hepatitis, increased glucose and lipids; lipodystrophy; must be taken between meals
Lopinavir (Kaletra) (fixed combination with ritonavir)	3 capsules bid	Nausea, vomiting, diarrhea, hepatitis; increase in glucose and lipids; lipodystrophy; take with food
Ritonavir (Norvir)	400 mg bid in combination with other protease inhibitors	As above
Nelfinavir (Viracept)	1250 mg bid	Diarrhea (~20%); increase in lipids; lipodystrophy; take with meal or snack
Saquinavir (Fortovase)	1200 mg tid or 400 mg bid with ritonavir	Nausea, diarrhea, abdominal pain, headache; hepatitis, increases in glucose and lipids
Amprenavir (Agenerase)	1200 mg bid, or 450 mg bid with 100 mg bid ritonavir	Lipodystrophy; take with food Rash, nausea, vomiting, diarrhea, circumoral paresthesias; lipodystrophy; can be taken with or between meals

TABLE 155-12 Antiviral Therapy (Non-HIV) in the ED

Diagnosis	Drug	Dosage	Route
Herpes encephalitis	Acyclovir	10 mg/kg q8h × 10 d (adult) 500 mg/m ² q8h (6 mo–12 yr)	IV
Mucocutaneous Herpes (immunocompromised)	Acyclovir	5 mg/kg q8h × 7 d (adult) 250 mg/m ² q8h (<12 yr)	IV
Varicella-zoster (immunocompromised)		Same as above for herpes encephalitis	IV
Herpes zoster (normal host)	Acyclovir, or famciclovir, or valacyclovir	800 mg 5 times/day × 7–10 d 500 mg tid × 7 d 1 g tid × 7 d	PO PO PO
Varicella (chickenpox)	Acyclovir	20 mg/kg (≤800 mg) qid (adults and children >2 yr) × 5 d	PO
Influenza A	Amantadine	100 mg bid × 10 d (adults and children >9 yr) 4.4–8.8 mg/kg per d, but <150 mg/d (children 1–9 yr)	PO
	Rimantadine	100 mg bid × 7 d (adults and children >10 yr) 5 mg/kg per d, but <150 mg/d (children 1–10 yr)	PO
	Oseltamivir	75 mg bid (adults) × 5 d	PO
	Zanamivir	10 mg (2 inhalations) bid × 5 d (adults and children >12 yr)	Inhalation

Source: From Koda-Kimble et al.²

TABLE 155-13 Adverse Effects of Selected Antiviral Agents

Drug	Adverse Effects
Acyclovir	IV: Phlebitis and irritation (9%); increase in BUN and creatinine (5–10%)—keep patient well hydrated; CNS toxicity (1%)—confusion, hallucinations (reversible) PO: Nausea/vomiting (7%), itching, rash (2%), hepatitis (1–2%)
Amantadine	Nausea, dizziness and insomnia (5–10%); depression, anxiety, hallucination, confusion, dry mouth, constipation, orthostatic hypotension, ataxia, peripheral edema (1–5%)
Famciclovir	Headache (6–9%), nausea (4–5%), diarrhea (1–2%)
Oseltamivir	Nausea, vomiting (9–10%), vertigo (1%)
Rimantadine	Insomnia, dizziness, headache, fatigue; nausea, vomiting, anorexia, dry mouth, abdominal pain (1–3%)
Valacyclovir	Headache (13–17%), nausea (10–16%), vomiting and diarrhea (1–7%)
Zanamivir	Bronchospasm, nasal/throat irritation, decline in respiratory function, headache, cough (1–2%)

TOXICOLOGY AND PHARMACOLOGY

GENERAL MANAGEMENT OF POISONED PATIENTS Jason B. Hack Robert S. Hoffman

It is generally accepted that, given a large enough exposure, all chemicals have the potential to be poisons. Inadvertent exposures to chemical substances have to fulfill specific criteria in order to be considered "nontoxic" (Table 156-1). Once fulfilled, these patients can be managed with only a brief observation period prior to discharge.

A *poisoning* occurs when exposure to a substance adversely affects the function of any system within an organism. The setting of the poison exposure may be occupational, environmental, recreational, or medicinal. A poisoning may result from varied portals of entry, including inhalation, insufflation, ingestion, cutaneous and mucous membrane exposure, and injection. Historically most poisonings have occurred when substances are tasted or swallowed. Toxins may be airborne in the form of gas or vapors or in a suspension such as dust. Caustics, vesicants, or irritants may directly affect the skin, or a toxin may pass transdermally and affect internal structures. Parenteral exposure is also common through intravenous or subcutaneous injection of medications or drugs of abuse.

A poison may affect the normal activity of an organism in a variety of ways. It may inhibit or alter cellular function, change organ function, or may change uptake or transport of substances into, out of, or within the organism. The toxin may prevent the organism from obtaining or utilizing essential substrates from the environment.

In 2000, there were more than 2 million toxic exposures reported to poison centers in the United States, just over half of which involved children younger than 6 years old.¹ Some authors currently list poisoning as the third leading cause of death in the United States, and between 1985 and 1995, the incidence of toxin-related deaths is said to have increased approximately 300 percent. Although many of these exposures were referred to as "accidents," most were preventable. School counselors, primary care physicians, and emergency physicians can educate families about poisonings, potentially poisonous substances, and techniques for protecting children from their environment. Nonfood (potentially harmful) items should not be stored in food areas, and toxins should not be stored in empty food containers. Hospitals and pharmacies must work together to recognize potential drug interactions, ensure patient identification, and develop procedures to check proper dosing, warning labels, and packaging on products with potential toxicity.

Poison centers are an integral part of the management of potentially exposed patients. These centers are typically staffed with specialists trained in the management of poisoned patients, who have extensive reference material at their disposal. Poison centers have immediate access to medical toxicologists if more extensive evaluation is required. Routine consultation in cases where toxic exposure is suspected can help focus diagnosis and treatment and may reduce costs and unnecessary hospitalizations.

RESUSCITATION

Diagnosis and resuscitation proceed simultaneously. The first priorities are always the ABCs (airway, breathing, and circulation). Once the airway and respiratory status is secured, abnormalities of blood pressure, pulse, rectal temperature, oxygen saturation and hypoglycemia must be corrected. Although the proper use of antidotes (Table 156-2) is essential in the treatment of poisoned patients, only in very rare in-

cidences (such as cyanide poisoning) would the administration of an antidote take precedence over completing the primary evaluation and normal attempts to stabilize the ABCs.

Patients may be unresponsive or have an altered mental status for many reasons. Four possible etiologies (hypoxia, opioid intoxication, hypoglycemia, and Wernicke's encephalopathy) are readily treated by the administration of specific antidotes. Within the first few minutes after the patient's arrival, the administration of empiric antidotes (the "coma cocktail"), including supplemental oxygen, naloxone, 50 mL D50W for adults and 1 g/kg glucose for children, and 100 mg thiamine in adults should be considered after taking into account the medical history, vital signs, and laboratory data immediately available. These treatments are simple, inexpensive, and generally without undue risk of an adverse reaction when used appropriately.

In unresponsive children thiamine is generally not administered empirically. However, 1 g/kg of glucose (2 mL/kg of D50W for adults, 4 mL/kg of D25W or 10 mL/kg of D10W for children) is often administered when serum glucose cannot be rapidly ascertained or hypoglycemia is confirmed. Naloxone (0.01 mg/kg titrated to effect) may be given, particularly in older children where unintentional or intentional opioid exposure cannot be excluded. Intentional poisoning of children as a form of child abuse does occur.

The suggestion that the administration of thiamine should precede the administration of D50W to prevent the precipitation of acute Wernicke's encephalopathy is unfounded.² The most important management issue with both D50W and thiamine is that both should be given in a timely manner in the emergency department so that these often occult diagnoses are added to the differential diagnosis and are treated promptly.

Although opioid intoxication often presents with the classic triad of central nervous system (CNS) depression, miosis, and respiratory depression, only respiratory status is useful as an indicator of a patient response to naloxone.³ Many toxins, though, produce miosis or CNS depression, and some opioids classically leave pupil size unaltered, making these findings less useful in isolation.

Naloxone, administered in a dose of 0.1 to 2.0 mg IV in adults and children is a competitive opioid antagonist that can be administered IV or IM, and is appropriate to use for a hypoventilating but nonintubated, opioid-intoxicated patient. Extremity restraints for the patient should be considered before administering the drug. Naloxone may completely reverse the symptoms observed, restoring effective ventilations and mental status for 20 to 60 min, so patients should be observed for 2 to 3 h afterward. The risks include the precipitation of an acute opioid withdrawal syndrome. Although acute withdrawal is never life-threatening in adults, vomiting from withdrawal can result in aspiration. Thus, the reflexive administration of large doses of naloxone should be discouraged. Patients who become resuscated may require additional naloxone doses administered either in intermittent boluses or via a continuous infusion. The latter is achieved by the administration of two-thirds the dose of the naloxone that fully aroused the patient in the initial bolus, but infused over an hour with the dose adjusted to the patient's ventilatory status.

EMERGENCY DEPARTMENT DIAGNOSIS

History

As much detailed information as possible must be obtained about the exposure. Ask about the number of exposed persons, the type of exposure, amount or dose, and route of exposure. In addition, the

TABLE 156-1 Criteria for Nontoxic Ingestions

Only one substance is involved in the exposure.
The substance must be absolutely identified.
The substance's product label must not contain any consumer product safety commission signal words indicating a potential hazard of toxicity. The exposure must have been unintentional. The route of exposure must be known. An approximate amount of the substance involved in the exposure must be known. The exposed individual must be free of symptoms for the extent of the observation period. Follow-up consultation must be easily available or a responsible parent or guardian must be present.

Note: All of the listed criteria must be fulfilled in order for an ingestion to be classified as nontoxic.

Source: Adapted from Mofenson HC, Grensher J, Caraccio TR: Ingestions considered nontoxic. *Emerg Med Clin North Am* 2:159, 1984, and Mofenson HC, Grensher J: The nontoxic ingestion. *Pediatr Clin North Am* 17:583, 1970.

patient's intent must be determined. Underlying motivation, potential for secondary gain, and perceived risk of arrest all may affect the history elicited from the patient. Corroborating information should be obtained from the patient's private physician, witnesses, or emergency medical technicians. Ask about the environment in which the patient was found, empty pill bottles or containers nearby, smells or unusual materials in the home, the occupation or hobbies of the patient, or the presence of a suicide note.

Toxicologic Physical Examination

Undress the patient completely for a comprehensive physical examination. Check the patient's clothing for objects still retained in the pockets or substances hidden on the patient's body (waistbands, groin, or between skin folds). Care must be taken when searching belongings, particularly pockets, because health care providers have been stuck by uncapped needles or lacerated by sharp objects.

Assess the general appearance of the patient. The presence of agitation, confusion, or obtundation should be noted. Examine the skin for cyanosis or flushing, excessive diaphoresis or dryness, signs of injury or injection, ulcers, or bullae. Bruising may be a clue for trauma, duration of unconsciousness, or coagulopathy. Examine the eyes for pupil size, reactivity, nystagmus, dysconjugate gaze, or excessive lacrimation. Hypersalivation or excessive dryness should be noted upon examination of the oropharynx. The chest examination should include careful evaluation of the lungs to assess for bronchorrhea, or wheezing, and the heart must be assessed for its rhythm, rate, and regularity. Bowel sounds, urinary retention, and abdominal tenderness or rigidity must also be noted. The extremities must be evaluated for tremor or fasciculation. Cranial nerves, reflexes, resting muscle tone, coordination, cognition, and the ability to ambulate all must be assessed.

Toxidromes

Toxidromes are grouped, physiologically based abnormalities of vital signs, general appearance, skin, eyes, mucous membranes, lungs, heart, abdomen, and neurologic examination that are known to occur with specific classes of substances and typically are helpful in establishing a diagnosis when the exposure is not well defined (Table 156-3). Similarly, certain clinical findings may help narrow the etiology possibilities (Tables 156-4 and 156-5).

Toxicologic Screen

In the acute care setting, the utility of toxicologic screening tests of blood and/or urine in many circumstances is very limited, and does not contribute significantly to the evaluation, management or outcome of

patients. Most toxicology screens are enzyme-multiplied immunoassay tests (EMITs), which are used to evaluate the presence of markers for commonly available substances including marijuana, opioids, cocaine, amphetamines, tricyclic antidepressants (TCAs), barbiturates, and benzodiazepines. Interpretation of test results often leads to confusion.

Positive results may occur with many substances because they persist in body fluids for days to weeks, depending on the chronicity of use. Thus, "falsely" positive results may not be related to the acute symptoms. Furthermore, positive results may occur from substances that cross-react with the assay (e.g., chlorpromazine, propranolol, pseudoephedrine, and selegiline for amphetamines; chlorpromazine, cyclobenzaprine, thioridazine, diphenhydramine, and cyproheptadine for TCAs). Negative results may be due to sampling error (e.g., very dilute urine after hydration) or from assay specificity (e.g., opioid screens do not detect methadone and meperidine; amphetamine screens do not detect MDMA; benzodiazepine screens do not detect rohypnol).

Patients may require emergent interventions before the tests return. Often basic supportive measures alone can successfully manage many commonly encountered ingestions or intoxications. The diagnosis of less frequently encountered exposures is usually dependent upon specialized testing that is not obtainable in a timely manner.

Toxicologic screens may have a place in the evaluation of children. The unexpected return of a positive result for a controlled or illegal substance should prompt further evaluation of the child's home environment and may require hospital admission for the child's protection. If the test result is replicated with a confirmatory study, authorities must be notified.

GENERAL DECONTAMINATION

The general approach to most toxic exposures involves the removal of the patient from the substance and the substance from the patient. Toxins outside the body must be washed away. Toxins within the body must be either bound within the gut lumen to make them unavailable for absorption or have their elimination enhanced from the gut, the blood, or the tissues.

Gross Decontamination

Decontamination is generally achieved by undressing patients completely and washing them thoroughly with copious amounts of water. Patients requiring assistance should be attended to by properly gowned staff in an isolated area. The towels used to dry patients and patient clothing, shoes, socks, watches, and jewelry should be handled as hazardous waste. Gross decontamination should occur prior to the patient's entry into the ED or other areas in the hospital. In mass casualty exposures, this will typically occur at a staging area adjacent to the ED (see Chap. 6).

Eyes

Ocular exposures should be treated immediately by copious irrigation (usually 2 L) with NS. Ophthalmic anesthetic such as 0.5% tetracaine may be necessary to relieve blepharospasm. Lid retractors may be required for adequate irrigation. Alkalies require specific considerations. Unlike acids which can be washed off, alkalies penetrate deep into tissues. Lengthy continuous irrigation (possibly 1 or even 2 h) may be required, until the tears in the conjunctival sac have stabilized at <8.0. The pH of normal tears is slightly acidic. The pH of NS solution is 5.6. Equilibration of 10 min or longer may be required for accurate pH determination. Ophthalmologic consultation is recommended.

Gastrointestinal Decontamination

Each of the methods used to decontaminate the gastrointestinal (GI) tract have potential benefits and risks that must be considered prior to

TABLE 156-2 Common Antidotes: Doses and Indications

Antidote	DOSE		Poison
	Pediatrics	Adult	
N-acetylcysteine	140 mg/kg PO load, followed by 70 mg/kg PO q4h for 18 total doses		Acetaminophen
Activated charcoal	1 g/kg PO		Most ingested poisons
Antivenom Fab	4–6 vials IV initially over 1 h may be repeated. 2 vials every 6 h for 18 h		Envenomation by <i>Crotalidae</i>
Calcium gluconate 10% (9 mg/mL elemental calcium)	0.6–0.8 mL/kg IV	10–30 mL IV	Hypermagnesemia, hypocalcemia (ethylene glycol, hydrofluoric acid), calcium channel antagonists, black widow spider venom)
Calcium chloride 10% (27.2 mg/mL elemental calcium)	0.2–0.25 mL/kg IV	10 mL IV	
Cyanide antidote kit			
Amyl nitrate	Not typically used	1 ampule in oxygen chamber of ambu-bag 30 s on/30 s off	Cyanide poisoning
Sodium nitrite	0.33 mL/kg IV (3% solution)	10 mL (3% solution)	Hydrogen sulfide (use only sodium nitrate)
Thiosulfate	Thiosulfate: 1.65 mL/kg IV	Thiosulfate: 12.5 g IV	
Deferoxamine	90 mg/kg IM (1 g max) or 15 mg/kg per h IV (1 g max)	2 g IM or 15 mg/kg per h (6–8 g/d max)	Iron
Dextrose	1 g/kg IV		Hypoglycemia
Digoxin Fab			Digoxin and cardiac glycosides
Acute		10–20 vials IV	
Chronic	1–2 vials IV	3–6 vials IV	
Ethanol 10% for IV administration	10 mL/kg over 30 min, then 1.5 mL/h*		Ethylene glycol, methanol
Folic acid/leucovorin	1–2 mg/kg q 4–6h IV		Methanol, methotrexate (only leucovorin)
Fomepizole	15 mg/kg IV, then 10 mg/kg q12h		Methanol, ethylene glycol, disulfiram
Glucagon	50 µg/kg	1–10 mg IV	Calcium channel blocker, β-blocker
Methylene blue	1–2 mg/kg Neonates: 0.3–1 mg/kg	1–2 mg/kg	Oxidizing chemicals (e.g., nitrites, benzocaine, sulfonamides)
Octreotide	1 µg/kg q6h SC	50–100 µg SC q6h	Refractory hypoglycemia after oral hypoglycemic agent ingestion
Naloxone	As much as is needed. Typical starting dose 0.4 mg–10 mg IV		Opioid, clonidine
Physostigmine	0.02 mg/kg IV	1–2 mg IV	Anticholinergic substances (not tricyclic antidepressants)
Pralidoxime (2-PAM)	20–40 mg/kg IV	1–2 g IV	Cholinergic substances
Protamine	1 mg neutralizes 100 U of administered heparin; administered over 15 min 0.6 mg/kg	25–50 mg IV: empiric	Heparin
Pyridoxine	Gram for gram ingestion if amount of isoniazid is known 70 mg/kg IV	5 g IV	Isoniazid, <i>Gyromitra esculenta</i> , rocket fuel
Sodium bicarbonate	1–2 mEq/kg IV bolus followed by 2 mEq/kg per h		Sodium channel blockers, alkalization of urine or serum
Thiamine	100 mg IV		Ethylene glycol, Wernicke syndrome, “wet” beri-beri
Vitamin K₁	2–5 mg/d PO	25–50 mg TID	Anticoagulants
Whole-bowel irrigation	0.5 L/h PO	1.5–2 L/h PO	Multiple indications

*This is an approximation. Dose should be titrated to level (see Chap. 166).

TABLE 156-3 Toxidromes

Toxidrome	Representative Agent(s)	Most Common Findings	Additional Signs and Symptoms	Potential Interventions
Opioid	Heroin Morphine	CNS depression, miosis, respiratory depression	Hypothermia, bradycardia. Death may result from respiratory arrest, acute lung injury	Ventilation or naloxone
Sympathomimetic	Cocaine Amphetamine	Psychomotor agitation, mydriasis, diaphoresis, tachycardia, hypertension, hyperthermia	Seizures, rhabdomyolysis, myocardial infarction. Death may result from seizures, cardiac arrest, hyperthermia	Cooling, sedation with benzodiazepines, hydration
Cholinergic	Organophosphate insecticides Carbamate insecticides	Salivation, lacrimation, diaphoresis, nausea, vomiting, urination, defecation, muscle fasciculations, weakness, bronchorrhea	Bradycardia, miosis/mydriasis, seizures, respiratory failure, paralysis. Death may result from respiratory arrest from paralysis, bronchorrhea, or seizures	Airway protection and ventilation, atropine, pralidoxime
Anticholinergic	Scopolamine Atropine	Altered mental status, mydriasis, dry/flushed skin, urinary retention, decreased bowel sounds, hyperthermia, dry mucous membranes	Seizures, dysrhythmias, rhabdomyolysis. Death may result from hyperthermia and dysrhythmias	Physostigmine (if appropriate), sedation with benzodiazepines, cooling, supportive management
Salicylates	Aspirin Oil of wintergreen	Altered mental status, respiratory alkalosis, metabolic acidosis, tinnitus, hyperpnea, tachycardia, diaphoresis, nausea, vomiting	Low-grade fever, ketonuria. Death may result from acute lung injury	MDAC, alkalinization of the urine with potassium repletion, hemodialysis, hydration
Hypoglycemia	Sulfonylureas Insulin	Altered mental status, diaphoresis, tachycardia, hypertension	Paralysis, slurring of speech, bizarre behavior, seizures. Death may result from seizures, altered behavior	Glucose containing solution intravenously, and oral feedings if able, frequent capillary blood for glucose measurement, octreotide
Serotonin syndrome	Meperidine or dextromethorphan and MAOI; SSRI and TCA; SSRI/TCA/MAOI and amphetamines; SSRI	Altered mental status, increased muscle tone, hyperreflexia, hyperthermia	Intermittent whole-body tremor. Death may result from hyperthermia	Cooling, sedation with benzodiazepines, supportive management, theoretical benefit—cyproheptadine

Abbreviations: CNS = central nervous system; MDAC = multidose activated charcoal; MAOI = monoamine oxidase inhibitor; SSRI = selective serotonin re-uptake inhibitor; TCA = tricyclic antidepressant.

their use. The three general methods of decontamination involve removal of the toxin from the stomach via the mouth, binding it inside the gut lumen, or mechanically flushing it through the GI tract. The toxin ingested, the time course, the patient's clinical status, and the skills of the physician at the bedside determine the choice of method(s) used. GI decontamination must never be initiated as a punitive action.

GASTRIC EMPTYING

Emesis

Emesis can be achieved by administration of syrup of ipecac. Syrup of ipecac is a plant-derived compound composed of two alkaloidal substances—emetine and cephaeline—that work both peripherally on the stomach and centrally on the chemotactic trigger zone to induce vomiting. Dosing of syrup of ipecac is 15 mL for children 1 to 12 years of age, and 30 mL for adults, usually followed by sips of water. The dose may be repeated only once if vomiting does not occur within 30 min. Approximately 90 percent of patients vomit within 20 min after the first dose, and up to 97 percent vomit after a second dose. A typical patient vomits less than three to five times, and symptoms usually resolve within 2 h.

The ingested toxin should be suspected as the etiology if protracted vomiting occurs. Contraindications to the administration of syrup of ipecac include ingestions that have the potential to alter mental status; active or prior vomiting; caustic ingestion; a toxin with more pulmonary than GI toxicity (e.g., hydrocarbons); and ingestions of toxins that have the potential for inducing seizures. Rare complications of syrup of ipecac include aspiration, Boerhaave syndrome, Mallory-Weiss tear, and intractable vomiting.

Indications for in-hospital use of syrup of ipecac are extremely limited. Most patients reach the hospital beyond the time frame when the toxin would still be expected to remain in the stomach, because either the toxin has been absorbed or has passed through the pylorus. Also, even when syrup of ipecac is given with activated charcoal less than 60 min after ingestion, it has not been demonstrated to alter outcome when compared to treatment with activated charcoal and a cathartic alone. Ipecac's administration also delays the time to administration of oral antidotes such as TV-acetylcysteine by 1 to 6.5 h.

Possible rare hospital indications for its use include very recent ingestions of substances not expected to compromise the airway or lead to altered mental status, hemodynamic derangement, or seizure; a recent ingestion of a pill that is known not to fit into the holes of the appropriately sized orogastric tube; or a substance known not to adsorb to activated charcoal (see the following sections).

*Listed are the most common or most classically seen with the agent.

Although debated by many authors, syrup of ipecac may still be indicated, especially when it can be given in the home immediately after an ingestion of a known toxin that does not have the previously listed contraindications while it still is expected to be in the stomach. This may be especially true in remote locations where transport times to definitive health care may be prolonged.

Orogastric Lavage

The principal method of gastric emptying in the emergency department is orogastric lavage, which is performed with the patient lying in the left lateral decubitus position. A 36- to 40-French tube is used for adults and a 22- to 24-French tube for children. The tube is inserted after careful measurement of the length from the chin to the xiphoid process. Correct positioning must be assessed by insufflation of air

to ensure accurate placement in the stomach. Lavage with room-temperature water is commonly continued until the effluent becomes clear. Before the tube is removed, activated charcoal should be instilled in a dose of 1 g/kg, if indicated. The contraindications to lavage include pills that are known not to fit into the holes of the orogastric lavage hose, nontoxic ingestions, non-life-threatening ingestions, caustic ingestions, any patient whose airway integrity is not assured, or toxic ingestions that are more damaging to the lungs than to the GI tract. Complications include insertion of the tube into the trachea, aspiration, esophageal or gastric perforation, decreased oxygenation during the procedure,⁴ and inability to withdraw the tube once inserted (knot formation).

Although the perceived benefits of orogastric lavage are the immediate return of small pills or pill fragments, and a reduction in the amount of substance available for further intoxication, studies typically

TABLE T56-5 Odors and Skin Findings

ODORS	
Almonds	Cyanide
Eggs	Hydrogen sulfide, mercaptans
Fish	Zinc sulfide
Garlic	Organic phosphorus compounds
Freshly mown hay	Phosgene
Geraniums	Lewisite
Swimming pool	Chlorine gas
Mothballs	Camphor, naphthalene, P-dichlorobenzene
Violets	Turpentine
Wintergreen	Methyl salicylate
Peanuts	Vacor
SKIN FINDINGS	
Cyanosis	Anything causing deoxyhemoglobin or methemoglobin Yellowing of skin Excessive consumption of vegetables containing carotene (e.g., carrots, squash), local coloration from cigarettes, dinitrophenol, picric acid
Flushing	Anticholinergic medications, scombroid, ethanol in patients aldehyde dehydrogenase deficient, rectal foreign body, disulfiram, niacin, nitrates
Gray	Metallic silver or gold
Eschar formation	Radioactive material, anthrax, brown recluse spider venom
Bullae	Barbiturates, chemotherapeutic agents
Red skin	Vancomycin, carbon monoxide, boric acid
Transverse lines across nails	Sign of major systemic insult (e.g., arsenic, chemotherapy)

demonstrate drug removal ranging from only 35 to 56 percent. Of three large studies that evaluated the clinical efficacy of orogastric lavage,^{5,6} only two showed any benefit from the procedure, and only if it was initiated in patients within 1 h of the ingestion. Indications for this procedure are generally limited to recent ingestion of a life-threatening toxin that requires ventilatory support because of depressed mental status, or risk of seizures.

TOXIN ADSORPTION IN THE GUT

Activated Charcoal

The most appropriate agent to decontaminate the GI tract is activated charcoal, which is produced by pyrolysis of carbonaceous materials and "activation" by steam cleaning to increase its surface area. Activated charcoal works by adsorbing the toxin within the gut lumen, making the toxin less available for absorption into the tissues. It also enhances elimination by establishing a free-drug concentration gradient favoring movement into the GI lumen to enhance elimination ("GI dialysis"),⁷ and it can also bind substances excreted in the bile, interrupting enterohepatic circulation. The benefits of this technique include its capability to decontaminate the gut without requiring invasive procedures, its rapid administration, and its proven safety in both adults and children.

Activated charcoal is typically given in a slurry of water or juice by mouth or through a nasogastric tube, in an activated charcoal-drug dose of 10:1 (thought to be the smallest dose of activated charcoal that can be given without reducing its efficacy)⁸ or in 1 g/kg, whichever is larger. In adults, the first dose of activated charcoal is often given with a cathartic to reduce GI transit time. Sorbitol and magnesium citrate solution are the most commonly used cathartics (see "Cathartics" below).

Activated charcoal should not be given if esophageal or gastric perforation are suspected, or if emergency endoscopy might be needed (as in caustic ingestion). Complications that are exceedingly rare, include aspiration and intraluminal impaction in patients with abnormal gut motility.

Clear indications for administration of activated charcoal are ingestion of any drug known to adsorb to it or after an unknown ingestion by patients with protected airways. There is no indication for activated charcoal in isolated ingestion of substances known not to adsorb to activated charcoal (such as iron, lithium, or lead).

Multiple-Dose Activated Charcoal

One dose of activated charcoal is usually sufficient to achieve a therapeutic effect. Multiple-dose activated charcoal, however, is indicated in specific instances, such as after ingestion of very large doses; substances that form bezoars in the GI tract; potentially injurious toxins that slow gut function; toxins that are released slowly into the gut lumen; and those with enterohepatic, enteroenteric circulation. Multiple-dose activated charcoal is usually given as follows: the first dose is up to 1 g/kg body weight, which is then followed by subsequent doses of 0.25 to 0.50 g/kg. Repeated doses of activated charcoal should be given in intervals ranging from 1 to 4 h. Although intubated patients having ingested life-threatening toxins who have decreased gut motility can receive multiple doses, the stomach must be suctioned just prior to the administration of the next dose of activated charcoal to minimize gastric distention.

To prevent excessive fluid loss and electrolyte imbalance, only the first dose of activated charcoal should be given with a cathartic, and only if the toxin itself is not expected to cause diarrhea.

Multiple-dose activated charcoal is contraindicated in patients with non-life-threatening ingestions that result in decreased gut motility, because of increased risks of aspiration from gastric distention, and impaction of charcoal within the gut.

Cathartics

Often, activated charcoal is administered with an osmotic cathartic, such as 70% sorbitol (1 g/kg), or a 10% solution of magnesium citrate (in a dose of 250 mL for adults and 4 mL/kg for children). Cathartics have been repeatedly shown to decrease the transit time for the passage of the activated charcoal (and presumably the adsorbed toxin) through the GI tract.^{9,10} Although most studies fail to show a benefit of administering a cathartic alone,^{11,12} several studies suggest that there is a decrease in peak serum plasma concentrations and area under the curve, when the cathartic is administered with activated charcoal.^{12,14} No definitive clinical human data, however, suggest that the addition of a cathartic to a dose of activated charcoal either limits the toxin's bioavailability or changes the patient's clinical outcome.

Indications for use of cathartics generally mirror those for the administration of activated charcoal. When multiple-dose activated charcoal is used, only the first dose is accompanied by a cathartic, to limit complications. Complications of cathartic administration include nausea and abdominal pain, severe volume depletion, electrolyte imbalances and fluid shifts, and hypermagnesemia in patients with renal compromise.

Contraindications for cathartic use are: ingestion of a substance that will result in diarrhea; children younger than age 5; patients with renal failure (magnesium-containing cathartics are contraindicated); intestinal obstruction; or ingestion of any caustic material.

Whole-Bowel Irrigation

Whole-bowel irrigation is the installation of large volumes of polyethylene glycol in an osmotically balanced electrolyte solution that causes neither fluid nor electrolyte shifts. This technique is accomplished in adults by the installation of 2 L/h polyethylene glycol solution either by mouth or through a nasogastric tube. In children, the volume administered is 50 to 250 mL/kg per h or as much polyethylene glycol solution as can be tolerated. The end point is clear rectal effluent.

When done properly, this technique produces a rapid catharsis by mechanically forcing ingested substances through the bowel at a rapid rate.

Contraindications include: patients with preceding diarrhea; ingestions that are expected to result in significant diarrhea (except for heavy metals, as these substances do not adsorb well to activated charcoal); and patients with absent bowel sounds or with obstruction. Complications include bloating, cramping, and rectal irritation from frequent bowel movements. Close nursing care is needed to maintain patient cleanliness.

Controlled studies clearly demonstrating improvement in clinical outcome after this procedure are lacking, but many authors describe limited symptomatology following potentially toxic doses of substances known not to adsorb to activated charcoal.¹⁵ Table 156-6 lists common indications for whole-bowel irrigation.

Frequently, an antiemetic is required to prevent the nausea and vomiting that results from gastric distention with large volumes of whole-bowel irrigation solution. Care must be taken to avoid phenothiazine derived antiemetics that may slow gut function. Generally, either metoclopramide or ondansetron are used for this purpose.

ENHANCED ELIMINATION

Alkalinization

Urinary alkalinization is beneficial in the treatment of certain ingestions. The urinary pH is manipulated to exploit physiologic properties of specific toxins. Only nonionized substances are free to move passively across membranes. Ionized particles must remain in the fluid-filled compartments in which they were formed. Weak acids are mostly uncharged at physiologic pH, but become charged in alkaline environments. After intravenous administration, bicarbonate becomes concentrated in the urine resulting in significant elevation of urinary pH (if the patient has a normal serum potassium). By significantly raising the urinary pH with intravenous sodium bicarbonate, toxins that are weak acids are converted from their nonionized form to their ionized form and are therefore held within the urinary collection system. This "ion trapping" keeps the toxin within the renal tubules, thereby enhancing its excretion out of the body in the urine. This creates an imbalance in the concentration gradient of the toxin between the blood and the urinary collection system, drawing more toxin into the renal tubular lumen. The ideal toxin that can be eliminated by this technique is one with substantial urinary excretion and with a pK_a less than the serum pH (Table 156-7).

Urinary alkalinization is typically achieved by the administration of an intravenous bolus of 1 to 2 mEq/kg sodium bicarbonate, followed by either intermittent boluses of sodium bicarbonate or a continuous intravenous infusion to achieve a urinary pH of 7.5 to 8.0. Serum pH should not be allowed to rise above 7.5 to 7.55. Pronounced hypokalemia may result from this technique and must be corrected aggressively. Hypokalemia induces the kidneys to reabsorb potassium and excrete hydrogen ions, inhibiting the production of alkaline urine. This may result in relatively acidic urine when compared to the serum pH.

The benefit of urinary alkalinization is a decrease in toxin serum half-life from increased urinary excretion. The risks include volume

* Indicates also removed by hemoperfusion.

overload (congestive heart failure, pulmonary edema), pH shifts, and hypokalemia. Therefore, contraindications to this procedure include patients who cannot tolerate the volume or sodium load, are hypokalemic, have renal insufficiency, and ingestion of a toxin that does not respond to alkalinization.

Acidification of Urine

Acidification of urine can somewhat enhance elimination of amphetamines, phencyclidine, and some other drugs. However, the risks, particularly in relation to rhabdomyolysis, far outweigh any benefits.

Forced Diuresis

Forced diuresis has never been shown to be effective for any ingestion. Given the potential of harm, this technique should not be used.

Hemodialysis/Hemoperfusion

Hemodialysis is generally reserved for specific toxins that must be both potentially life-threatening and amenable to removal by this method (see Table 156-7). The benefits include the ability to remove toxins that are already absorbed from the gut lumen, removal of substances that do not adhere to activated charcoal, and the ability to remove both the parent compound and the active toxic metabolites. Hemodialysis is much less effective when the toxin ingested has a large volume of distribution (>1 L/kg), has a large molecular weight (more than 500 Da), or is highly protein bound.

Hemodialysis is rarely absolutely contraindicated, but relative contraindications include hemodynamic instability, very small children, and patients with poor vascular access or profound bleeding diatheses. Risks of hemodialysis are typically minimal in experienced centers, but they include large fluid shifts, electrolyte imbalances, infection and bleeding at the catheter site, and intracranial hemorrhage. Exchange transfusion should be considered in small children who cannot receive hemodialysis because of technical limitations.

Hemoperfusion, which is also used for decontamination of a patient's systemic circulation, involves placing a filter filled with activated charcoal into the circuit of the hemodialysis machine. This filtration alleviates the constraints of protein binding and molecular size, both of which **limit** the utility of hemodialysis. Toxins that can be removed by this method must adsorb well to activated charcoal and have a small volume of distribution. While potentially useful for phenobarbital, phenytoin, and ethchlorvynol, in practice, it is only commonly recommended for theophylline overdoses.

4. Changes in gut pH or motility [e.g. ranitidine (Zantac) and ketoconazole (Nizoral)]

Distribution interactions usually involve drugs that are normally highly protein bound. Increased concentrations of a highly bound agent can occur by displacement from its binding site by another agent. For example, sulfonylureas and warfarin (Coumadin), which are over 90 percent protein bound, when given together may increase the international normalized ratio (INR) and increase the risk of bleeding. Metabolism interactions can occur when a medication decreases or increases the metabolism of another agent. Of particular importance are those medications that are metabolized by the cytochrome P450 (P450) enzyme family. There are two mechanisms for P450-mediated interactions, induction and inhibition. An induction interaction is the result of decreased degradation or increased synthesis of P450 enzymes, thereby accelerating the conversion of active medication to its inactive metabolites. For instance, nafcillin administered with warfarin induces metabolic enzymes that increase the metabolism of warfarin, resulting in a decreased anticoagulant effect. An inhibition interaction, which can refer to competition of substrates (drugs) for a site or enzyme inactivation, results in a decreased rate of drug metabolism, leading to a prolonged half-life and a potential for increased pharmacodynamic effects. For example, the concomitant use of metronidazole (Flagyl) and warfarin decreases warfarin metabolism, resulting in an increase in anticoagulant effect. Agents commonly associated with interactions with other agents are presented.

ANTICOAGULANTS

Concurrent administration of warfarin with agents such as alcohol, macrolides, sulfonamides, azole antifungals, and amiodarone (Coronarone) may significantly increase the anticoagulation activity. Some nonsteroidal anti-inflammatory drugs (NSAIDs), such as phenylbutazone and naproxen, have been reported to displace warfarin from plasma proteins, whereas others do not appear to have effects. Selective cyclooxygenase 2 (Cox-2) inhibitors may slightly elevate prothrombin times. Chronic alcohol ingestion, nafcillin, barbiturates, and rifampin may significantly decrease the anticoagulation activity.¹

ANTIMICROBIAL AGENTS

Although most drug interactions are sources of concern, some are predictable and can be used to enhance the effect of some antimicrobials.² In fact, the interaction of probenecid in combination with penicillins or cephalosporins has been used to decrease the need for multiple doses of shorter-acting antibiotics by inhibiting their elimination.

Some of the more troubling adverse effects of drug interactions concern antimicrobials that induce or inhibit hepatic or renal metabolism of other drugs. The agents most commonly associated with these types of drug interactions are rifampin, erythromycin, isoniazid, and the azole antifungals. For example, rifampin, an inducer of the hepatic P450 system, increases clearance of many medications and therefore reduces efficacy. Medications that have been shown to interact with rifampin include digoxin, calcium channel blockers, amiodarone, 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors, azole antifungals, corticosteroids, and theophylline.

ANTIRETROVIRAL AGENTS

The increasing complexity of highly active antiretroviral therapy (HAART) for treating human immunodeficiency virus infection warrants special attention for drug interactions. The most common drug interactions occur with the use of a nonnucleoside reverse transcriptase inhibitor or a protease inhibitor, which are metabolized primarily by the P450 system and inhibit or induce the metabolism of other agents that use the P450 system. This interaction can be quite prob-

157 PRINCIPLES OF DRUG INTERACTIONS

George Delgado, Jr. Jamie Pilarowski

The use of medications to treat disease is not without peril. Clinicians are required to assess the risks and benefits of drug therapy before implementing such treatment. For a clinician to treat certain conditions, it may be necessary to use multiple medications. Using multiple medications can increase the risk of drug interactions through an increase or decrease in efficacy or toxicity due to one agent or multiple agents. Although a drug interaction can be predicted at times, drug interactions may not consistently result in the same clinically observable outcome and may vary due to dosing, differences between agents in a certain class, concomitant disease states of a patient, and duration of administration.

The mechanisms of these drug interactions are pharmacokinetic and pharmacodynamic in nature. Pharmacokinetic mechanisms of drug interactions can occur in one of the four different phases of the body's processing of medication: absorption, distribution, metabolism, and elimination. Some interactions that involve absorption include:

1. Prevention of absorption through binding of the medication in the gut [e.g., ciprofloxacin (Cipro) and antacids]
2. Increased absorption by inhibition of gut lining metabolism [e.g., felodipine (Plendil) and grapefruit juice]
3. Changes in absorption capacity by alteration of gut flora (e.g., ampicillin and oral contraceptives)

lematic because of the typical HAART regimen consisting of two nucleoside reverse transcriptase inhibitors in addition to a nonnucleoside reverse transcriptase inhibitor or a protease inhibitor. For example, a HAART regimen that includes ritonavir (Norvir; a strong inhibitor of cytochrome P4503A4) and used concomitantly with certain 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors can significantly increase the risk of rhabdomyolysis.³¹⁴

THEOPHYLLINE

Theophylline is still used in children and on occasion in adults to provide preventative and symptomatic relief of bronchospasm in patients with chronic asthma, bronchitis, and emphysema. Interventions are discussed in detail in Chap. 173. When adding a macrolide or fluoroquinolone, caution must be used because the interaction may result in an increase in theophylline levels.

CARDIOVASCULAR DRUGS

Antihypertensives such as metoprolol succinate (Lopressor), propranolol hydrochloride (Inderal), and verapamil (Calan and Isoptin) exhibit decreased bioavailability secondary to induction by medications such as rifampin and phenobarbital (Luminal), which are strong inducers of the P450 system.⁵ The end result of this interaction is the lowering of these agents below therapeutic levels. Cimetidine (Tagamet), a P450 inducer, may produce the opposite effect. Another significant inhibition interaction can be seen with the azole antifungal agents and the dihydropyridine calcium channel blockers, such as amlodipine (Norvasc) and felodipine. This combination inhibits the metabolism of calcium channel blockers and should be avoided. Certain calcium channel blockers also have been shown to increase other drug levels through a decreased clearance. For example, diltiazem (Cardizem), nifedipine (Procardia and Adalat), and verapamil can decrease the clearance of theophylline by more than 25 percent. Another example is the coadministration of cyclosporine with diltiazem or verapamil, which can result in a lower maintenance dose for cyclosporine. Verapamil is also responsible for increasing the bioavailability of simvastatin (Zocor). The dose of simvastatin should be reduced if the combination of the two cannot be avoided.

Digoxin, due to its narrow therapeutic index and kinetic profile, should be taken into consideration when discussing drug-to-drug interactions. Digoxin's long half-life, large volume of distribution, fairly extensive tissue binding, and high percentage of renal excretion (>80 percent) combined with its narrow therapeutic index set the path for numerous interactions. Some of the most clinically relevant drug interactions include amiodarone, spironolactone (Aldactone), and verapamil, which decrease digoxin clearance and increase serum digoxin levels. In addition, serum digoxin levels rise with quinidine coadministration through a decrease in digoxin clearance and displacement of digoxin from binding sites in tissue. Diuretics also may play a role in interactions by potassium and magnesium depletion, which may increase the risk of digoxin side effects, such as arrhythmias. (3-blockers, such as carvedilol (Coreg), have been shown to increase the bioavailability of digoxin when given in combination.

QT PROLONGATION

Various individual or classes of drugs, electrolyte imbalances, and some congenital syndromes prolong the QT interval, which itself potentiates the development of torsades de pointes. Some of these drugs may cause QT prolongation alone or in combination with other drugs that have the same potential. For example, quinidine, ibutilide (Corvert), amiodarone, and haloperidol (Haldol) can cause QT prolongation and or torsades de pointes on their own, but other drugs, such as the azole antifungals, when used in combination with agents known to prolong QT intervals may further increase the risk of developing this arrhythmia.

HERBAL MEDICINE

With the overwhelming increase in the number of patients consuming herbal and dietary supplements in addition to their prescription medications, it is important to consider the potential for interactions between them.⁶¹⁸ Because herbal products are not strictly regulated and tested by the Food and Drug Administration, the data regarding these interactions are limited. The data that do exist are from case reports or from other countries. Table 157-1 lists a summary of some of the important herbal and drug interactions. The Natural Medicines Comprehensive Database (<http://www.naturaldatabase.com>) and the NIH Office of Dietary Supplements, IBIDS Consumer Database (<http://www.dietary-supplements.info.nih.gov>) are other sources of information.

ANTIEPILEPTIC DRUGS

Epilepsy is a chronic disease state in which patients may require years of treatment with antiepileptic drugs. Some epileptic patients will require treatment with more than one antiepileptic drug to maintain seizure control. Further, concomitant disease states may require the administration of other drug therapies, thus increasing the potential for interactions. ■

Many of the older antiepileptic drugs are metabolized by the P450 system and are inducers or inhibitors of these enzymes. Carbamazepine (Tegretol), phenobarbital, phenytoin, and primidone (Mysoline) are inducers, whereas valproic acid (Depakene) is an inhibitor. In addition, some of these older agents may be more highly protein bound (i.e., phenytoin and valproic acid), which can have an effect on drug interactions. Most of the newer antiepileptic drugs undergo minimal or no metabolism by the P450 system, so many possible drug interactions can be avoided. In addition, many of the newer agents do not induce or inhibit enzymes involved in the metabolism of other drugs.

One clinically significant drug interaction that is important to keep in mind with coadministration of antiepileptic drugs is the reduction of contraceptive efficacy via increased metabolism and clearance of oral contraceptive drugs. Antiepileptic drugs implicated in this type of interaction include carbamazepine, phenytoin, phenobarbital, oxcarbazepine (Trileptal), and felbamate (Felbatol). Not all of the newer antiepileptic drugs are known to contribute to this interaction, but caution should be advised and the patient counseled on alternative methods of birth control.

Other drugs that are susceptible to increased metabolism via enzyme induction by phenytoin, carbamazepine, phenobarbital, and primidone are theophylline, warfarin, digoxin, cyclosporine, antiretroviral agents, and griseofulvin. The induction caused by these antiepileptic drugs could decrease the efficacy of these drugs and potentially cause treatment failure.

Valproic acid, an enzyme inhibitor, may increase plasma concentrations of phenytoin, carbamazepine, phenobarbital, and lamotrigine (Lamictal), thus putting the patient at risk of supratherapeutic levels if used in combination without dosage adjustment and monitoring.

PSYCHOTROPICS

There are several antidepressant and antipsychotic medications in use today, but only some of the more important interactions with these agents are discussed. One of the most impressive and significant interactions concern a specific class of antidepressants known as the monoamine oxidase inhibitors. These agents [phenelzine (Nardil), selegiline (Eldepryl), and tranylcypromine (Parnate)] are not as commonly prescribed today due to newer agents that have a better safety profile. Monoamine oxidase inhibitors have a rare but potentially fatal interaction when taken with specific foods high in tyramine content and with certain drugs. A marked pressor effect is seen and may develop into hypertensive crisis with subsequent cerebral vascular accident and death. Symptoms include headache, stiff neck, nausea,

TABLE 157-1 Herbal Interactions

Herbal Medication	Potential Interaction	Effect/Possible Mechanism
Coenzyme Q	Warfarin	Decreased INR (coenzyme Q contains vitamin K derivatives)
Danshen	Warfarin	Increased INR (decreased warfarin clearance/increased bioavailability; also, danshen may contain coumarin derivatives); hemorrhage reported
Dong Quai	Caffeine; theophylline Antiplatelet drugs; warfarin	Exaggerated sympathomimetic activity Increased INR/increased bleeding tendency (platelet inhibition; dong quai contains coumarin derivatives)
Feverfew	Antiplatelet drugs (NSAIDs, ticlopidine, clopidogrel, dipyridamole); warfarin Anti-serotonin migraine drugs (e.g., sumatriptan)	Inhibition of platelet aggregation (increased risk of bleeding) Inhibition of serotonin release (increased risk of serotonin syndrome–like picture)
Garlic	Warfarin Antihyperglycemic agents	Increased INR (potential fibrinolytic/antiplatelet activity of garlic); hemorrhage reported Hypoglycemia (additive effect on glucose levels)
Ginger	Antiplatelet drugs; warfarin Antihypertensives	Platelet inhibition Variable effects (may cause loss of BP control in patients on antihypertensives)
Ginkgo	Antiplatelet drugs; warfarin; aspirin; rofecoxib Trazodone	Antiplatelet activity/increased bleeding tendency (CNS hemorrhage reported with warfarin) Increased production of one of the active metabolites of trazodone (potential for trazodone toxicity including coma)
Ginseng	Warfarin Antihypertensive agents Antihyperglycemic agents	Decreased INR (increased warfarin metabolism) Increase or decrease in blood pressure Hypoglycemia (additive effect of glucose levels)
Kava	Antiplatelet drugs; warfarin Benzodiazepines	Increased risk of bleeding (platelet inhibition) Increased anxiolytic properties (additive effect)
St. John's wort	Tricyclic antidepressants, theophylline, indinavir, monoamine oxidase inhibitors, cyclosporin, oral contraceptives, warfarin, alprazolam, simvastatin, tacrolimus Digoxin SSRI	Decreased levels of mentioned agents (enzyme induction by St. John's wort) Decreased digoxin levels (increased P-glycoprotein activity) Increased serotonin effects
Yohimbine	Clonidine, tricyclic antidepressants	Hypertension (α_2 antagonism)

Abbreviations: CNS = central nervous system; INR = international normalized ratio; NSAIDs = nonsteroidal anti-inflammatory drugs; SSRI = serotonin selective reuptake inhibitor.

1024 SECTION 14 • TOXICOLOGY AND PHARMACOLOGY

vomiting, diaphoresis, and an abrupt increase in blood pressure. Some of the common medications that must be restricted in patients on monoamine oxidase inhibitors include meperidine (Demerol), dextromethorphan, asthma inhalants, carbamazepine, decongestants (topical and systemic), and agents with sympathomimetic activity (see Chap. 160).

Another psychotropic agent with the potential for drug interactions is haloperidol. Haloperidol, a phenothiazine antipsychotic agent, is metabolized by the P450 system (primarily 2D6 and 3A4). Carbamazepine and other inducers may decrease plasma concentrations of haloperidol, chlorpromazine (Thorazine), clozapine (Clozaril), and risperidone (Risperdal), whereas valproic acid may inhibit metabolism of certain psychotropic agents.^{10,11}

The most common and troubling drug interactions with lithium include NSAIDs, angiotensin converting enzyme inhibitors, and diuretics. The NSAIDs and angiotensin converting enzyme inhibitors decrease lithium clearance and increase lithium concentrations, whereas diuretics can produce either effect depending on the class of the diuretic (i.e., where the diuretic works in the renal system). For example, loop and thiazide diuretics increase lithium concentrations by increasing lithium reabsorption. Conversely, carbonic anhydrase inhibitors and osmotic diuretics can increase lithium excretion. Caffeine and theophylline also can increase lithium excretion.

CONCLUSION

One of the many challenges of medicine is choosing the most appropriate medication, which may be complicated further by the use of multiple agents and comorbid conditions that may alter the pharmacodynamics and pharmacokinetics of these medications. A few of the significant drug interactions are reviewed in this chapter. As more drugs gain approval and the popularity of herbal supplements continues to grow, so will the potential for interactions. Awareness of the general pharmacokinetic properties of a given class of medication may help to avoid a potentially fatal drug interaction.

deficit disorder, panic and phobia disorders, anxiety disorders, eating disorders, chronic pain syndromes, peripheral neuropathies, nocturnal enuresis, migraine headache prophylaxis, and selected drug-withdrawal therapy. Pediatric and adolescent use has increased significantly over the past few years. There are currently eight different TCAs available in the United States (Table 158-1), but many more varieties are available in other countries. The five most commonly reported TCAs involved in drug exposures include amitriptyline (40 percent), imipramine (17 percent), doxepin (14 percent), nortriptyline (12 percent), and desipramine (6 percent). Two related antidepressants, maprotiline and amoxapine, have minor structural differences when compared with traditional TCAs but have similar toxicity in overdose and thus will be included in this chapter. Cyclobenzaprine (Flexeril) is a muscle relaxant that is almost structurally identical to amitriptyline but lacks antidepressant activity. It tends to have less cardiotoxicity than amitriptyline but still can produce significant central nervous system (CNS) sedation and antimuscarinic toxicity in overdose.² Therapeutic doses of TCAs are highly variable. Initially, lower doses are used, followed by gradual increases until the desired therapeutic response is achieved. In addition, this process allows most patients to become acclimated to the typical TCA-induced adverse effects such as CNS sedation and dry mucous membranes.

TCA-related drug toxicity is not just limited to cases of drug overdose (Table 158-2). There are at least seven different possible mechanisms for developing TCA-related drug toxicity while taking therapeutic doses. First, mild to moderate toxicity will develop commonly if unacclimated individuals are started on higher therapeutic doses. Second, toxicity can result when TCAs are combined with other medications having similar pharmacologic actions (e.g., antihistamines, antipsychotics). Third, a subset of the population consists of slow metabolizers of TCAs, and as such, these people will develop higher plasma TCA levels for any given dose. Fourth, many drugs have the potential to inhibit the metabolism of TCAs, resulting in elevated TCA plasma levels. Fifth, some TCAs are available as mixed-drug formulations combined with either benzodiazepines or antipsychotic agents, having the potential for additional drug toxicity. Sixth, patients with certain medical conditions such as underlying heart problems or seizure disorders are more susceptible to TCA toxicity at therapeutic doses. Seventh, TCAs have the potential to produce serotonin syndrome, especially in combination with other serotonergic medications (see Chap. 159).

TRICYCLIC ANTIDEPRESSANTS

Kirk C. Mills

EPIDEMIOLOGY

Although their popularity has decreased in recent years, tricyclic antidepressants (TCAs) remain a frequent cause of drug exposure and overdose, in most cases requiring emergent medical care. Approximately 1 in every 30 adult exposures to a pharmaceutical medication involves a TCA.¹ The 2001 Annual Report of the American Association of Poison Control Centers Toxic Exposure Surveillance System demonstrates that TCAs are associated with more drug-related deaths than any other class of prescription medication.¹ Over the past decade there have been an average annual reporting of 18,000 exposures and 110 associated deaths related to TCAs. The relatively low exposure-to-death ratio of TCAs underscores their low therapeutic index and potential for severe toxicity resulting in death. Most reported TCA exposures occur in young adults, with approximately 60 percent of all exposures believed to be intentional.

TCAs are used primarily for the treatment of major depression. In addition, they are prescribed frequently for other psychiatric and medical conditions such as obsessive-compulsive disorder, attention-

TABLE 158-1 Tricyclic Antidepressants

Generic Name	Trade Name(s)	Formulations (mg)	Adult Daily Dose (mg)	Active Metabolites
Amitriptyline	Elavil	10, 25, 50, 75, 100, 150	75-300	Nortriptyline
Amoxapine*	Asendin	25, 50, 100, 150	50-300	7-Hydroxyamoxapine 8-Hydroxyamoxapine
Clomipramine	Anaftanil	25, 50, 75	50-200	Desmethyldclomipramine
Cyclobenzaprine	Flexeril	10-mg tablet	20-40	None
Desipramine	Norpramin Pertofrane	10, 25, 50, 75, 100, 150	75-200	None
Doxepin	Adapin, Sinequan	10, 25, 50, 75, 100, 150 Oral solution 10 mg/mL	75-300	Desmethyldoxepin
Imipramine	Tofranil	10, 25, 50	75-200	Desipramine
Maprotiline*	Ludiomil	25, 50, 75	75-150	Desmethyldmaprotiline
Nortriptyline	Pamelor, Aventyl	10, 25, 50, 75 Oral solution 2 mg/mL	75-150	None
Protriptyline	Vivactil	5, 10	15-40	None
Trimipramine	Surmontil	25, 50, 100	75-200	Desmethyldtrimipramine

*See text for clarification.

TABLE 158-2 Mechanisms for TCA Drug Toxicity at Therapeutic Doses

Development of serotonin syndrome
Drug interactions with medications that inhibit hepatic metabolism (P450 system)
Drug interactions with medications sharing similar pharmacologic actions
Elevated levels of TCAs due to genetically slow hepatic metabolism
Patients with preexisting cardiovascular or CNS disease
Some combination TCA medications contain other active ingredients (e.g., antipsychotics)
Unacclimated individuals starting on high therapeutic doses

PATHOPHYSIOLOGY

TCAs have a distinct chemical structure consisting of three aromatic rings: a central seven-member ring, two outer benzene rings, and an aminopropyl side chain connected to the central ring. There are only minor structural differences among the TCAs, usually on the central aromatic ring or aminopropyl side chain. Amoxapine is unique in that it has an aromatic side chain. Maprotiline has an ethylene bridge across a six-member center ring, giving it a tetracyclic chemical structure. It is not surprising that other chemicals that share the same basic tricyclic chemical structure as the TCAs, such as carbamazepine and phenothiazines, would manifest similar toxicity in overdose.

TCAs are nonselective agents that exhibit a multitude of pharmacologic effects (Table 158-3) and have considerable variation in potency. There are subtle and potentially clinically significant pharmacologic differences among the TCAs at therapeutic plasma levels. However, these differences become less important at the higher plasma levels typically seen in overdose. Only a few of their pharmacologic actions are believed to have a direct therapeutic effect, such as inhibi-

tion of amine reuptake (norepinephrine, serotonin) and antagonism of postsynaptic serotonin receptors (5-HT₂). Thus the remaining pharmacologic actions are essentially without therapeutic benefit but significantly contribute to TCA-related adverse effects and overdose toxicity. Most clinical findings seen in TCA overdose can be explained by the following seven pharmacologic actions, listed in descending order of general potency.

Antihistaminic Effects

TCAs are potent inhibitors of peripheral and central postsynaptic histamine receptors. Doxepin is a prime example, but its nonspecific pharmacologic activity makes it impractical to use for treatment of seasonal allergies or other allergic conditions. Antagonism of central histamine receptors leads primarily to CNS sedation and may contribute significantly to the development of coma frequently seen in TCA overdose.

Antimuscarinic Effects

TCAs are competitive inhibitors of acetylcholine at central and peripheral muscarinic receptors but do not antagonize acetylcholine at nicotinic receptors. This action, commonly referred to as being *anticholinergic*, is imprecise and inaccurate. Central antimuscarinic symptoms vary from agitation to delirium, confusion, amnesia, hallucinations, slurred speech, ataxia, sedation, and coma. Peripheral antimuscarinic symptoms include dilated pupils, blurred vision, tachycardia, hyperthermia, hypertension, decreased oral and bronchial secretions, dry skin, ileus, urinary retention, increased muscle tone, and tremor. Antimuscarinic symptoms are especially common when TCAs are combined with other medications that also have antimuscarinic activity. Examples include antihistamines, antipsychotics, antiparkinsonian drugs, antispasmodics, and some muscle relaxants.

TABLE 158-3 Pharmacologic Profile of Tricyclic Antidepressants

Pharmacologic Activity	Potency	Clinical Presentation	Treatment
Antagonism of postsynaptic histamine receptors	++ to ++++	Sedation	Supportive care alone
Antagonism of postsynaptic muscarinic receptors	++ to ++++	Sedation, coma, agitation, confusion, hallucinations, seizures, mydriasis, dry mucous membranes, dry skin, tachycardia, mild hypertension, hyperthermia, ileus, urinary retention, tremor	Supportive care alone (physostigmine contraindicated)
Antagonism of postsynaptic α -adrenergic receptors	++ to ++++	Sedation, miosis, orthostatic hypotension, reflex tachycardia	Intravenous fluids Norepinephrine
Inhibition of norepinephrine reuptake	+ to ++++	Agitation, mydriasis, diaphoresis, tachycardia, early hypertension	Supportive care alone
Inhibition of serotonin reuptake	+ to ++++	Sedation, mydriasis, myoclonus, hyperreflexia (see serotonin syndrome)	Supportive care alone Consider cyproheptadine for treatment of serotonin syndrome
Inhibition of voltage-gated sodium channels	+ to ++++	Impaired conduction, wide QRS, other conduction abnormalities; impaired cardiac contractility; wide complex sinus tachycardia, ventricular ectopy Hypotension	Sodium bicarbonate Hyperventilation Hypertonic saline Intravenous fluids Sodium bicarbonate Hypertonic saline
Inhibition of voltage-gated potassium channels	+ to +++	Prolongation of QT interval, ventricular ectopy, torsades de pointes	Magnesium sulfate Cardiac overdrive pacing
Antagonism of postsynaptic serotonin (5-HT) receptors	+ to ++	None, possible therapeutic benefit	None
Antagonism of postsynaptic GABA-A receptors	+ to ++	Seizures	Benzodiazepines Phenobarbital or propofol
Antagonism of postsynaptic dopamine receptors	+ to ++	Extrapyramidal symptoms ranging from dystonic reactions to neuroleptic malignant syndrome	Supportive care

Physostigmine is an inhibitor of acetylcholinesterase activity and potentially can reverse antimuscarinic symptoms. Historically, it was used to reverse TCA-induced antimuscarinic symptoms, but its use is often associated with life-threatening complications. Although antimuscarinic symptoms are a common finding in TCA overdose, they are not directly responsible for TCA-related deaths. Therefore, antimuscarinic symptoms are an important clinical marker of TCA toxicity, but they do not require specific therapy other than supportive care alone. Physostigmine has no role in the current management of TCA overdose in the ED.

Inhibition of α -Adrenergic Receptors

Inhibition of postsynaptic central and peripheral α -adrenergic receptors is a characteristic action of most TCAs. They do not inhibit β -adrenergic receptors. TCAs have a much greater affinity for α_1 - than α_2 -adrenergic receptors. Inhibition of α_1 receptors produces CNS sedation, orthostatic hypotension, and pupillary constriction. This action frequently offsets antimuscarinic-induced pupillary dilatation. Thus patients with TCA toxicity can present with constricted, dilated, or midpoint-sized pupils. Orthostatic hypotension is often associated with reflex tachycardia. The antihypertensive effect of clonidine can be negated by TCAs because of their ability to block the binding of clonidine to α_2 receptors.

Inhibition of Amine Uptake

Inhibition of amine reuptake is believed to be the most important mechanism by which TCAs are efficacious in treating depression. TCAs are potent inhibitors of norepinephrine (NE) and serotonin (5-HT) reuptake but have little affinity for inhibition of dopamine (DA) reuptake.³ Inhibition of neurotransmitter reuptake leads to increased synaptic levels and subsequent augmentation of the neurotransmitter response. Inhibition of NE reuptake is thought to produce the early sympathomimetic effects occasionally seen in some TCA overdoses and may contribute to the development of cardiac dysrhythmias. Serotonin syndrome results from increased 5-HT brainstem activity and has been produced by TCAs that are particularly potent 5-HT uptake inhibitors such as clomipramine and amitriptyline. In general, TCAs must be used in combination with other serotonergic agents to produce serotonin syndrome. Myoclonus and hyperreflexia often are attributed to increased serotonin activity.

Sodium Channel Blockade

TCA-induced cardiotoxicity is the single most important factor contributing to patient mortality. Life-threatening cardiotoxicity results from TCA-induced inhibition of sodium influx through voltage-dependent sodium channels. Inhibition of fast sodium channels in His-Purkinje cells leads to delayed depolarization and conduction abnormalities.⁴ Impaired sodium entry into myocardial tissue leads to decreased contractility. Sodium channel blockade is often referred to synonymously as *membrane stabilizing*, *quinidine-like*, or *local anesthetic effect*. Sodium channel blockade results in a prolongation of phase 0 of the action potential, which becomes more pronounced with rapid heart rates, hyponatremia, and acidosis. This effect expresses itself on the electrocardiograph (ECG) as prolongation of PR and QRS intervals and right-axis deviation (RAD). The RAD is most pronounced in the terminal 40 ms of limb leads, as demonstrated on ECG by a terminal R wave in lead aVR and an S wave in lead I. Rapid influx of sodium is necessary for the release of intracellular calcium stores and subsequent myocardial contractility. Some of the negative chronotropic effect of sodium channel blockade can be attenuated by the sinus tachycardia secondary to antimuscarinic activity. Bradycardia is particularly worrisome when accompanied by QRS complex widening because it indicates profound sodium channel blockade. Lo-

cal changes in electrical conduction can predispose to ventricular dysrhythmias by establishing reentry loops. In summary, severe sodium channel blockade culminates in depressed myocardial contractility, various types of heart blocks, hypotension, cardiac ectopy, widening of the QRS complex, and RAD of the terminal 40 ms.

Sodium channel blockade can be overcome in part by serum alkalization (pH 7.50-7.55) and increasing the serum sodium concentration. In humans, intravenous sodium bicarbonate (NaHCO_3) is thought to be more effective than either hyperventilation (alkalinizes blood) or sodium chloride (increases $[\text{Na}^+]$) in treating TCA cardiotoxicity. One explanation for the greater effectiveness of NaHCO_3 is that it produces both alkalemia and increased serum $[\text{Na}^+]$. The mechanism by which blood alkalization partially reverses sodium channel blockade remains unknown. Previously, it was believed to be related to enhancement of plasma TCA serum protein binding. Alkalization probably decreases the overall inhibition to sodium ion influx. Recent animal data suggest that hypertonic saline (7.5% saline) may be more efficacious than NaHCO_3 or hyperventilation in reversing TCA cardiotoxicity.⁵ Whether this finding also will be applicable to humans is currently unknown. Hypertonic saline is believed to act primarily by increasing the extracellular sodium concentration gradient, thus favoring the inward movement of sodium ions.

Potassium Channel Antagonist

TCAs block myocardial potassium channels and inhibit the efflux of potassium ion during repolarization. This effect is seen on ECG as QT interval prolongation, which is more pronounced at slower heart rates. Many TCA overdose patients develop sinus tachycardia, which is partially protective against severe QT_c interval prolongation. Torsades de pointes is a life-threatening complication of severe QT interval prolongation, but it is seen rarely in TCA overdoses.⁶

GABA-A Receptor Antagonist

Generalized seizures occur commonly in the setting of TCA overdoses. Possible mechanisms for these seizures include TCA-induced γ -aminobutyric acid receptor A (GABA-A) antagonism, neuronal sodium channel blockade, central antimuscarinic activity, and effects on biogenic amines. The exact etiology of these seizures remains speculative, but TCA-induced antagonism of the GABA-A receptors may represent the most important mechanism. All drugs that inhibit GABA-A neurotransmission are associated with seizures. Benzodiazepines and barbiturates are potent GABA-A agonists and are considered the anticonvulsants of choice in treating TCA-induced seizures. Propofol (Diprivan) is a short-acting intravenous anesthetic with anticonvulsant activity. It should be considered for patients with resistive seizures, especially in the setting of hypotension.

PHARMACOKINETICS

All TCAs share similar pharmacokinetic properties. They are highly lipophilic and readily cross the blood-brain barrier, and peak plasma levels occur between 2 and 6 h after ingestion at therapeutic doses. Gastrointestinal absorption can be prolonged because of their antimuscarinic effect on gut motility. Bioavailability is only 30 to 70 percent because of extensive first-pass hepatic metabolism. They are highly protein bound to α_1 acid glycoproteins. Their apparent volume of distribution is extremely large and ranges from 10 to 50 L/kg. Tissue TCA levels are commonly 10 to 100 times greater than plasma levels. Only 1 to 2 percent of the total-body burden of TCAs is found in the blood. These pharmacokinetic properties explain why attempts at removing TCAs by hemodialysis, hemoperfusion, peritoneal dialysis, or forced diuresis generally are unproductive.

TCAs are eliminated almost entirely by hepatic oxidation, which consists of *iV*-demethylation of the amine side-chain groups and

hydroxylation of ring structures. The removal of a methyl group from the tertiary amine side chain usually produces an active metabolite designated by the desmethyl prefix (see Table 158-1). These active metabolites often will have different pharmacologic activities when compared with the parent compounds. Amoxapine and maprotiline both have active metabolites. Although secondary amines such as desipramine, nortriptyline, and protriptyline are effective antidepressants, their metabolites generally are considered inactive. Clinical toxicity from tertiary TCAs usually lasts longer than that from secondary TCAs alone because of the production of active metabolites. Some TCAs undergo enterohepatic circulation prior to their eventual oxidation, conjugation, and renal elimination, but this does not significantly contribute to their toxicity.

The average elimination half-life of TCAs is approximately 24 h (range 6-36 h) at therapeutic doses, but this can increase to 72 h after overdose. Inhibition of TCA metabolism by other drugs that use the same hepatic enzymes can prolong the half-life of TCAs. This carries the risk of elevating TCA plasma levels and producing clinical TCA toxicity at therapeutic doses. Approximately 7 percent of the U.S. population are genetically slow metabolizers of TCAs. This predisposes them to develop higher plasma levels at any given daily TCA dose.

TOXICITY

Therapeutic doses for TCAs are highly variable and are determined by many factors but range from 1 to 5 mg/kg per d (see Table 152-1). Any dose greater than this has the potential to produce TCA toxicity. Life-threatening symptoms usually occur with ingestions of greater than 10 mg/kg in adults. Pediatric patients are particularly susceptible to the antimuscarinic activity of TCAs. Other patients at higher risk for TCA toxicity include patients who have coingested cardiotoxic or CNS-depressive medications, geriatric patients, and patients with heart disease. Desipramine is the most potent sodium channel blocker among the TCAs.⁷ It has twice the fatality rate of other TCAs. Some TCAs, especially desipramine, are able to precipitate severe cardiotoxicity (e.g., wide QRS complex, hypotension) without producing significant antimuscarinic symptoms. TCA-related fatalities are commonly associated with ingestions of greater than 1 g. Most TCA overdose fatalities occur within the initial hours after ingestion, often before the patient reaches the hospital. Fatalities more than 24 h after ingestion are unusual with appropriate medical therapy.

While quantitative plasma TCA levels are very helpful in monitoring chronic drug therapy, results are rarely available to emergency physicians during the time of patient evaluation and therefore have negligible impact on patient care. Some studies have shown that patients with a combined plasma level of parent TCA and metabolite of greater than 1000 ng/mL are at greater risk for developing seizures and cardiotoxicity. However, the severity of clinical toxicity does not always correlate with the extent of plasma TCA elevation. Patients can develop severe toxicity at plasma levels less than 1000 ng/mL.^{8,9} Conversely, patients with plasma TCA levels much greater than 1000 ng/mL may not develop seizures or ventricular dysrhythmias. Serious toxicity rarely develops at therapeutic levels alone (<300 ng/mL). When this occurs, other causes should be entertained to explain the patient's condition. As always, the most important thing is to treat the patient and not the drug level.

An interesting but confounding characteristic of TCAs is their ability to undergo significant postmortem drug redistribution.¹⁰ Plasma levels can increase by as much as 10- to 50-fold after death as tissue binding sites release TCAs back to the blood. This is a time-dependent process. The diagnostic accuracy of postmortem TCA levels is inversely proportional to the time they were obtained after death. The relevance of TCA postmortem drug redistribution to emergency physicians relates to ED deaths of patients taking TCAs therapeutically.

CLINICAL FEATURES

The clinical presentation of TCA toxicity varies tremendously from mild antimuscarinic symptoms to severe cardiotoxicity secondary to sodium channel blockade. In up to 70 percent of TCA poisonings, coingested drugs also are involved, and the additional toxicity from these coingestants should be considered when evaluating these patients. Antimuscarinic symptoms commonly serve as markers for TCA toxicity (e.g., dry mouth and axillae, sinus tachycardia), but they alone are rarely responsible for patient fatalities. Moreover, antimuscarinic symptoms are not uniformly present in TCA toxicity. As an example, sinus tachycardia is the most frequent dysrhythmia noted in TCA toxicity, but it is only present in approximately 70 percent of symptomatic patients. Altered mental status is the most common symptom reported following TCA exposure.

Mild to moderate TCA toxicity may present as drowsiness, confusion, slurred speech, ataxia, dry mucous membranes and axillae, sinus tachycardia, urinary retention, myoclonus, and hyperreflexia. Antimuscarinic syndrome classically is associated with decreased bowel tones and ileus. However, bowel function is fairly resistant to inhibition, and the presence of active bowel tones does not rule out the possibility of antimuscarinic syndrome. Mild hypertension is observed occasionally and rarely requires treatment. Nontolerant individuals occasionally develop coma and respiratory depression after relatively small overdoses without obvious peripheral antimuscarinic effects and without QRS complex widening. Overflow urinary incontinence may be mistaken for normal micturition in pediatric (diaper-dependent) patients.

Serious toxicity is almost always seen within 6 h of major TCA ingestion and consists of the following symptoms: coma, cardiac conduction delays, supraventricular tachycardia, hypotension, respiratory depression, premature ventricular beats, ventricular tachycardia, and seizures.⁸ Secondary complications from serious toxicity include aspiration pneumonia, anoxic encephalopathy, hyperthermia, and rhabdomyolysis. Pulmonary edema is a well-recognized complication of TCA overdose. Seizures usually are generalized and brief in duration. The exception to this rule is seen in amoxapine and maprotiline overdoses. These agents can cause status epilepticus. Amoxapine seizures commonly occur without corresponding QRS complex widening.

DIAGNOSIS

TCA toxicity should be suspected in all patients with a positive serum TCA drug screen in conjunction with corresponding clinical toxicity and/or characteristic ECG abnormalities. Most cases ultimately will prove to be associated with elevated quantitative TCA plasma levels. However, these are not routinely available to the emergency physicians, nor do they have an impact on ED care. Conversely, qualitative TCA drug tests are available in most hospitals and have a rapid turnaround time, but they cannot differentiate between therapeutic and toxic levels. False-positive qualitative serum TCA drug screen results can occur with diphenhydramine, carbamazepine, cyclobenzaprine, cyproheptadine, and phenothiazines. Some of these medications also can produce typical TCA ECG abnormalities and similar clinical toxicity. False-negative serum TCA drug tests are extremely unusual. They should be repeated with a new specimen if there is a high clinical suspicion for TCA exposure. Urine drug testing may be helpful in identifying other toxicologic causes for the patient's condition. The differential diagnosis of TCA toxicity encompasses those drugs which can mimic any one of the three criteria used in making the diagnosis (Table 158-4). However, the quintessential point for emergency physicians is that the initial treatment for all these medications is identical and should not be delayed until definitive drug test results become available.

ECG abnormalities are seen commonly with TCA toxicity and generally are useful in identifying patients at increased risk for seizures and ventricular dysrhythmias. The classic TCA electrocardiogram is

TABLE 158-4 Differential Diagnosis of Tricyclic Antidepressant Toxicity

Drug	False-Positive Serum Drug Screen	Wide QRS/Right Axis Deviation	Antimuscarinic Activity	Point of Differentiation
Carbamazepine	Possible	At levels greater than 20 µg/mL	Yes	History of seizure disorder Elevated serum carbamazepine level
Cyclobenzaprine	Possible	Very unlikely but theoretically possible	Yes	History of cyclobenzaprine use for muscle pain or back problems
Diphenhydramine	Possible	At moderate to high doses	Yes	History of over-the-counter drug use, allergies, or insomnia
Phenothiazines	Possible	Yes, dose dependent	Yes	History of psychotic disorder treated with antipsychotic medication
Class IA antiarrhythmics	No	Yes	Yes	History of heart problems History of leg cramps (quinine)
Class IC antiarrhythmics	No	Yes	No	History of heart problems
Propranolol	No	Seen at moderate to high doses	No	Bradycardia almost always seen Positive response to glucagon
Propoxyphene	No	Often seen in overdose	No	Opiate toxidrome Reversal with naloxone (may require large doses)
Cocaine	No	At high doses	No	Sympathomimetic presentation Positive urine cocaine drug screen
Lithium	No	At elevated serum levels	No	History of bipolar disorder Elevated serum lithium level
Hyperkalemia	No	At increased serum levels	No	Elevated serum [K ⁺]

shown in Figure 158-1, consisting of sinus tachycardia, RAD of the terminal 40 ms (lead aVR), and prolongation of the PR, QRS, and QT intervals. This classic ECG pattern is seen frequently in moderate to severe TCA toxicity, but its absence does not eliminate the possibility of TCA toxicity during the first 6 h after ingestion. Typical ECG findings resolve over the next few days. Moderate prolongation of the QT interval is noted frequently, even at therapeutic TCA doses. Nonspecific ST-segment and T-wave abnormalities are observed commonly in TCA overdose. Less common ECG abnormalities include right bundle branch block and high-degree atrioventricular blocks.

Life-threatening complications can occur in the absence of significant ECG abnormalities.⁹ However, these complications are more likely in the presence of a widened QRS complex greater than 100 ms and/or RAD of the terminal 40 ms of greater than 120 degrees. The risk of seizures increases as the QRS complex exceeds 100 ms, and ventricular dysrhythmias are more likely if QRS complex prolongation exceeds 160 ms. RAD is demonstrated commonly as a positive terminal R wave in lead aVR and a negative S wave in lead I (Figure 158-2). Widening of the QRS complex and positive deflection of the terminal QRS complex in lead aVR are equally helpful in identifying patients at risk for serious toxicity.¹¹ They usually occur together but can occur in exclusion of each other. The development of RAD of the terminal 40 ms and/or QRS complex widening appears to be less predictable of TCA-induced cardiotoxicity in young children.¹² Pediatric electrocardiograms tend to have a wider range of acceptable variant features, and this complicates the ECG identification of TCA toxicity.

ECG abnormalities universally develop within 6 h of ingestion and typically resolve over 36 to 48 h.¹³ The identification of either **QRS complex widening of greater than 100 ms or terminal RAD greater than 120 degrees warrants NaHCO₃ therapy** and admission to a monitored hospital bed. Unfortunately, up to 10 percent of the population will have a prolonged QRS complex of more than 100 ms or terminal RAD without exposure to sodium channel blocking drugs. Therefore, these ECG abnormalities in isolation are not 100 percent specific for TCA tox-

icity. Many patients on TCA therapy do not have prior electrocardiograms available for comparison. Thus any observed ECG abnormalities must be assumed attributable to TCA exposure until proven otherwise.

TREATMENT

All patients should be evaluated immediately for alterations of consciousness, hemodynamic instability, and respiratory impairment. Every patient requires an intravenous line, continuous ED cardiac monitoring, and an electrocardiogram. Serial electrocardiograms will be required in most patients. Suggested laboratory studies include determinations of serum electrolyte, creatinine, and glucose levels. A quantitative serum acetaminophen determination is recommended in all overdose patients. Most symptomatic patients will require arterial blood gas measurement. Patients with antimuscarinic symptoms may require a urinary catheter to prevent urinary retention and a nasogastric tube if bowel sounds are absent. Patients who are asymptomatic initially may deteriorate rapidly and therefore should be monitored closely for several hours. Emergency physicians should report all TCA exposures to a regional poison control center.

Gastrointestinal Decontamination

Although the best method of gastrointestinal decontamination in TCA ingestions remains undefined, a few generalizations are still possible.¹⁴ Syrup of ipecac cannot be recommended. Activated charcoal (AC) has been shown to bind TCAs effectively and to decrease their absorption. Therefore, all patients should receive 1 g/kg of AC. Whether gastric lavage and AC is better than AC alone remains unproven. Studies have shown that the gastric lavage is most effective when it is performed within the first few hours after ingestion. Most emergency physicians opt to perform gastric lavage and give AC to patients who present relatively early after TCA ingestion. The proper method of performing gastric lavage in alert patients is to place the

patient in the left lateral decubitus position to prevent pulmonary aspiration. Obtunded patients require endotracheal intubation prior to performing gastric lavage. Asymptomatic patients with reliable histories of minimal TCA ingestions can be treated with AC alone and observed for toxicity. Some authors have recommended giving repeat doses of AC to enhance TCA elimination, but these recommendations should be viewed cautiously in the setting of decreased intestinal motility.

Sodium Bicarbonate Therapy

Indications for NaHCO_3 therapy include QRS complex widening greater than 100 ms, hypotension refractory to fluid hydration, terminal RAD in aVR of greater than 3 mm, and ventricular dysrhythmias. Sodium bicarbonate has been shown to improve conduction, increase contractility, and suppress ventricular ectopy. It is given as an initial bolus of 1 to 2 mEq/kg, which can be repeated until patient improvement is noted or until blood pH equals 7.50 to 7.55 (Figure 158-3). Alkalinization beyond this point can be deleterious and therefore is discouraged. Continuous infusions of NaHCO_3 usually are administered as 3 ampules (50 mEq/50 mL) placed in 1 L of D5W or 2 ampules added to D5/NS (slightly hypertonic with NaHCO_3 added) solution and run at a rate of 2 to 3 mL/kg per h. Adjustments in the intravenous rate are made based on blood pH measurements, serum sodium level, and clinical response to therapy. Hypokalemia is an expected complication of NaHCO_3 therapy. Intravenous potassium supplementation usually is required, and serum potassium levels should be measured frequently.

Altered Level of Consciousness

Patients with altered level of consciousness require a trial of intravenous dextrose, thiamine, naloxone, and oxygen to rule out reversible causes of CNS depression. Antagonism of postsynaptic muscarinic, histamine, and α -adrenergic receptors contributes to the development of altered mentation in TCA overdoses. Coma from TCA toxicity typically is rapid in onset. Unresponsive patients may have unrecognized head or neck trauma. Flumazenil should not be given to patients suspected of having mixed-drug overdoses involving TCAs and benzodiazepines because this may precipitate generalized seizures. There is a very high incidence of pulmonary aspiration among TCA overdose patients who present comatose to the ED. Agitation is observed commonly prior to the onset of coma, as well as in previously comatose patients as they awaken. Agitation is best controlled with reassurance, decreased environmental stimulation, and benzodiazepines. As mentioned previously, physostigmine should not be administered to patients taking TCAs.

Seizures

Most seizures occur within the first 3 h following ingestion. Typically, these seizures are generalized and brief in duration. Multiple seizures are reported in approximately 10 to 30 percent of TCA overdoses. Focal seizures are atypical and require further neurologic evaluation. Seizures are especially common with maprotiline and amoxapine ingestions and require aggressive management because status epilepticus is frequently associated with these two particular antidepressants. Benzodiazepines (e.g., diazepam, lorazepam) are the anticonvulsants of choice to stop existing seizure activity. Barbiturates (e.g., pheno-barbital) are indicated to treat seizures resistant to benzodiazepines. The initial intravenous dose of phenobarbital is 15 mg/kg, but this can be increased in patients with continued seizure activity and adequate blood pressure. Hypotension is a major side effect. Endotracheal intubation and respiratory support will be required when benzodiazepines are combined with barbiturates or propofol. Phenytoin is an ineffective anticonvulsant for stopping TCA-induced seizures. Physostigmine and NaHCO_3 do not stop TCA-induced seizures. If seizures continue despite adequate dosing with benzodiazepines and phenobar-

bital, consideration should be given to paralyzing the patient with a neuromuscular blocking agent. This will stop the physical manifestations of the seizure and its secondary effects, which include metabolic acidosis, hyperthermia, rhabdomyolysis, and renal failure. It does not stop brain seizure activity. Therefore, following the induction of muscle paralysis, these patients require electroencephalographic (EEG) monitoring and continued anticonvulsant therapy.

Hypotension

Hypotension should be treated initially with isotonic crystalloid fluids in increments of 10 mL/kg. In the setting of impaired cardiac contractility, pulmonary edema can develop if excessive fluids are administered. Hypotension that does improve with appropriate fluid challenges should be treated with NaHCO_3 (regardless of QRS complex width). Vasopressors should be used when hypotension is unresponsive to fluids and sodium bicarbonate therapy. The most effective vasopressor is norepinephrine (1 $\mu\text{g}/\text{min}$ titrated to effect up to 30 fjg/min) because it directly competes with TCAs at α -adrenergic receptors. Dopamine is less effective than norepinephrine in reversing TCA-induced hypotension.¹⁵ In many cases, dopamine administration actually will cause a lowering in systolic blood pressure due to its β -adrenergic and dopaminergic actions that promote vasodilation. If used, it should be adjusted at the upper range of the dose (12-20 ng/kg per min). A pulmonary artery catheter should be placed in patients whose hypotension is refractory to fluid, NaHCO_3 , and vasopressor therapy. Mechanical irritation of the heart during pulmonary artery catheter placement may precipitate life-threatening conduction abnormalities and ventricular dysrhythmias. Hypotension induced by TCAs represents a potentially reversible cause of cardiovascular collapse. Mechanical support of the circulation with cardiopulmonary bypass, overdrive pacing, or aortic balloon pump assistance may be warranted in patients with refractory hypotension, although no studies document their effectiveness.

Dysrhythmias

TCAs frequently alter cardiac rate, conduction, and contractility. Asymptomatic patients with sinus tachycardia, isolated PR and QT interval prolongation, or first-degree atrioventricular (AV) block do not require specific pharmacologic therapy. Conduction blocks greater than first-degree AV block are worrisome because they can progress rapidly to complete heart block secondary to impaired infranodal conduction. Most patients with QRS complex prolongation greater than 100 ms should be treated with NaHCO_3 therapy, although this is somewhat controversial. This recommendation is made despite the absence of randomized, controlled human trials demonstrating NaHCO_3 therapy benefits in otherwise asymptomatic patients with QRS complex prolongation.¹⁶ Nonetheless, the early use of sodium bicarbonate in the setting of sodium channel blockade has become a common practice for treating QRS complex widening. Hyperventilation represents a reasonable alternative to sodium bicarbonate therapy in the setting of renal failure, pulmonary edema, or cerebral edema.

Ventricular dysrhythmias should be treated immediately with sodium bicarbonate administration. Lidocaine is the second agent of choice in treating ventricular dysrhythmias. Excessive lidocaine administration is capable of producing seizures. Bretylium generally is considered a third-line drug for ventricular dysrhythmias. Synchronized cardioversion is appropriate in patients with unstable dysrhythmias. Torsade de pointes should be treated initially with 2 g of IV magnesium sulfate. Efforts should be made to rule out other causes of torsades de pointes. Overdrive pacing frequently is required to prevent a recurrence of this dysrhythmia. IV isoproterenol may be of some benefit in treating recurrent torsade de pointes when overdrive pacing is not available. The following medications are contraindicated in the treatment of TCA-induced dysrhythmias: all class IA and IC antiarrhythmic agents, β -blockers, calcium channel blockers, and all class III antiarrhythmic agents.

DISPOSITION

Patients who remain asymptomatic 6 h after ingestion do not require hospital admission for toxicologic reasons. They may still require hospital admission because of other coexisting medical or psychiatric conditions. Psychiatric evaluation is warranted for intentional drug ingestions. All symptomatic patients require hospital admission to a monitored bed. Patients demonstrating signs of moderate to severe toxicity should be admitted to an intensive care unit. Hospitalized patients can be cleared medically after 12 to 24 h of being asymptomatic—including a normal or baseline electrocardiogram, normal mental status, and resolution of all antimuscarinic symptoms.

macologic activity and have drastically different toxicologic behavior than MAOIs and TCAs. As a group, the newer antidepressants are the most popular form of psychopharmacologic therapy for the treatment of major depression. They are also commonly prescribed in the treatment of many other psychiatric disorders such as obsessive-compulsive disorder, panic disorders, and eating disorders. The newer antidepressants are being used increasingly in older children and adolescent patients. However, fluvoxamine (Luvox) and sertraline (Zoloft) are the only newer antidepressants that are approved by the Food and Drug Administration (FDA) for pediatric use. Over the past decade, the American Association of Poison Control Centers Toxic Exposure Surveillance System has reported annual increases in drug exposures to newer antidepressant agents.¹ Fortunately, the newer antidepressants produce less severe toxicity in overdose and are associated with fewer fatalities than either MAOIs or TCAs. For some of the newer antidepressants, very little overdose information is available to base treatment recommendations. Importantly, all antidepressants, especially the MAOIs and selective serotonin reuptake inhibitors (SSRIs), have the potential to produce the serotonin syndrome, a recently recognized drug-induced disorder.

GENERAL PRINCIPLES OF NEWER ANTIDEPRESSANTS

The newer antidepressants are a heterogeneous group of drugs that differ significantly in chemical structure, mechanism of action, pharmacokinetic characteristics, and adverse effect profile. Nonetheless, they also share many important similarities that are summarized in the following eight points. These points are not repeated for each individual drug.

1. Most newer agents do not significantly inhibit cardiac sodium, calcium, or potassium ion channels. Therefore, they do not demonstrate the same cardiotoxicity or electrocardiographic conduction abnormalities typically seen with TCAs. Exceptions to this rule are citalopram and to a much lesser extent fluoxetine and venlafaxine.
2. These agents do not inhibit monoamine oxidase activity and are not associated with tyramine-like reactions. The use of indirect sympathomimetics is not contraindicated.
3. These agents have negligible affinity for acetylcholine, dopamine, γ -aminobutyric acid (GABA), glutamate, or (3-)adrenergic receptors. Although their exact mechanism of action remains poorly understood, it is traditionally attributed to inhibition of neurotransmitter reuptake (except mirtazapine).
4. Newer antidepressants (except bupropion) appear to have a much higher safety margin than the MAOIs and TCAs. Nonetheless, they can still cause fatalities, especially at very high doses or when combined with other drugs. There is extremely limited human data on the "typical" presentation or optimal management. Therefore, current management recommendations may require modification as more information becomes available. Emergency physicians should routinely contact a regional poison control center (PCC) to report exposures. Also, consultation with a medical toxicologist is available through most regional PCCs.
5. Attempts at enhancing the elimination of newer antidepressants via hemodialysis, hemoperfusion, forced diuresis, or **multiple-dose activated charcoal** are unlikely to be successful and therefore are not recommended. Whole-bowel irrigation does not offer any advantage over single-dose activated charcoal in providing gastrointestinal decontamination to patients exposed to newer antidepressants.
6. The newer antidepressants are not detected by routine hospital serum and urine drug screens. Certain specialty laboratories do have the capability to measure parent drug and metabolite plasma levels, but this information is only useful for the confirmation of suspected drug overdose. Specific levels are not immediately available, nor do they affect patient management. Postmortem drug redistribution is likely to occur with the newer antidepressants, affecting forensic investigation.

NEWER ANTIDEPRESSANTS AND SEROTONIN SYNDROME Kirk C.

Mills

The newer antidepressants are commonly referred to as *atypical*, *heterocyclic*, or *second-generation antidepressants*. These terms distinguish them from the more traditional monoamine oxidase inhibitors (MAOIs) and tricyclic antidepressants (TCAs). This distinction is important because newer antidepressants are more selective in their phar-

7. The newer antidepressants are metabolized primarily by hepatic enzyme systems (cytochrome P450 pathways). Drug interactions can be expected when two medications that share the same metabolic pathway are given together. In addition, hepatic dysfunction can lead to elevated drug levels and subsequent drug toxicity.
8. All the newer antidepressants carry warnings against combination with MAOIs because the two can precipitate serotonin syndrome. Although the manufacturers' contraindications do not specify other serotonergic medications, risks and benefits should be carefully assessed before combining these as well.

TRAZODONE

Trazodone hydrochloride (Desyrel) was released in the United States in 1982 for the treatment of endogenous depression. During the past decade, the frequency of reported trazodone exposures has increased markedly, but the fatality rate remains quite low (1 in 1200 exposures). This is approximately seven to ten times less than the fatality rate for MAOI or TCA exposures. The average daily therapeutic dose for trazodone is between 150 and 400 mg, with a maximum dose of up to 600 mg restricted to psychiatric inpatients. Trazodone is available as 50-, 100-, and 150-mg tablets. There is a low potential for trazodone abuse, and a distinct withdrawal syndrome has not been observed with its abrupt discontinuation. Trazodone is a category C risk in pregnancy.

Trazodone is a triazolopyridine derivative that is structurally unrelated to other antidepressants. Its antidepressant action is believed to be due to a combination of serotonin [5-hydroxytryptamine (5-HT)] reuptake inhibition and antagonism of postsynaptic 5-HT₂ receptors.² Trazodone is a moderately potent nonselective α -adrenergic receptor blocker with at least five times greater affinity for α_1 than α_2 -adrenergic receptors. Consequently, trazodone is frequently associated with orthostatic hypotension, which is maximal within the first 6 h of use and can be minimized by taking the medication at bedtime. Sedation, which is a common side effect of trazodone therapy, is believed to be secondary to inhibition of central α -adrenergic and histamine receptors.

Trazodone is absorbed rapidly and completely, with peak plasma levels occurring between 1 and 2 h following oral administration. It is highly protein bound and has a moderate volume of distribution (1.2 L/kg). Trazodone primarily undergoes hepatic oxidation by the cytochrome P450 isoenzyme system. It has one active metabolite, m-chlorophenylpiperazine (m-CPP), which has a complex pharmacologic profile, such as inhibition of 5-HT uptake, stimulation and inhibition of multiple postsynaptic serotonin receptors, and interactions with other neurotransmitter systems. The overall contribution of m-CPP to the therapeutic and toxic effects of trazodone is currently under investigation. The half-life of trazodone ranges from 5 to 9 h at therapeutic doses but can increase up to 13 h in overdose.

The adverse-effect profile for trazodone is very favorable when compared with other antidepressants except for its association with priapism. Trazodone is one of the most common causes of drug-induced priapism. The estimated incidence of priapism ranges from 1 in 1000 to 1 in 10,000 patients. Any patient with a history of increased frequency, duration, or inappropriate penile or clitoral engorgement should discontinue trazodone therapy immediately. Human volunteer and laboratory animal studies have proven that trazodone is far less cardiotoxic than TCAs. Therapeutic use of trazodone has been reported occasionally to be arrhythmogenic, especially in patients with underlying cardiac risk factors such as conduction abnormalities or ischemic heart disease. Examples of cardiac rhythm abnormalities reported in association with trazodone therapy include sinus arrest, sinus bradycardia, various atrioventricular blocks, complete heart block, atrial fibrillation, and ventricular dysrhythmias (premature ventricular beats or torsade de pointes). The most frequently reported dose-related

adverse effects are drowsiness, dizziness, dry mouth, nausea and vomiting, and orthostatic hypotension. There have been rare case reports of patients experiencing reversible liver enzyme elevation, jaundice, and abnormal liver histology in association with trazodone therapy.

Acute Overdose Toxicity

There is no established toxic dose for trazodone. **As a general guideline, serious toxicity in an average adult is not expected with ingestions of less than 2 g. This safety margin is reduced significantly when other medications are coingested with trazodone.** The most common symptom of acute trazodone poisoning is central nervous system (CNS) depression. Other CNS-related symptoms include ataxia, dizziness, coma, and seizures. Trazodone rarely produces coma or seizures when it is the only drug ingested. Pupils are usually of normal size and remain reactive to light. Infrequently, patients may complain of muscle weakness. Trazodone-induced CNS symptoms show marked improvement within 6 to 12 h after ingestion and are almost always resolved by 24 h. Orthostatic hypotension is the most frequently reported cardiovascular abnormality noted in trazodone overdose and usually responds to fluid administration. Mild abnormalities of sinus rhythm, such as sinus bradycardia and tachycardia, are encountered frequently. The most common electrocardiographic abnormality is moderate prolongation of the QT_c interval. Polymorphic ventricular tachycardia (torsade de pointes) has been reported in rare cases. Commonly reported gastrointestinal complaints include nausea, vomiting, and nonspecific abdominal pain. Respiratory depression is observed infrequently with pure trazodone overdoses. Priapism has been reported following an acute overdose of 3.5 g.

Treatment

An intravenous line should be started and cardiac monitoring initiated on all patients. In pure trazodone ingestions, significant neurologic and cardiac toxicity is not expected, and supportive care is usually the only treatment required. Specific antidotal therapy is not available. Gastrointestinal decontamination can be applied selectively in patients in whom the dose ingested can be calculated accurately. Ingestion of 2 g requires only 1 g/kg of activated charcoal as long as trazodone is ingested as a single agent and the patient does not have any underlying cardiac or neurologic risk factors. Gastric lavage is probably unnecessary. Ingestions of more than 2 g of trazodone or coingestions have a higher incidence of coma, seizures, and respiratory arrest. In these patients, early gastric lavage followed by administration of activated charcoal is indicated. Hypotension should be treated initially with isotonic intravenous fluid administration. If the use of a vasopressor becomes necessary, direct-acting vasopressors (e.g., norepinephrine) are recommended. Drugs with (3)-adrenergic receptor activity (e.g., dopamine) theoretically can potentiate the hypotension in the presence of trazodone-induced α -adrenergic receptor antagonism. Patients who have remained asymptomatic for at least 6 h can be discharged safely from the emergency department, assuming that any necessary psychiatric evaluation has been completed or arranged. All intentional trazodone ingestions should be evaluated properly for the presence of other drugs (e.g., acetaminophen). Patients with neurologic and/or cardiac symptoms persisting longer than 6 h after ingestion will require hospital admission to a monitored bed. In addition, patients with coingestants associated with delayed toxicity will require prolonged observation or formal hospital admission.

NEFAZODONE

Nefazodone (Serzone), was approved in 1995 for the treatment of depression. It is both structurally and functionally related to trazodone. Nefazodone inhibits serotonin reuptake and also antagonizes postsy-

naptic 5-HT₂ receptors.³ It has little affinity for other receptors except slight antagonism of postsynaptic α₁ receptors. Nefazodone is available in 50-, 100-, 150-, 200-, and 250-mg tablets. The recommended effective dose for nefazodone is between 300 and 600 mg/d. Although nefazodone is absorbed rapidly, it has a bioavailability of only 20 percent due to extensive first-pass hepatic metabolism. Peak levels occur within 1 h, and its elimination half-life ranges from 2 to 6 h. It is 99 percent protein-bound, with a relatively small volume of distribution. It has three active metabolites: hydroxynefazodone, desethylhydroxynefazodone, and m-CPP. The hydroxynefazodone metabolite is pharmacologically equivalent to the parent compound. The m-CPP metabolite is noteworthy only because it is also produced by trazodone. Nefazodone can inhibit the metabolism of terfenadine, astemizole, cisapride, and pimozide, which in turn can lead to life-threatening prolongation of the QT interval (torsade de pointes). Certain benzodiazepines such as alprazolam and triazolam have markedly increased CNS effects in the presence of nefazodone. Carbamazepine inhibits the metabolism of nefazodone by up to 75 percent. Overall, nefazodone has a favorable adverse-effect profile. Compared with placebo, however, nefazodone has a higher incidence of headache, dizziness, drowsiness, asthenia, tremor, dry mouth, nausea, constipation, and blurred vision. It also predisposes patients to postural hypotension and priapism but not to the same degree as trazodone. Nefazodone has a category C rating in pregnancy.

Treatment

Experience with nefazodone in overdose is extremely limited. Unpublished premarketing data suggest that nefazodone is relatively safe in overdose. The most common symptoms reported include nausea, vomiting, and somnolence. There were no fatalities with pure nefazodone ingestions ranging from 1000 to 11,200 mg. Based on its pharmacokinetic profile, the onset of nefazodone toxicity would be expected to occur within the first 6 h following an overdose. At present, management of nefazodone overdoses should follow the aforementioned guidelines for trazodone.

BUPROPION

Bupropion (Wellbutrin) has been available in the United States since 1989 for the treatment of major depression. The actual incidence and severity of bupropion exposures are unknown. However, since bupropion has been approved recently for the treatment of smoking cessation (Zyban), the potential for bupropion poisoning is considerable. The same pharmaceutical company manufactures bupropion under two trade names: Wellbutrin and Zyban. For smoking cessation, Zyban (150 mg) is administered either once or twice daily for no more than 12 consecutive weeks. The maximum daily dose of Zyban is 300 mg. Wellbutrin comes in a variety of doses and formulations, including sustained-release tablets (100 and 150 mg) and regular-release tablets (75 and 100 mg). The recommended starting dose of Wellbutrin is 100 mg given twice daily, gradually increasing up to 300 mg/d. The incidence of seizures increases drastically at doses of greater than 450 mg/d, and higher doses therefore are prohibited. The combination of the two bupropion preparations is obviously contraindicated. Other contraindications include patients with bulimia, anorexia nervosa, epilepsy, or taking MAOIs. Bupropion is a category B drug in pregnancy. The information in this section is derived from studies using only the Wellbutrin form of bupropion. It is assumed that this information is equally applicable to Zyban exposures.

Bupropion has a monocyclic phenylaminoketone chemical structure that resembles those of the phenylethylamines (e.g., amphetamine).⁴ However, bupropion does not produce stimulant effects or drug-addictive behavior at therapeutic doses. The therapeutic mechanism of action for bupropion is poorly understood but currently attrib-

uted to a weak ability to inhibit neuronal reuptake of serotonin, norepinephrine, and dopamine. It does not directly stimulate postsynaptic receptors. Bupropion is absorbed rapidly after oral administration and undergoes extensive first-pass hepatic metabolism. It is highly protein-bound, has an extremely large volume of distribution, and readily crosses the blood-brain barrier. Peak plasma levels occur within 2 h for regular-release tablets and within 3 h for sustained-release preparations. Its elimination half-life ranges between 14 and 20 h. Bupropion has one important metabolite, hydroxybupropion, that is less potent than bupropion, preferentially inhibits norepinephrine reuptake, and may contribute to seizure development.

Bupropion antidepressant therapy is well tolerated. It does not produce CNS depression, orthostatic hypotension, or cardiovascular changes or impair sexual function at therapeutic doses. The most commonly reported adverse effects are of mild severity and include dry mouth, dizziness, agitation, nausea, headache, constipation, tremor, anxiety, confusion, blurred vision, and increased motor activity. Seizures have been reported with therapeutic doses, but are rare. The drug should be discontinued and the patient should receive emergency department evaluation for a first seizure. Bupropion has been reported to infrequently produce catatonia, hallucinations, psychosis, and paranoia that probably are related to its dopaminergic activity. Rarely, angioedema and urticaria, including plaque-like lesions on the palms, have been described. Skin allergy becomes evident within the first few weeks of therapy. The drug must be stopped; if not, the rash can progress to angioedema or Stevens-Johnson syndrome.

Abrupt discontinuation of bupropion has not been associated with any withdrawal symptoms but may pose a slight theoretical risk of precipitating neuroleptic malignant syndrome because bupropion is considered a dopamine agonist. Bupropion is relatively free of significant drug interactions. In general, bupropion should not be combined with SSRIs, lithium, MAOIs, TCAs, dopaminergic drugs (e.g., levodopa), or drugs that are known to lower patient seizure threshold (e.g., phenothiazines).

Acute Overdose Toxicity

Bupropion differs from other new antidepressants in that it has a low toxic-to-therapeutic ratio. Toxicity can occur at doses equal to or just slightly greater than the maximum therapeutic dose of 450 mg/d. As a general rule, significant toxicity is not expected in pure bupropion overdose with adult ingestions of less than 450 mg. The largest case series of bupropion overdoses reported that symptomatic patients ingested a mean of 2310 mg, and the lowest symptomatic dose was 200 mg.⁵ Patients who remained asymptomatic ingested a mean of 1325 mg, and the largest asymptomatic dose was 4000 mg. The most commonly reported symptoms in pure bupropion overdose include sinus tachycardia (43 percent), lethargy (41 percent), tremor (24 percent), generalized seizures (21 percent), confusion (14 percent), and vomiting (14 percent). Mild hyperthermia is reported occasionally. Sinus tachycardia is the most common electrocardiographic abnormality. An isolated case of moderate QT-interval prolongation has been reported in conjunction with a massive bupropion overdose. Otherwise, bupropion does not produce myocardial conduction abnormalities. Hypotension is unexpected in pure bupropion overdoses but has been reported in mixed-drug overdoses. Hypertension is usually of only mild to moderate severity. Coma and cardiac arrest have been reported in severe bupropion overdoses. The hallmark of bupropion toxicity is generalized seizures. The actual incidence of seizures is unknown but probably is greater than the estimated 21 percent obtained by retrospective studies. There is no correlation between the development of seizures and the presence of other symptoms such as sinus tachycardia. Therefore, **seizures can develop in otherwise asymptomatic patients.** Seizures usually occur within the first 1 to 4 h after ingestion of regular-release bupropion. The average time of seizure onset is

3.7 h, but they may be delayed for up to 8 h. Recent case reports suggest that sustained-release preparations may predispose patients to seizures up to 14 h after exposure. Laboratory study findings are usually normal except for rare cases of mild hypokalemia.

Treatment

Possible early onset of generalized seizures should be anticipated in all cases of bupropion ingestion. A peripheral intravenous line should be established and cardiac monitoring initiated in all patients. Rapid gastrointestinal decontamination is recommended using gastric lavage and administration of 1 g/kg of activated charcoal. Syrup of ipecac is contraindicated due to risk of seizures. Significant cardiotoxicity is not expected except in mixed-drug overdoses. Sinus tachycardia is rarely of hemodynamic significance. Seizures that last longer than 5 min, are focal in nature, or repetitive should be treated aggressively with benzodiazepines. Diphenylhydantoin (phenytoin) is generally less effective than benzodiazepines or phenobarbital in stopping drug-induced seizures but was reportedly effective in stopping seizure activity in one case of bupropion-induced status epilepticus. Hospital admission is recommended for all patients with seizures, sinus tachycardia, or lethargy. Asymptomatic patients having ingested only regular-release bupropion should be observed for 8 h before discharge. In many cases, a psychiatric evaluation also may be necessary. Patients ingesting more than 450 mg of sustained-release bupropion require longer periods of monitoring, probably for 24 h, although consensus guidelines have not yet been established.

MIRTAZAPINE

Mirtazapine (Remeron), a tetracyclic compound structurally unrelated to other currently available antidepressants, has been available in the United States since 1996.⁶ In contrast to all other atypical antidepressants, mirtazapine does not inhibit neuronal amine uptake. Instead, it blocks central presynaptic α_2 -adrenergic receptors and postsynaptic serotonin receptors, subtypes 5-HT₂ and 5-HT₃. This has the net therapeutic effect of increasing central norepinephrine and serotonin (5-HT) neurotransmission. Mirtazapine has a high affinity to block histamine (H₁) receptors and a moderate affinity to block muscarinic receptors. Mirtazapine is commonly associated with somnolence (antihistamine effect) and less often associated with weight gain and increased appetite. It is supplied as 15-, 30-, and 45-mg tablets, with an average daily dose range of between 15 and 45 mg. It is rated category C in pregnancy. Mirtazapine has a similar pharmacokinetic profile as other atypical antidepressants. It is absorbed rapidly and completely following oral administration. Bioavailability is approximately 50 percent due to significant first-pass hepatic metabolism. Peak levels occur within 2 h after ingestion. Mirtazapine is metabolized by the hepatic oxidase enzyme system (cytochrome P450) with only minor active metabolites. The elimination half-life for mirtazapine averages 26 h for males and 37 h for females. The difference in mirtazapine half-life between men and women is attributed to decreased cytochrome P450 metabolism in females. Mirtazapine is highly protein-bound (85 percent) and has a large volume of distribution (5 L/kg). Plasma levels are unlikely to be affected by attempts at extracorporeal removal. Postmarketing surveillance identified a rare incidence of agranulocytosis associated with mirtazapine.

Acute Overdose Toxicity

Mirtazapine appears to be associated with limited toxicity in overdose. Very few cases of mirtazapine overdose have been reported in the medical literature. The most common signs and symptoms were sedation, confusion, sinus tachycardia, and mild hypertension.⁷ Doses up to 1350 mg have been tolerated without significant sequelae. The risk of coma and respiratory depression is greatest at larger doses or when com-

bined with other CNS-depressant drugs. Vital-sign abnormalities are rarely of clinical significance and have not required specific treatment.

Treatment

Treatment guidelines have not been established for mirtazapine overdoses. Based on the currently available data, the following recommendations seem logical but may require modification as experience with mirtazapine increases. For this reason, PCC consultation is strongly encouraged for most cases involving the use of mirtazapine. Fortunately, mirtazapine toxicity usually resolves over 24 h with supportive care alone. Single-dose activated charcoal is the gastrointestinal decontamination method of choice. Gastric lavage may be warranted in selected patients presenting early after large overdoses or with significant coingestants. Syrup of ipecac is contraindicated, and whole-bowel lavage is unnecessary. Symptomatic patients should be admitted to a monitored bed, but significant cardiac toxicity is unlikely. Electrocardiographic abnormalities other than sinus tachycardia have not been reported. Asymptomatic patients can be medically cleared after 8 h of observation.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

SSRIs represent a structurally heterogeneous group of drugs that share a selective affinity to inhibit presynaptic serotonin reuptake without significantly affecting norepinephrine or dopamine reuptake. The increase in synaptic serotonin levels may not entirely explain their therapeutic effects.⁸ As with most antidepressant agents, acute alterations in biogenic amine levels do not correlate with immediate clinical response to drug therapy. Secondary receptor and cellular compensatory mechanisms currently are believed to play an important role in their mechanism of action. SSRIs are essentially devoid of direct presynaptic or postsynaptic receptor interactions. Thus they are associated with very few unwanted pharmacologic actions, in contrast with TCAs.

SSRIs represent the most common form of pharmacotherapy for depression in the United States. They are also the most frequent class of antidepressants reported in drug overdoses. Fatalities are uncommon, with an average of only 1 death in every 1000 drug exposures. There are currently five SSRIs available in the United States: fluoxetine (Prozac, released in 1988), sertraline (Zoloft, released in 1991), paroxetine (Paxil, released in 1993), fluvoxamine (Luvox, released in 1994), and citalopram (Celexa, released in 1998). There are slight potency differences between SSRIs, but their clinical efficacy appears to be comparable. The following represents the suggested average daily dose and maximum daily dose for SSRIs: fluoxetine (average 20-80 mg, maximum 80 mg), paroxetine (average 20-50 mg, maximum 50 mg), citalopram (average 20-60 mg, maximum 60 mg), sertraline (average 50-200 mg, maximum 200 mg), and fluvoxamine (average 50-300 mg, maximum 300 mg). In pregnancy, all SSRIs have a category C rating for teratogenic risk.

The SSRIs have similar pharmacokinetic profiles, including rapid and complete oral absorption, peak plasma levels occurring 4 to 8 h after ingestion (citalopram, 2 to 4 h), significant first-pass hepatic metabolism, a high degree of protein binding (except citalopram), and a large volume of distribution. Fluoxetine is the only SSRI with a clinically significant active metabolite, norfluoxetine, that is equally potent as fluoxetine. The half-lives of fluoxetine and norfluoxetine are 2 to 4 days and 7 to 14 days, respectively. The effects of fluoxetine may last for up to 5 weeks because of the prolonged period necessary to allow for norfluoxetine metabolism. Sertraline and paroxetine have similar half-lives of approximately 24 h. The half-life of citalopram is estimated at 33 h, whereas fluvoxamine has the shortest half-life at 15 h. The SSRIs are metabolized almost entirely by the hepatic cytochrome P450 isoenzyme system. It is becoming increasingly recognized that the SSRIs can inhibit the metabolism of other drugs dependent on the cytochrome P450 isoenzyme system.⁹ Clinically significant drug in-

teractions are most likely to occur with drugs that have a low therapeutic index, e.g., TCAs, antipsychotics, anticonvulsants, benzodiazepines, opiates, theophylline, warfarin, terfenadine, astemizole, pimozide, and cisapride. SSRIs are contraindicated in combination with MAOIs. A 2-week abstinence ("washout") period for most SSRIs and a 5-week abstinence period for fluoxetine are needed before prescribing MAOIs. The administration of other serotonergic agents in combination with SSRIs also should be avoided whenever possible.

The most serious drug-related adverse effect of SSRI psychopharmacotherapy is the potential to produce serotonin syndrome (see below). Other CNS-related adverse effects include headache, sedation, insomnia, dizziness, weakness or fatigue, tremor, and nervousness. Seizures are very uncommon but have been reported with all SSRIs. Serotonin has varying effects on the dopaminergic system. In many cases, extrapyramidal-related symptoms such as dystonic reactions, akathisia, dyskinesia, hypokinesia, and parkinsonian symptoms have been reported in association with SSRI therapy.¹⁰ Consequently, SSRIs should be used cautiously with antipsychotic agents because SSRIs can potentiate antidopaminergic activity. Gastrointestinal complaints such as nausea, diarrhea, constipation, vomiting, and anorexia are reported commonly by patients taking SSRIs. Other adverse effects less commonly reported include dry mouth, increased sweating, blurred vision, hyponatremia, and hypoglycemia. Hyponatremia is believed to be secondary to inappropriate secretion of antidiuretic hormone [syndrome of inappropriate secretion of antidiuretic hormone (SIADH)]. Sexual dysfunction (e.g., anorgasmia) is a relatively common SSRI-related adverse effect and is reversible with drug discontinuation. Priapism has been reported but is extremely rare. A withdrawal syndrome consisting of nonspecific neurologic, psychiatric, and gastrointestinal symptoms has been described in conjuncture with abrupt SSRI discontinuation. It is less likely to occur with fluoxetine because it has a long-acting metabolite.

Acute Overdose Toxicity

Despite the tremendous popularity of SSRIs, there is limited information on their toxicity in overdose. The greatest amount of human overdose experience has been with fluoxetine.¹¹ The information from case series involving the other SSRIs is consistent with the information accumulated on fluoxetine.^{12,15} However, important differences may exist between the different SSRIs that will become evident only with greater exposure of patients to individual SSRIs. Fortunately, all of the SSRIs are characterized by a high therapeutic-to-toxic ratio, and fatalities are uncommon with pure SSRI overdoses. Approximately 50 percent of all adult patients and 75 percent of pediatric patients remain asymptomatic following SSRI overdose. The most common symptoms seen in SSRI overdose include nausea, vomiting, sedation, tremor, and sinus tachycardia. These symptoms are almost identical to the adverse-effect profile of SSRIs except for sinus tachycardia, which is more common in overdose and rarely reported as an adverse effect. Less frequently observed symptoms include mydriasis, seizures, diarrhea, agitation, hallucinations, hypertension, and hypotension. Sertraline may produce mild CNS stimulation in pediatric patients.¹³ Sinus bradycardia was observed more frequently in fluvoxamine overdoses than with other SSRIs. Citalopram produced QRS widening in approximately one-third of cases when more than 600 mg was ingested.¹⁵ In another case series, prolongation of the QT interval has been reported in association with significant citalopram ingestions. Other SSRIs have been reported rarely to produce similar electrocardiographic abnormalities. In most cases, the electrocardiographic abnormalities gradually resolve over 24 h. Tachycardia, mild hypotension, and lethargy are seen more commonly when SSRIs are combined with ethanol. Mixed-drug ingestions can produce a wide variety of additional symptoms depending on the coingestant toxicity. Serotonin syndrome can occur as a consequence of acute SSRI overdose. The results of laboratory tests are usually normal in SSRI overdoses. As mentioned previously, SSRI therapy

has been associated with drug-induced SIADH secretion, which may result in symptomatic hyponatremia.

Treatment

Patients who intentionally overdose with SSRI require establishment of a peripheral intravenous line and cardiac monitoring. Overall, pure SSRI overdoses are associated with limited toxicity except for the infrequent development of life-threatening complications such as generalized seizures and serotonin syndrome. The optimal method of gastrointestinal decontamination in SSRI poisoning remains undetermined. Based on the high therapeutic index and unlikelihood of serious toxicity, single-dose activated charcoal (1 g/kg) is logical for most ingestions, and gastric lavage is probably unnecessary in the majority of SSRI overdoses. However, gastric lavage may have greater utility in the setting of mixed-drug overdoses or if extremely large doses of SSRIs have been ingested recently. Due to the potential for seizures and CNS sedation, syrup of ipecac is contraindicated in adult intentional ingestions.

All patients should be observed for at least 6 h, during which supportive care is generally all that is required. Psychiatric evaluation is warranted for intentional ingestions. Hospital admission is recommended for all patients who remain tachycardic or lethargic 6 h after ingestion. Patients at higher risk for complications include those with underlying seizure disorders, symptoms of serotonin syndrome, or mixed-drug overdoses that have the potential for additional or delayed toxicity. Sodium bicarbonate therapy is indicated in cases of SSRI-induced QRS prolongation, primarily seen after citalopram ingestions of greater than 600 mg, and is administered in an identical manner as described in Chap. 158. Other SSRIs have been associated only rarely with QRS widening. Benzodiazepines are recommended as initial anticonvulsant therapy. Barbiturates are probably equally effective as benzodiazepines but are more sedating. There have been rare reports of delayed seizures, up to 16 h after ingestion. Delayed onset of serotonin syndrome or extrapyramidal reactions are theoretical possibilities that should be considered in all patients.

VENLAFAXINE

Venlafaxine (Effexor) is a bicyclic compound that is structurally different from other antidepressants. It was released in 1994 for the treatment of depression. In contrast to the SSRIs, venlafaxine is a nonselective inhibitor of serotonin, norepinephrine, and dopamine reuptake.¹⁶ Whether this nonselectivity offers any advantage over SSRIs, bupropion, trazodone, nefazodone, or mirtazapine is currently unknown. Venlafaxine has no significant direct effect on presynaptic or postsynaptic neurotransmitter receptors and does not inhibit MAO activity. It is available in 25-, 37.5-, 50-, 75-, and 100-mg tablets. The recommended starting dose is 75 mg/d, which can be increased gradually up to a maximum daily dose of 225 mg. It has a category C rating in pregnancy.

Peak levels occur 2 h after ingestion. It is poorly protein-bound (27 percent), and it has volume of distribution of 6 to 7 L/kg and a half-life of approximately 5 h. The majority of venlafaxine undergoes hepatic cytochrome P450 oxidation, but it is a weak inhibitor of cytochrome P450 enzyme activity. To date, no significant pharmacokinetic drug interactions have been reported. It has one active metabolite, O-desmethylvenlafaxine, that is pharmacologically similar to its parent drug, except for a longer half-life of 11 h. The adverse-effect profile for venlafaxine is similar to that for SSRIs. The only notable exception is the occurrence of mild to moderate hypertension when doses exceed 225 mg/d, which is probably secondary to inhibition of norepinephrine reuptake. Venlafaxine has the same potential as other serotonin agonists to produce serotonin syndrome. Therefore, it should not be combined with MAOIs or other serotonin agonists. Because of its shorter half-life, venlafaxine requires only a 1-week abstinence

period before initiating MAOI therapy. However, a 2-week abstinence period is still required after MAOI discontinuation before starting venlafaxine therapy.

Acute Overdose Toxicity

Information regarding venlafaxine toxicity in overdose is limited to isolated case reports. Unfortunately, most of these cases also include significant coingestants, confounding the interpretation of "pure" venlafaxine toxicity. Sympathetic nervous system stimulation, via inhibition of norepinephrine reuptake, predisposes patients to tachycardia, hypertension, diaphoresis, tremor, and mydriasis. These symptoms are seen frequently in venlafaxine overdoses. Severe hypotension, requiring vasopressors, was reported in one case. Otherwise, most vital-sign abnormalities are of moderate severity and do not require specific pharmacologic therapy. CNS sedation is also reported commonly and occasionally progresses to coma requiring endotracheal intubation and ventilatory support. Generalized seizures are reported frequently and tend to occur early after ingestion. Electrocardiographic abnormalities include sinus tachycardia, QRS widening, and QT_c-interval prolongation. In most cases, symptoms completely resolve gradually over 36 h with supportive care alone.

Treatment

There are no established guidelines for treating venlafaxine overdoses. All patients require at least 6 h of observation. Venlafaxine toxicity is often precipitous and should be anticipated in all intentional overdoses. Patients require establishment of a peripheral intravenous line and cardiac monitoring. Venlafaxine appears to have greater toxicity in overdose than SSRIs and probably deserves more aggressive gastric decontamination. Gastric lavage should be strongly considered for most intentional ingestions with early presentation. Accidental ingestions can be treated with single-dose activated charcoal alone. Benzodiazepines are the anticonvulsants of choice. Hypertension and sinus tachycardia rarely require specific pharmacologic therapy. (3-blockers have the theoretical disadvantage of allowing unopposed α -adrenergic receptor stimulation. Sodium bicarbonate therapy should be considered in venlafaxine overdoses associated with QRS widening of greater than 100 ms. All symptomatic patients should be admitted to a monitored bed.

SEROTONIN SYNDROME

Serotonin syndrome is a rare but important idiosyncratic drug-induced complication of antidepressant therapy.¹⁷ It can be produced by any drug or, more commonly, by a combination of drugs that increase central serotonin neurotransmission (Table 159-1). The stimulation of specific postsynaptic serotonin receptors (5-HT_{1A} and 5-HT₂) is required for full expression of this syndrome. Drugs (such as ondansetron) that block serotonin postsynaptic receptors are incapable of inducing this syndrome. Most cases occur at therapeutic levels, with fewer than 13 percent of cases being associated with drug overdose. Serotonin syndrome is characterized by alterations in cognition and behavior, autonomic nervous system function, and neuromuscular activity. The degree of abnormality in any one area is highly variable. Serotonin syndrome usually occurs either relatively soon after the dose of a potent serotonin agonist (MAOI or SSRI) has been increased or shortly after a second serotonergic agent (e.g., dextromethorphan) has been added. The importance of serotonin syndrome in emergency practice is twofold. First, the diagnosis of serotonin syndrome is very challenging due to its nonspecific symptomatology. Mild cases of serotonin syndrome frequently are attributed to other psychiatric and medical disorders. Severe cases are often misdiagnosed as neuroleptic malignant syndrome. Second, **without proper recognition of patients at risk for serotonin syndrome, emergency physicians may**

TABLE 159-1 Serotonergic Potential of Various Drugs

Extreme Potency	Moderate Potency	Low Potency	None
Amitriptyline	Amphetamine	Amantadine	Acetaminophen

Note: The serotonergic potential of the drugs listed was determined by both objective and subjective criteria and can be influenced by different doses and formulations.

Abbreviations: LSD = lysergic acid diethylamide; MDMA = 3,4-methylenedioxymethamphetamine; NSAIDs = nonsteroidal anti-inflammatory drugs.

inadvertently precipitate serotonin syndrome by administering serotonergic agents (e.g., meperidine). Therefore, emergency physicians should exercise the same drug-interaction precautions in treating patients taking newer antidepressants as those listed in Chap. 160.

The true incidence and severity of serotonin syndrome are unknown. Prospective studies on serotonin syndrome tend to overestimate its incidence and underestimate its severity. Conversely, case reports often are associated with incomplete documentation and tend to overestimate the severity and underestimate the incidence of serotonin syndrome. The most commonly reported signs and symptoms associated with serotonin syndrome are listed in Table 159-2. Interestingly, muscle rigidity, when present, is especially prominent in the lower extremities. This finding can serve as a valuable clinical marker for serotonin syndrome. Patients with ataxia should be examined carefully for lower extremity hypertonia. Unilateral muscle rigidity or focal neurologic findings have not been reported. Seizures are always generalized and usually short-lived. Hyperthermia is usually of moderate severity, but temperatures greater than 41°C (106°F) have been reported. Hypertension is twice as common as hypotension and is associated with a more favorable prognosis.

TABLE 159-2 Clinical Presentation of Serotonin Syndrome*

Cognitive-Behavioral	%	Autonomic Dysfunction	%	Neuromuscular Dysfunction	%
Confusion/disorientation	54	Hyperthermia	46	Myoclonus	57

*Percentages are based on a retrospective study of 127 cases of serotonin syndrome. Source: Adapted from Mills,¹⁷ with permission.

There are no confirmatory laboratory tests for serotonin syndrome. Therefore, the diagnosis of serotonin syndrome is based entirely on clinical suspicion and exclusion of other psychiatric and medical conditions. Serum chemistry tests, drug levels, cerebrospinal fluid analysis, and brain computed tomographic scan results are usually within normal limits. The differential diagnosis for serotonin syndrome is identical to those conditions listed in Table 160-3.

The initial treatment of serotonin syndrome includes discontinuing all serotonergic drugs and providing appropriate supportive care. All patients with serotonin syndrome should be admitted to the hospital until their symptoms have resolved completely. More severely ill patients require admission to an intensive care unit. Approximately 25 percent of patients require endotracheal intubation and ventilatory support. Most patients will show dramatic improvement within 24 h of symptom onset. However, fatalities have been reported. There is an estimated 11 percent mortality rate associated with serotonin syndrome.

At present, there are no accepted guidelines for the use of serotonin antagonists in the treatment of serotonin syndrome. Isolated human case reports suggest that cyproheptadine, methysergide, and propranolol have the potential to be effective antiserotonergic agents. Benzodiazepines are nonspecific serotonin antagonists and can be used to decrease patient discomfort and promote muscle relaxation. Cyproheptadine (Periactin) appears to be the most effective antiserotonergic agent in humans.^{17,18} It should be on most hospital formularies. The initial dose is 4 to 8 mg PO. This dose can be repeated in 2 h if no response is noted to the initial dose. Cyproheptadine therapy should be discontinued if no response is noted after 16 mg has been administered. Patients who respond to cyproheptadine are usually given 4 mg every 6 h for 48 h to prevent recurrences. The use of dopamine agonists (e.g., bromocriptine) has no accepted role in managing patients with serotonin syndrome. Dantrolene (0.5-2.5 mg/kg IV every 6 h, maximum 10 mg/kg per 24 h or 50 to 100 mg bid PO) is a nonspecific muscle relaxant that is used occasionally in serotonin syndrome, but it should be restricted primarily to the treatment of malignant hyperthermia. Patients with muscle rigidity, seizures, or hyperthermia should be monitored closely for rhabdomyolysis and/or metabolic acidosis. Once a patient recovers from serotonin syndrome, it is best to avoid future exposure to serotonergic drugs (see Table 159-1), although the risk of recurrence is unknown.

EPIDEMIOLOGY

Monoamine oxidase inhibitors (MAOIs) have been in clinical use for almost 50 years; they were the first effective agents in the treatment of major depression. However, because of their inherent toxicity and the

development of safer antidepressants, MAOIs are generally now reserved for atypical or refractory cases. Despite their declining popularity, there were still 200,000 MAOI prescriptions filled in the United States during 2000 (personal communication, GlaxoSmithKline). Emergency physicians should recognize that MAOIs have a low therapeutic index, generally cause severe toxicity in overdose, predispose to tyramine reactions, and can produce serotonin syndrome in combination with other serotonergic agents. There are only three antidepressant MAOIs available in the United States: phenelzine (Nardil), tranylcypromine (Parnate), and isocarboxazid (Marplan). The American Association of Poison Control Centers Toxic Exposure Surveillance System recorded approximately 6000 exposures to MAOIs during the past decade.¹ Of these exposures, 80 percent occurred in adults, 60 percent were intentional ingestions, and 75 percent of patients developed symptoms. There were also 58 reported MAOI-related deaths during the same 10-year period, averaging 1 death for every 100 exposures. However, the mortality may increase up to 33 percent following intentional MAOI overdose, as reported in one case series.² In contrast, trazodone (an atypical antidepressant) averages 1 death for every 1200 exposures. This disparity underscores the greater toxicity of MAOIs when compared with newer antidepressant agents.

The only federally approved indication for MAOI antidepressant therapy is for the treatment of nonendogenous depression (i.e., atypical depression or depression refractory to other antidepressants). Other conditions that have shown positive responses to MAOI antidepressant therapy include social phobia disorders, panic disorders, post-traumatic stress syndrome, obsessive-compulsive disorder, bulimia, and narcolepsy. MAOIs are not approved for use in children younger than 16 years of age. Several newer MAOI antidepressants with improved safety and tolerability have been developed, but they are available only outside the United States. The most popular of the newer more selective MAOIs is moclobemide (Aurorix), and it is widely available in Canada and Europe. Surprisingly, it can be purchased in the United States over the Internet without a prescription.

St. John's wort (*Hypericum perforatum*) is a popular over-the-counter herbal treatment for depression. It contains many active ingredients, some of which have the ability to inhibit monoamine oxidase and block serotonin reuptake.³ A specific history of herbal supplement use should be sought because most patients do not consider St. John's wort a "drug." Although generally safe, St. John's wort still should be viewed with caution because even mild MAOI activity may become more clinically significant in overdose or with certain drug interactions.

Selegiline (Eldepryl) is a MAOI that is devoid of antidepressant activity but is used as an adjunct in the treatment of Parkinson disease.⁴ However, at increasing doses, it has activity similar to that of traditional MAOI antidepressants (see below). Some drugs have MAOI activity as an unrelated pharmacologic action such as procarbazine (Matulane), a chemotherapeutic agent for severe Hodgkin lymphoma, and furazolidone (Furoxone), a synthetic nitrofurantoin with antimicrobial and antiprotozoan activity. Patients taking these medications may be predisposed to MAOI-related drug interactions. Although the information in this chapter has relevance to all drugs with MAOI activity, it focuses primarily on phenelzine, tranylcypromine, isocarboxazid, and selegiline toxicity.

PATHOPHYSIOLOGY

Monoamine oxidase (MAO) is an intracellular enzyme bound to the outer mitochondrial membrane.⁵ It has been identified in most human cells. A notable exception is erythrocytes, which do not contain mitochondria. MAO removes amine groups from both endogenous and exogenous biogenic amines. This oxidative deamination process is the primary mechanism by which endogenous biogenic amines such as norepinephrine (NE), dopamine (DA), and 5-hydroxytryptamine

(serotonin or 5-HT) become inactivated. A second important function of MAO is to decrease the systemic availability of absorbed dietary biogenic amines (e.g., tyramine) via hepatic and intestinal metabolism. Therefore, inhibition of MAO leads to the accumulation of neurotransmitters in presynaptic nerve terminals (both centrally and peripherally) and allows for increased systemic availability of dietary amines. Monoamine oxidase has a negligible role in metabolizing circulating catecholamines, which are either secreted endogenously (e.g., by the adrenal gland) or administered intravenously (e.g., epinephrine). This function is accomplished by the enzyme catechol-O-methyl transferase (COMT), which is located extraneuronally and is not affected by MAOIs.

MAO is actually two separate isoenzymes, designated MAO-A and MAO-B. Each isoenzyme has its own relative preference for different neurotransmitters, dietary amines, and MAOIs. These substrate preferences are entirely dose-dependent and can be overcome at higher substrate concentrations or MAOI doses (e.g., selegiline). For example, MAO-A has a 1000 times greater affinity for serotonin than MAO-B, but the ability of MAO-B to metabolize serotonin increases at higher serotonin concentrations. Norepinephrine is metabolized primarily by MAO-A, whereas MAO-A and MAO-B have equal ability to metabolize dopamine and tyramine. Overall, the human brain contains more MAO-B than MAO-A, with MAO-B predominance increasing with advancing age. Dopamine neurons appear to lack MAO-B activity and have limited MAO-A activity.⁶ Significant MAO-B activity has been detected in surrounding astrocytes and glial cells. Thus dopamine inactivation may depend on astrocyte and glial cell metabolism. Interestingly, MAO-B is the exclusive isoenzyme found in serotonergic neurons. This paradox may be explained by simple conservation of energy, where the MAO-B isoenzyme has a lower affinity for 5-HT and allows for more 5-HT to become recycled. It also allows for increased metabolism of nonserotonin bioamines, thus keeping the neuron free of false neurotransmitters. Intestinal MAO activity is mostly secondary to MAO-A, whereas approximately equal proportions of both isoenzymes are found in the liver. This dual representation of both isoenzymes in the liver affords greater protection against a tyramine reaction.

MAOIs share structural similarities with endogenous amines (e.g., NE, 5-HT, DA), and this allows them to act as potential substrates for MAO. The antidepressant activity of phenelzine, tranylcypromine, and isocarboxazid generally has been attributed to their ability to increase NE and 5-HT neurotransmission by increasing presynaptic concentrations of serotonin and norepinephrine. The actual mechanism by which they exert their therapeutic effects remains unproved but is probably related to delayed postsynaptic receptor modifications (e.g., downregulation). Other potential mechanisms of action include indirect release of neurotransmitters and inhibition of neurotransmitter reuptake. MAOIs also inhibit other enzyme systems (e.g., pyridoxal phosphokinase, diamine oxidase, etc.), but this finding is of uncertain clinical significance. At therapeutic doses (10 mg per d), selegiline has limited effects on NE and 5-HT metabolism. The therapeutic benefit of selegiline in Parkinson disease is thought to be related to increased striatal dopamine neurotransmission and protection against neuronal damage from oxidative stress.^{4,6} However, at doses greater than 30 mg per d, selegiline is capable of increasing presynaptic NE and 5-HT concentrations and thus has the potential to produce drug-related toxicity similar to that of phenelzine and tranylcypromine.

All the currently available MAOI antidepressants are irreversible and nonselective (MAO-A, MAO-B) in their enzyme inhibition. MAOIs form irreversible covalent bonds with the MAO enzymes, and this renders the enzyme permanently inactive. Once an irreversible MAOI has been discontinued, it takes approximately 2 weeks before new enzyme synthesis has returned MAO activity to 50 percent of normal. MAOIs do not affect enzyme production. Reversible MAOIs competitively inhibit MAO activity. Thus new enzyme synthesis is not necessary to restore MAO activity, and MAO activity will return grad-

usually to normal over a period of hours as the drug-enzyme complex spontaneously dissociates. Examples of reversible MAOIs include moclobemide, toloxatone, brofaromine, cimoxatone, and befloxatone. These agents are currently not available in the United States.

All MAOIs are absorbed rapidly and completely from the gastrointestinal tract.⁷ They have relatively low bioavailability because of a large first-pass effect of hepatic metabolism. Their dependence on hepatic metabolism predisposes them to potential drug interactions with other drugs requiring hepatic oxidation. Peak drug levels usually occur within 1 to 3 h of ingestion. They have relatively large volumes of distribution (1-5 L/kg) and are highly protein-bound. Elimination half-life averages between 2 and 3 h. It is important to recognize that clinical toxicity is usually delayed well after most of the MAOI has already been metabolized. Thus blood MAOI levels do not correlate with clinical toxicity. Selegiline has many active metabolites, such as desmethyleselegiline, amphetamine, and methamphetamine. Tranylcypromine has long been suspected of having amphetamine as a metabolite, but this has rarely been detected. Phenelzine metabolism results in multiple active metabolites such as B-phenylethylamine, which also serves as a substrate for MAO-B. The pharmacokinetic profile of most MAOIs suggests that attempts at extracorporeal removal (e.g., hemodialysis) or administering repeat doses of activated charcoal would be unsuccessful in significantly reducing MAOI plasma levels.

TYRAMINE REACTION

Tyramine is an exogenous dietary amine that normally is metabolized by intestinal and hepatic MAO enzymes.⁸ In patients taking a nonselective MAOI, a greater amount of tyramine is able to reach the systemic circulation. Tranylcypromine is associated more frequently with tyramine reactions than phenelzine or isocarboxazid. Selegiline (MAO-B selective) is unlikely to produce a tyramine reaction if taken at therapeutic doses. Tyramine is classified as an indirect sympathomimetic and is structurally similar to amphetamine. Like most indirect sympathomimetics, tyramine enters the presynaptic neuron through amine uptake pumps. Once inside the neuron, indirect sympathomimetics are capable of releasing presynaptic stores of norepinephrine and to a lesser degree serotonin and dopamine. Tyramine also can displace epinephrine from the adrenal gland. This action produces the "cheese" reaction (aged cheese contains a large amount of tyramine). In similar fashion, broad (fava) beans contain large quantities of dopamine.

Tyramine is found in over 70 foods and beverages, and any one of these sources may trigger such a reaction.⁹ It has been reported that less than 30 percent of patients comply with a MAOI-restrictive diet. In addition, approximately 4 to 8 percent of compliant patients will experience a tyramine reaction during their course of therapy. Nonetheless, newer guidelines call for avoiding only a few high-risk food groups such as meat or fish that is not fresh, sauerkraut, aged meats and cheeses, alcohol (Chianti wine and vermouth), pickled fish (hering), concentrated yeast extracts, and broad beans.

The tyramine reaction is typically of rapid onset, occurring within 15 to 90 min of ingestion of the dietary amine. The severity of this reaction is highly variable and partially related to the total amount of tyramine ingested. The hallmark symptom of the tyramine reaction is a severe occipital or temporal headache. Other associated symptoms include hypertension, diaphoresis, mydriasis, neck stiffness, pallor, neuromuscular excitation, palpitations, and/or chest pain. Most symptoms resolve gradually over 6 h without specific therapy, but fatalities have been reported rarely, usually due to intracranial hemorrhage or myocardial infarction. Therefore, an electrocardiogram should be obtained on all patients with tyramine-associated chest pain. Focal neurologic findings or a persistent, severe headache warrants investigation with a computed tomographic (CT) scan of the head.

In cases of severe hypertension, the drug of choice remains phenolamine, which is given IV in 2.5- to 5-mg doses every 5 to 15 min

until the blood pressure is controlled. The half-life of phenolamine is approximately 20 min, and its duration of action less than 1 h. Nitroprusside is another rapidly acting direct vasodilator that is always administered as a continuous infusion (1—4 μ g/kg per min). In cases of moderate hypertension, nifedipine and prazosin have been reported to be effective. Newer recommendations for the treatment of accelerated chronic hypertension discourage the use of nifedipine due to concerns of excessive blood pressure reduction. These concerns may not apply to the acute hypertension seen in tyramine reactions. (3-Adrenergic blockers should be considered contraindicated due to unopposed α -receptor stimulation. Hospital admission should be strongly considered for patients whose symptoms do not resolve completely within 6 h of onset. Patients who are asymptomatic after 4 h of observation can be discharged safely home.

DRUG INTERACTIONS

Chronic MAOI drug therapy predisposes to many potentially significant drug interactions (Table 160-1). However, documentation of human MAOI-drug interactions is often limited to single case reports or case series. Controlled human studies are impractical due to the life-threatening nature of these reactions. Animal studies often have limited applicability to human toxicity. Most important, emergency physicians should never administer medications to patients taking MAOIs unless absolutely necessary. Drug compatibility with MAOIs always should be confirmed prior to drug administration.

TABLE 160-1 Drugs with MAOIs*

Indirect Sympathomimetics	Miscellaneous Drugs
Benzphetamine	(3-Blockers
Bretylium	Bupropion
Cocaine	Buspirone
Dexfenfluramine	Caffeine
Diethylpropion	Carbamazepine
Dopamine	Cyclobenzaprine
Ephedrine	Dextromethorphan
Fenfluramine	Disulfiram
Guanethidine	Ergot alkaloids
Isometheptene	Fentanyl
Mephentermine	Furazolidone
Metaraminol	Ketamine
Methamphetamine	Levodopa (L-dopa)
3,4-Metilylenedioxymethamphetamine (MDMA)	Lithium
Methylidopa	Meperidine
Methylphenidate	Mirtazapine
Pemoline	Oral hypoglycemic agents
Phentermine	Phenothiazines
Phencyclidine	Procarbazine
Phenylpropanolamine	St. John's wort
Propylhexedrine	Sumatriptan
Pseudoephedrine	Theophylline
Reserpine	Tramadol
Ritodrine	Tricyclic antidepressants

syndrome in Chap. 159, on

Tyramine

SECTION 14 • TOXICOLOGY AND PHARMACOLOGY

Drug interactions involving MAOIs can be grouped into three categories: pharmacodynamic, pharmacokinetic, and idiosyncratic. The most common pharmacodynamic reaction involves indirect-acting sympathomimetics. They have the potential to produce a hyperadrenergic condition similar to the tyramine reaction (see above) and can be found in over-the-counter preparations, drugs of abuse, and some prescription products. Pharmacokinetic drug interactions have been noted with MAOIs because they are metabolized through the cytochrome oxidase enzyme system and thus can inhibit the metabolism of other drugs. The potentiation of opiate and sedative-hypnotic drugs is an example of this type of enzyme inhibition. Tranylcypromine and phenelzine have been shown to increase insulin release and predispose to hypoglycemia, especially in patients taking oral sulfonylurea agents. Insulin dosage also may warrant reduction. Serotonin syndrome (see Chap. 159) is a rare, potentially life-threatening idiosyncratic reaction. It occurs most commonly when MAOIs are combined with other serotonergic agents. However, specific emphasis pertaining to emergency physicians is placed on the avoidance of using meperidine,¹⁰ dextromethorphan, or tramadol in combination with MAOIs. Even after a patient discontinues MAOI therapy, it still takes 2 weeks before 50 percent of MAO enzyme activity returns. Consequently, there always should be at least a 2-week abstinence period between the time of MAOI discontinuation and the time that any contraindicated drug is administered. This recommendation is particularly important to prevent the development of serotonin syndrome.

It is also important to note which medications are generally considered safe in patients on MAOIs (Table 160-2). Aspirin, acetaminophen, ibuprofen, and morphine have been used in combination with MAOIs without complications. Morphine should be given in decreased doses due to impaired morphine metabolism and enhanced opiate effects. Direct-acting sympathomimetic agents (e.g., norepinephrine) can be used with caution, employing the lowest possible effective dose. Direct sympathomimetics do not rely on the release of neurotransmitters for their activity, and they are inactivated by the enzyme COMT, which is unaffected by MAOIs.

TABLE 160-2 Drugs Considered Safe with MAOIs*

Direct sympathomimetics
Albuterol aerosol
Dobutamine
Epinephrine
Isoproterenol
Methoxamine
Norepinephrine
Terbutaline
Miscellaneous drugs
Acetaminophen
Aspirin
Barbiturates
Benzodiazepines
Calcium channel blockers
Cephalosporins
Corticosteroids
Granisetron
Inhalation anesthetics
Lidocaine
Morphine
Nitroglycerin
Nitroprusside
Nonsteroidal anti-inflammatory drugs
Ondansetron
Penicillins
Phentolamine
Procainamide
Tropisetron

*Always use the lowest effective dose.

CLINICAL FEATURES (ACUTE OVERDOSE)

MAOIs have a dangerously low toxic-to-therapeutic ratio. Ingestions of greater than 2 to 3 mg/kg of body weight can be life-threatening, and doses of less than 2 mg/kg still may produce mild to moderate toxicity. The lethal-dose MAOI toxicity is reported to be between 4 and 6 mg/kg.¹¹ Deaths have been reported in adults with as little as 170 mg of tranylcypromine and 375 mg of phenelzine. Selegiline overdoses have not been reported but should be assumed to produce toxicity similar to that of the traditional MAOI antidepressants until determined otherwise. The average therapeutic dose of tranylcypromine ranges from 20 to 40 mg per d, with a maximum dose of 60 mg per d. It is available as a small, round, red 10-mg tablet. Therapeutic doses of phenelzine range between 45 and 75 mg per d, with a maximum of 90 mg per d. The drug comes as a small, round, orange 15-mg tablet. Isocarboxazid is manufactured as a 10-mg tablet with therapeutic doses ranging between 10 and 60 mg per d. Selegiline has a standard dose of 10 mg per d and comes as an aqua 5-mg capsule.

An important clinical aspect of MAOI is that **symptoms of overdose are characteristically delayed** between 6 and 12 h after ingestion but can be delayed as long as 24 h. The delayed onset of toxicity is believed to be secondary to the gradual accumulation of NE and 5-HT in the brain and in peripheral sympathetic neurons. Symptoms of MAOI overdose are most consistent with a hyperadrenergic state secondary to excessive stimulation of α - and β -adrenergic receptors, but symptoms related to excessive serotonin receptor activity are also seen. Patients on chronic MAOI therapy may show earlier signs of toxicity due to preexisting enzyme inhibition. In severe cases, the hyperadrenergic state can be followed rapidly by hypotension and central nervous system depression resembling a sympatholytic condition. Toxicity usually persists for 1 to 4 days after ingestion.

The signs and symptoms of MAOI toxicity are often nonspecific. Even in its most severe form, it can resemble numerous other conditions (see below). Most clinical overdose information has come from single case reports or case series, with tremendous variation in presentation. Hence there is no "typical" presentation to MAOI toxicity, nor is there an orderly progression of symptoms. The clinician should anticipate the appearance of life-threatening symptoms in all MAOI overdose patients. The initial symptoms of MAOI overdose are reported to include headache, agitation, irritability, nausea, palpitations, and tremor. The earliest signs of MAOI toxicity include sinus tachycardia, hyperreflexia, hyperactivity, fasciculations, mydriasis, hyperventilation, nystagmus, and generalized flushing. In cases of moderate toxicity, opisthotonus, muscle rigidity, diaphoresis, chest pain, hypertension, diarrhea, hallucinations, combativeness, confusion, marked hyperthermia, and trismus may become evident. A peculiar ocular finding described as "Ping-Pong gaze" has been observed with some cases of MAOI toxicity and refers to bilateral wandering horizontal eye movements. The mechanism of this gaze disorder is unknown. In all cases, it resolves gradually as the patient improves. Severe toxicity is accompanied by bradycardia, cardiac arrest, hypoxia, papilledema, hypotension, seizures, coma, and worsening hyperthermia. Hypotension is an ominous finding that commonly remains resistant to therapeutic attempts at correction. Fetal demise, cerebral edema, pulmonary edema, and intracranial hemorrhage all have been reported in association with MAOI overdoses. The most common electrocardiographic abnormality seen in MAOI toxicity is sinus tachycardia, but T-wave abnormalities are not uncommon. Deaths usually are secondary to multiple-organ failure.

DIAGNOSIS

There are no confirmatory laboratory or drug tests. MAOI overdose remains a clinical diagnosis based solely on the history of excessive MAOI ingestion. Plasma MAOI levels and drug screens cannot be re-

lied on to assist in making the diagnosis of MAOI toxicity for two reasons. First, all commonly used drug screens are qualitatively unable to detect MAOIs. Second, specific quantitative plasma MAOI levels are not available routinely in most hospitals, nor do they correlate with observed clinical toxicity. Selegiline is likely to produce amphetamine metabolites, which can be detected on most urine drug screens. Tranlycypromine has the potential to produce amphetamine metabolites, but these have been detected rarely. The best use of laboratory tests is to assist in the differential diagnosis of MAOI toxicity and to identify possible complications of MAOI overdose, which include hypoxia, rhabdomyolysis, renal failure, hyperkalemia, metabolic acidosis, hemolysis, and disseminated intravascular coagulation. Leukocytosis and thrombocytopenia are seen commonly with MAOI toxicity.

The differential diagnosis of an MAOI overdose includes all drugs and medical conditions capable of producing a hyperadrenergic state, altered mental status, and/or muscle rigidity. As evidenced by the extensive number of conditions listed in Table 160-3, the differential diagnosis of unknown MAOI ingestion is extremely challenging. In addition, MAOI toxicity also can be associated with a sympatholytic presentation, thus broadening the differential possibilities even further. In reality, without a history of exposure to MAOIs, it is highly unlikely that the correct diagnosis will be made in the ED, since no confirmatory tests are available.

An interesting diagnostic dilemma exists when a patient on chronic MAOI therapy presents with elevated blood pressure. At therapeutic doses, hypertension can result from tyramine reactions, spontaneous hypertensive crisis, and serotonin syndrome. Tyramine reactions are likely to occur in close relation to food or drug ingestions containing indirect sympathomimetics. Spontaneous hypertensive crisis is a rare condition, usually occurring in relation to recent MAOI dosing.¹² Serotonin syndrome occurs most commonly shortly after exposure to other serotonergic agents and usually is associated with significant cognitive-behavioral and neuromuscular abnormalities.

TABLE 160-3 Differential Diagnosis of Monoamine Oxidase Inhibitor Overdose

Intoxications	Medical conditions	Adverse drug reactions
Amphetamines	Heat stroke	Dystonic reactions
Antimuscarinics	Hypoglycemia	Malignant
Cathinone	Hyperthyroidism	hyperthermia
Clonidine (early)	Pheochromocytoma	Serotonin syndrome
Cocaine		Tyramine reaction
Lysergic acid		Spontaneous
diethylamide		hypertensive crisis
(LSD)		Neuroleptic malignant
Methylphenidate		syndrome
MDMA*		
Nicotine (early)		
Phencyclidine		
Phenylpropanolamine		
Strychnine		
Theophylline		
Tricyclic		
antidepressants		
(early)		
Withdrawal states	Infectious diseases	Psychiatric
Ethanol	Encephalitis	Lethal catatonia
(delirium	Meningitis	
tremens)	Rabies	
Sedative-	Sepsis	
hypnotics	Tetanus	
Clonidine		
P-Blockers		

*3,4-Methylenedioxymethamphetamine.

TREATMENT

General Care

All potential MAOI overdose patients require immediate attention, establishment of at least one preferably large-bore peripheral intravenous line, cardiac monitoring, supplemental oxygen, and gastric decontamination. General laboratory tests should be ordered on all patients, with particular emphasis on identifying early hyperkalemia, metabolic acidosis, and rhabdomyolysis. There are no known antidotes for MAOI toxicity. ED management therefore is directed toward supportive care and early treatment of complications. Onset of toxicity is usually gradual and delayed, sometimes up to 24 h after ingestion. However, the abrupt development of seizures, coma, respiratory insufficiency, hyperadrenergic storm, and cardiovascular collapse is entirely possible. Greater toxicity for any given dose of MAOI is predicted in the setting of significant underlying medical problems, pediatric patients, geriatric patients, or coingested drugs.

The best method of gastric decontamination in the setting of MAOI overdose has never been studied. Therefore, the following recommendations are general guidelines based on the pharmacokinetic profile of MAOIs as well as results of human case reports. **Syrup of ipecac is contraindicated.** Activated charcoal should be administered as a single dose of 1 g/kg as soon as possible. Multiple-dose administration of activated charcoal is not expected to be advantageous. Gastric lavage is recommended in all significant ingestions and should be performed within the first 2 h of ingestion to maximize drug removal. Since MAOIs are absorbed rapidly, delayed gastric lavage or whole-bowel irrigation is unlikely to be of any clinical benefit. Hemodialysis, hemoperfusion, and peritoneal dialysis have no established role in the treatment of MAOI poisoning. Urinary acidification is not recommended because it is ineffective at enhancing MAOI elimination and predisposes to acute renal failure secondary to myoglobin precipitation within renal tubules.

Management of Specific Conditions

HYPERTENSION The acutely hypertensive patient should be treated only with short-acting intravenous antihypertensive agents because of the potential to develop precipitous hypotension. In most cases, an intraarterial catheter is required for accurate blood pressure monitoring. The traditional antihypertensive agents of choice are phentolamine and nitroprusside. Phentolamine is a nonspecific α -adrenergic receptor blocker usually administered in 2.5- to 5.0-mg boluses every 10 to 15 min until blood pressure elevation is controlled. It also can be given as a continuous infusion (0.2-0.5 mg per min) for maintenance therapy. Phentolamine use is commonly associated with reflex tachycardia. Nitroprusside is as effective as phentolamine. It is given as a continuous infusion with an initial rate of 1 μ g/kg per min and then titrated according to blood pressure response. Prolonged high doses of nitroprusside can predispose to cyanide toxicity, but this potential complication is rarely noted in the ED. The addition of thiosulfate to nitroprusside infusions eliminates the possibility of cyanide toxicity. Nitroglycerin is indicated for the relief of anginal chest pain and in patients with signs of myocardial ischemia. Fenoldopam is a recently approved short-acting parenteral antihypertensive agent.¹³ Its mechanism of action is secondary to peripheral dopamine (D₁) receptor stimulation. It reportedly does not cross the blood-brain barrier. Fenoldopam is administered as a titratable infusion with a suggested starting dose of 0.05 to 0.1 μ g/kg per min. Intravenous diltiazem is expected to be an effective antihypertensive agent, but its long duration of action makes it less desirable than the previously mentioned shorter-acting agents. β -Blockers pose a theoretical risk of increasing the blood pressure through unopposed vasoconstriction and would

appear to be contraindicated. Despite this concern, (3-blockers have been used occasionally to treat hyperadrenergic symptoms in MAOI overdose without serious complications. At best, p-blockers should be used with great caution in the setting of MAOI toxicity. Labetalol is a p-blocker with slight α -receptor blocking ability. The theoretical benefit of its α -blocking capacity must be balanced against its (3-blocking activity, which is seven times greater.

HYPOTENSION Hypotension carries a poor prognosis in MAOI overdose. Isotonic intravenous fluid boluses of 10 to 20 mL/kg are the initial treatment of hypotension. When vasopressors are required, it is important to avoid all indirect-acting agents (see Table 160-1). Norepinephrine is the vasopressor of choice, with epinephrine as the second choice. MAOI patients usually demonstrate an increased sensitivity to vasopressors, and lower initial doses are recommended.

DYSRHYTHMIAS Sinus tachycardia rarely calls for specific drug therapy unless it is producing cardiac ischemia. Lidocaine and procainamide are the most effective antiarrhythmics in treating MAOI-induced ventricular dysrhythmias. Bradycardia may degrade quickly into asystole in the later stages of the overdose and requires pacemaker placement. Pharmacologic treatment of bradycardia includes atropine, isoproterenol, and dobutamine. Bretylium should be avoided due to its indirect sympathomimetic activity.

SEIZURES Benzodiazepines are the anticonvulsants of choice in treating MAOI-induced seizures. Barbiturates are as effective as benzodiazepines but may cause hypotension, especially at higher doses. Phenytoin is generally ineffective in stopping drug-induced seizures. General anesthesia and/or muscle paralysis may be necessary in cases of status epilepticus to prevent the metabolic acidosis, hyperthermia, and rhabdomyolysis that commonly accompany persistent seizure activity. Muscle paralysis is best accomplished using nondepolarizing neuromuscular blocking agents. The action of succinylcholine may be enhanced by MAOIs. Pancuronium is probably less desirable than other nondepolarizing agents (e.g., vecuronium) because of its propensity to produce elevations in heart rate and blood pressure. Electroencephalographic monitoring is required when muscle paralysis is used to control the peripheral manifestations of seizure activity. See Chap. 232 for details of treating seizures.

HYPERTHERMIA Antipyretics generally are ineffective at lowering drug-induced fever. Benzodiazepines are useful first-line agents by reducing muscle hyperactivity and thus decreasing secondary heat production. Increasing evaporative and conductive heat loss is essential for the successful treatment of hyperthermia. This is best accomplished by using cool mist spray, evaporative fans, and ice baths. Hyperthermia is often resilient in the setting of persistent muscle rigidity. Muscle paralysis (nondepolarizing agents) should be considered when diffuse rigidity is refractory to benzodiazepine therapy. Dantrolene has been used successfully as a muscle relaxant in resistant cases of muscle rigidity. The intravenous dose of dantrolene ranges from 0.5 to 2.5 mg/kg every 6 h. Dantrolene should be used only when other measures have failed to relieve muscle rigidity. Older reports of MAOI-induced hyperthermia cited successful treatment with phenothiazines (chlorpromazine). However, these agents are not currently recommended owing to their potential to lower the seizure threshold, worsen hypotension, and produce extrapyramidal reactions.

ADMISSION CRITERIA

All intentional MAOI overdoses and accidental exposures of greater than 1.0 mg/kg require admission to an intensive care unit. Accidental exposures of less than 1.0 mg/kg still require hospital admission but are unlikely to develop life-threatening complications. Therefore, these patients can be admitted to a less acutely monitored bed. Asymp-

tomatic patients should be monitored for at least 24 h before medical clearance. Vital-sign abnormalities should be recognized early and treated appropriately. Dietary and medication restrictions should be followed meticulously during the hospitalization. All patients should be instructed to avoid contraindicated foods and medications for a minimum of 2 weeks. Consultation with a medical toxicologist through the nearest regional poison control center is strongly recommended. Patients who require transfer to hospitals with intensive care units should be transferred as soon as possible to avoid the problems anticipated with delayed onset of toxicity. All patients being transferred should be accompanied by medical personnel capable of performing advanced cardiac life support and endotracheal intubation. It is important to remember that **even a single MAOI pill may produce life-threatening drug interactions** such as serotonin syndrome under the right circumstances.

ANTIPSYCHOTICS

Richard A. Harrigan
William J. Brady

A group of antipsychotic drugs, classically termed *neuroleptics*, have been in use since the 1950s for the treatment of schizophrenia and other related psychoses (Table 161-1). Although they have revolutionized the treatment of these disorders, these agents are known to cause myriad adverse effects, both in therapeutic and toxicologic situations. A propensity to affect neurologic function led to the term *neuroleptic*, which is less appropriate today in light of the development of newer agents for the treatment of schizophrenia that are less likely to cause these effects; thus, these agents are now usually classified as *antipsychotic* agents (see Table 161-1). In addition to the treatment of various psychoses, however, these drugs also are used for nonpsychiatric con-

TABLE 161-1 Pharmacologic Classification of Typical and Atypical Antipsychotic Agents

Class	Generic Name	Brand Name
TYPICAL ANTIPSYCHOTICS		
Phenothiazines		
Aliphatic	Chlorpromazine	Thorazine
	Triflupromazine	Vesprin
Piperazine	Fluphenazine	Prolixin
	Perphenazine	Trilafon
	Prochlorperazine	Compazine
Piperidine	Trifluoperazine	Stelazine
	Thioridazine	Mellaril
	Mesoridazine	Serentil
Thioxanthenes	Thiothixene	Navane
Butyrophenones	Haloperidol	Haldol
Diphenylbutylpiperidines	Pimozide	Orap
Dihydroindolones	Molindone	Moban
Dibenzazepines		
Dibenzoxazepine	Loxapine	Loxitane
ATYPICAL ANTIPSYCHOTICS		
Dibenzazepines		
Dibenzodiazepine	Clozapine	Clozaril
Thienobenzodiazepine	Olanzapine	Zyprexa
Dibenzothiazepine	Quetiapine	Seroquel
Benzisoxazoles	Risperidone	Risperdal
Benzisothiazol piperazine derivative	Ziprasidone	Geodon

ditions, such as chemical restraint of agitated or violent patients; control of nausea and emesis; pain and nausea relief in various headache syndromes; suppression of hiccups; and control of various involuntary motor disorders, including Tourette syndrome, Huntington chorea, and various disorders of the basal ganglia.

Conventional, or *typical*, antipsychotics are a diverse group of older agents that gained widespread acceptance for the control of the positive symptoms (e.g., hallucinations, delusions, and disordered thought) of schizophrenia and related psychoses. These agents cause numerous adverse effects, however, and do little if anything to ameliorate the cognitive dysfunction and negative symptoms (e.g., withdrawal, flat affect, and loss of drive) that are also characteristic of the disease. Thus, a newer class of *atypical* antipsychotic drugs has emerged, featuring improved clinical efficacy and a different side-effect and toxicologic profile. Despite the numerous adverse effects seen with antipsychotic agents, their therapeutic index is high, and lethal ingestion is rare. The most recent Toxic Exposure Surveillance System summary of fatal exposures from the American Association of Poison Control Centers lists only 23 reported deaths with an antipsychotic agent as the principal agent ingested; in only 6 of those cases was the antipsychotic the sole agent involved.¹

PHARMACOLOGY

The *typical antipsychotics* share a similarity in pharmacotherapeutic and adverse-effect profiles. They are all dopamine receptor antagonists; this blockade in the limbic system is thought to be primarily responsible for the antipsychotic activity of these agents. Dopaminergic antagonism in the basal ganglia also occurs, causing disinhibition of cholinergic neurons; this, in turn, may lead to various involuntary movement disorders, termed *extrapyramidal side effects*, as discussed below. In addition to blocking dopaminergic receptors, typical anti-

psychotics also block, to varying degrees, α -adrenergic (principally α_1), muscarinic, and histaminic receptors. α_1 -adrenergic antagonism leads to orthostatic hypotension and reflex tachycardia because of peripheral vasodilatation. Anticholinergic activity at muscarinic sites leads to hyperthermia, tachycardia, pupillary dilatation, dry mouth, urinary retention, and constipation. Histamine blockade results in central nervous system sedation. Generally speaking, drugs of higher potency (i.e., low milligram-per-day dosage) tend to cause significant dopaminergic antagonism and thus are more likely to cause extrapyramidal effects; examples include haloperidol, fluphenazine, and thiothixene. Drugs of lower potency (i.e., high milligram-per-day dosage) are less likely to cause extrapyramidal effects, but are more likely to cause sedation and orthostatic hypotension, because of strong antihistaminic and anticholinergic/muscarinic effects. Examples of lower-potency drugs include chlorpromazine and thioridazine. It should be emphasized, however, that all typical antipsychotics could cause some degree of extrapyramidal symptoms, sedation, orthostatic hypotension, and various anticholinergic effects.

The newer *atypical antipsychotics*, in addition to featuring varying degrees of antagonistic activity at dopaminergic, α -adrenergic, histaminic, and cholinergic/muscarinic receptor sites, block serotonergic sites with varying affinity. These drugs exhibit greater clinical efficacy in that they also improve negative symptomatology and cognitive dysfunction, and they are less likely to cause extrapyramidal effects and thus are more attractive than the typical antipsychotics. There is evidence that these newer agents also are effective in treatment-resistant patients who are so labeled due to treatment failures with the typical antipsychotic agents.

The pharmacokinetics of all antipsychotic agents are similar, given well-controlled, therapeutic situations. Bioavailability is erratic and peak plasma levels occur 2 to 6 h after oral administration, although clinical effects are seen within the first 30 to 60 min. Of the new atypical antipsychotics, only ziprasidone is currently available in injectable form. Protein binding, lipophilicity, and volume of distribution are uniformly high for all antipsychotics, rendering dialysis an ineffective means of treating toxicity. Elimination is by hepatic metabolism—both hepatic microsomal enzyme oxidation and enterohepatic circulation—followed by renal excretion, to varying degrees. The newer atypical antipsychotics all carry warnings regarding use in patients with concomitant hepatic disease. Only quetiapine and ziprasidone do not carry such precautions in renal disease, because of trivial excretion of unchanged drug by the kidney. Plasma-level monitoring can establish compliance, but is not generally recommended with the antipsychotics, in either therapeutic or toxicologic assessment situations.

ADVERSE EFFECTS

Extrapyramidal Disorders

Although these dopaminergic receptor-mediated side effects can be seen with any antipsychotic agent, they are classically associated, and most frequently seen, with the typical agents, especially those of higher potency. However, any of the following conditions can occur with all antipsychotic drugs, as well as with other structurally similar agents that are not classified as antipsychotics, such as droperidol, promethazine, metoclopramide, and prochlorperazine.

Dystonic reactions are involuntary muscle contractions that may affect the muscles of the neck (torticollis), jaw (trismus), trunk (opisthotonos), tongue, or those surrounding the eye (oculogyric crisis). Laryngospasm, although rare, may also occur, and threaten the airway. Dystonia may involve an isolated muscle group or, more frequently, a combination of the above. Affected patients commonly exhibit evidence of adrenergic hyperactivity, including diaphoresis, tachycardia, tachypnea, and hypertension, and are often in obvious pain and quite anxious.² A history of therapeutic (including long-acting depot preparations of

some antipsychotics such as fluphenazine and haloperidol) and illicit drug use is key; dystonic reactions have been reported with a variety of agents, including tricyclics, "street Valium" (haloperidol), and cocaine.² Acute treatment includes administration of diphenhydramine 25 to 50 mg IM or IV; the latter route provides the most rapid relief, usually within 10 min. If symptoms are not relieved, the dose may be repeated in 15 to 30 min, or an alternative agent can be used, such as benztropine (Cogentin) 1 to 2 mg, optimally via either parenteral route. Benzodiazepines may serve as adjunctive therapy and are especially useful when cocaine is the offending agent. **Because of the prolonged effects of the dystonia-inducing agent, oral therapy with either diphenhydramine or benztropine should be continued for 2 to 5 days.**²

Akathisia is a condition in which patients demonstrate motor restlessness with corresponding anxiety; it can be mistaken for a worsening of the underlying psychiatric disorder. This assumption may lead to a dose increase of the offending agent, thus making the symptoms worse. Administration of diphenhydramine or related agents may be diagnostic and therapeutic; a reduction in dose of the antipsychotic, or a switch to a less potent agent, is a possible long-term solution. *Bradykinesia*, or drug-induced parkinsonism, is another extrapyramidal side effect of this drug class and should be treated in a similar fashion.

Tardive Dyskinesia

This involuntary movement disorder is idiosyncratically associated with chronic therapy, and classically—although not exclusively—with the typical antipsychotic agents. Symptoms include involuntary, repetitive, choreoathetoid movements of the face, mouth, and tongue, and may be mild or severe and debilitating; uncommonly, the limbs and trunk are also affected. Elderly patients, especially those with diabetes mellitus and organic brain disorders, seem to be at increased risk. The overall incidence is approximately 5 percent per year of exposure to the offending agent. The pathophysiology of tardive dyskinesia is unclear. Traditionally, it has been attributed to an emerging supersensitivity of dopaminergic receptors in the striatum under chronic blockade by the antipsychotic agent. Alternate theories also implicate other neurotransmitters, whereas others invoke the possibility of direct neurotoxicity resulting in free radical production. The new atypical antipsychotics are believed to be much less likely to cause this syndrome, although this is not yet clear. A number of drugs and treatment modification strategies have been advanced as therapeutic options for tardive dyskinesia; there are no emergency management issues other than recognizing the syndrome.³

Neuroleptic Malignant Syndrome

This syndrome is an idiosyncratic, rare, and potentially fatal reaction most commonly associated with the use of antipsychotic drugs, although other drug classes also have been implicated. Clinical features include hyperthermia, muscle rigidity, autonomic instability, and alteration in mental status. Neuroleptic malignant syndrome (NMS) may occur at any time during therapy with the causative agent or may present when dopamine agonist therapy is discontinued. Risk factors include age (young or middle-aged adults are most commonly affected); a concomitant condition of exhaustion, dehydration, or a general debilitated state; and a history of NMS. Typically, patients present with high fever, from 39°C (102.2°F) to 42°C (107.6°F), but onset of hyperthermia may be delayed.⁴ Manifestations of autonomic dysfunction include tachycardia, labile hypertension, pallor, vasoconstriction, and diaphoresis.⁵ A "lead-pipe" rigidity of the musculature is almost universal, while other manifestations of motor dysfunction also may occur, including tremors, myoclonus, dystonia, dyskinesia, dysphagia, dysarthria, and opisthotonos. Alteration in mental status ranges from confusion and agitation to stupor or coma.⁴ Characteristic laboratory findings include leukocytosis, myoglobinuria, and elevation of crea-

tine phosphokinase. Metabolic acidosis, renal insufficiency, electrolyte abnormalities, and elevated hepatic transaminases may also occur. The differential diagnosis includes meningoencephalitis, tetanus, rabies, collagen vascular disease, malignant hyperthermia, lethal catatonia, heatstroke, thyroid storm, pheochromocytoma, strychnine poisoning, and toxicity from a variety of drugs, including anticholinergic poisoning and the serotonin syndrome. Perhaps the two syndromes most difficult to distinguish from NMS are malignant hyperthermia and lethal catatonia, as all three feature fever and muscle rigidity. Malignant hyperthermia is associated with causative exposure to certain anesthetic agents, whereas lethal catatonia, a type of heat exhaustion, follows a period of manic hyperactivity and does not feature autonomic instability.

The cornerstone of treatment of NMS is supportive care, with rapid cooling, fluid and electrolyte repletion, and critical care monitoring all being paramount. Intubation should be considered, and aggressive muscle relaxation should be pursued with intravenous benzodiazepines (e.g., lorazepam 2 mg IV, diazepam 5 mg IV). The offending pharmacologic agent should be discontinued, or the previously withdrawn dopamine agonist should be restarted.^{4,5} Dantrolene (1 mg/kg to 2.5 mg/kg IV initially; titrate to effect, max 10 mg/kg cumulative), a nonspecific skeletal muscle relaxer that is employed in the treatment of malignant hyperthermia, also has been used with good results, especially in cases wherein muscle rigidity is a predominant feature.⁵ Specific therapy for NMS has been advocated, some of which is based on the presumed pathophysiology of the syndrome, which is central dopamine depletion.^{4,5} Bromocriptine, carbidopa/levodopa, and amantadine have been used with equivalent success, both alone and in combination.⁵ Centrally acting dopa-mine agonists may be most important in the treatment of significant hyperthermia and mental status alteration, and vasodilators such as minoxidil (2.5 mg PO) and nitroprusside (start at 0.3 mg/kg per min) should be considered when vasoconstriction is a problem. Aggressive therapy has led to a reduction in mortality from NMS.

Selected Miscellaneous Adverse Effects

In addition to the various dopamine-related side effects just described (extrapyramidal disorders, tardive dyskinesia, and NMS), the antipsychotics may cause a variety of other untoward effects, some of which are highlighted here. All antipsychotics may cause sedation and impair mental capacity to some degree; patients should be cautioned regarding activities requiring mental alertness, such as driving and operating heavy machinery. Photosensitivity may occur with the typical antipsychotics, especially the phenothiazines; it is not characteristic of the atypical agents, with the exception of risperidone. To varying degrees, all may lower the seizure threshold. Both typical and atypical agents are pregnancy category C, with the exception of clozapine, which is category B; none of these agents are recommended in breast-feeding women. Clozapine therapy carries the risk of agranulocytosis and is reserved for use in severely ill schizophrenics who have failed conventional treatment regimens; weekly monitoring of the leukocyte count is indicated. Weight gain, hyperglycemia, and hyperlipidemia are variably associated with the atypical antipsychotics, with the apparent exception of ziprasidone. This agent does have a propensity to increase the QT interval on the electrocardiogram, however, and thus it is not recommended for use with other drugs that lengthen the QT interval or in uncorrected conditions predisposing to QT prolongation (e.g., hypokalemia, hypomagnesemia).⁶

ACUTE OVERDOSE

Clinical Features

In general, overdose with these drugs features an exaggerated version of the response that is expected, based on knowledge of the aforemen-

tioned adverse effects. Central nervous system depression, ranging from mild sedation to deep coma, frequently occurs and is attributable to anticholinergic and antihistaminic effects. Some degree of sedation is generally seen with overdose of any antipsychotic drug, but has been found to occur more frequently with chlorpromazine.⁷ Seizures may be seen, as well as dysfunction in temperature regulation.^{7,8} Anticholinergic and extrapyramidal effects may occur as with nontoxic ingestion and tend to vary with the potency of the drug; low-potency compounds tend to cause anticholinergic effects, and high-potency agents tend to cause extrapyramidal disorders.²

Cardiovascular effects may be seen as alterations in heart rate, blood pressure, and cardiac conduction. Tachycardia can be attributed both to anticholinergic effects and to a reflex response to vasodilatation. Hypotension is caused by both α_1 -adrenergic blockade and a direct depressant effect on the myocardium. Atrioventricular and intraventricular conduction disturbances may also occur, as well as other electrophysiologic effects, ranging from asymptomatic prolongation of the QT interval to fatal ventricular dysrhythmia.^{9,10} The piperidine phenothiazines (e.g., thioridazine) are the antipsychotic drugs with the highest potential for serious dysrhythmia: they may behave like type Ia antidysrhythmics in overdose, possibly causing wide-complex tachycardia and torsade de pointes.^{6,8} Prolongation of the QT interval, torsade de pointes, and sudden death are all well-documented to have occurred with haloperidol, yet the frequency of occurrence is significantly less than with thioridazine.⁶ Although not an antipsychotic, droperidol, a butyrophenone-derivative similar to haloperidol, deserves mention here because of its utility both as an antiemetic and in the chemical control of the agitated patient. Droperidol received a Food and Drug Administration (FDA)-prompted drug warning advisory in December 2001, citing the risk of QT prolongation and torsade de pointes. It was accompanied by a recommendation that droperidol use be restricted to clinical situations wherein other agents fail, and then only if the corrected QT interval is <440 msec in males and <450 msec in females; the scientific rationale behind this was recently reviewed and questioned in the emergency medicine literature.⁹

Clinical experience with overdose involving the newer atypical agents is relatively sparse, but emerging. Clozapine, with its profound anticholinergic effects, causes central nervous system depression and seizures, but appears to be unlikely to cause cardiac conduction disturbances or agranulocytosis. Risperidone principally causes neurologic (lethargy, spasms, and dystonia), cardiovascular (tachycardia, QT prolongation, and wide-complex tachycardia), and electrolyte disturbances. **In massive overdose risperidone is also associated with miotic pupils and a wider variety of dysrhythmias, including supraventricular tachycardias and bradycardia.** In most cases, risperidone overdose is well-tolerated.^{10,11} Olanzapine poisoning causes central nervous system depression—at times profound and requiring intubation for airway protection—and miosis.¹² Quetiapine overdose may lead to alterations in neurologic (depressed sensorium) and cardiovascular (hypotension and tachycardia) status, and in one case of massive overdose, it was associated with significant prolongation of the QT interval.¹³ Ziprasidone, the newest atypical antipsychotic agent, is contraindicated in cases of known or suspected QT-interval prolongation but has limited overdose data available; thus far, mild sedation and some prolongation of the QT interval have been observed without serious neurologic or cardiovascular complications.^{14,15}

Treatment

Supportive care and decontamination of the gastrointestinal tract are the key principles of treatment (Table 161-2). Patency of the airway and assurance of adequate ventilation are paramount, especially in light of the fact that these agents may cause profound alterations in level of consciousness. Oxygen and naloxone should be administered to all patients with altered mental status, and blood glucose should be

TABLE 161-2 Care of the Acute Ingestion

Airway, breathing, IV access, and cardiac monitor
Altered mental status
Naloxone 0.4 mg to 2.0 mg IV; titrate to effect (usual maximum 10 mg)
Dextrose 25 g (50 mL) of D50 solution IV (if rapid glucose determination suggests low blood sugar, or if is unavailable) and repeat X1 if no response.
Hypotension
Crystalloid infusion
Norepinephrine 4 mg/500 mL D5W; begin at 2-4 μ g/min; titrate to effect
Ventricular dysrhythmias
Sodium bicarbonate, 1-2 mEq/kg IV bolus; if infusion necessary, 100-150 mEq/L D5W, titrate over 4-6 h with target arterial pH approximately 7.50
Lidocaine 1.0-1.5 mg/kg IV bolus; maintenance infusion of 2 g/250 mL D5W at 1-4 mg/min
Torsade de pointes
Magnesium sulfate 2-4 g TV
Overdrive pacing
Isoproterenol 2 mg/250 mL D5W at 5 μ g/min
Gastrointestinal decontamination Activated charcoal 1-2 g/kg PO If patient is intubated, orogastric lavage using >34 French tube, followed by activated charcoal
Seizures Benzodiazepines
Lorazepam 2-4 mg IV (2 mg per min); may repeat if necessary (consider airway protection) Diazepam 5-10 mg IV (5 mg per min); may repeat if necessary (consider airway protection)
Phenobarbital up to 20 mg/kg IV at maximum 50 mg per min
Fosphenytoin 15-18 mg/kg PE IV at maximum 150 mg PE per min

rapidly assessed at the bedside. Crystalloid intravenous fluids should be given for hypotension. If further therapy is needed, vasopressors with (3-adrenergic activity theoretically should be avoided (e.g., dopamine, epinephrine, and isoproterenol), because the α -adrenergic blockade seen with the antipsychotic agents results in unopposed P-adrenergic agonism, causing vasodilatation and worsening hypotension.

Continuous cardiac monitoring and a 12-lead electrocardiogram are cardinal management features. The QT interval should be determined and monitored. Ventricular dysrhythmias should be managed with type Ib antidysrhythmic agents (e.g., lidocaine), avoiding class Ia agents (e.g., quinidine, disopyramide, and procainamide), which may worsen cardiac toxicity. Wide-complex tachycardias should be treated with intravenous sodium bicarbonate due to the potential for blockade of fast sodium channels with certain agents, especially thioridazine.^{7,8} Torsade de pointes, if it occurs, should be managed with cardiac pacing, isoproterenol, or magnesium infusion.^{7,16}

Gastrointestinal decontamination should be instituted as soon as the patient is stabilized; in most cases, PO administered activated charcoal (1 g/kg) will suffice. Gastric lavage should be considered in patients who present to the ED very soon after a life-threatening ingestion. Multidose activated charcoal is theoretically indicated because of the partial metabolism by enterohepatic circulation. High protein binding and a large volume of distribution, general characteristics of this drug class, render hemodialysis and forced diuresis ineffective management techniques.

In addition to stabilization of the airway and cardiovascular status and attention to gastrointestinal decontamination, other therapy may be given as needed. Intravenous benzodiazepines, phenobarbital, and phenytoin should be considered for control of seizures. Electrolyte disturbances have been reported sporadically; serum chemistries should be obtained in serious ingestions, especially to exclude other causes of altered mental status and dysrhythmia, which may occur. Specific drug levels are not readily available and are not helpful in the

acute management of these patients. Acute extrapyramidal disorders should be treated as described above.

Disposition

Patients with alteration in mental status, which usually includes a depressed level of consciousness, and patients with evidence of cardiotoxicity are best managed in the intensive care unit. Thioridazine has been shown to cause serious dysrhythmias both early in the clinical course and after a significant delay; patients ingesting this agent warrant electrocardiographic monitoring for at least 24 h, even if asymptomatic.^{7,8} Patients should receive appropriate psychiatric evaluation after ED assessment and treatment if they are asymptomatic, have a physical examination and electrocardiogram without evidence of lingering toxicity (e.g., no QT-interval prolongation), and are not believed to have ingested a piperidine phenothiazine. If psychiatric evaluation is not warranted, they may be discharged from the ED.

LITHIUM

Sandra M. Schneider
Daniel J. Cobaugh

EPIDEMIOLOGY

Apart from treatment of bipolar disorder, many other medical and psychiatric uses for lithium have been suggested, including impulsive/aggressive behavior, neutropenia, alcohol dependence, cluster and migraine headaches, and hypothyroidism. Lithium toxicity may result from accidental or intentional overdose or from an alteration in lithium

clearance. The true incidence of toxicity and subsequent medical outcomes are not known because there is no mandatory reporting requirement for toxic exposures in the United States.

It has been estimated that up to 75 to 90 percent of patients who are chronically treated with lithium will develop toxicity some time in their therapy. For the year 2001, the American Association of Poison Control Centers has reported over 4,607 potential toxic exposures to lithium. Of these, 253 were in children. There were 44 that resulted in death.¹

PATHOPHYSIOLOGY

Lithium is thought to cause toxicity through several mechanisms. It has the ability to compete with other similar-molecular-weight ions, including sodium, potassium, magnesium, and calcium, displacing them from both intracellular and bone sites. Competition with and displacement of other ions can result in lithium retention and subsequent toxicity. Therefore, activities, medical conditions, and medications that affect water and electrolyte balance can contribute to lithium toxicity. Loss of salt, water, or both leads to an increase in proximal reabsorption of lithium and a rise in lithium level. Inhibition of arginine vasopressin and the resulting hydro-osmotic effects also have been attributed to lithium. Some of the toxic effects of lithium may be due to inhibition of 3-glycogen synthase kinase (GSK) that is present in high quantities in brain and is involved in cell proliferation and differentiation.²

It is also thought that lithium, through adenylate cyclase inhibition, causes decreases in intracellular cyclic adenosine monophosphate (cAMP). Decreases in cyclic guanosine monophosphate (cGMP) also may occur. It has been suggested that lithium may increase inositol monophosphate (IMP) and reduce free inositol through inhibition of IMP. Activated inositol may interact with G proteins to form intracellular messengers that enhance intracellular calcium release and activate protein kinase C.³ Lithium is also thought to interfere with the release and reuptake of the neurotransmitter norepinephrine at the nerve terminal site. Lithium may enhance serotonin release from the hippocampus. Lithium has been implicated in the serotonin syndrome when combined with other medications that alter serotonin. It also may have a protective effect against apoptosis and promote growth and regeneration of axons.⁴ Finally, risk of lithium toxicity exists when it is combined with a variety of medications. Most often toxicity involves a drug-drug interaction with lithium. A number of these potential drug interactions are listed in Table 162-1. Herbal diuretics may in-

crease toxicity.⁵ In addition, the use of succinylcholine and vecuronium in patients taking lithium may result in a prolonged neuromuscular blockade.

The pharmacokinetics of lithium also play a vital role in toxicity. The absorption of lithium is rapid and complete following oral administration. There is delayed uptake and elimination in the brain, recently confirmed by magnetic resonance imaging (MRI).⁶ The difference in the concentration in the brain and serum may vary two- to threefold.⁶ **Serum levels do not predict central nervous system (CNS) levels.** Delayed absorption may occur with sustained-release products and following ingestion of a large number of pills. Toxic effects appear later and last longer. Lithium has a volume of distribution of 0.79 L/kg, which is similar to that of body water. Lithium distribution to and from the CNS is slower, resulting in CNS symptoms that do not correlate with serum levels. Sustained toxic effects, even after hemodialysis, can be due to the slow distribution in the CNS. Lithium is not bound to plasma proteins. The half-life of lithium is reported to be approximately 29 h. There is no appreciable hepatic metabolism, and it is excreted primarily unchanged in the urine. The presence or development of renal insufficiency is an important factor in the development of lithium toxicity. Sodium and water loss due to heat and exercise may lead to lithium retention. The elderly are prone to toxicity due to a decreased volume of distribution and reduced renal clearance.

CLINICAL EFFECTS

Adverse effects are common with lithium, occurring in 35 to 90 percent of treated patients.⁷ The most common adverse effects (Table 162-2) are hand tremor, polyuria due to loss of urinary concentration ability, and rash. Hand tremor occurs in up to 65 percent of patients at some time,⁸ and worsening of a baseline tremor is an important signal of developing toxicity. Decreasing the intake of caffeine or adding a beta blocker may improve the tremor, but often a decrease in dose is necessary.⁷ Neurologic side effects include memory loss, decreased mental concentration, and fatigue. Ataxia and dysarthria can develop and often will improve with cessation of therapy. Long-term lithium treatment can lead to electroencephalographic changes, including diffuse slowing, an increase in theta and delta waves, and a decrease in alpha activity.

A decrease in urinary concentrating ability occurs in most patients but is largely asymptomatic. Up to 12 percent of patients will develop nephrogenic diabetes insipidus.⁹ In some patients, incomplete distal renal tubular acidosis develops (defect in urine acidification without acidemia).

Gastrointestinal (GI) side effects, including nausea, vomiting, and diarrhea, are common at initiation of treatment and generally are transient. They can be decreased by giving the dose with food or dividing the dose over the day. GI symptoms that develop during the course of treatment may signal toxicity. Cardiovascular changes develop in part because lithium interferes with the sodium-potassium pump, leading to intracellular hypokalemia. This results in electrocardiographic findings of U waves, flattened or inverted T waves, and ST-segment depression. Bradycardia, QT_c prolongation, bundle-branch block, and junctional dysrhythmias have been reported. Cardiac effects occur in 20 to 30 percent of patients. Other less common side effects include syncope due to sinus node dysfunction, induced hypothyroidism, and a folliculitis that occurs mainly in the spring.

Lithium toxicity may result from acute intentional overdose, from chronic exposure, or as a result of a change in lithium clearance (e.g., medications, dehydration, or salt depletion). Toxicity developing in patients taking chronic lithium therapy may be due to a change in the daily dose of medication or physiologic changes impairing elimination of the drug. Renal failure or intravascular volume depletion is a precipitating cause in nearly all cases of chronic toxicity.⁹ Other factors known to precipitate lithium toxicity are listed in Table 162-3.

Patients with acute overdose may have elevated serum concentrations with limited signs of toxicity. Acute ingestions classically cause more GI toxicity and less CNS toxicity. After ingestion, there is delay in transport of lithium into the intracellular compartment and across the blood-brain barrier. With time, equilibration occurs, and toxicity develops. Neurologic symptoms often develop as GI symptoms are abating. Levels in patients with an acute ingestion do not correlate well with either symptoms or prognosis.

Patients with chronic exposure have lower serum concentrations and higher cellular levels and classically display earlier and greater neurologic changes. Levels in such patients correlate better with prognosis and toxicity. Acute-on-chronic ingestions have aspects of both profiles of ingestion. As in most toxicities, the best guideline for therapy is the patient's condition, not the serum concentration of the implicated agent.

TABLE 162-3 Factors Precipitating the Development of Lithium Toxicity (Excluding Drug Interactions)

Renal failure
Volume depletion
Hyperthermia/neuroleptic malignant syndrome
Infection
Congestive heart failure
Diabetes mellitus
Preexisting cerebral pathology (white matter infarct, frontal meningioma, HIV)
Gastroenteritis Surgery
Cirrhosis Decreased sodium intake

Recognizing lithium toxicity may be challenging, particularly in patients with chronic overdose. Table 162-4 lists a common grading system for toxicity. Patients commonly present with muscle fasciculations, ataxia, agitation or lethargy, and muscle weakness. At times, it may be difficult to distinguish between lithium toxicity and organic delirium. Although most patients present with slowing of their cognitive function, cases of lithium toxicity presenting as mania have been reported. As toxicity worsens, confusion, lethargy, stupor, and finally, coma develop. Rarely, extrapyramidal signs develop. Proximal muscle weakness, extensor plantar response, and auditory, visual, and tactile hallucinations have been reported. The electroencephalogram shows diffuse slowing and disorganization, with frontal intermittent rhythmic delta activity in severe cases.

In addition to neurologic changes, renal dysfunction is common. Lithium at therapeutic doses has been implicated in nephrogenic diabetes insipidus as well as in decreased creatinine clearance, oliguria, and albuminemia. There appears to be a relationship between these effects on renal function and lithium serum concentration. Due to diabetes insipidus, patients complain of polyuria and polydipsia. Fluid losses may exacerbate toxicity. Acute renal failure may develop, particularly in patients with preexisting renal impairment, advanced age, diabetes, hypertension, or dehydration.

GI symptoms are common in both acute and chronic toxicity. Patients present with gastroenteritis, nausea, vomiting, diarrhea, bloating, or generalized abdominal pain. Leukocytosis can occur. Cardiac abnormalities are more common in acute toxicity, with hypotension, conduction abnormalities, and ventricular dysrhythmias. Electrocardiographic changes with transient ST-segment depression and T-wave inversion are seen in some patients. As indicted earlier, QT_C prolongation, conduction abnormalities, and bradycardia are seen. Less common effects include hyperthermia, hypothermia, peripheral neuropathy, and severe leukopenia.

Up to 10 percent of patients die, generally of respiratory failure or cardiovascular collapse. Most patients who recover will have no long-term sequelae. Chronic renal failure occasionally develops. Permanent cerebellar damage may develop and progress over several weeks following the toxic episode.¹⁰ These patients have truncal ataxia, ataxic gait, scanning speech, and diffuse incoordination. Short-term memory loss, dementia, and a tremor of the hands and head accompany the

cerebellar signs. Most patients improve over several months, but symptoms are permanent in some patients. Permanent seizure disorder has been reported.

TREATMENT

As in all toxicities, initial stabilization of patients must include protection of the airway, ventilatory support, and hemodynamic support. Intravenous access, cardiac monitoring (including a 12-lead electrocardiogram), and laboratory analysis of blood and urine, including renal function, fluid/electrolytes, calcium, magnesium, complete blood count, urine specific gravity, and drug concentration for lithium, acetaminophen, and other possible ingestants, should be obtained. A complete medical history, including an assessment of baseline neurologic function, must be documented. It is also necessary to search for precipitating factors such as volume depletion or electrolyte imbalance. A complete listing of medications (prescription, over-the-counter, and herbal agents) taken in the preceding week should be obtained. The neurologic examination should be focused on the issues discussed above.

Seizures should be treated with intravenous benzodiazepines (see Chap. 232). Refractory seizures may require phenobarbital or general anesthesia. **Phenytoin decreases renal excretion of lithium** and often is ineffective in drug-induced seizures.

GI decontamination is difficult in lithium toxicity. Often these patients present with chronic toxicity, and there is no role for gastric decontamination. Activated charcoal is ineffective at adsorbing lithium at gastric pH.¹¹ Its use is not contraindicated, however, because it may be effective in cases of poly drug toxicity. Gastric lavage or ipecac is as effective in lithium overdose as in other drug overdoses, and if it is done early after ingestion, some drug can be removed. Since lithium tablets are often quite large, small-bore tubing may be ineffective in removing the drug. Whole-bowel irrigation (polyethylene glycol, 2 L/h in adults and 500 mL/h in children) is helpful, especially in cases where sustained-release lithium products have been ingested. Whole-bowel irrigation initiated in the first hour can remove 60 percent of the drug.¹²

Aggressive hydration with normal saline is important. Nearly all patients with significant toxicity have some sodium and volume deficit. Sodium and water depletion interferes with lithium elimination, and this increases and prolongs toxicity. In fact, in volume-depletion states, lithium may be resorbed preferentially by the kidney in an attempt to counter sodium loss. Volume repletion reestablishes normal elimination kinetics. Forced diuresis does not enhance lithium elimination once fluid losses have been replaced. In fact, loop and thiazide diuretics can be dangerous because they further sodium and water loss.¹³

Although nearly all toxicologists agree that hemodialysis should be used for severely toxic patients, the threshold for initiating this treatment is still debated. Patients with levels greater than 3.5 mEq/L (4.0 mEq/L in acute ingestion), patients with little change in their lithium level of 1.5 to 3.5 mEq/L after 6 h of hydration, or patients with sustained levels of more than 1.0 mEq/L after 36 h will benefit from hemodialysis.¹⁴ In addition, patients with renal failure, those with rapidly increasing levels, or those who have ingested sustained-

TABLE 162-4 Grading of Lithium Toxicity

Level	Clinical Features	Treatment
Grade 1	1.5-2.5 mEq/L: nausea, vomiting, tremor, hyperreflexia, ataxia, agitation, muscular weakness	Hydration, Kayexalate
Grade 2	2.5-3.5 mEq/L: stupor, rigidity, hypertonia, hypotension	Hydration, Kayexalate, possible dialysis
Grade 3	>3.5 mEq/L: coma, seizures, myoclonus, collapse	Hemodialysis

Note: Levels are valid in chronic ingestions only.

release preparations should be considered for treatment. However, a recent study of the outcome of patients meeting these criteria, treated with and without dialysis, showed no major difference, suggesting that these criteria may be conservative.¹⁵ Addition of bicarbonate to the dialysate has been shown to lead to greater intracellular extraction of lithium.¹⁶

The goal of hemodialysis is to reduce the serum lithium level to less than 1 mEq/L. Because of the cellular concentration of lithium, an increase in serum levels following termination of dialysis is common.¹⁵ Drug levels must be monitored for up to 8 h following dialysis. If levels rise to greater than 1 mEq/L, hemodialysis should be re-instituted. Use of either high-volume continuous venovenous hemofiltration (HV-CVVH) or hemodialysis followed by continuous venovenous hemofiltration (CVVHD) may prevent a rebound in level.^{17,18,19} Peritoneal dialysis and charcoal hemoperfusion have been used but are less effective than hemodialysis (Table 162-5). Because of the intracellular concentration of lithium in the CNS, neurologic symptoms may persist and even worsen during treatment.

In less severe toxicity, sodium polystyrene sulfonate (SPS, or Kayexalate; 15 g PO qid or 30 g PR) may be useful in decreasing serum half-life of lithium.²⁰ Approximately 75 percent of lithium is bound to SPS in vitro compared with less than 25 percent when activated charcoal is used. Although experience with SPS is limited, it may be useful for mild to moderate toxicity. Because SPS is an exchange resin, large electrolyte shifts may occur during its use, and the electrolyte level must be monitored and derangements treated aggressively.

Treatments mentioned in anecdotal case reports, such as sodium bicarbonate and acetazolamide (both in urinary alkalization) and aminophylline, cannot be recommended at this time. Among treatments found to be ineffective or harmful are water loading, diuretics (furosemide, thiazide, ethacrynic acid, or spironolactone), and ammonium chloride.

DISPOSITION

Admission decisions must be weighed by the presence and persistence of factors predisposing the patient to toxicity, the acuity of the toxicity, and the circumstances that led to the toxicity. Acute ingestions must be treated as already described, and patients should be monitored for 4 to 6 h, even if asymptomatic, and receive psychiatric consultation. **Any patient with acute ingestion of a sustained-release preparation should be admitted.** Patients with levels of greater than 1.5 mEq need admission.

Patients with grade 1 chronic toxicity without additional risk factors may be managed with hydration for 4 to 6 h. Once levels return to the normal range (less than 1.5 mEq), there is clinical improvement, and usually, after psychiatric evaluation, the patient may be discharged. Repeat values obtained within 24 h by home health services can be considered. Patients with grade 2 or 3 chronic toxicity require admission.

TABLE 162-5 Comparison of Half-Life of Lithium with Treatment

Therapy	Serum Half-Life, h	Clearance, mL/min
No treatment	14-54	15
Saline		15
Peritoneal dialysis		10-15
Hemodialysis	4-6	50
Sodium polystyrene sulfonate	12

BARBITURATES

Raquel M. Schears

Barbiturates have been in common clinical use for a century. These agents possess sedative properties, which are used to reduce anxiety, and hypnotic properties, which are used to induce sleep, hence their informal classification as sedative-hypnotics. The therapeutic efficacy of these agents in the emergency department is best illustrated in their use as anticonvulsants in the treatment of seizure disorders, for conscious sedation to facilitate procedures, and as induction agents in rapid-sequence intubation.¹ There are also recent case series reports of administering barbiturates to treat severe withdrawal from alcohol and

- γ -hydroxybutyrate (GHB), resistant to benzodiazepine therapy.² The prophylactic use of barbiturates as antihypertensives in the management of elevated intracranial pressure (ICP) has been abandoned for lack of supporting evidence.^{3,4} Currently, inducing "barbiturate coma" is considered a last resort for intractable ICP elevations after all medical and surgical treatment has failed.⁵ Also recently challenged is the efficacy of prescribing barbiturate-containing combination analgesics available in the United States and Canada, for the treatment of migraine headache and other chronic pain disorders. The United Kingdom, France, Germany, and Australia have removed these agents from the market because of their high liability of physical dependence and abuse, coupled with their potential risk of lethal overdosage and lack of outcome-based benefit.⁶

Barbiturate abuse, both prescription and illicit, peaked in the 1970s. The availability, as measured by sales and by the accidental death rate, was significantly correlated with their use for suicide. During the last two decades, the number of toxic exposures involving barbiturates and the incidence of overall barbiturate-related deaths have declined dramatically. This trend has been attributed to the advent and popularity of safer sedative-hypnotics such as the benzodiazepines and other major tranquilizers, rescheduling of barbiturates to class II, III, and IV drugs, and improvements in supportive care in overdose settings. Since 1990, there have been U.S. reports of increasing illicit barbiturate use among adolescent populations. Reasons for this include youth misperceptions that barbiturates are harmless, and even helpful when taken in combination with cocaine and methamphetamines to mitigate unpleasant stimulant extremes. By 1998, forensic data from mass suicide rituals and state-required reporting by Oregon physicians prescribing medications to assist in their patients' suicide, continued to underscore both the predictable lethality and strategic preference for prescription barbiturates used in intentional overdose.⁷ The *2000 Annual Report of the American Association of Poison Control Centers* documented that barbiturates were involved in 4484 reported poisonings, with half of these recorded as intentional overdoses, which resulted in 16 fatalities.⁸ Although children were involved in 1138 of the total reported barbiturate poisonings, none died from their exposure.⁸ Overall (in adults and children), barbiturates consistently rank among the top 5 toxic agents in overdosage, associated with major complications and fatalities.

PHARMACOLOGY

The parent compound, barbituric acid (2,4,6-trioxohexahydropyrimidine), itself has no central depressant activity. R group substitutions, primarily at position 5, give these compounds their sedative-hypnotic properties. Substituting sulfur for the oxygen at position 2 creates a thiobarbiturate, which is more lipid soluble than an oxybarbiturate (Figure 163-1). High lipid solubility allows an agent to rapidly transit the blood-brain barrier and confers a shorter duration of action and greater degree of hypnotic activity. By convention, barbiturates have been classified according to their duration of action (Table 163-1).

Long-acting barbiturates tend to be weaker acids (lower pK^a values), less lipid soluble, and less protein bound than shorter-acting barbiturates. This translates to a delayed onset of action, decreased volume of distribution, and longer duration of action when compared

with short-, ultrashort-, and intermediate-acting compounds. Furthermore, tissue permeability of long-acting barbiturates is uniquely affected by body fluid pH changes. Only nonionized drug is membrane permeable. Phenobarbital has a pK_R of 7.24 and is 95 percent ionized at pH 7.4. Ionization will increase in a basic medium, and permeability will decrease. (Conversely, an acidic medium will facilitate phenobarbital permeability by maintaining more drug in a nonionized state.) Alkaline diuresis takes advantage of this equilibrium and forces the remaining 5 percent of the drug into an ionized form. Thus, the charged drug is trapped under basic conditions for renal elimination. Unfortunately, ion-trapping as a drug elimination strategy only works for long-acting barbiturates.

Short-, ultrashort-, and intermediate-acting barbiturates are not affected by body pH changes. Secobarbital, for example, has a pK_a of 7.9 and is 98 percent nonionized at pH 7.4. Rate of barbiturate delivery to the membrane determines tissue permeability with these classes. These compounds are stronger acids (higher pK_a values), more lipid soluble, and more protein bound, enabling a more rapid onset of action, greater volume of distribution, and shorter duration of action compared with the long-acting barbiturates.

Bulk absorption of barbiturates occurs in the stomach and small intestine, where most of the drug exists in a nonionized state. Overall, barbiturates readily diffuse into the body tissues and cross the blood-brain barrier, with highest concentrations occurring in the brain, liver, kidney, and adipose tissue. Barbiturates are excreted in breast milk and easily cross the placenta. Fetal blood barbiturate concentrations closely reflect maternal plasma levels. Interestingly, in utero exposure to phenobarbital has been significantly linked to a distinctive pattern of physical abnormalities in infants,⁹ and in separate reports, with verbal intelligence deficits in adult men.¹⁰ Tolerance develops with chronic barbiturate use, and higher doses are required to produce the same effects. Most barbiturates are metabolized in the liver to inactive by-products. Hepatic biotransformation occurs primarily through routes involving the cytochrome P450 microsomal enzyme system. All barbiturates are capable of inducing the activity of this enzyme system, which affects many other drug actions. For example, patients with chronic barbiturate use will have an increased rate of metabolism of oral contraceptives, anticoagulants, and corticosteroids when taken concurrently. Depending on the degree of hepatic biotransformation, variable amounts of barbiturates are excreted unchanged in the urine. Barbitals and phenobarbital are less protein bound and thus most dependent on the renal excretion pathway. Elimination half-life of barbiturates can be greatly accelerated in infants and children and very prolonged in the elderly and in patients with liver or renal disease. The main action of barbiturates is to depress activity in nerve and muscle tissues. In the central nervous system (CNS) this is accomplished by enhancing the action of the primary inhibitory neurotransmitter γ -aminobutyric acid (GABA) at the postsynaptic membrane. Additionally, barbiturates may act by inhibiting calcium-mediated excitatory neurotransmitter release at the presynaptic junction.

CLINICAL FEATURES

Mild to moderate barbiturate intoxication closely resembles the drug "high" produced by alcohol. Drowsiness, disinhibition, ataxia, slurred speech, and mental confusion are common features that escalate with increasing dose. The progressive CNS depression seen with *severe* barbiturate intoxication predictably manifests as a range from stupor to coma to complete neurologic unresponsiveness. Scales gauging the depth of coma are useful in describing patient presentation and monitoring interval changes in the level of consciousness during treatment in overdose settings.¹¹ The most common vital sign abnormalities seen in overdose are hypothermia, respiratory depression, and hypotension. The abnormal temperature control and respiratory depression are centrally mediated phenomena, whereas hypotension is primarily a result of increased vascular capacitance and venous pooling. The end prod-

uct of these derangements can be a patient who is cold, apneic, and in shock. Pulse rate is not diagnostic; pupil size, light reactivity, nystagmus, and deep tendon reflexes are variable. Gastrointestinal tract motility is slowed, resulting in delayed gastric emptying and ileus. Skin bullae, referred to as "barbiturate blisters," are uncommon and may indicate nothing more than the effects of local skin pressure.¹¹ Even when it is known that a barbiturate was ingested, it is prudent to consider coingestions and alternate explanations for the observed symptom complex.

Early deaths in barbiturate overdose result from cardiovascular collapse and respiratory arrest. Most common complications are hypoglycemia, followed by the delayed pulmonary problems of aspiration pneumonia, noncardiogenic pulmonary edema, and adult respiratory distress syndrome. Current mortality rates range between 1 and 3 percent and are more often the result of multiple organ system failure. Lethal dose is uncertain, but severe poisoning can be assumed if more than 10 times the hypnotic dose has been ingested in a single exposure.¹¹

The Oregon reporting data on physician-assisted suicide indicated all 27 patients who received prescriptions of either secobarbital (&9 g) or phenobarbital (6 g), achieved their death wish. The median interval between ingestion to unconsciousness was 10 min (range, 1 to 30 min), and the mean interval between ingestion and death was 30 min (range, 4 min to 26 h).⁷

Laboratory evaluation in barbiturate overdose should include determination of glucose levels, blood chemistries, complete blood count, arterial blood gas measurement (if indicated), toxicology screen, chest radiograph, and an electrocardiogram. Barbiturate serum levels are useful in establishing the diagnosis of a comatose patient and should be obtained and used to distinguish long- from short-acting agents because treatment approaches differ. As a rule of thumb, patients presenting with a serum concentration of more than 10 mg/dL

for a long-acting barbiturate, more than 7 mg/dL for an intermediate-acting barbiturate, and more than 3 mg/dL for a short-acting barbiturate, left untreated, have a greater risk of death from the exposure.¹¹ These measurements are not reliable in predicting clinical course in overdose because they do not reflect brain barbiturate concentrations and may underestimate the clinical condition of a patient in the setting of polydrug exposure. Such levels are also invalid in chronic barbiturate abusers who have developed physiologic tolerance and in patients with renal or hepatic disease who have decreased clearance.¹¹

TREATMENT

In barbiturate overdose, reaching a treatment center predicts favorable outcome largely because supportive management alone is effective over a broad range of serum concentrations.

Airway Assessment and Stabilization

Airway assessment and stabilization are the first management priorities. Intubation in severe sedative-hypnotic overdose is often required and should precede any attempt at gastrointestinal evacuation. Standard monitoring of vital signs, cardiac electrical activity, pulse oximetry, intravenous access, and supplemental oxygen therapy should be initiated on ED arrival.

Volume Expansion

Volume expansion is the mainstay of circulatory support in barbiturate-induced shock. In the absence of cardiac failure, rapid infusion of 1 to 2 L of isotonic intravenous fluid is indicated; administration of bolus therapy, e.g., 200-mL aliquots, is prudent in the elderly, those with cardiac decompensation, or in the setting of known renal impairment.

If fluid resuscitation fails to correct hypotension, vasopressors such as dopamine and norepinephrine should be initiated.

Gastric Emptying

Gastric lavage should not be considered unless a patient has ingested a potentially life-threatening amount of barbiturates *and* the procedure can be undertaken within 60 min of ingestion.¹²

Lavage is not superior to activated charcoal alone. Given the CNS depression associated with this overdose, the induction of emesis should be avoided. The patient should be intubated for airway protection prior to performing lavage when it is indicated. Oral activated charcoal augments drug extraction by adsorbing drugs from the gastrointestinal tract. Multiple-dose activated charcoal (MDAC) is beneficial in reducing serum phenobarbital concentrations; however, no significant difference in clinical outcome has yet been demonstrated. **Still**, most studies suggest that activated charcoal is at least as effective as gastric lavage and may be better, given its immediate functional effectiveness. The current toxicology Position Statement is to consider MDAC only if a patient has ingested a life-threatening amount of phenobarbital.¹³ Loading dose of activated charcoal is 50 to 100 g. Concurrent administration of cathartic agents remains unproven and is not recommended; standard MDAC is 20 to 50 g every 4 h.

Forced Diuresis

Forced diuresis with fluid loading and diuretic therapy is most effective for phenobarbital. Intravenous furosemide should be titrated to effect a urinary flow of 4 to 6 mL/kg per h. Diuresis is contraindicated in the setting of hypotension or shock. Iatrogenic congestive heart failure and fluid overload preclude the usefulness of this therapy for other barbiturates that have limited renal excretion."

Urinary Alkalinization

Urinary alkalinization (see Chap. 156) will promote the excretion of long-acting barbiturates (e.g., phenobarbital) only. **Alkalinizing the urine is not effective for shorter-acting barbiturates** because these drugs are primarily metabolized by the liver with negligible renal excretion, exist as stronger acids, and are often more protein bound. The utility of this strategy requires that the drug be appreciably excreted in the urine and that more of it can be trapped in its ionized form in the tubular fluid under basic conditions, to facilitate increased renal excretion. The 5- to 10-fold increase in basal renal excretion rate for phenobarbital, is accomplished by giving a 1 to 2 mEq/kg sodium bicarbonate bolus IV, followed by 50 to 100 mEq in 500 mL of D5W. The drip rate is considered sufficient when an arterial pH of 7.45 to 7.50, urinary pH of 8.0, and urinary output of 2 mL/kg per h is maintained. Serum potassium must remain at least 4 mEq/L to achieve continuous urinary alkalinization. Adequacy of therapy should be monitored every 2 to 4 h.

Hemodialysis and Hemoperfusion

Hemodialysis and hemoperfusion are techniques that are used to maximize barbiturate elimination; these techniques are reserved for patients who are deteriorating despite institution of aggressive supportive care. Effectiveness of these modalities was previously limited by drug characteristics and technical difficulties. However, recent reports of high-efficiency hemodialysis, which uses high blood flow rates, demonstrate a rapid fall in phenobarbital levels linked to dramatic improvement in clinical condition.¹⁴

Further research into this modality must be undertaken before it can be recommended as the preferred mode of extracorporeal therapy for refractory phenobarbital intoxication.

DISPOSITION

Mild to moderate barbiturate intoxication responds well to general supportive care and including a single dose of activated charcoal. Frequent reassessment of neurologic status and vital sign parameters indicating improvement over 6 to 8 h allow eventual patient transfer to psychiatric services. Severe overdose will require intensive care unit admission, ongoing medical stabilization (MDAC only for lethal phenobarbital ingestion), and delayed psychiatric intervention. Early poison center contact and specialty service consultation is recommended.

BARBITURATE ABSTINENCE SYNDROME

Barbiturates are notorious for their rapid development of tolerance, high liability for physical dependence and abuse, and multiple drug interactions. Abrupt discontinuation of barbiturates in a chronically dependent user will produce minor withdrawal symptoms within 24 h and major life-threatening symptoms within 2 to 8 days. The severity of the withdrawal reflects the degree of physical dependence and drug half-life. Cessation of short-acting barbiturates results in more severe abstinence symptoms than stopping long-acting barbiturates. This is consistent with the clinical observation that the brain has more time to adapt to declining drug concentrations that are gradual. Clinical manifestations of abstinence mimic those described for alcohol withdrawal. *Minor symptoms* include anxiety, restlessness, depression, insomnia, anorexia, nausea, vomiting, muscle twitching, abdominal cramping, and sweating. *Major symptoms* include psychosis, hallucinations, delirium, generalized seizures, hyperthermia, and cardiovascular collapse.

Priorities in the treatment of major abstinence symptoms are cardiovascular stabilization and seizure control. Intravenous benzodiazepines usually are effective in treating seizures, although intravenous barbiturates may be required. Due to the mortality associated with sedative-hypnotic abstinence, gradual in-hospital withdrawal of the addicting agent is recommended.

BENZODIAZEPINES

George M. Bosse

Benzodiazepines are pharmacologic agents commonly used for the treatment of anxiety, insomnia, seizures, and alcohol withdrawal. They also are used in conscious sedation as well as general anesthesia. Table 164-1 lists common generic benzodiazepines currently approved for use in the United States.

Benzodiazepines are frequently agents of accidental and intentional overdose. In the 2000 Annual Report of the American Association of Poison Control Centers Toxic Exposure Surveillance System, benzodiazepines accounted for 49,849 exposures, both as single agents and in combination with other drugs.¹ Although the ingestion of benzodiazepines alone appears to result in relatively few deaths, increased rates of morbidity and mortality do result from mixed overdose. Parenteral administration of benzodiazepines may also result in significant complications, particularly respiratory depression and hypotension.

PHARMACOLOGY

A specific benzodiazepine receptor has been identified in the central nervous system (CNS).² Specific peripheral receptor sites also have been identified, but the predominant clinical effects of benzodiazepines are mediated through the CNS receptors. Although the receptor has not been fully characterized, research supports the existence

of a neuronal cell-surface protein complex containing a benzodiazepine receptor, a 7-aminobutyric acid (GABA) receptor, and a chloride channel. GABA is an inhibitory neurotransmitter. Effects of stimulation of GABA pathways include sedation, anxiolysis, and striated muscle relaxation. Stimulation of the benzodiazepine receptor appears to increase the sensitivity of the GABA-receptor complex to stimulation by GABA. The enhancement of GABA transmission by the administration of benzodiazepines is thought to occur either by increasing the affinity of the GABA receptor for its ligand or by improving coupling between the GABA receptor and its associated chloride channel. Increased GABA output leads to inhibitory effects throughout the neuroaxis and the resulting typical clinical effects of benzodiazepines. The presence of an endogenous ligand for the benzodiazepine receptor has been proposed, but such a ligand has not been identified conclusively.

In general, benzodiazepines are well absorbed from the gastrointestinal tract. The onset of action after oral ingestion is limited more by the rate of absorption from the gastrointestinal tract than by the relatively rapid passage from the bloodstream into the brain. With the exception of lorazepam and midazolam, intramuscular injection of benzodiazepines results in unpredictable absorption.

Benzodiazepines are all relatively lipid-soluble, with some variation among the agents. Increased lipid solubility is associated with more rapid diffusion across the blood-brain barrier. After single doses, the more highly lipophilic benzodiazepines have a shorter onset of action but also a shorter duration of activity. This short duration of activity occurs because of rapid egress of the drug from the brain and bloodstream into inactive tissue storage sites. For this reason, the half-life may not be a good indicator of the duration of action in an acute ingestion. For example, diazepam is a derivative with a long elimination half-life but a relatively short duration of action.

Benzodiazepine derivatives undergo metabolism by hepatic biotransformation through either oxidation or conjugation. Several derivatives are metabolized by both oxidative and conjugative processes. Oxidation often produces active metabolites that prolong the biologic half-life of the parent compounds. Oxidation is more susceptible to impairment by such factors as disease states (e.g., chronic liver disease), demographic characteristics (e.g., old age), and concurrent treatment with drugs that impair oxidizing capacity (e.g., cimetidine, estrogen, isoniazid, ethanol, and phenytoin). Conjugation is a rapid process that produces inactive metabolites. Examples of agents that undergo conjugation primarily include oxazepam, lorazepam, and temazepam. Administration of benzodiazepines that undergo conjugation may be safer in susceptible groups. Other approved agents in the United States undergo both oxidation and conjugation.

Selection of a benzodiazepine for use by a physician depends on the clinical properties of the particular derivative. Although individual drugs are marketed for specific conditions, there is considerable overlap of activity. For this reason, some hospital formulary committees have limited the number of available agents.

CLINICAL FEATURES

Isolated benzodiazepine overdose is notable for the relative lack of significant rates of morbidity and mortality.³ Most reported cases of serious toxicity have occurred in the setting of coingestion of other agents or with parenteral administration. Death due solely to benzodiazepine overdose is rare in otherwise healthy individuals. However, deaths in seemingly isolated overdoses have been reported and appear to be more likely with short-acting derivatives, such as triazolam, alprazolam, and temazepam.

The clinical presentation of benzodiazepine intoxication is nonspecific. Clinical assessment also may be difficult because of the frequent coingestion of other agents. Except for additive effects, drug interactions of benzodiazepines with other sedative-hypnotics are unusual.

TABLE 164-1 Benzodiazepines Approved for Use in the United States

Generic Name	Brand Name	Half-Life,	Metabolite h* Characteristics!
Alprazolam	Xanax	6-26	Inactive
Clorazepate dipotassium	Tranxene	1.1-2.9	Active
Chlordiazepoxide	Librium	5-30	Active
Clonazepam	Klonopin	39	Inactive
Diazepam	Valium	20-70	Active
Estazolam	Prosom	10-24	Inactive
Flurazepam	Dalmane	2-3	Active
Lorazepam	Ativan	9-19	Inactive
Midazolam	Versed	2-5	Inactive
Oxazepam	Serax	5.4-9.8	Inactive
Quazepam	Doral	25-41	Active
Temazepam	Restoril	10-16	Inactive
Triazolam	Halcion	1.6-5.4	Inactive

*Elimination of half-life of parent compound.

f Some of the derivatives listed as having inactive metabolites actually are converted to active compounds. However, rapid metabolism results in no appreciable accumulation of active intermediates.

The nonspecific presentation of benzodiazepine toxicity is similar to that of other sedative-hypnotics. However, other agents can have at least a few distinguishing features. Chloral hydrate is known to precipitate cardiac dysrhythmias. Ethchlorvynol can produce prolonged coma and may be suspected by the presence of a vinyl-like odor. Glutethimide may give rise to fluctuating levels of CNS impairment and anticholinergic signs. Barbiturates are more likely than benzodiazepines to produce coma and depressant myocardial effects.

The predominant manifestations of benzodiazepines are neurologic. CNS effects include drowsiness, dizziness, slurred speech, confusion, ataxia, and general incoordination and impairment of intellectual function. Coma, particularly if prolonged, is atypical and should prompt suspicion of intoxication with other agents or a non-toxin-related medical condition. The elderly are more prone to manifest the CNS effects of benzodiazepines.

Paradoxical reactions, including excitement, anxiety, aggression, hostile behavior, rage, and delirium, have been reported but are quite uncommon. Although unclear, the etiology of such effects is probably not idiosyncratic. Benzodiazepines may have a disinhibiting effect, which, in the presence of various extrinsic factors, can lead to such actions as aggressive or hostile behavior. Other effects that have been reported and that have unclear etiologies include headache, nausea, vomiting, chest pain, joint pain, diarrhea, and incontinence.

Uncommonly, respiratory depression and hypotension may occur, generally with either parenteral administration or in the presence of coingestants. Intravenous administration is more likely to cause serious cardiorespiratory effects with rapid administration of large doses. In addition, the elderly and those with underlying cardiorespiratory disease are more susceptible to adverse effects of intravenous administration. The use of propylene glycol as a diluent in parenteral preparations of diazepam also has been implicated as a factor in cardiorespiratory arrest.

Extrapyramidal reactions have been associated with the use of benzodiazepines. Various allergic, hepatotoxic, and hematologic reactions also have been reported, but they are infrequent. In general, benzodiazepines have no long-term organ-system toxicity other than that which can be ascribed to indirect effects from CNS or cardiorespiratory depression.

Laboratory data in benzodiazepine ingestion are of limited value. Determination of serum benzodiazepine levels is not indicated routinely because they do not correlate well with the clinical state. Qualitative testing may be helpful, but the laboratory may not test routinely for all available derivatives. Familiarity with laboratory capabilities at a given institution is essential.

TREATMENT

Benzodiazepines often are ingested with other agents, and the history frequently is inaccurate. Therefore, in patients with depressed or altered mental status, administration of concentrated dextrose, thiamine, and naloxone (see Chap. 156) should be considered. Induction of emesis should be avoided in benzodiazepine overdose because CNS depression may ensue. Gastric lavage is safer and is recommended if the amount ingested is large or in coingestions with toxic agents. Activated charcoal binds benzodiazepines effectively and should be administered in most situations. Elimination enhancement by forced diuresis, hemodialysis, or hemoperfusion is not effective, and most patients do not manifest toxicity serious enough to warrant consideration of such measures. The patient should be monitored closely for CNS and respiratory depression.

Indications for observation or hospital admission include significant alterations in mental status, respiratory depression, and hypotension. If CNS depression persists or is profound, other agents or conditions must be considered. Unfortunately, there is insufficient literature to recommend a specific duration of appropriate emergency department observation.

Flumazenil is a unique selective antagonist of the central effects of benzodiazepines,⁴ although there have been inconclusive claims that it may be effective in other drug overdose. Potential clinical applications include the management of benzodiazepine overdose and reversal of benzodiazepine-induced conscious sedation. Its use in benzodiazepine toxicity may obviate the need for tracheal intubation and respiratory support. As a diagnostic aid in obscure alterations of mental status, flumazenil may reduce the need for expensive and invasive procedures, such as computed tomography or lumbar puncture.

However, flumazenil has limited utility in the emergency department.⁵ It is useful mainly in reversing the effects of benzodiazepines administered for diagnostic and therapeutic procedures. Even in such cases, management is usually accomplished safely and easily by allowing the effects of the benzodiazepine to subside without antidotal administration. The plasma elimination half-life of flumazenil is approximately 1 h. Its duration of action is variable and depends on the dose of flumazenil and the benzodiazepine administered. **Recurrent benzodiazepine toxicity may result once the effects of flumazenil have worn off.** This is less likely for an agent with a short duration of action, such as midazolam. The dose of flumazenil is 0.2 mg IV every minute to response or to a total of 3 mg.

Several considerations should limit the empirical administration of flumazenil to a poisoned patient (see Table 165-3). Generalized seizures have occurred in patients given flumazenil after coingestions of benzodiazepines and seizure-inducing agents, particularly cyclic antidepressants.^{6,7} Seizure activity after flumazenil administration also has occurred in patients physically dependent on benzodiazepines and in patients receiving benzodiazepines for control of a seizure disorder. The putative explanation for this convulsive activity is either the reversal of the cerebroprotective and anticonvulsive effects of benzodiazepines or the precipitation of a benzodiazepine withdrawal syndrome. Another reason to avoid empirical administration of flumazenil in overdose patients is that the history is often unreliable or unavailable. **Flumazenil is also contraindicated in patients with a suspected elevation of intracranial pressure, such as in severe head injury.** This contraindication is due to its effects on cerebral hemodynamics. In all cases of benzodiazepine toxicity, supportive care is the cornerstone of treatment.

BENZODIAZEPINE ABUSE AND WITHDRAWAL

Genuine physiologic addiction to benzodiazepines may occur, particularly with prolonged use and high doses.^{3,8} However, the abuse potential of benzodiazepines appears to be low in comparison with that of agents such as alcohol, cocaine, opiates, and barbiturates.^{9,10} Benzodiazepine abuse usually occurs in individuals with a history of abuse of other psychoactive drugs. Primary drug abuse with benzodiazepines alone is not common.

Benzodiazepine withdrawal may occur on abrupt discontinuation and is more likely in patients with prolonged use and high doses. Because of the long biologic half-life of several derivatives, withdrawal manifestations may not occur for several days to over 1 week after the benzodiazepine has been discontinued. Unfortunately, it is often difficult to distinguish between withdrawal and underlying symptoms for which the drugs were prescribed initially.

Reported withdrawal manifestations include anxiety, irritability, insomnia, nausea, vomiting, tremor, sweating, and anorexia. Serious manifestations, including confusion, disorientation, psychosis, and seizures, also have been reported. For patients with an acute organic brain syndrome, a history of possible benzodiazepine withdrawal always should be pursued. Withdrawal reactions may be avoided by dose tapering. Treatment of withdrawal reactions may be accomplished by drug substitution or by reintroduction of a benzodiazepine and subsequent tapering.

NONBENZODIAZEPINE HYPNOSEDATIVES

Raquel M. Schears

The term *nonbenzodiazepine hypnosedative* is currently used to refer to a diverse group of agents that share the ability to promote sleep and allay anxiety, categorically exclusive of the benzodiazepines. Several of these chemical entities, such as ethchlorvynol, meprobamate, glutethimide, and methaqualone, are rarely subscribed for clinical use, yet ingestions continue to be reported.¹ Newer agents such as buspirone, zaleplon, and zolpidem are commonly prescribed, making toxicity and overdose characteristics important to recognize (Tables 165-1 and 165-2). EM physicians encounter the effects of these agents in patients presenting with symptoms of intentional overdose, recreational misuse, alleged assault, withdrawal syndromes, or during major trauma evaluations when detected on drug screen.

In the U.S., some chemical compounds exist that possess secondary hypnosedative properties, but were primarily labeled as nonfood,

nondrug products. This initial designation allowed these agents to be marketed as untested dietary supplements or industrial solvents, without a legitimate clinical purpose. Lacking prior proof of safety and efficacy, the human hazards posed by such entities tend to be revealed and responded to gradually as morbidity patterns and evidence of lethality mounts. Relevant in this context are 7-hydroxybutyrate (7HB), and its precursors 7-hydroxybutyrolactone (7BL) and 1,4-butanediol (BD), which convert to 7HB in vivo. These drugs are creating novel public health issues and dangerous toxicity in acute ingestion and abrupt withdrawal. Despite increasing FDA regulations since 1990, whereby 7HB manufacture and sales were banned, up until recently (March, 2000) when 7HB was designated a Federal Schedule I Controlled Substance enforced by the DEA, these compounds continue to be easily accessible and widely abused.² Statistics on raves, circuit parties, and bodybuilder club cultures indicate these drugs are increasingly prevalent in intentional misuse and overdose.^{3,4} 7HB and its congeners are further indicted as agents used in drug-facilitated sexual assault (7SA), episodes of polydrug abuse among consenting gay and bisexual men prompting high-risk sexual behavior, and have been linked to driving impairment as single-agent exposures in forensic reports.^{4,6} Curtailing illicit and licit use of 7HB and related compounds is proving more difficult than previously anticipated. These observations create an imperative for EM physicians to be well versed in the presentation and management of 7HB-related emergencies.

Agents in this chapter share certain pharmacologic and clinical similarities. These drugs tend to be highly lipophilic and concentrate in the central nervous system (CNS), causing variable degrees of CNS depression with gradual redistribution and eventual hepatic degradation. Clinically, mild intoxication manifests as sedation and incoordination, which progresses to lethargy, worsening ataxia, and deepening coma in overdose. It is recognized that reaching a treatment center predicts a favorable outcome in all types of overdose, including those seen with the nonbenzodiazepine hypnosedatives. In fact, declining mortality associated with these agents over broad dose ranges is attributed mostly to improvements in standard supportive care. Therefore general treatment guidelines take precedence in management of all these agents in overdose (see Chap. 156). Departures from general clinical presentation or management in overdose unique to a specific agent are covered in the discussion specific to the agent below.

7-HYDROXYBUTYRATE (7HB) AND 7HB-RELATED COMPOUNDS: 7- HYDROXYBUTYROLACTONE (7BL) AND 1,4-BUTANEDIOL (BD)

7HB is an endogenous metabolite of 7-aminobutyric acid (7ABA), the major inhibitory neurotransmitter in the CNS. 7HB functions as a putative neurotransmitter or neuromodulator itself, capable of inducing profound CNS depression. It produces a biphasic dopamine response and triggers the release of endogenous opiate-like substances. 7HB centrally mediates sleep cycles, emotional control, and retention of memory. It also functions in glucose metabolism, temperature regulation, and blood flow. Ingestion of 7HB results in rapid gastrointestinal (GI) absorption, with peak plasma concentrations and coincident clinical effects occurring within 30 to 60 min. 7HB quickly crosses the blood-brain barrier, concentrating in the CNS, kidney, heart, and muscle tissue. The average drug half-life is 30 min. 7HB is metabolized in the liver and then almost completely oxidized to carbon dioxide and water by the lungs and expired. Less than 2 percent of 7HB is eliminated unchanged in the urine, and this occurs so rapidly that after 12 h it is undetectable. Exposed adults can experience comatose states typically lasting 1 to 2 h, with spontaneous recovery of consciousness usually within 4 hours.

7HB was developed as an anesthetic more than 40 years ago. It had escaped clinical use in the United States until late 2002, when Orphan

(continued)

*Agent causes significant life-threatening abstinence syndrome requiring hospital admission.

^fLegal synthesis in USA terminated 1984.

JProdrug metabolizes to DEA controlled schedule drug in the respective drug class category.

#Due to the fluctuating legal status of GHB, Orphan Medical (1-888-8ORPHAN) maintains the current legislative status of GHB by state. §All agents have both sedative and hypnotic properties; maximum adult hypnotic dose listed can be given in divided doses to that total dose/day for sedative purposes.

Medical began marketing it as Xyrem (sodium oxybate), a schedule III controlled substance. Currently it is the only FDA-approved form of 7HB available for the treatment of cataplexy associated with narcolepsy. All use of the medication is tracked through an industry-sponsored registry (see Table 165-2). It is hoped that by monitoring physician prescription practices and patient consumption, tight control over American distribution will be ensured. In Europe, 7HB has long been used to manage alcohol and narcotic withdrawal and treat narcolepsy.

Unregulated sales of -yHB in the United States began in the 1980s when it was first sold to bodybuilders as a health food product allegedly capable of "fat-burning" metabolic powers during sleep. In the 1990s it was marketed to ravers as "liquid ecstasy" for its purported euphoric effects when used during all-night dance parties. Drug-facilitated sexual assault also surfaced in connection with "yHB, flunitrazepam, and most recently 7HB congeners, during the last 5 years. Very small quantities of these drugs are required to cause rapid onset of disinhibition, passivity, loss of will to resist, relaxation of muscles, and lasting anterograde amnesia. 7HB is an odorless, colorless, and nearly tasteless liquid, powder, or capsule.⁷ Concerns regarding such illicit use, compounded by the growing popularity of 7HB, prompted passage of a 1996 federal law, the Drug-Induced Rape Prevention and Punishment Act, which sets prison terms of up to 20 years for anyone convicted of using any controlled substance with the intent to commit a violent crime, including sexual assault. Also within the last few years, -yHB-related agents have become increasingly recognized as prevalent drugs of abuse for their aphrodisiac effects, and a corre-

sponding public health problem has developed among consenting gay and bisexual men who frequent "circuit parties." These are ticketed multiday gatherings with an estimated annual attendance in the United States in the hundreds of thousands. In a recent survey of circuit party participants (N = 295), nearly all respondents reported use of drugs during the party weekends, including ecstasy (75 percent), ketamine (58 percent), crystal methamphetamine (36 percent), 7HB or 7BL (25 percent), and Viagra (12 percent). Two-thirds of the men reported having sex (oral or anal), 49 percent reported having anal sex, and 28 percent reported having unprotected anal sex during the 3-day period. An association was found between the use of drugs and risky sexual behavior.⁴

7HB can be ordered from other countries via the Internet, is relatively inexpensive and easy to synthesize from its related compounds. A common method of synthesizing illicit 7HB is to react liquid 7BL with an equal volume of water in the presence of a base to open its ring structure. On a volume basis, the potency of 7BL is twice that of 7HB prepared by this method. Consumers of these agents may not recognize these potency differences, leading to dosing errors and serious side effects. Also, the direct sale of "natural" dietary supplements containing the newer-generation 7HB precursors, 7BL and BD, are the subject of several FDA health risk warnings, partial manufacturer recalls, and extensive Internet marketing strategies which assure consumer anonymity, flexible supply, and continued demand. 7BL is sold in herbal products (unregulated) and is a component of acetone-free nail polish removers and cyanoacrylate glue. It has greater bioavailability and faster onset of action (20 min) than 7HB on an equimolar

**Half-life given at therapeutic dose; generally half-life in overdose is considerably longer. M = active metabolites. Fatal dose is an estimate complicated by history of tolerance, coingestion, and patient reliability. Extracorporeal methods: HP = hemoperfusion, HD = hemodialysis, > denotes preferred method; ND = no data; V_d = volume of distribution; ARDS = acute respiratory distress syndrome.

Source: Adapted from Lee D: Sedative-hypnotic agents, in Goldfrank LR, Howland MA (eds): *Goldfrank's Toxicologic Emergencies*, 7th ed. New York, NY: McGraw-Hill, 2001, p. 932, with permission.

basis. Usually these substances are considered alternatives to "ecstasy" or methamphetamine and are often coingested with alcohol, which in the case of BD potentiates toxicity. BD competes with ethanol, the preferred substrate of alcohol dehydrogenase (ADH) in vivo. This competitive inhibition of ADH delays onset of BD metabolism and may consequently mask symptoms for up to 8 h in patients with concurrent exposure. Historical clues to 7HB intoxication are very similar from case to case and commonly involve this scenario: patient reports going out drinking, and either develops a sudden sense of extreme drunkenness after just one or two drinks, or experiences an abrupt onset of uncharacteristic aggressive behavior, followed by sudden drowsiness, dizziness, euphoria, or coma with rapid reawakening and amnesia.^{2,3}

Clinical Features of Toxicity

The toxic effects of 7HB and "/HB-related compounds target the CNS, cardiovascular system, and respiratory system, but spare hepatorenal function. Symptoms include labile level of consciousness (agitation, combativeness, somnolence, coma, sudden reawakening emergence), variable neuromuscular movement (hypotonia, tremor, myoclonus, seizure-like activity), vomiting, hypothermia, bradycardia, respiratory depression, apnea, and death. Solid evidence that 7HB and 7HB-related compounds alone cause lethal outcome in overdose exists. Since 1992, the DEA has documented 9600 adverse 7HB reactions or overdoses in 46 states, and identified 71 "yHB-related fatalities, the majority of which occurred after 1996. In 15 of these deaths, a 7HB-

related compound was the sole drug isolated in forensic analysis.^{2,7} Over the last 10 years, ED encounters for 7HB-related poisonings are up 100-fold, and at least 30 cases of 7HB DFSA have been clearly documented (data from NIDA and NIH National Symposium, Bethesda, MD, 6/27/2000). The burden of additional toxicity risk contributed by websites claiming the hazards of these drugs are exaggerated is not known. However, casual attitudes of friends attending 7HB overdose victims have been linked to fatal delays in obtaining emergency medical treatment.^{2,3}

Clinical effects are dose-related. Low doses produce euphoria, nystagmus, ataxia, and dizziness; moderate doses produce sedation; and high doses produce coma, respiratory depression, apnea, and rarely, death. Under controlled conditions, 10 mg/kg results in amnesia, hypotonia, and ataxia; 30 mg/kg induces euphoria, drowsiness, and dizziness. Doses of 50 mg/kg produce unconsciousness. Doses above 50 mg/kg cause bradycardia, respiratory depression, and seizure-like activity. Since most 7HB is "home brewed," dose purity and strength are uncertain, and anywhere between one-half teaspoon and 4 table-spoons have been reported to elicit adverse effects. Mixed in alcoholic beverages, the two sedatives are synergistic. Likely clinical features in the ED include: Glasgow coma scale (GCS) scores as low as 3 to 5, may be followed by emergence delirium and vomiting, which appears inversely related to initial GCS score; i.e., 85 percent of the vomiting reported in exposure case series had GCS scores of 8 or less.⁸ Mild bradycardia, moderate bradypnea with Cheyne-Stokes respirations, and seizure-like activity have also been noted. Urinary and fecal incontinence are commonly seen with 7BL and BD overdose. Episodes

of marked agitation on stimulation (intubation, sternal rub) are the hallmark of 7HB intoxication, along with findings of only mild respiratory acidosis despite periods of prolonged apnea and hypoxia.

Treatment

No standard treatment protocol or antidote exist for 7HB intoxication. However, several supportive measures are recommended, which begin with the ABCs of resuscitation. Aspiration precautions are advised because of the potential for sudden changes in mental status. Furthermore, airway protection via rapid sequence intubation (RSI) followed by assisted ventilation may be the best strategy in managing both the profound CNS and respiratory depression seen in serious 7HB intoxication. (Because 7HB functions as an anesthetic induction agent, RSI can proceed with paralytic agents alone.) Secondly, improper manufacture of 7HB using recipes obtained via the Internet often results in mixtures of 7BL and sodium hydroxide or lye, which can lead to caustic alkaline burns of the esophagus and lungs with aspiration.

Neither naloxone nor flumazenil has been effective in reversing unconsciousness induced by 7HB, and the use of physostigmine to reverse coma may be dangerous and lacks supportive evidence. In other overdose settings in which bradycardia complicates presentation, physostigmine administration has caused asystole and cardiac arrest. The bradycardia seen in 7HB intoxication is attributed to central vagal activity, and responds to atropine if simple stimulation fails to suffice. Routine cardiovascular monitoring, establishment of intravenous access, and laboratory testing for electrolyte balance, blood glucose level, and arterial blood gas measurement are considered good management. Drug screening is costly and of little value in most patients presenting with 7HB overdose. 7HB is only detectable in the urine for 6 to 12 h after ingestion, resulting in many false-negative results.

Both charcoal and lavage are of limited value for single 7HB ingestion due to the small amount of drug ingested and its rapid absorption.⁹ Patients with symptoms of mild intoxication who improve rapidly (after 6 h or less of observation) and clear completely can be discharged from the ED. All others should be admitted for observation. Serious GHB and GHB precursor intoxication, complicated by coingestion of alcohol or other CNS depressants, often will require emergent airway stabilization and cardiovascular support. Because of the altered hepatic metabolism seen **in patients taking BD concurrently with alcohol, it is recommended that these patients be observed until their blood alcohol concentrations are not detectable.** The role of gastric decontamination for coingestants also lacks proven efficacy if more than 1 h has elapsed since ingestion, or if less than life-threatening amounts were taken.¹⁰ Extracorporeal elimination methods have not been evaluated in GHB overdose.

Drug Facilitated Sexual Assault

When a patient presents to the ED seeking treatment for alleged drug-facilitated sexual assault, the best recommendation is compassionate advocacy and a complete evaluation. Currently, this is accomplished through supporting the psychological state of the victim and collecting evidence of the alleged crime. Many ED jurisdictions in the U.S. utilize sexual assault nurse examiners (SANE), specifically trained in this sensitive role. The presence of a clinical symptom pattern consistent with drug-facilitated sexual assault and a history of drug ingestion within 72 h are indications for toxicologic screenings. Both blood and urine specimens should be obtained. (Minimum collection: single gray topped tube for blood, refrigerate; 100 mL of urine.) Specimens should be submitted for testing according to strict chain-of-custody procedures, which will be critical if the case is prosecuted. Drug screening requires patient consent, and SANE must inform the patient what drugs will be included in the screen. Any documentable use of recreational or prescription drug use by the victim should be recorded in the medical record prior to the findings of positive results of the drug

screen if negative impact on the victim's credibility is to be minimized. A complete toxicologic screen can cost upwards of \$800. Currently, the strategy of many SANE programs has been to turn over the biological specimens collected with the rape kit to the appropriate law enforcement authorities. Thus the screening costs are passed on to the investigating agency. If a report is not generated regarding the incident, but the victim wants a toxicologic screen, the victim should be informed of the cost and financial burden.¹¹

A previously free nationwide urine testing program developed to assess the incidence of drug use in sexual assault cases recently reported the findings on ethanol, 7HB, flunitrazepam, and nine other drug classes (amphetamines, barbiturates, benzodiazepines, cannabinoids, cocaine, methaqualone, opiates, phencyclidine, and propoxyphene). Of the 1179 samples, 468 were negative for all substances tested. There were no samples identified as positive for phencyclidine or methaqualone. Of the remainder (711 samples) 35 percent of the drug-positive samples contained multiple drugs. The drug found in the majority of the positive specimens was ethanol, followed by cannabinoids, cocaine, benzodiazepines, amphetamines, and 7HB. Although many drugs appear to be associated with the crime of sexual assault, the prevalence of 7HB and related compounds is of special concern because of the lack of routine screening tests available to detect these drugs.⁵

Detection of 7HB and 7HB-related drugs requires targeted analysis such as gas chromatography-mass spectrometry. Currently, forensic laboratory screening of biological specimens for 7HB can be facilitated through contacting the National Medical Services Laboratory in Willow Grove, PA at 1-800-522-6671 or go to www.nmslab.com, for further information.

Withdrawal

Sharply contrasting with overdose, there are numerous recent small case series documenting the existence of tolerance and dependence liability with chronic 7HB use.¹² 7HB dependence is characterized by multiple daily doses taken around the clock (every 1 to 3 h) for months to years, often with a history of multiple unsuccessful attempts to self-taper. Furthermore, high-frequency users appear to be at the greatest risk for developing manifestations of severe delirium and psychosis as part of an acute life-threatening withdrawal syndrome that occurs rarely with abrupt discontinuation of 7HB use. The spectrum of acute withdrawal is similar to that seen with other hypnosedatives, including benzodiazepines, barbiturates, and alcohol, suggesting a common mechanism. Usually patients report only 6 to 8 h of abstinence before the onset of craving and symptoms that consistently include a triad of anxiety, tremor, and insomnia. Several other historical associations have been documented, including the presence of emotional lability, prior diagnosis of nonpsychotic psychiatric disorders, and/or substance abuse in the majority of patients suffering from 7HB withdrawal symptoms. Presentation to the ED is often delayed until more severe symptoms of agitation and vivid hallucinations are experienced. The observed withdrawal syndrome can last 5 to 15 days. Severe withdrawal is characterized by mild autonomic instability, and progressive psychosis and delirium, which develop within 2 days of last use. Patients require ICU monitoring for the degree of physical and chemical restraint needed to maintain sedation, control CNS symptoms, and prevent injury. Patients often suffer complications of pulmonary edema, hyperthermia, and rhabdomyolysis, and are at high risk for 7HB relapse on hospital discharge. The critical need for psychiatric assessment and treatment for chemical dependence is best anticipated from the ED and incorporated into the treatment of acute withdrawal.¹²

The treatment of 7HB withdrawal is also evolving. Although there are no prospective studies, it seems that the similarity of 7HB withdrawal to that of benzodiazepines, ethanol, and other hypnosedatives, place a GABA agonist as first-line treatment in the ED. Huge intra-

TABLE 155-11 Antiviral Agents for HIV Infection

venous doses of benzodiazepines (diazepam 100 mg/24 h; 2.5 g/4 d) initiated early for sedation purposes and to decrease severity and duration of symptoms has been described. Barbiturates (pentobarbital 1 to 2 mg/kg IV every 30 to 60 min with slow taper over 5 to 6 d) are considered alternatives for cases refractory to benzodiazepines. Chloral hydrate, 1 gm PO is another option. Other agents, such as IV propofol or fentanyl, can be given in an ICU setting under the direction of a toxicologist.

Low-dose antipsychotics (haloperidol and risperidone) have also been used successfully. However, administering antipsychotics may adversely affect thermoregulation, precipitate acute dystonic reactions, and lower the seizure threshold. For these reasons, the current best strategy is to avoid these agents in the management of acute 7HB withdrawal.

BUSPIRONE

Buspirone, introduced in 1984, is a prototype anxiolytic drug from the azapirone family. The agent is not chemically or pharmacologically related to the other hypnosedatives, although its efficacy profile is comparable with that of the benzodiazepines. Clinical indications for buspirone use are not fully delineated; however, it appears most useful in the treatment of conditions such as chronic anxiety, especially in the elderly, and mixed anxiety-depression states. It does not affect 7 ABA or benzodiazepine receptors, and therefore produces less sedation, euphoria, psychomotor impairment, and ethanol potentiation. It does affect CNS serotonergic, dopaminergic, and noradrenergic neurotransmission, but the mechanisms are not fully understood. Buspirone appears to have several merits when compared to the hypnosedatives, including a virtual absence of abuse potential, a wide margin of therapeutic safety, and no documented delayed toxicity or withdrawal reactions with abrupt discontinuation of chronic use.¹³

Buspirone is rapidly absorbed, highly protein-bound, and widely distributed to the tissues. Metabolism occurs in the liver, with at least one active metabolite generated. Fecal elimination accounts for 20 to 40 percent of drug clearance. Experience in overdose may be limited by the drug's wide margin of safety. Patients have taken up to 3 g (which is 150 times the average anxiolytic dose) in overdose without lasting ill effects. Most common clinical symptoms in overdose are nonspecific drowsiness and dysphoria. Rarely, hypotension, bradycardia, seizures, GI upset, dystonia, and priapism have also been described. Spontaneous acute hypertensive reactions have developed in patients taking buspirone and monoamine oxidase inhibitors concurrently. No other adverse drug interactions or unexpected toxicities have emerged with buspirone use.¹³ Treatment in overdose is supportive. Serum levels are not useful clinically, and extracorporeal methods of elimination enhancement have not been evaluated.

CHLORAL HYDRATE

Introduced in 1869, chloral hydrate (a schedule III drug with recognized abuse potential) is the oldest hypnosedative agent, and was used as a popular sedative in clinical medicine until the advent of barbiturates largely supplanted its use in the early 1900s. Chloral hydrate is still used effectively for promoting sedation in children because in therapeutic doses it does not depress respiratory drive or circulatory function. Drawbacks include its narrow margin of safety, minimal analgesic activity, and propensity to develop tolerance and physical dependence. Withdrawal symptoms mimic those of alcohol abstinence. Toxic doses produce severe CNS and respiratory and cardiovascular depression. Ethanol potentiates the sedative effects of chloral hydrate when taken in combination. This observation led to the street use of the two substances for malicious intent, as in slipping someone a "Micky Finn" or "knockout drops."

Chloral hydrate absorption occurs rapidly and completely from the GI tract. It is a well-known mucous membrane irritant, especially

when taken in quantity or undiluted. It functions as a CNS depressant via an unknown mechanism of action. Toxic doses also depress myocardial contractility, shorten the refractory period, and sensitize the myocardium to catecholamines. These factors create the substrate for resistant ventricular dysrhythmias that are the leading cause of mortality in overdose.¹⁴ Chloral hydrate is lipid-soluble and easily transits all cell membranes. Volume of distribution and protein-binding properties are moderate. Metabolism occurs in the liver via alcohol dehydrogenase and results in the generation of a longer-acting active metabolite, trichloroethanol ($t_{1/2}$ = 4 to 12 h), thought responsible for most of the drug's sedative action and toxic effects in overdose. Neither the parent drug nor the metabolite induces hepatic enzyme activity.

Clinical clues to the ingestion of chloral hydrate are a pearlike breath odor, hypotension, cardiac dysrhythmias, and GI bleeding. Because chloral hydrate is radiopaque and can cause intestinal perforation, abdominal x-rays may help narrow the differential diagnosis and guide decontamination. Electrocardiogram (ECG) often shows a shortened QT interval indicative of the decreased refractory period seen in chloral hydrate overdose. Persistent ventricular dysrhythmias commonly signal terminal events, because they are resistant to standard antidysrhythmic therapy. Propranolol, a β -adrenergic antagonist, is considered the drug of choice in treating dysrhythmias associated with chloral hydrate overdose. Consider overdrive pacing in the management of persistent fatal dysrhythmias. Avoid β -adrenergic drugs such as epinephrine, isoproterenol, and dopamine, which are capable of potentiating dysrhythmias in the catecholamine-sensitized myocardium. If hypotension does not respond to volume loading, an acting pressor such as norepinephrine is first-line therapy. Serum levels are rarely helpful in guiding clinical management. Barring evidence of intestinal perforation, gastric lavage and activated charcoal can be administered for ingestions presenting to the ED within an hour, once the airway has been controlled. Hemodialysis and hemoperfusion have been shown to be beneficial in severe overdose.

ETHCHLORVYNOL

Ethchlorvynol, a schedule IV drug, was marketed initially in 1955 as an alternative to barbiturates, possessing a more rapid onset and shorter duration of action. However, the drug's high abuse potential, coupled with its tendency toward tolerance, physical dependence, and life-threatening withdrawal, overshadowed any claim of superior efficacy. The drug is available as a liquid-filled capsule, allowing both intravenous and oral abuse.

Ethchlorvynol is absorbed rapidly from the GI tract. It is highly lipophilic, concentrates in the CNS, and possesses a large volume of distribution. Its biphasic distribution is characterized by an initial period of adipose tissue deposition after ingestion (3 to 5 h), with sedative effects that disappear only to resurface later (7 to 10 h), when the drug redistributes from fat stores. Ethchlorvynol is moderately protein-bound and metabolized in the liver, but does not induce microsomal enzymes. It also crosses the placenta and causes neonatal withdrawal symptoms. Mechanisms of CNS sedative action and hepatic degradation are unknown. Ethanol potentiates its CNS depressant effects.

Distinguishing clinical clues in oral and intravenous overdose are a vinyl-like breath odor (although the patient may report a mintlike taste in the mouth), dyspnea, and dry cough. CNS effects include nystagmus, lethargy, and extremely prolonged coma. Isoelectric electroencephalographic (EEG) tracings have been reported, but do not preclude full recovery. Hemodynamic instability progresses from an initial bradycardia to severe hypotension and hypothermia. Noncardiogenic pulmonary edema can be seen in massive ingestions, although it is more characteristic of intravenous overdose. Polydrug exposures that potentiate CNS depression can result in acute respiratory arrest and cardiovascular collapse. Successful treatment of

ethchlorvynol overdose centers on the usual attention to supportive care and general decontamination. Serum levels of ethchlorvynol are not helpful in guiding management except to confirm diagnosis or trigger use of an extracorporeal elimination method in refractory cases. Charcoal hemoperfusion is superior to hemodialysis because of the drug's degree of protein binding and redistribution characteristics. Forced diuresis is not recommended because the risks of inducing pulmonary edema outweigh the minimal benefit gained from strategic enhancement of renal elimination.

GLUTETHIMIDE

Glutethimide was introduced in 1954 as a safe, nonaddicting hypnosedative drug substitute for barbiturates. However, its clinical usefulness was quickly eclipsed by recognition of its potential adverse effects, which closely resembled those of barbiturates. Similarities include its ability to induce prolonged coma, addiction, tolerance, and severe withdrawal. In large overdose, several complications (e.g., cerebral and pulmonary edema, hypotension, seizures, and sudden apnea) make treatment of this schedule II substance more difficult. Illicit abuse involves the street belief that taking combinations of codeine and glutethimide produce a similar but longer-acting euphoria than can be obtained with intravenous heroin use. Side effects with chronic use include "hangover," headaches, blurred vision, rash, bone marrow suppression, hypocalcemia, and osteomalacia.

Poor water solubility causes glutethimide to be slowly and erratically absorbed from the GI tract. However, coingestion of alcohol markedly enhances drug dissolution and absorption. The drug is lipophilic and initially concentrates in the CNS and adipose tissue, with eventual redistribution. Drug half-lives up to 40 h have been observed in overdose. Glutethimide has a large volume of distribution, is moderately protein-bound, and is capable of inducing hepatic microsomal enzymes. Hepatic degradation results in several active metabolites that may play a role in the prolonged fluctuating coma seen in overdose.¹⁵ Glutethimide crosses the placenta, and fetal blood concentrations equal those of the mother. Minimal amounts of unchanged drug are excreted in breast milk.

Clinical manifestations of glutethimide overdose mirror those seen with barbiturate toxicity with two exceptions. Anticholinergic symptoms are prominent, and the unique fluctuating nature of the prolonged coma complicates management. Mydriasis, dry mucous membranes, tenacious secretions, tachycardia, hypertension, ileus, urinary retention, hyperpyrexia, delirium, seizures, and agitation may be observed.

Serum levels of one of the active metabolites, 4-HG, may correlate better with toxicity than do levels of the parent compound. As with ethchlorvynol, complete clinical recovery is possible despite an isoelectric EEG if the patient has been spared the insults of cerebral hypoxia and/or ischemia. Coingestion of other CNS depressants, prolonged coma, and age over 60 years, predict negative outcomes in glutethimide overdose.¹⁵

Late gastric lavage (12 h after ingestion) has been shown to be beneficial in obtunded patients because of the drug's anticholinergic effect of delaying gastric emptying. In asymptomatic patients presenting 4 h or more after ingestion, the poor water solubility of glutethimide limits the effectiveness of lavage. Activated charcoal is recommended in all patients, but the utility of multiple-dose activated charcoal (MDAC) remains unproven. The use of physostigmine to reverse anticholinergic CNS toxicity is not recommended. Forced diuresis is not effective and can precipitate the development of pulmonary edema. Improvement in clinical outcomes for the elderly and those patients with severe intoxications (serum glutethimide levels >40 mg/L) has been documented using extracorporeal techniques to increase drug clearance. Hemoperfusion is the preferred method, but efficacy remains controversial, limiting its application to overdose patients not responding to supportive measures alone. Given the potential for delayed, erratic absorption and characteristic fluctuating mental status,

admission and prolonged observation of patients with significant exposures is indicated.

MEPROBAMATE

Meprobamate has been in clinical use since 1955 as an anxiolytic hypnosedative; this remains its only approved use in the U.S. Meprobamate is classified as a schedule IV drug because of known potential for inducing tolerance and dependence. Several combination products remain available even though the abuse potential of meprobamate probably surpasses that of the benzodiazepines, which are the currently favored, considerably safer, prescription alternative for anxiolysis. Thus toxic exposures continue to be reported, with intentional overdose, commonly implicated as the rationale. More significantly, carisoprodol (Soma), a widely prescribed, noncontrolled skeletal muscle relaxant whose active metabolite is meprobamate, is clearly emerging as a street drug of abuse. Often carisoprodol is combined with acetaminophen and codeine. The combination is known as "Soma-Do" and "Soma-Coma." According to the 2001 Annual Report of the American Association of Poison Control Centers, exposures and fatalities attributable to carisoprodol vastly outnumbered those reported for meprobamate (see Table 165-1). It has also recently been shown that physicians groups commonly prescribing carisoprodol are not sufficiently aware of either its abuse potential or that it is metabolized to a controlled substance.¹⁶

Absorption of meprobamate occurs in the small intestine. The compound is poorly water soluble, stable in acidic environments, and able to decrease gastric motility. These characteristics lend themselves to the development of gastric concretions. Meprobamate has a large volume of distribution, is poorly protein bound, and is metabolized primarily in the liver, where it can induce microsomal enzymes. Approximately 10 percent of the drug is excreted unchanged in the urine. Meprobamate crosses the placenta, and fetal blood levels approximate those of the mother. It is also excreted in breast milk. Meprobamate depresses the CNS by reducing sensory transmission, particularly in the thalamus. In overdose, meprobamate also concentrates in myocardial tissue, causing direct cardiotoxicity, manifesting as depressed contractility and hypotension, often in the absence of respiratory depression.

Clinical features of meprobamate toxicity are similar to those of the other hypnosedatives. CNS symptoms range in mild exposures from nystagmus and dysarthria to ataxia, confusion, and deep coma in overdose. In contrast to barbiturates, hypotension may be an early sign of toxicity occurring in lesser stages of coma. Prolonged and fluctuating coma is due to continued drug absorption from concretions. Hypotension is the hallmark of serious meprobamate overdose. Also, seizures, cardiac dysrhythmias, and pulmonary edema have been reported rarely. Abstinence syndromes reflecting the degree of physical dependence and tolerance develop quickly, usually within 1 to 2 days of drug discontinuation, and can be severe.

Utility of serum levels of meprobamate is limited but confirmative of ingestion. It may guide the need for extracorporeal removal. The treatment approach after stabilization of the airway and circulation centers on gastric decontamination given meprobamate's propensity to form concretions. Single- and multiple-dose activated charcoal MDAC appear to be safe and effective in increasing the clearance of meprobamate, although solid clinical outcome data are lacking.¹⁷ Delayed gastric lavage and whole-bowel irrigation using a polyethylene glycol solution until rectal effluent is clear is advocated but not well studied. According to some anecdotal reports, gastrostomy and endoscopic removal of concretions have been successful. Hemoperfusion is the preferred extracorporeal method to enhance drug elimination when usual intensive supportive measures fail or serum levels dictate. Forced diuresis is not advised because the limited benefit of increasing the amount of drug cleared renally must be balanced against the greater risk of inducing pulmonary edema. Management of hypoten-

sion should include the early use of vasopressors and inotropes to avoid fluid overload.

METHAQUALONE

One of the more ubiquitous hypnosedative barbiturate substitutes, methaqualone was introduced in 1965 and withdrawn from the U.S. market in 1984 because promotions of safety and nonaddictiveness proved false. High abuse potential owed to methaqualone's popularity as a street aphrodisiac. The college pastime of "hiding out," slang for a standard combination of 300 mg methaqualone ingested with wine, was used for attainment of characteristic deep relaxation, disinhibition, and euphoria.¹⁸ In the 1980s the drug was used more often to mitigate the unpleasant side effects of popular stimulants as a "cocaine downer." Even though clandestine manufacture continues abroad, supporting drug smuggled into the United States, actual reports of toxicity and mortality are becoming rare. Cessation of legal synthesis and readily available benzodiazepine alternatives explain this trend.

The drug is a CNS depressant like all the other hypnosedatives, but its mechanism of action is more of a mystery. In contrast to other hypnosedatives, which depress muscle tone and reflexes, methaqualone increases muscle tone and motor activity by selectively depressing polysynaptic spinal reflexes at high dose. Methaqualone is rapidly absorbed from the GI tract, is highly lipophilic, and concentrates in the brain, adipose tissue, and liver. It exists as a weak base with a large volume of distribution and is highly protein bound. The majority of its metabolism occurs in the liver; no active metabolites are generated, and microsomal enzymes are moderately induced.

Clinically, hypertonicity, clonus, hyperreflexia, and muscle twitching are unique features in overdose. Additionally, the usual hypnosedative symptom profile of lethargy, ataxia, dysarthria, seizures, and coma at escalating dose is observed. Hyperacusis is also reported and may be a helpful diagnostic clue to ingestion. More often the drug-induced dissociative "high," poor judgment, and coincident impulsive behavior, result in death due to trauma, as opposed to fatalities resulting from direct toxic effects in overdose.¹⁸ Cardiopulmonary symptoms include hypotension due to decreased myocardial contractility and respiratory depression. However, such symptoms occur less commonly than with other hypnosedatives, even in comatose patients. Coingestion of other CNS depressants can lead to severe respiratory depression and sudden apnea. Pulmonary edema can be seen as a result of increased capillary permeability, a risk common to most hypnosedative agents.

GI distress and hemorrhage have been noted in methaqualone overdose. Drug-induced inhibition of platelet aggregation, prolonged prothrombin and partial thromboplastin times, and decreased factors V and VII are causative. As with other hypnosedative agents, decontamination and supportive care remain the mainstays of therapy. Specific management considerations for methaqualone overdose include early use of benzodiazepines to control hypertonicity and seizures, along with administration of blood products (i.e., platelets, vitamin K, fresh-frozen plasma) in the setting of hemorrhage. Charcoal hemoperfusion is more effective than hemodialysis in clearing methaqualone, but is reserved for patients who fail to respond to maximal supportive therapy or whose serum methaqualone levels are greater than 10 to 15 mg/dL. Severe abstinence symptoms occur in chronic users when this drug is stopped abruptly and require hospital admission for gradual withdrawal.

ZALEPLON AND ZOLPIDEM

In 2000, zaleplon, a pyrazolopyrimidine derivative, became the newest available nonbenzodiazepine hypnosedative drug developed to combat insomnia. It is marketed for its rapid absorption and onset, as well as its significant presystemic metabolism ($t_{1/2} = 1$ h). Zaleplon has inactive metabolites that are primarily renally excreted. The comparative

efficacy of zaleplon and zolpidem has not been formally established. However, zaleplon does not produce the cognitive impairment, next-day sedation, amnesia, or rebound insomnia after discontinuation of nightly use that is seen with zolpidem and benzodiazepine derivatives. There have been no case reports of fatal acute overdose with zaleplon as a single substance, and evidence for pharmacologic tolerance or withdrawal is lacking. The abuse potential of zaleplon is comparable to that seen with triazolam in healthy volunteers with a history of drug abuse (i.e., considerably less than alcohol, cocaine, opiates, and barbiturates).¹⁹

Zolpidem is the other short-acting hypnosedative agent introduced in 1988 for the treatment of jet lag, anxiety, and insomnia. It is an imidazopyridine derivative, structurally different from benzodiazepines and other hypnosedatives. It binds preferentially to one of the benzodiazepine receptor subtypes (omega-1, benzodiazepine-1) in the CNS. Zolpidem is rapidly absorbed, has an onset of action within 30 min, and is effective for up to 6 h. It is metabolized in the liver to inactive metabolites that are excreted in the urine and feces. The advantage of zolpidem over the benzodiazepines had been the absence of reported addiction, tolerance, or withdrawal symptoms in most patients. Also, it had been extensively marketed to the elderly as a safer alternative to the benzodiazepines, which were shown to increase fall and fracture risk. However, recent studies indicate that these risks remain for older persons taking zolpidem.²⁰ Also, the potential for abuse, previously believed to be limited by the presence of adverse effects of the drug at higher doses, has begun to surface. Still, to date only fifteen cases of abuse or dependence have been noted in the literature.²¹ Apparently the drug is chronically abused for its psychomotor stimulant action, and tolerance and withdrawal effects can result, including rebound insomnia and seizures on abrupt discontinuation. Recently the WHO Expert Committee on Drug Dependence recommendations listed zolpidem, diazepam, and α -HB for international control.²² Experience in acute overdose is limited, but there are a few case reports of coma and rapidly remitting respiratory failure attributed to zolpidem alone.

Signs of acute zolpidem overdose in larger series commonly include drowsiness, vomiting, and rarely coma with respiratory depression. These symptoms escalate with dose and are complicated by coingestion of other psychotropic drugs and ethanol. In most cases, symptoms of intoxication remit rapidly, and therapy is usually limited to general supportive measures. Treatment is not aided by obtaining serum drug levels; the utility of MDAC and extraorporeal elimination enhancement methods has not been evaluated in overdose.

Anecdotaly, flumazenil has been effective in reversing the CNS and respiratory actions of zolpidem.²³ The recommended initial dose is 0.2 mg intravenously given over 30 s. If no improvement in consciousness is observed within 30 s, an additional dose of 0.3 mg may be administered over 30 s. This dosing regimen (0.2 mg followed by 0.3 mg) can be repeated one more time, to a total dose of 1 mg, at an interval of 1 min if adequate consciousness is not obtained. Flumazenil at a total dose of 1 mg or less IV leaves 50 percent of the benzodiazepine receptors unoccupied, and therefore should limit the risk of acute withdrawal so long as this dose is not exceeded. Flumazenil is best avoided in multidrug exposures seen in the majority of adult overdose presenting to the ED, for fear of precipitating seizures. Contraindications to the use of flumazenil are shown in Table 165-3. In the event of a flumazenil-induced seizure, a therapeutic dose of benzodiazepine should be effective.

TABLE 165-3 Contraindications to Flumazenil

Suspected TCA overdose
Co-ingestion of seizure inducing agents
Known seizure disorder
Suspected or known physical dependence to benzodiazepines
Overdose of unknown agents
Suspected increased intracranial pressure

ETHANOL

Ethanol is unique among drugs of potential abuse. It is legal and culturally acceptable in most societies—and therefore ubiquitous. While potentially acutely and chronically toxic, it confers health benefits when used moderately. Finally, most medical morbidity associated with acute intoxication is the result not of direct drug effect, but of secondary injuries.

Ethanol is the most frequently used and abused intoxicant in the United States¹ and most other societies, including those where it is proscribed. Nearly three-quarters of adult Americans consume at least one alcoholic drink each year. Beer ranks as the fourth most popular beverage in terms of volume consumed, after soft drinks, milk, and coffee. Adult consumption of beverages containing ethanol peaked in 1980-1981 at 2.77 gallons per person of pure ethanol, but by 1997 this had declined to 2.2 gallons.¹

Distilled spirits typically contain ethanol volumes of 40 to 50 percent (80 to 100 proof), although brands with volumes of 75 percent or more exist. Wines have an ethanol volume of 10 to 20 percent, while beers range from 2 to 6 percent. One drink is considered to be 0.5 oz or 15 g of alcohol, which is equivalent to 12 oz (355 mL) of beer, 5 oz (148 mL) of wine, or 1.5 oz (44 mL) of 80 proof spirits. Ethanol is also a constituent of mouthwashes (up to 75 percent volume), colognes (40 to 60 percent), and medicinal preparations (0.4 to 65 percent).

Though the statistics that show that the cost to society of alcohol abuse can be numbing, a few are worthy of mention here. Ethanol use in the U.S. cost \$185 billion in 1998 and contributes to approximately 100,000 deaths per year,¹ dwarfing the value of any potential health benefits that might accrue from its use. Forty per cent of motor vehicle fatalities (15,000/year) are related to alcohol use. One-quarter of the victims of interpersonal trauma report alcohol use by their assailants,² and alcohol abuse as reported by the injured woman is the strongest predictor for acute injury related to domestic violence.³ The prevalence and lifelong risk of alcohol abuse or dependence are 7 and 13 percent, respectively.⁴

Data from the 1995 National Hospital Ambulatory Medical Care Survey indicates that 2.7 percent of all ED visits are related to alcohol use.⁵ Ethanol has been detected in the blood of 15 to 40 percent of ED patients, depending on locale. However, despite its prevalence, emergency physicians and inpatient specialists fail to recognize 50 percent of patients with ethanol dependence. The formal diagnosis of alcoholism has rested on instruments such as the CAGE and the Michigan Alcohol Screening Test. In the clinical setting, pointed questioning, when appropriate, about quantity of ethanol intake, medical complications usually caused by drinking, and whether the patient or others has ever felt he or she had a drinking problem will usually uncover such problems. It is increasingly clear that the ED-based interventions can be quite effective in treatment of alcoholism and its consequences.^{6,7}

Pathophysiology

Ethanol is a central nervous system depressant which inhibits neuronal activity. Alcohol intoxication is associated with the depression of the excitatory neurotransmitter glutamate and alcohol increases the inhibitory activity of the neurotransmitters 7-aminobutyric acid (GABA) and glycine. Alcohol may also affect phosphorylation of proteins involved in ligand-gated channels that provide signaling functions. Changes in the number and sensitivity of these receptors that occur with chronic alcohol use appear to underlie at least some components of the alcohol withdrawal syndrome. The clinically observed cross-tolerance that exists between ethanol and other sedative-hypnotic agents, including benzodiazepines and barbiturates, appears related to the similar effects that these agents have on brain chemistry. Ethanol absorption occurs in the mouth and esophagus to a small extent, in the stomach and large bowel to a moderate extent, but chiefly in the proximal portion of the small bowel. Approximately 2 to 10 percent of ethanol may be excreted by the lungs, in urine, or in sweat, the proportion being dependent on blood concentration. The remainder is metabolized to acetaldehyde in the liver by one of two pathways. In the cell, cytosol alcohol dehydrogenase with nicotinamide adenine dinucleotide as a cofactor produces acetaldehyde, which in turn is metabolized by aldehyde dehydrogenase. The second pathway, which is clinically significant at high blood ethanol concen-

trations and has increased activity with repeated exposures to ethanol, is a microsomal alcohol oxidizing system. Gender-related differences in the metabolism of ethanol explain the considerably higher blood ethanol levels in women versus men after similar dosing on a gram-per-kilogram basis. Women have a smaller volume of distribution (0.6 L/kg) for ethanol than men (0.7 L/kg) and have decreased first-pass metabolism of ethanol because their gastric walls contain less alcohol dehydrogenase than do those of men.⁸

Clinical Features

Symptoms and signs of ethanol intoxication include slurred speech, nystagmus, disinhibited behavior, central nervous system depression including coma, and decreased motor coordination and control. A lowering of blood pressure or even hypotension with resultant reflex tachycardia are common secondary to a decrease in total peripheral resistance or as a result of volume loss. Changes in posture may result in syncope.⁹ However, when hypotension is present, other causes must be considered.

Because of the phenomenon of tolerance, blood alcohol levels correlate poorly with degree of intoxication. While death from respiratory depression may occur in unhabituated individuals at concentrations of 400 to 500 mg/dL, it is not uncommon for some alcoholics to appear minimally intoxicated at blood concentrations as high as 400 mg/dL.¹⁰ Although most states have adopted 80 or 100 mg/dL as the legal definition of intoxication for the purposes of driving a motor vehicle, there is considerable evidence to suggest that impairment may be seen with levels as low as 5 mg/dL, especially in unhabituated individuals.

A mild lactic acidosis may be seen. However, **significant acidosis should never be attributed to alcohol intoxication**, and should prompt an aggressive search for another cause. In the presence of volume depletion, a mild contraction alkalosis may be noted, as may pre-renal azotemia.

Treatment

Management of acute ethanol intoxication consists of attending to associated injuries or medical illness and observation until clinical sobriety is attained. A careful examination should be performed to evaluate for complicating injuries or medical conditions. Ethanol levels are not necessarily required for mild or moderate intoxication when no other abnormality is suspected. It is appropriate in all patients with depressed level of consciousness or altered mental status. The most appropriate fluid is D5NS. This fluid addresses volume issues as well as glycogen depletion.

Hypoglycemia should be excluded by a bedside glucose determination. In the event of severe depression of mental status, causes other than alcohol ingestion must be considered, especially subdural hematoma, which can occur in the absence of external signs of trauma.

Fluid administration does not hasten alcohol elimination;¹¹ therefore intravenous access for fluid administration alone is unnecessary in uncomplicated cases of mild to moderate intoxication unless clinical signs of volume depletion are present. Any alcoholic with CNS depression, even if apparently attributable to intoxication, should receive thiamine. Folate and other vitamins are indicated only if there are clinical signs or laboratory confirmation of deficiency. Ethanol does not bind to activated charcoal, which should be administered only if other substances have been ingested that are adsorbable. Careful and serial observation is crucial, as in the vast majority of uncomplicated cases rapid improvement occurs over a few hours. **Mental status that fails to improve and any deterioration should be considered secondary to other causes** and evaluated aggressively. Respiratory depression may result in carbon dioxide retention, which on rare occasion may require intubation. Unhabituated patients eliminate ethanol from the bloodstream at a rate of 15 to 20 mg/dL per h, while alcoholics average 25 to 35 mg/dL per h.

Alcoholics should be questioned about concomitant drug use. In the past, ethylene glycol or methanol was occasionally substituted for or combined with ethanol. Today cocaine has clearly become the most common concomitant drug used by alcoholics. The attraction of abusing these drugs together may relate to the formation of a metabolite, cocaethylene, which although less potent than cocaine, has a half-life that is 3 to 5 times longer.¹² The risk of sudden death among users of both drugs simultaneously may be as high as 20 times that with cocaine alone.

Ethanol is the most common cause of an osmolar gap (see Chap. 27) (Table 166-1). The concomitant presence of an anion-gap (AG) metabolic acidosis may help characterize the presence of a coingestant. Methanol and ethylene glycol poisoning are associated with significant widened AG-type acidosis. The metabolic derangements ascribed to alcohol toxicity are readily reversed by volume repletion.

A long-running debate continues about whether alcohol ingestion complicates the care of the injured patient. Some feel that it does, either by increasing trauma severity through mechanical means (some have proposed decreased tone in the abdominal musculature), or through its toxic effects in combination with trauma to injured organs, particularly the brain. However, most studies have found that expenditures for diagnostic studies and morbidity are similar in intoxicated and sober trauma victims when controlling for severity of trauma.

Disposition

Morbidity and mortality in association with acute intoxication are predominantly the result of injuries, often motor vehicle collisions related to ethanol-induced deficits in judgment or physical capabilities. Patients with acute ethanol intoxication alone rarely require hospital admission. However, questions frequently arise over alcoholics who appear clinically sober while still having considerable blood ethanol concentrations. Medical judgment of mental competence should not be confused with any particular blood alcohol concentration level. Patients whose intoxication has resolved to the extent that they do not constitute a danger to themselves or others, *and* who will not be responsible for their own transportation, may be discharged on their own recognizance or preferably in the company of responsible friends or relatives who can assist them and take some responsibility for their care. Patients who are to drive themselves home should have ethanol levels close to zero, not merely below a given state's legal level for driving, as there is the theoretical potential for psychometric disability at very low levels, and the potential liability for the emergency physician is unfortunately huge.

ISOPROPANOL

Isopropanol, also known as isopropyl alcohol and 2-propanol, is commonly found in the home as rubbing alcohol. It is also used widely in

TABLE 166-1 Substances that Contribute to the Osmolar Gap

Substance	Molecular Weight	mOsm/L at 100 mg/dL	Correction Factor
Ethanol	46	22	4.6
Isopropanol	60	17	6.0
Methanol	32	31	3.2
Ethylene glycol	62	16	6.2

Note: To estimate concentration of an alcohol in mg/dL, use the following formula: (osmolar gap — 10) X correction factor. This estimation is only valid if the alcohol is the only unmeasured abnormal contributor to osmolality. Measured osmolality, if higher than predicted by the known concentration(s) of the measured alcohol(s), implies the presence of another osmotically active substance.

industry as a solvent and disinfectant and is a component of a variety of skin and hair products, jewelry cleaners, detergents, paint thinners, and antifreeze. Poisoning usually results from ingestion, but may also occur after inhalation or dermal exposure in poorly ventilated areas—for example, during alcohol sponge bathing. Toxicity occurring after administration of an isopropanol enema has also been reported. Its principal metabolite, acetone, does not cause the eye, kidney, cardiac, or metabolic toxicity caused by the metabolites of methanol and ethylene glycol.

Isopropanol is approximately twice as potent as ethanol in causing central nervous system depression and its duration is two to four times that of ethanol. As a result it is on occasion utilized as a substitute intoxicant by alcoholics as well as in suicide attempts. After ethanol, it is the second most commonly ingested alcohol. Though more toxic than ethanol, it is considerably less so than methanol or ethylene glycol.

Pathophysiology

Isopropanol is a clear, volatile liquid with a bitter, burning taste and an aromatic odor. It is rapidly absorbed after being ingested, with 80 percent of an oral dose being absorbed after 30 min and complete absorption within 2 h. The substance has a volume of distribution of 0.6 to 0.7 L/kg. Small and clinically insignificant amounts are resecreted by the salivary glands and stomach.

The kidneys excrete 20 to 50 percent of an absorbed dose unchanged. However, the major pathway for the metabolism of isopropanol is in the liver (50 to 80 percent), where it is oxidized to acetone by alcohol dehydrogenase (Figure 166-1). Acetone is excreted primarily by the kidneys, with some excretion through the lungs. However, similar to ETOH but unlike methanol and ethylene glycol, significant acidosis ascribable solely to isopropanol or its metabolites does not occur. A hallmark of isopropanol toxicity is ketonemia and ketonuria, but without elevated blood glucose or glycosuria. This feature (i.e., presence of ketones) helps differentiate isopropanol ingestion from poisoning with ethylene glycol or methanol.

Isopropanol most closely follows concentration-dependent (first-order) kinetics. The half-life of isopropanol in the absence of ethanol is 6 to 7 h, while the half-life of acetone is 22 to 28 h. The long half-life of acetone may be the cause of the prolonged symptomatology often associated with isopropanol poisoning. Ethanol administration has not been used clinically to inhibit isopropanol metabolism to acetone.

The toxic dose of 70 percent isopropanol is approximately 1 mL/kg, with the lethal dose in an adult approximately 2 to 4 mL/kg. As lit-

tie as 0.5 mL/kg may cause symptoms, but survival has been reported following ingestions of up to 1 L. Children are especially susceptible to toxic effects and may develop symptoms with as little as three swallows of 70 percent isopropanol.

Clinical Features

The clinical features of isopropanol intoxication are similar to those seen with ethanol intoxication except that the duration of symptoms and signs is longer and central nervous system depression may be more profound because of the formation of acetone. Onset of symptoms occurs within 30 to 60 min, with peak effects in a few hours. Nystagmus is usually present. Severe poisoning is marked by early onset of coma, respiratory depression, and hypotension.

Massive ingestion may cause hypotension secondary to peripheral vasodilatation, with contributions possible from hemorrhagic gastritis. Serious dysrhythmias are rare.

Hemorrhagic gastritis secondary to gastric irritation appears early and is a striking feature of isopropanol ingestions, resulting in nausea, vomiting, abdominal pain, and upper gastrointestinal hemorrhage.

Hypoglycemia may occur secondary to depressed gluconeogenesis. Less common complications include hepatic dysfunction, acute tubular necrosis, myoglobinuria, hemolytic anemia, rhabdomyolysis, and myopathy.

Isopropanol poisoning should be suspected when the fruity odor of acetone or smell of rubbing alcohol is present on the breath. Patients will have ketonuria and ketonemia without glycosuria or hyperglycemia, in the presence of an elevated osmolar gap. A spurious increase in serum creatinine as a result of acetone may sometimes be seen. Generally there is no abnormal anion gap, although this may be seen as a result of hypotension and related lactic acidosis. The use of alcohol screening panels helps detect unsuspected isopropanolism.

Although isopropanol levels of 50 mg/dL are associated with mild intoxication in individuals who are not habituated to ethanol, alcoholic patients may be considerably more resistant to the central nervous system effects of isopropanol.

Treatment

If there is suspicion of isopropanol poisoning, intravenous access should be established. If indicated, there should be bedside testing for blood glucose, and administration of thiamine and naloxone. Patients should be monitored for central nervous system or respiratory depression. Because of the rapid absorption of isopropanol, there is no utility to performing gastric lavage. Activated charcoal binds isopropanol poorly and is not necessary in the absence of ingestion of adsorbable substances. Laboratory studies are guided by the results of examination and clinical condition. Serum electrolytes, CBC, glucose, and acetone should generally be obtained. Blood type and screen may be appropriate in anticipation of the possibility of significant gastric hemorrhage. In severely obtunded patients, airway management may require intubation and ventilatory support. Hypotension usually responds to intravenous fluids. In severe cases, support with vasopressors may be required. Patients with severe hemorrhagic gastritis may require blood transfusion. If a significant acidosis is present, vigorous investigation for another cause must be made. Hemodialysis is indicated when hypotension is refractory to conventional therapy, results in hemodynamic instability, or when the predicted peak isopropanol level is greater than 400 mg/dL. Hemodialysis is effective in eliminating both isopropanol and acetone. Peritoneal dialysis is less effective than hemodialysis.

Disposition

Patients with lethargy or prolonged central nervous system depression should be admitted to the hospital. Those who remain asymptomatic

FIG. 166-1. Metabolic pathway of isopropanol.

for 6 to 8 h may be discharged or referred for substance abuse counseling or psychiatric evaluation.

METHANOL

Methanol—also referred to as methyl alcohol, wood spirits, or wood alcohol—is used widely in commercial, industrial, and marine solvents. A product of wood distillation, it is a component of many paint removers, varnishes, shellacs, windshield washing fluids, and antifreeze formulations. Methanol poisoning has resulted from the consumption of contaminated whiskey, accidental ingestion by desperate alcoholics, or intentional ingestion during suicide attempts. Methanol is also present in measurable but small amounts in wine and distilled spirits, accounting for the fact that low levels may be detectable in the blood after binge drinking. Methanol's toxicity is due to the formation of two toxic metabolites, formaldehyde and formic acid. Therapeutic strategies are therefore based on prevention of the formation of these metabolites or their removal from the body.

Pathophysiology

Methanol is a colorless, volatile liquid with a distinctive odor. It is well absorbed from the gastrointestinal tract, with peak levels attained 30 to 90 min after ingestion. Most incidents of toxicity occur after oral ingestion, but significant absorption may also occur through the lungs or skin. The serum half-life after mild toxicity is 14 to 20 h. With severe toxicity, this increases to 24 to 30 h. Methanol has a volume of distribution of 0.6 to 0.7 L/kg.

Following ingestion, highest concentrations are found in the kidney, liver, and gastrointestinal tract, but high levels are also found in the vitreous humor and optic nerve. Most methanol—90 to 95 percent—is eliminated by the liver, while renal excretion accounts for 2 to 5 percent; pulmonary excretion is minimal. In overdose situations, elimination follows saturation (zero-order) kinetics.

Toxicity from methanol poisoning results from the metabolism by hepatic alcohol dehydrogenase of methanol to formaldehyde and formic acid (Figure 166-2). The accumulation of formic acid is associated with the onset of clinical symptoms. Lactate is produced from formate-induced inhibition of mitochondrial respiration, as a result of tissue hypoxia, and to a lesser extent as a result of a decrease in the intracellular $NAD^+/NADH$ ratio caused by the oxidation of methanol and thus stimulation of anaerobic glycolysis and lactate production. Formaldehyde production in the retina causes optic papillitis and retinal edema, in severe cases resulting in blindness. Since folate is a cofactor in the breakdown of formic acid to carbon dioxide and water, alcoholics who are folate-deficient may be especially susceptible to methanol toxicity due to increased accumulation of formic acid.

The amount of methanol required to cause toxicity varies; death has been reported after ingestion of a dose as small as 15 mL of a 40 percent solution. Although 30 mL of a 40 percent solution is considered the minimal lethal dose, amounts as large as 500 to 600 mL have been ingested with survival reported.

Clinical Features

The symptoms of methanol poisoning may not appear for up to 12 to 18 h after ingestion because of the time it takes for methanol to be metabolized to its toxic metabolites. The delay in symptoms may be even longer if ethanol has been ingested and is competing with methanol for metabolism by alcohol dehydrogenase. The cardinal clinical manifestations of methanol poisoning are central nervous system depression similar to that of ethanol, visual disturbances, abdominal pain, nausea and vomiting, and wide-anion-gap metabolic acidosis. As with isopropanol, the early phase of elation commonly seen in ethanol intoxication is absent.

On arrival at the hospital, the victim may be confused or, in severe cases, comatose. There may be complaints of headache or vertigo, and seizures may occur. Visual disturbances are seen in approximately 50 percent of patients. These include diplopia, blurred vision, decreased visual acuity, photophobia, descriptions of "looking into a snow field," constricted visual fields, and blindness. The clinician may find nystagmus, fixed and dilated pupils, retinal edema, and optic atrophy or hyperemia of the optic disk. Computed tomography of the brain may reveal basal ganglia infarcts consistent with the parkinsonian syndrome, which has been reported after methanol poisoning. Methanol is a potent mucosal irritant and causes severe abdominal pain as well as nausea and vomiting in over one-half of cases; pancreatitis has also been commonly reported. However, serious ingestions may occur without gastrointestinal symptoms. Although an increased osmolar gap is usually present with serious methanol ingestion, **methanol poisoning with a normal osmolar gap can be seen.** This is due to completed conversion of methanol to its toxic metabolites.

Hypotension and bradycardia are late findings and suggest a poor prognosis. Outcome is best correlated with the severity of the acidosis rather than serum methanol concentration.

Diagnosis of methanol poisoning rests on history, the presence of the characteristic clinical features outlined above, and the presence of a wide-anion-gap metabolic acidosis and osmolar gap. While confirmation of a tentative diagnosis depends on identification of the substance in the bloodstream, treatment should be initiated based on compatible clinical presentation to avoid morbidity resulting from delay. In any case, serum methanol determinations at many institutions depend on outside laboratories and may not be available for several hours. However, if the ethanol level is known, the methanol level can be estimated from the osmolar gap (see Table 166-1).

FIG. 166-2. Metabolism of methanol in the liver.

Normal methanol blood concentration from endogenous sources is 0.05 mg/dL. Asymptomatic individuals usually have peak levels below 20 mg/dL, while levels above 50 mg/dL indicate serious poisoning. Central nervous system symptoms usually appear when levels rise above 20 mg/dL, eye problems are associated with levels greater than 50 mg/dL, and the risk of fatality rises with levels greater than 150 to 200 mg/dL.

The differential diagnosis should include other potential causes of a wide-anion-gap metabolic acidosis—i.e., ethylene glycol, diabetic ketoacidosis, paraldehyde, isoniazid, salicylates, iron, lactic acidosis, phenformin, uremia, carbon monoxide, cyanide, alcoholic ketoacidosis, and toluene.

Treatment

Intravenous access should be established, with immediate bedside testing for blood glucose and administration of thiamine and naloxone if indicated. The general measures involved in treatment are 1) supportive care, 2) correction of acidosis, 3) administration of fomepizole or ethanol to decrease conversion to toxic metabolites, and 4) dialysis to eliminate the methanol. Unless the patient presents immediately after the ingestion, gastric aspiration or lavage is unlikely to be of benefit. Activated charcoal is ineffective in the absence of ingestion of other, adsorbable substances. Serum electrolytes, CBC, glucose, and ethanol level (if there is any possibility of coingestion of this substance), in addition to a methanol level are generally needed as a minimum. Care should be taken to maintain an adequate airway with intubation if necessary for proper airway protection and ventilatory support. Sodium bicarbonate should be administered with the goal of maintaining a near normal pH, since correction of metabolic acidosis moderates some of the toxic effects of methanol poisoning, including visual impairment.

Prevention of metabolism of methanol to its toxic metabolites by competitive inhibition of alcohol dehydrogenase is a mainstay of methanol ingestion management. Ethanol has to a great extent been supplanted by a pharmacologically superior agent, fomepizole (also referred to as 4-methylpyrazole).^{13,14} A competitive inhibitor of alcohol dehydrogenase, fomepizole has an affinity for the enzyme that is 8000 times that of ethanol.¹⁵ In addition, it does not produce central nervous system depression or metabolic toxicity, and it does not require the monitoring of levels and dosage adjustments. Fomepizole is administered in a loading dose of 15 mg/kg, followed by doses of 10 mg/kg every 12 h for four doses. Each dose is given by slow intravenous infusion over 30 min. More frequent dosing (q4h) is required during hemodialysis because fomepizole is removed during the procedure.

Ethanol, the traditional initial treatment of methanol intoxication, competitively inhibits the metabolism of methanol by alcohol dehydrogenase. Ethanol's affinity for the enzyme is 10 to 20 times that of methanol, and its presence largely inhibits the formation of the toxic metabolites. Blood ethanol level should be maintained between 100 and 150 mg/dL to completely inhibit formation of toxic metabolites. Blood concentrations below 100 mg/dL are considerably less effective and therefore increase the risk of severe toxicity. Ethanol may be administered IV, PO, or by nasogastric tube.

Oral administration uses 20 to 30% concentration usually by nasogastric tube. Higher concentrations can lead to gastritis. Also, oral loading presents significant risks should alterations in mental status ensue.

Intravenous administration is preferred, though it may result in superficial thrombophlebitis. The intravenous solution should contain 10 percent ethanol in D5W. If the recommended solution of 10 percent ethanol in D5W is utilized, the loading dose is 10 mL/kg and maintenance is 1.5 mL/kg per h. When intravenous ethanol is not immediately available, oral therapy can be initiated with commercial distilled spirits. To calculate the ethanol content of distilled spirits, the following formula may be used:

$$\text{ethanol (g)} = \text{volume of beverage (mL)} \times 0.9 \times (\text{proof}/200)$$

Ethanol levels should be assayed on a frequent basis, with the dose adjusted to maintain a concentration of 100 to 150 mg/dL. If dialysis is initiated, a higher maintenance infusion starting at 0.24 g/kg per h will be necessary, as ethanol is dialyzable. As hypoglycemia may occur with ethanol administration, especially in children, blood glucose levels should be monitored closely.

Indications for treatment and doses of fomepizole and ethanol are shown in Table 166-2.

Fomepizole should be considered the drug of choice when inhibition of alcohol dehydrogenase is desired. Ethanol is indicated in the presence of known fomepizole allergy or when fomepizole is not readily available. Case reports suggest that fomepizole is safe to use in children, who are especially susceptible to some of the side effects of ethanol.¹⁶ Fomepizole is expensive: the current cost of the loading dose alone is greater than \$1000, compared with just a few dollars for ethanol. Although there is no formal study of the cost effectiveness of fomepizole, it seems likely that much if not all of its cost would be offset by savings in intensive care monitoring, laboratory tests, and nursing manpower. **Use of fomepizole or alcohol does not alter the indications for dialysis.**

Folate is a cofactor for the conversion of formic acid to carbon dioxide. It is especially important to provide supplements to alcoholic patients

TABLE 166-2 Indications and Treatment for Methanol and Ethylene Glycol Poisoning

Agent	Indications for Treatment	Treatment
Methanol	Methanol >20 mg/dL	Ethanol
	Ingestion \geq 0.4 mg/kg History, symptoms suggestive of poisoning	Loading dose: 10% ethanol in D5W at 10 mL/kg over 30 min* Infusion: 10% ethanol in D5W at 1.5 mL/kg per h to maintain ethanol level at 100–150 mg/dL [†] or Fomepizole 15 mg/kg over 30 min, then 10 mg/kg q12h \times 4 doses and Folinic acid 1 mg/kg IV (max 50 mg) q4h NaHCO ₃ 1 mEq/kg IV for severe acidosis
Ethylene glycol (EG)	EG >20 mg/dL	Ethanol
	Suspicion of ingestion Suspicion and anion gap acidosis	Loading dose: 10% ethanol in D5W at 10 mL/kg over 30 min* Infusion: 10% ethanol in D5W at 1.5 mL/kg per h to maintain ethanol level at 100–150 mg/dL [†] or Fomepizole 15 mg/kg over 30 min, then 10 mg/kg q12h [‡] \times 4 doses and Thiamine 100 mg IV Pyridoxine 100 mg IV 10% Calcium gluconate 10 mL IV for hypocalcemia NaHCO ₃ 1 mEq/kg IV for severe acidosis

*A 100-kg person will require 1 L of fluid.

[†]If ethanol <100 mg/dL, reload using following formula: Desired ETOH concentration in mg/dL—actual concentration in mg/dL \times 0.6 L/kg \times kg.

[‡]During dialysis dosage must be altered. Consult hospital pharmacist or poison control center.

who may be folate deficient. Administration of folic acid 50 mg IV every 4 h for several days to all patients is recommended.

Indications for dialysis are shown in Table 166-3. These indications are the same for patients treated with fomepizole. Hemodialysis is considerably more effective than peritoneal dialysis, but peritoneal dialysis may be utilized if hemodialysis is unavailable. Dialysis eliminates both the parent compound and its toxic metabolites. Dialysis and fomepizole or ethanol are continued until levels are zero and acidosis has resolved.

Disposition

Disposition decisions are based on criteria identical to those used for ethylene glycol poisoning (see below). It should be emphasized that **asymptomatic patients with a history of any possible methanol ingestion should be admitted** and treatment initiated, even if no acidosis is evident.

ETHYLENE GLYCOL

Ethylene glycol has many commercial uses as a coolant (antifreeze), preservative, and glycerine substitute; it has also been used in lacquers, cosmetics, polishes, and detergents. It accounted for 4938 poison exposures and 16 deaths in the United States as reported to poison control centers in 2001.¹⁷ It may be ingested as an alcohol substitute by alcoholics, in suicide attempts, and accidentally by children. Ethylene glycol's toxicity is the result of the formation of two toxic metabolites, formaldehyde and formic acid. As with methanol, therapeutic strategies are based on prevention of formation of these metabolites or their removal from the body.

Pathophysiology

Ethylene glycol is a colorless, odorless, sweet-tasting substance. It is highly water-soluble and rapidly absorbed when ingested orally, but not when exposure is via the lungs or skin. Peak blood levels occur within 1 to 4 h of an ingestion. The volume of distribution is 0.83 L/kg and the plasma half-life is 3 to 5 h. Ethylene glycol is metabolized in the liver and kidneys to toxic metabolites—aldehydes, glycolate, oxalate, and lactate—which in turn cause toxicity to the lungs, heart, and kidneys. These metabolites also cause the metabolic acidosis associated with ethylene glycol poisoning.

Ethylene glycol is metabolized to glycoaldehyde by alcohol dehydrogenase (Figure 166-3). This conversion involves the reduction of NAD^+ to NADH, which causes inhibition of the citric acid cycle and formation of lactic acid. Glycoaldehyde is further metabolized to glycolic acid and to glyoxylic acid, which in turn are converted to several new compounds. Pyridoxal phosphate is a cofactor in the conversion of glyoxylic acid to glycine, which is nontoxic, while thiamine pyrophosphate is the cofactor in the conversion of glyoxylic acid to another nontoxic compound called α -hydroxy-p-ketoadipate. A deficiency of either pyridoxal phosphate or thiamine may shift the metabolism of ethylene glycol to the production of toxic metabolites.

Glyoxylic acid is also metabolized to formic acid and oxalic acid. Glycolic acid contributes to the metabolic acidosis observed in ethylene glycol poisoning. Oxalate crystalluria is a striking feature caused by calcium oxalate salt deposition, but occurs in the urine in only about 50 percent of cases.

The potentially lethal dose in adults is 2 mL/kg, although survival has been reported after ingestions ranging from 240 to 2000 mL.

TABLE 166-3 Indications for Dialysis with Methanol Poisoning

Signs of visual or central nervous system dysfunction
Peak methanol levels >20 mg/dL
pH <7.15
History of ingesting >30 mL

FIG. 166-3. Metabolic pathway of ethylene glycol.

Clinical Features

Ethylene glycol poisoning often exhibits three distinct clinical phases, the severity and progression of which depends on the amount ingested. The initial phase is characterized by central nervous system depression, usually within 1 to 12 h after ingestion. Patients may appear inebriated, with slurred speech and ataxia but without the odor of ethanol on their breath. Hallucinations, coma, seizures, and death may also occur during this initial phase. These central nervous system symptoms correlate with peak glycoaldehyde production. The optic fundus is usually normal, differentiating the syndrome from methanol poisoning, although nystagmus and ophthalmoplegia may be observed. Lumbar puncture may demonstrate elevated CSF pressure and protein and a few polymorphonuclear cells.

The second, cardiopulmonary phase develops 12 to 24 h after ingestion. Tachycardia, mild hypertension, and tachypnea are the most common symptoms; congestive heart failure, acute respiratory distress syndrome, cardiomegaly, and circulatory collapse are also observed. Myositis has also been reported less commonly during this phase.

The third phase, marked by nephrotoxicity, occurs 24 to 72 h after ingestion. Early symptoms consist of flank pain and costovertebral angle tenderness. Oliguric renal failure and acute tubular necrosis ensue. Complete anuria may occur, but most patients recover without renal damage if they receive appropriate therapy. Nephrotoxicity is caused by aldehyde metabolites and oxalic acid. Two forms of urinary calcium oxalate crystals may be identified on microscopic evaluation of the urine. The dihydrate form (octahedral crystals) shows tent-shaped crystals, and the monohydrate form (monoclinic crystals) shows crystals that are dumbbell- or prism-shaped. The monohydrate form was at one time felt to represent a salt of hippurate, explaining previous reports of hippurate crystals in the urine.

Hypocalcemia may develop secondary to precipitation of calcium as calcium oxalate and may be severe enough to cause tetany and prolongation of the QT interval. Elevated serum creatine phosphokinase levels may accompany and explain the generalized myalgias experienced by some patients.

Ethylene glycol intoxication should be considered when a patient presents with inebriation and no ethanol scent on the breath, a wide-anion-gap metabolic acidosis with osmolar gap, and calcium oxalate crystalluria. The mechanisms of anion-gap metabolic acidosis and osmolar gap are similar to those observed with methanol.

Tentative diagnosis and initiation of treatment should be based on history and characteristic clinical presentation. As with methanol poisoning, confirmation of a tentative diagnosis depends on identification of the substance in the bloodstream, but treatment should be initiated

based on compatible clinical presentation to avoid morbidity resulting from delay. Serum levels greater than 20 mg/dL are likely to result in toxicity. Survival has been reported with levels up to 650 mg/dL, while fatality has been associated with levels >98 mg/dL.

Leukocytosis is common and should not be considered a manifestation of infection unless clinical signs are present. One-third of patients may have hypocalcemia, with shortening of the QT interval present on the electrocardiogram. Serious intoxication has been reported in the absence of an osmolar gap or calcium oxalate crystalluria. The mechanism for the absence of an osmolar gap is based on the same explanation as given for methanol (above).

As with methanol, the differential diagnosis should include other potential causes of a wide-anion-gap metabolic acidosis.

Treatment

The management of ethylene glycol poisoning is similar to that of methanol poisoning. Indications for gastric emptying and guidelines for administration of sodium bicarbonate are the same as those given for methanol, above. If the patient is hypocalcemic, 10 mL of calcium gluconate 10 percent should be given IV. Pyridoxine 100 mg and thiamine 100 mg IM or IV should be administered daily to facilitate metabolism of ethylene glycol by nontoxic pathways. Magnesium has also been shown to be a cofactor in the metabolism of toxic metabolites and should be given if patients are hypomagnesemic, as is often the case with alcoholics.

Laboratory tests that may be useful in evaluating patients suspected of ethylene glycol ingestion include complete blood count; serum electrolytes; acetone; alcohol toxicology panel with ethanol, isopropanol, and methanol determinations; electrolytes; blood urea nitrogen; creatinine; salicylate level; arterial blood gases; urinalysis; serum ethylene glycol level; calcium; creatine phosphokinase (CPK); and magnesium levels. Lactate levels should also be determined if the reason for the severe acidosis is unclear.

Competitive inhibition of alcohol dehydrogenase's breakdown of ethylene glycol with fomepizole or ethanol should be initiated in the ED when overdose is suspected or confirmed. Fomepizole (see above) has supplanted ethanol as the initial treatment of choice.¹⁸ Dosing is the same for ethylene glycol as for methanol. Ethanol's affinity for alcohol dehydrogenase is 100 times that of ethylene glycol, resulting in a prolongation of the half-life of ethylene glycol to 17 h. Indications for treatment and doses of fomepizole or ethanol are shown in Table 166-2.

Oral and intravenous dosing guidelines for ethanol are identical to those outlined for methanol, above. Due to ease of administration, greater affinity for alcohol dehydrogenase, and a superior side-effect profile, fomepizole is the drug of choice unless it is not readily available or there is a history of allergy to fomepizole. Fomepizole has been well tolerated by children in case reports,¹⁹ though the overall magnitude of clinical experience is considerably less than for adults.

Indications for dialysis are shown in Table 166-4. Although there are reports of patients with normal renal function who met other standard criteria for hemodialysis who were treated effectively and safely with fomepizole alone,¹⁵ we feel that use of the agent should not change the indications for hemodialysis. As for methanol, fomepizole or ethanol administration and dialysis should be continued until serum blood levels of whichever substance has been ingested are zero and acidosis has resolved.

As with methanol, hemodialysis has been shown to be considerably more effective, but peritoneal dialysis may be used if hemodialysis is unavailable.

Disposition

Any patient with the serious signs and symptoms associated with ethylene glycol or methanol intoxication, or a history of significant ingestion even in absence of symptoms, should be admitted to an intensive care setting. Suicidal patients should receive a psychiatric evaluation when their condition improves and prior to discharge from any facility.

Patients seen at facilities unable to provide hemodialysis or intensive care should be transferred if sufficiently stable as soon as possible to institutions capable of providing such care. Because the symptoms of ethylene glycol and methanol intoxication may be delayed, patients who have ingested these substances should be admitted to the hospital for observation and laboratory testing even if they are initially asymptomatic.

OPIOIDS Suzanne Doyon

Opioids refer to all agonist, antagonist, endogenous, and exogenous substances that possess morphine-like activity. In the United States, the most commonly abused opioids are heroin and methadone. In 2001, heroin-related visits occurred in 0.1 percent of all ED encounters and in 13 percent to 14 percent of ED encounters involving substances of abuse in the United States. That same year, mentions of prescription opioid analgesics, including methadone, also constituted 0.1 percent of all ED encounters. ED mentions of hydrocodone (Vicodin) and oxycodone (Percocet, OxyContin) have almost doubled since 1999, while mentions of codeine have significantly decreased.¹

PHARMACOLOGY

Opioids modulate nociception in the terminals of afferent nerves in the central nervous system (CNS) and peripheral nervous system (PNS) and the gastrointestinal tract. They are agonists at the μ , κ , and δ receptors in these tissues. Importantly, the International Union of Pharmacology has adopted a new nomenclature for opioid receptors. The μ is now called OP3, κ , OP2, and δ , OP1, reflecting the chronologic order of discovery. Although there are similarities between these receptor types, such as linkage to a G-protein, they vary largely and are considered nonuniform. Furthermore, individual receptors have specific and different distribution throughout the CNS and PNS.² The orphanin, sigma, and epsilon receptors are no longer considered opioid receptors because they lack sensitivity to naloxone or are not found in humans.³

Importantly, binding of a drug to a receptor is not limited to one receptor type. Specificity and affinity of a drug for opioid receptors is variable. For example, tramadol possesses 1/6000 the affinity of morphine at the OP3 receptor site.

Stimulation of the OP3 receptors, further subdivided into subtypes a and b, results in analgesia, respiratory depression, cough suppression, and, occasionally, euphoria.³ For example, most of the analgesic effect of morphine is mediated via OP3a stimulation. All currently available opioids have some activity at the OP3b receptor and result in

some degree of respiratory compromise. Stimulation of OP2 receptors results in spinal analgesia, miosis, and diuresis. The clinical role of OP1 receptors is largely unknown.³

Interestingly, there is a lot of interplay between opioid receptors and other receptors. For example, iV-methyl-D-aspartate (NMDA) receptor blockade enhances the analgesic effect of morphine. Another example of receptor interplay is the localized release of dopamine in the mesolimbic pathway (often referred to as the "pleasure pathway") common to almost all OP3 and OP1 opioids. The end result is a variable feeling of euphoria. Heroin and fentanyl, two exquisitely lipophilic opioids that have high affinity for the OP3 and OP1 receptors, are euphoria-inducing. A third example of receptor interplay is the induction of mast cell histamine release by morphine and meperidine.³

PHARMACOKINETICS

A detailed discussion of the absorption, distribution, and elimination of opioids is beyond the scope of this chapter. However, knowledge of duration of action and elimination half-life is useful and is provided in Table 167-1. Most opioids are more effective given parenterally than orally. This phenomenon is due to variable but significant first pass effect. Opioids with good oral potency are codeine, oxycodone, levorphanol, and methadone. The metabolism of codeine, morphine, propoxyphene, oxycodone, meperidine, and methadone is mostly hepatic. The hepatic metabolites may be pharmacologically active. Concurrent use or abuse of benzodiazepines, barbiturates, and alcohol is common. Coingestants, like antiretroviral agents, can inhibit the hepatic metabolism, especially the metabolism of methadone. Further discussion of opioid pharmacology is found in Chaps. 36 and 38.

CLINICAL FEATURES

The opioid intoxication toxidrome encompasses a wide variety of signs and symptoms. Opioids cause respiratory depression, mental status changes, analgesia, miosis, orthostatic hypotension, nausea and vomiting (especially if opioid-naïve), histamine release resulting in localized urticaria and bronchospasm, decreased gastrointestinal (GI) motility, and urinary retention secondary to increased vesical sphincter tone. The depression of the mental status can be variable but may be extremely profound. The respiratory depression may also be variable. One should look for shallow respirations, cyanosis, bradypnea, hypercarbia, and hypoxia. Miosis is not universally present. In fact, normal or even enlarged pupils have been documented secondary to exposure to meperidine, morphine, propoxyphene, pentazocine, and diphenoxylate. Mydriasis can also result from coingestants or may signal severe cerebral hypoxia.

TABLE 167-1 Classification and Characteristics of Major Opioid Agonists

	Analgesic Dose Equivalent to 10 mg of Morphine (mg)	Analgesic Duration of Action (h)	Elimination Half-Life (h)
Natural			
Codeine	120	4-5	2.2-3.6
Morphine	10	4-5	1.4-2.4
Semisynthetic			
Heroin	5	4-5	0.5
Hydromorphone (Dilaudid)	1.3	4-5	2-3
Oxycodone (Percodan, OxyContin)	10	4-5	—
Oxymorphone (Numorphan)	1	4-6	2-3
Hydrocodone (Vicodin)	10	4-6	3.5-4.5
Synthetic			
Diphenoxylate (Lomotil)	2.5	—	—
Fentanyl (Sublimaze)	0.125	1	1.5-6.0
Meperidine (Demerol)	75	2-4	2.4-4.0
Methadone (Dolophine)	65	4-5	24-48
Propoxyphene (Darvon)	240	4-6	6-12

DIAGNOSIS

The diagnoses of opioid overdose or withdrawal remain clinical. The classic triad of coma, miosis, and respiratory depression strongly suggests opioid intoxication, chronic or acute. Studies attempted to determine clinical criteria predictive of the presence of opioid overdose. The criteria of respirations ≥ 12 breaths/min, presence of miosis, and circumstantial evidence of opioid use (drug paraphernalia, needle marks, presence of a tourniquet, bystander corroboration) were highly sensitive in predicting response to naloxone (92 percent), hence establishing the diagnosis of exposure to opioids.⁴ Unfortunately, in this study, only a respiratory rate was used as a measure of respiratory depression, not an assessment of depth or quality of respirations, nor a pulse oximetry or blood gas measurement. A detailed review suggests examination of the urine for opioids may aid in the diagnosis of opioid intoxication but the results have a high false negative rate and are not immediately available to the clinician.⁴

The diagnosis of opioid withdrawal is established when a constellation of withdrawal symptoms are temporally related to the abrupt cessation of a licit or illicit opioid, or both.

Differential Diagnosis

The differential diagnosis of opioid overdose includes the effects of other agents such as clonidine, organophosphates and carbamates, phenothiazines, sedative-hypnotic agents, and carbon monoxide. Clonidine overdoses are characterized by periods of apnea that respond to tactile or auditory stimulation. Organophosphate and carbamate overdoses cause muscle fasciculations, profuse vomiting and diarrhea, and sweating. Phenothiazines cause CNS depression and miosis from decreased adrenergic tone. Olanzapine and risperidone overdoses are associated with profound CNS depression and miosis. 7-Hydroxybutyrate is also associated with profound CNS depression, bradypnea, and, occasionally, miosis. Sedative-hypnotic agent and carbon monoxide cause profound CNS depression but are not usually associated with miosis. Hypoglycemia, hypoxia, CNS infections, postictal states, and pontine hemorrhages should also be considered in the differential diagnosis.

The differential diagnosis of withdrawal includes drugs and toxins that promote an adrenergic state, other drug withdrawals, and other conditions such as hyperthyroidism. Most patients will volunteer the diagnosis of opiate withdrawal in their history.

TREATMENT

Proper airway management is crucial to proper treatment of opioid-intoxicated individuals. Bag-valve-mask support may be needed initially to help maintain adequate oxygenation. It may be followed by the administration of naloxone, endotracheal intubation, or both.

Naloxone was introduced in 1976. It is a pure antagonist at all OP receptors, with particular affinity for the OP3 receptor. Naloxone competitively binds to the OP receptors preventing the binding of any other agonist, partial agonist, or mixed agonist-antagonist, but without producing any effect, positive or negative, on the receptor proper. Naloxone can fully reverse the opioid-induced respiratory depression, mental status changes, miosis, and analgesia. Administration of naloxone to opioid-naïve individuals results in little or no effect, even when large, supratherapeutic doses are used. Opioid antagonists, such as naloxone and the longer-acting naltrexone, have been studied in the treatment of acute spinal cord injury, cocaine and ethanol dependence, acute overdoses of ethanol, clonidine, and valproic acid with mixed results.

Naloxone can be administered intravenously, intratracheally, intramuscularly, subcutaneously, intralingually, and occasionally, in the erectile tissue of the penis. The intravenous route is preferred. Onset of action after intravenous injection is extremely rapid, in the order of

1 to 2 min. The duration of action of naloxone is 20 to 60 min, shorter than that of most opioids. Its elimination half-life is 60 to 90 min.

The reversal effects of a dose of naloxone is variable and is largely dependent on the dose of opioid. A very small dose, for example 0.05 mg IV, is recommended in an opioid-dependent individual who presents with CNS depression but with minimal respiratory depression. Naloxone 0.4 mg IV is recommended in the non-opioid-dependent individual who presents with CNS depression but with minimal respiratory depression. This dose, however, may induce withdrawal in the opioid-dependent individual. Escalating doses (titration) of naloxone 0.05 to 0.4 mg IV can be administered until desired effect. Incremental dosing of naloxone will avoid the acute precipitation of opioid withdrawal. A full 2.0 mg IV should be administered to the patient presenting with significant respiratory depression, regardless of drug use history. In the latter cases, repeated doses of 2 mg IV every 3 min are recommended, until a maximum of 10 mg IV has been reached or respiratory depression is reversed. Exposures to propoxyphene, fentanyl, pentazocine, or dextromethorphan, and sustained-release preparation of oxycodone may require these larger-than-ordinary doses.

Recent literature recommends the same dose ranges in the pediatric patient. However, there is one exception to this recommendation, naloxone 0.01 mg/kg IV is still recommended to treat CNS and respiratory depression in the neonate in the immediate postpartum period.⁵

The therapeutic dose of naloxone varies somewhat from the diagnostic dose. Reversal of opioid toxicity with naloxone will last 20 to 60 min. Repeated intravenous boluses or naloxone infusions are occasionally required in order to support respirations. This is especially true for long-acting opioids such as propoxyphene, methadone, or Levo-alpha-acetylmethadol (LAAM), or for sustained-release preparations. A continuous infusion should only be considered if the patient has responded to the naloxone bolus and requires multiple subsequent boluses. To calculate the infusion rate and dose, the initial bolus dose that was successful in reversing the respiratory depression, i.e., the "wake-up dose," is determined. Administer two-thirds of the wake-up dose per hour by intravenous infusion. For example, two-thirds of a 1-mg dose is approximately 0.6 mg. Multiplying that dose by a factor of 10 equals 6 mg. Mix 6 mg of naloxone in 1 L of D5W and run at 100 mL/h. Adjustments in infusion rates may be required if the patient develops respiratory depression (rebolus and increase infusion rates) or withdrawal symptoms (decrease infusion rates). It is recommended that patients maintained on naloxone infusions be admitted to a monitored unit.⁵

Naloxone has a remarkably safe profile. The most common adverse effects associated with naloxone (anxiety, nausea, vomiting, diarrhea, abdominal cramps, piloerection, yawning, and rhinorrhea) are related to the precipitation of the opioid withdrawal syndrome. Again, the precipitation of opioid withdrawal can be minimized by careful naloxone dosing.^{5,8}

Endotracheal intubation is a therapeutic option in some cases of opioid overdoses with severe respiratory depression unresponsive to naloxone, where adequate ventilation cannot be achieved by bag-valve-mask.⁹ Endotracheal intubation offers the advantage of protecting the airway, easy access for suctioning, alternate route of administration for naloxone, and total airway control. Rapid sequence intubation, omitting the administration of anesthetic/ sedative agents, is the preferred technique. In experienced hands, endotracheal intubation is not associated with many complications.

For ingested opioids, gastric decontamination may be worthwhile. Syrup of ipecac and gastric lavage are not recommended because of the potential risk of aspiration of stomach contents in patients with altered mental status. Activated charcoal should be administered if large amounts of opioids have been ingested with 1 h of presentation to the ED. This time frame can be extended under special circumstances. Fifty grams of activated charcoal PO, followed by a cathartic such as sorbitol 0.5 to 1.0 g PO are standard doses. Delayed and multiple

doses of activated charcoal may be useful in diphenoxylate hydrochloride-atropine sulfate (Lomotil) overdoses and in cases of large ingestions of sustained-release preparations.

An acetaminophen level should be obtained in cases of propoxyphene, oxycodone, hydrocodone, tramadol, and codeine overdose, as well as any intentional suicidal ingestion.

The optimal observation period after an opioid intoxication has not been defined for most opioids. Although some authors report a 0 percent incidence of recurrence of toxicity, a more recent, larger, and better-designed study including exposures to a multitude of different opioids reported a 30 percent incidence of recurrence of toxicity.¹⁰ Therefore, an observation period of 4 to 6 h in the ED is recommended for most cases of opioid intoxication. Except in certain cases illustrated below, it is acceptable to discharge the opioid-intoxicated patient after this reasonable period of observation, especially if the patient has demonstrated complete resolution of all symptoms and signs. The moderate to severely intoxicated patient with an exposure to a long-acting opioid like propoxyphene, methadone, or LAAM, or after an ingestion of a sustained release preparations usually requires a 24- to 48-h hospital admission.⁸ A psychiatric evaluation is needed for all exposures with suicidal intent.

SPECIAL CONSIDERATIONS

Meperidine

Meperidine and its metabolite, normeperidine, are proconvulsive agents. Normeperidine is reported to have twice the convulsant activity of meperidine. This explains why meperidine overdoses may cause seizures in the absence of hypoxia.⁸ Normeperidine is largely renally excreted and will accumulate in cases where renal function is diminished: chronic renal failure, cancer, elderly, and sickle cell patients. Orally administered meperidine is more likely to lead to an accumulation of the toxic metabolite than is parenterally administered meperidine because of a large first-pass effect. Therefore, patients with underlying renal dysfunction who receive oral meperidine, especially repeated doses, are at increased risk of developing toxic seizures. Seizures are quite variable in pattern, from multifocal myoclonus to generalized tonic-clonic seizures. Patients with meperidine-induced seizures are observed for 24 to 48 h in the hospital and should receive a full seizure diagnostic evaluation. Seizures are best treated with small amounts of benzodiazepines only and avoidance of meperidine.

Serotonin Syndrome

The combination of meperidine or dextromethorphan with monoamine oxidase inhibitors (MAOIs) can result in an increase in the amount of serotonin in the neuronal terminals in the CNS. The serotonin syndrome is characterized by disorientation, severe hyperthermia, hypo-/hypertension, and muscle rigidity. Deaths have been reported. Treatment involves the administration of benzodiazepines, aggressive cooling methods, and the avoidance of naloxone.

Propoxyphene

Propoxyphene and its metabolite, norpropoxyphene, are cardiotoxic and neurotoxic. Propoxyphene overdoses have been associated with intraventricular conduction disturbances, heart block, prolonged QT interval, and ventricular bigeminy. Both propoxyphene and norpropoxyphene block fast sodium channels in myocardial tissue. Seizures have also been documented secondary to propoxyphene overdoses. Naloxone cannot reverse either of these independently occurring effects. For propoxyphene overdose, place the patient on a cardiac monitor. If, after 6 h, the patient is asymptomatic and the electrocardiogram (ECG) is normal, the patient can be referred to psychiatry or

discharged. Symptomatic patients or those with an abnormal ECG should be admitted and monitored for 24 to 48 h. The administration of sodium bicarbonate, 1 mEq/kg IV, may reverse the cardiotoxic effects of propoxyphene, by overcoming the sodium channel blockade and restoring sodium channel function.

Mixed Agonist-Antagonists

The mixed agonist-antagonists include pentazocine (Talwin), butorphanol (Stadol), and nalbuphine (Nubain). These agents have variable but mostly antagonist activity at the OP3 receptor. They may cause significant naloxone-responsive respiratory depression in overdose. Mixed agonists-antagonists usually precipitate withdrawal when taken in excess by an opioid-dependent individual, hence reducing the potential for abuse.

Diphenoxylate Hydrochloride-Atropine Sulfate (Lomotil)

Diphenoxylate hydrochloride-atropine sulfate is a frequently prescribed antidiarrheal agent. The medication is manufactured in a pill form containing a combination of diphenoxylate hydrochloride 2.5 mg and atropine sulfate 0.025 mg (Lomotil). It is a schedule IV drug. Initially, an anticholinergic toxidrome dominates the clinical picture, with flushing, tachycardia, hyperthermia, hallucinations, dry mucous membranes, and urinary retention. These signs and symptoms regress as the patient enters the second phase of intoxication, which is characterized by a predominantly opioid-like picture caused by the effects of diphenoxylate hydrochloride. There are two important caveats to remember when treating a patient intoxicated with this mixed ingestion. First, children younger than 6 years of age can be particularly sensitive to diphenoxylate hydrochloride. Second, absorption can be delayed up to 6 to 12 h in some cases. Current recommendations are that all children younger than age 6 years be admitted to the hospital and closely observed for 24 h because signs of respiratory depression may be delayed and severe. Multiple-dose activated charcoal is recommended in all cases of moderate to severe Lomotil intoxication. Adults appear to be somewhat resistant to the toxic effects of Lomotil but should still be observed in the ED for 6 h.

Tramadol

Tramadol (Ultram, Ultracet) overdoses are associated with agitation, hypertension, respiratory depression, seizures, and death, especially at doses exceeding 500 mg orally in an adult. Treatment remains supportive. Naloxone is ineffective in reversing seizures. Withdrawal to tramadol is expected in long-term tolerant individuals. It is treated the same way as other opioid-withdrawal syndromes.

Oxycodone

Oxycodone has become a very popular street drug of abuse. Sustained-release oxycodone preparations (OxyContin) are readily available in the United States. Large overdoses have resulted in life-threatening toxicity and death.⁸ Crushing the tablet will destroy the drug-delivery mechanism and make the drug immediately available. Ingestion, insufflation, or injection of crushed oxycodone is common and is associated with a large number of deaths in the United States. Large OxyContin overdoses may be resistant to even large doses of naloxone.⁸

Acute Lung Injury

Special mention must be made of opioid-induced acute lung injury (previously known as noncardiogenic pulmonary edema), a rare complication associated with toxicity from some drugs, including opioids. Acute lung injury can occur immediately or be delayed up to 24 h following heroin or methadone abuse and should be suspected in any

patient who develops tachypnea, rales, or decreased oxygen saturation with a normal cardiac silhouette on x-ray. An older study reported a 48 percent incidence among heroin abusers.¹⁰ However, street heroin in the United States was less potent (i.e., lower concentration) at the time of the study than currently, and adulterants may have played a role in pulmonary toxicity. The pathophysiology is poorly understood, but some degree of direct capillary injury is present. Treatment includes positive oxygenation, intubation, and use of end-expiratory pressure. Monitoring with Swan-Ganz catheterization is recommended. Naloxone, diuretics, and digoxin are usually not indicated.

Mixed Drugs

The administration of naloxone as an antidote for heroin-cocaine (Speedball) and heroin-scopolamine (Polo, Homicide, Sting, etc.) mixtures may "unmask" the underlying cocaine or scopolamine intoxication. Cocaine has a relatively short duration of action but the same is not true of scopolamine. Unmasked scopolamine overdoses often require control with benzodiazepines. Physostigmine can be given to reverse scopolamine toxicity, but should only be given by experienced physicians familiar with the use of this antidote.¹¹

Body Stuffers/Packers

Retained drug packets pose special challenges to the clinician. Current literature supports the use of a polyethylene glycol solution (GoLYTELY) administered by nasogastric tube at a rate of 2 L/h in adult patients, until the rectal effluent is clear. Multiple dose activated charcoal is also recommended. Large doses of naloxone may be required to reverse the respiratory depression associated with the leakage or breakage of the packets.

Contaminants

Intravenous heroin continues to contain many adulterants, including strychnine, quinine, lactose, and talc. The actual role of many adulterants in the etiology of medical illnesses attributable to intravenous drug usage remains largely unknown. An exception to this statement must be made in the case of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). A meperidine analog was synthesized in the 1980s that contained a contaminant called MPTP. When used IV, it caused a severe form of movement disorder similar to Parkinson disease. MPTP is metabolized by monoamine oxidase B in the substantia nigra to mercaptopyrazidepyrimidine (MPP), which is directly neurotoxic.¹²

Medical Complications

Chap. 306 discusses Medical complications from intravenous drug use.

OPIOID WITHDRAWAL

Downregulation of endogenous endorphins, dynorphins, and opioid receptors occurs from chronic usage. Abrupt cessation of opioid use does not allow time for upregulation of receptors and results in increased neuronal firing and withdrawal.

Opioid withdrawal usually starts with feelings of anxiety, insomnia, yawning, lacrimation, diaphoresis, rhinorrhea, and diffuse myalgias. It then progresses to piloerection, mydriasis, nausea, profuse vomiting, diarrhea, and abdominal cramping. Opioid withdrawal reactions are very uncomfortable but are not of themselves life-threatening. Vomiting and aspiration of gastric contents can cause pneumonitis and vomiting and diarrhea can cause dehydration and electrolyte disturbances. Onset of withdrawal is usually within 12 h of last heroin usage and within 30 h of last methadone exposure. It can

be precipitated by the administration of antagonists such as naloxone or the longer-acting naltrexone or the administration of partial agonists such as buprenorphine. Symptoms of opioid withdrawal can be rendered more tolerable by the administration of the central α_2 -agonist clonidine, antiemetics, and antidiarrheal agents. Clonidine may be used at a dose of 5 μ g/kg PO if the blood pressure is above 90 mm Hg systolic.

The management of opioid-dependent individuals hospitalized for medical or surgical reasons remains controversial. It is generally agreed upon that detoxification from opioids during the acute course of a medical illness is usually unsuccessful. Alleviation of withdrawal symptoms should be the goal of therapy. Daily administration of a verified dose of methadone PO (or half the verified dose IM if the patient's status is NPO) is recommended to inhibit withdrawal symptoms and reduce craving. This applies only to individuals who are actively enrolled in a methadone maintenance program and in whom the dose can be verified. The habitual user who is not on methadone maintenance therapy can receive methadone 20 mg PO or 10 mg IM. These dosages should inhibit withdrawal symptoms but not induce euphoria. **No methadone should be administered to the habitual user until the appearance of withdrawal symptoms.** Buprenorphine (Buprenex) is a partial agonist that is, in its parenteral form, Food and Drug Administration approved for the treatment of pain. Suprenorphine (Suboxone) in its oral form is approved for the treatment of opioid detoxification and for opioid maintenance. It is not currently approved for the treatment of opioid withdrawal. However, some authors have demonstrated that buprenorphine 0.3 to 1.2 mg IV or IM every 6 h can safely be administered to medically ill opioid-dependent patients experiencing withdrawal.¹³ The practice of administering buprenorphine before discharging a patient, or in an outpatient nondrug treatment setting, is strongly discouraged. If buprenorphine is administered before the onset of objective signs of withdrawal, it will precipitate withdrawal in the opioid-dependent individual who recently used an opioid.

COCAINE, AMPHETAMINES, CAFFEINE, AND NICOTINE

Jeanmarie Perrone Robert S.
Hoffman

COCAINE AND AMPHETAMINES

The life-threatening nature of cocaine toxicity is common knowledge as a result of the many reports of actors, musicians, and athletes who have died from the drug. These drugs produce toxicity by activating the sympathetic nervous system. Although cocaine abuse is the most commonly reported cause of serious stimulant toxicity, amphetamines and other substances that resemble cocaine also produce unique toxic complications. The regional prevalence of each of these drugs of abuse may help the clinician discern which agent is present in a patient with sympathomimetic findings.

Epidemiology

Cocaine abuse is a major problem in the United States, especially in urban areas, although any assessment of prevalence is limited. The 2000 National Household Survey on Drug Abuse reported that 1.2 million Americans were current cocaine users.¹ This represents 0.5 percent of the population aged 12 years and older. The estimated number of persons using crack cocaine in the year 2000 was 265,000.² Cocaine use is highest among young persons aged 18 to 25 years and appears to be increasing in this age group. In 1998, it was estimated that there are more than half a million new cocaine users each year.² ED visits by cocaine-abusing patients have tripled since 1988. Fatal injuries (homicides, suicides, falls, and overdoses) following cocaine use are a leading cause of death among young adults in New York City, and probably in many other urban environments as well.³ A 3-year study demonstrated cocaine metabolites in 26 percent, and free cocaine in 18 percent, of all patients with fatal injuries. Methamphetamine use is reported as a frequent cause of drug-related ED visits in the western United States, and its use is increasing in other regions.

Cocaine

Cocaine is the naturally occurring alkaloidal extract of *Erythroxylum coca*, a plant indigenous to South America. The water-soluble hydrochloride salt is absorbed across all mucosal surfaces, including the oral, nasal, gastrointestinal, and vaginal epithelium; thus cocaine can be applied topically, swallowed, or injected intravenously. Although the hydrochloride form is most often insufflated (snorted) or injected intravenously, ether extraction yields crack cocaine, a form that is stable to pyrolysis and can be smoked, producing the popping sound that characterizes its name. The onset and duration of action vary with the route of administration. When cocaine is insufflated nasally, the peak effect occurs within 30 min and the duration of effect is 1 to 3 h. The delayed and prolonged effect is a result of vasoconstrictive properties that limit mucosal absorption. A portion of insufflated cocaine is swallowed and thus absorbed from the stomach as well. Gastrointestinal absorption is also delayed by vasoconstriction, producing a peak effect at 90 min and a duration of effect as long as 3 h. Both the intravenous and the inhalational routes produce a rapid peak effect (within 30 s to 2 min), with a duration of effect of 15 to 30 min. This rapidly intense onset but brief duration of drug effect is theorized to explain why more crime and increased risk of human immunodeficiency virus (HIV) infection is associated with this highly addictive drug; more frequent use is required to maintain the "high." Each use increases the risk. Cocaine is primarily metabolized to ecgonine methyl ester by plasma cholinesterase. Relative deficiency of this enzyme may predispose affected patients to life-threatening toxicity.⁴ Benzoyllecgonine is the other major metabolite excreted in the urine and is the one routinely tested by most urine toxicology screens.

Cocaine is both a local anesthetic and a central nervous system (CNS) stimulant. Like other local anesthetics, cocaine inhibits conduction of nerve impulses by blocking fast sodium channels in the cell membrane. Cocaine also has quinidine-like effects on conduction causing QRS widening and QT_c prolongation. Thus, in large doses, cocaine may exert a direct toxic effect on the myocardium resulting in negative inotropy, wide-complex dysrhythmia, bradycardia, and hypotension. Central effects are mediated through activation of the sympathetic nervous system via enhanced effects of excitatory amino acids and blockade of presynaptic reuptake of norepinephrine, dopamine, and serotonin. The resultant excess of neurotransmitters at postsynaptic receptor sites leads to sympathetic activation, producing the characteristic physical findings of mydriasis, tachycardia, hypertension, and diaphoresis, and predisposing the user to dysrhythmias, seizures, and hyperthermia. Cocaine use produces a euphoria associated with enhanced alertness and a general sense of well-being. It is thought that the psychological addiction, drug craving, and withdrawal effects are mediated through interference with dopamine and serotonin balance in the central nervous system. Subsequent dopamine depletion at the nerve terminals may account for the dysphoria and depression associated with long-term abuse. Many of the ED visits attributed to cocaine are for the depression associated with chronic abuse.

Amphetamines

Amphetamines comprise a broad class of structurally similar derivatives of phenylethylamine. The derivative methamphetamine, also known as "ice," is abused by ingestion, intravenous injection, inhalation, or insufflation. Methylphenidate (Ritalin), widely prescribed for attention deficit disorder, has become a popular drug of abuse by insufflation of crushed tablets. As with cocaine, amphetamine's absorption and peak effects occur rapidly with inhalation, insufflation, and intravenous injection. However, the effects of some amphetamines such as methamphetamine (MDA) and methylenedioxymethamphetamine (MDMA) may persist for 12 h.

Amphetamines enhance the release and block the reuptake of catecholamines and may also directly stimulate catecholamine receptors. Some amphetamine metabolites inhibit monoamine oxidase, thus also increasing cytoplasmic concentrations of norepinephrine. Certain amphetamine derivatives can also induce release of serotonin and affect central serotonin receptors. These serotonergic effects account for the hallucinogenic properties of some amphetamine derivatives such as MDMA and methylenedioxymethamphetamine (MDEA or mescaline). Dopamine receptor activity may contribute to the withdrawal phenomenon. Mortality from amphetamine toxicity, like that from cocaine, is a result of hyperthermia, dysrhythmias, seizures, hypertension (intracranial hemorrhage or infarction), and encephalopathy.

The stimulants ephedrine and phenylpropanolamine produce toxic syndromes similar to those caused by cocaine and amphetamines, although there are some distinguishing features. Phenylpropanolamine, previously available in many over-the-counter diet aids and decongestants, was withdrawn from the market in December 2000, because of the increased risk of intracranial hemorrhage associated with its use.⁵ It is primarily a peripheral α -adrenergic agonist that causes significant vasoconstriction resulting in hypertension and, often, a marked reflex bradycardia. Although less-commonly available now, overdose from supplies in the home may lead to hypertensive encephalopathy or cerebrovascular accident.

Ephedrine is a plant-derived indirect-acting sympathomimetic with both α - and (3)-adrenergic activity caused by the release of dopamine and norepinephrine from neuronal stores. It is widely available as a "natural" stimulant in health food supplements promoted for dieting, energy, and to stay alert. Significant cardiovascular and neurologic toxicity, psychosis and severe hypertension have been reported, including several deaths.⁶

CLINICAL FEATURES

Cardiac

Cocaine induces dysrhythmias, myocarditis, cardiomyopathy, and myocardial ischemia and infarction. Other vascular complications include aortic rupture and aortic and coronary artery dissection. Even at relatively low doses, cocaine induces vasoconstriction in coronary arteries,⁷ one of the proposed mechanisms of cocaine-induced myocardial ischemia and infarction. Coronary vasoconstriction is exacerbated by β -adrenergic blockade and antagonized by phentolamine, suggesting that it is mediated through the stimulation of α -adrenergic receptors.^{7,8} This effect is even further potentiated by cigarette smoking. Myocardial ischemia has also been demonstrated in chronic abusers undergoing cocaine withdrawal. It is thought that cocaine withdrawal is a dopamine-depleted state, resulting in intermittent coronary spasm. Animal data demonstrate increased platelet aggregation and thrombogenesis, accelerated atherosclerosis, direct myocardial toxicity, and increased myocardial oxygen demand.

A profile of the patient at risk for myocardial ischemia can be elucidated from a compilation of 91 case reports of patients with cocaine-induced myocardial infarction and a prospective evaluation of patients with cocaine-associated chest pain.^{9,10} The average patient with cocaine-associated myocardial infarction was young and male (mean age 32.8 years, range 18 to 52; male:female ratio, 7:1) and most (83 to 89%) were cigarette smokers and regular cocaine users. Two-thirds of patients presented within 3 h of cocaine use, and all routes of cocaine administration were reported. Of the patients with follow-up cardiac catheterization, coronary artery disease was present in 31%. Electrocardiographic (ECG) abnormalities were variably present, and both Q-wave and non-Q-wave infarctions occurred. Many studies have reported myocardial infarction in patients with atypical histories and unremarkable ECGs.

Myocardial ischemia and infarction and aortic dissection are also reported in association with ephedrine, phenylpropanolamine, or amphetamine use. Additionally, reports of mitral and aortic valve abnormalities associated with use of the amphetamine combination phentermine-fenfluramine prompted a voluntary recall of these drugs. Cardiopulmonary toxicity from other amphetamine diet aids has also been reported.

Central Nervous System

A vast array of neurologic syndromes is described in association with cocaine abuse, most commonly seizures, intracranial infarctions, and hemorrhages. Pathology results from the hyperadrenergic tone, inducing severe transient hypertension, hemorrhage, or focal vasospasm and, sometimes, exacerbation of underlying abnormalities of cerebral blood vessels. In a dog model, lethal doses of intravenous cocaine initially induced seizures, lactic acidosis, hyperthermia, and death.¹¹ Progression of toxicity could be prevented by sedation and cooling. In this animal model, diazepam was an optimal sedative because it prevented hyperthermia and seizures and improved survival.

Although coronary vasospasm has been well documented in humans exposed to cocaine, a recent study using magnetic resonance angiography also demonstrated cerebral vasoconstriction following cocaine administration.¹² Other CNS manifestations reported include spinal cord infarctions, cerebral vasculitis, and intracranial abscesses. Acute dystonic reactions following cocaine use and withdrawal are also reported. Choreoathetosis and other repetitive movements (termed "crack dancing") are associated with cocaine and amphetamine intoxication, and all seem to be related to dopamine dysregulation. An interesting syndrome termed "cocaine washout" occurs in patients following a prolonged crack binge. Patients have a depressed level of consciousness but can be aroused to normal with stimulation. Resolution of lethargy can take up to 24 h. Unilateral blindness occurs

secondary to central retinal artery occlusion and bilateral blindness from diffuse vasospasm. A syndrome of corneal abrasions and ulcerations secondary to smoke and irritation is known as "crack eye." Keratitis caused by methamphetamine use is described as well.

Amphetamines, phenylpropanolamine, and ephedrine are also associated with intracranial hemorrhages, infarctions, encephalopathy, and seizures. Amphetamines also cause a CNS vasculitis resulting in focal neurologic deficits. A profound paranoid psychosis occurs with chronic amphetamine abuse and withdrawal.

Pulmonary

Respiratory effects of cocaine use have become more prevalent with the epidemic of crack cocaine smoking. Pulmonary hemorrhage, barotrauma, pneumonitis, asthma, and pulmonary edema are described. Pneumomediastinum, pneumothorax, and pneumopericardium result from barotrauma secondary to the Valsalva maneuver performed following inhalation or insufflation in an attempt to enhance drug effect. Pneumonitis, asthma, and bronchiolitis may be immunologic phenomena or the result of the numerous adulterants known to be present in cocaine. A recent case control study in an urban ED examined the association between bronchospasm and cocaine use. The authors demonstrated a higher incidence of recent cocaine use in patients presenting with new-onset bronchospasm as compared with age- and sex-matched urban ED patients.¹³ Another study demonstrated bronchoconstriction following the inhalation of crack but not following intravenous injection of cocaine.¹⁴ This suggests that such bronchospasm may be a result of local airway irritation. Acute lung injury may be catecholamine-mediated, in view of a similar syndrome described in patients with adrenergic excess from pheochromocytoma and intracranial hemorrhage. Upper airway irritation and a presumed thermal uvulitis occurs in patients smoking crack cocaine.

Gastrointestinal

Patients who are thought to have swallowed poorly packaged cocaine following police pursuit are called "body staffers." Such patients are often brought to the hospital by police and may or may not show signs of cocaine intoxication. In contrast, the "body packer" swallows a large number of well-sealed packages of cocaine in order to smuggle drugs into this country. Because of the large quantities of relatively pure drug contained in these packages, toxicity and death can occur if even a single bag ruptures.

Cocaine-induced mesenteric vasospasm may contribute to the many reported cases of intestinal ischemia, bowel necrosis, ischemic colitis, and splenic infarctions. In addition, gastrointestinal bleeding and perforation occur in association with cocaine use.

Renal

Traumatic and nontraumatic rhabdomyolysis occurs secondary to cocaine or amphetamine use. In an early series of cocaine-induced rhabdomyolysis, one-third of patients developed acute renal failure and half of those died.¹⁵ Risks for developing rhabdomyolysis include altered mental status, seizures, dysrhythmias, and hemodynamic instability including cardiac arrest.¹⁵ **Patients whose initial serum creatine phosphokinase (CPK) is less than 1000 U/L with normal creatinine, white blood cell count, and only one or no risks in addition to cocaine itself, are unlikely to develop complications**¹² and need not necessarily be admitted for this alone. In addition to renal failure resulting from rhabdomyolysis, stimulants may further exacerbate renal injury through hyperthermia, vasoconstriction, hypotension, and hypovolemia. Clinicians must be aware of this potential late complication and augment fluid resuscitation to maintain a urine output of 1 to 3 mL/kg per h. Renal infarction has been described following intravenous cocaine use.

The Pregnant Patient

Cocaine is a potent vasoconstrictor that alters uteroplacental blood flow. An increased incidence of spontaneous abortions,¹⁶ abruptio placentae, fetal prematurity, and intrauterine growth retardation results from cocaine abuse in pregnancy.¹⁷ Both spontaneous abortions and abruptio placentae appear to occur from placental vasoconstriction and increased uterine contractility, with concomitant maternal hypertension. Intoxication of a breast-fed infant secondary to maternal cocaine use has been reported as well. Methamphetamine abuse during pregnancy has similar detrimental effects on fetal growth.

DIAGNOSIS

The cocaine- or amphetamine-intoxicated patient can often be identified initially by vital signs. Adrenergic stimulation may produce tachycardia, tachypnea, hypertension, and sometimes hyperthermia. The patient's mental status can range from normal to paranoid or severely agitated to coma. Organ-system involvement may be suspected from symptoms such as chest pain, palpitations, dyspnea, headache, or focal neurologic complaints. The patient may be postictal or may present with seizures. Other physical findings may include mydriasis and diaphoresis. In the absence of an adequate history, it may be difficult to distinguish this presentation from other conditions of catecholamine excess, such as withdrawal from alcohol or sedative-hypnotics. Metabolic (lactic) acidosis may be present following seizures or as a result of vasoconstriction and hypoperfusion. As with all intoxicated patients, occult trauma and hypoglycemia must be excluded.

Concomitant use of alcohol and other drugs frequently alters the clinical presentation. For example, a patient ingesting both opioids and stimulants may present with a decreased level of consciousness and few if any other revealing findings. When the opioid is reversed with naloxone, the stimulant effects are unmasked, often with impressive findings.

Laboratory Evaluation

Any patient with significant agitation or elevated temperature should have a chemistry panel and creatine phosphokinase (CPK) obtained to screen for a metabolic acidosis, renal failure, or rhabdomyolysis. Hyponatremia, often with altered mental status, occasionally occurs following the use of hallucinogenic amphetamines (e.g., MDMA). Cardiac markers including myocardial band enzymes of creatine phosphokinase (CPK-MB) or troponin are appropriate to screen for cardiac injury. A urine test strip positive for hemoglobin with only few or no red blood cells by microscopy suggests rhabdomyolysis. Obtain baseline coagulation and liver function studies in patients with hyperthermia, because these values increase dramatically in the first 24 h. Most patients with altered mental status who do not awaken with glucose or naloxone should undergo computed tomography of the head, because associated neurovascular injuries are common. A chest radiograph and ECG are fundamental to the evaluation. Laboratory confirmation of cocaine or amphetamine use is readily available but must be interpreted with caution. Because urine drug screening for the cocaine metabolite benzoylecgonine is sensitive to 200 to 300 ng/mL, cocaine use within the past 24 to 72 h will typically be detected, depending on dose and chronicity of cocaine use. Cocaine can be detected in chronic users by more sensitive techniques (radioimmunoassay, gas chromatography) for up to 2 weeks after last use of the drug, so a positive drug screen requires clinical correlation. Most of the rapid screening tests for cocaine are fairly specific for cocaine metabolites and exhibit little cross-reactivity. However, amphetamine immunoassays cross-react with interfering substances and other phenylethylamine compounds, so they are not very specific. In addition, excessive use of certain nasal inhalers that contain stimulant-class drugs may cross-react with immunoassay methods and yield false-positive tests.

TREATMENT

The basic protocol specific to stimulants outlined in Chap. 156 should be followed. Charcoal should be given. Intravenous access should be obtained and supplemental oxygen delivered to those with potential cardiac or CNS ischemia. **The cornerstone of therapy is adequate sedation and monitoring of vital signs.** The patient with hypertension and tachycardia will often respond to treatment with benzodiazepines, which decrease central sympathetic outflow. Lorazepam 2 mg or diazepam 5 mg can be administered intravenously and titrated with repeated doses to decrease the autonomic excess and CNS stimulation. Haloperidol, droperidol, and chlorpromazine should be avoided as these lower the seizure threshold and may contribute to hyperthermia or dysrhythmias. A core temperature should be measured. Hyperthermia is potentially lethal and patients must be cooled rapidly to decrease subsequent morbidity and mortality. Application of ice packs, and coolmist spray to the skin and fans to increase heat loss by convection and evaporation may decrease temperature adequately. See Chap. 193 Heat Emergencies, for further discussion of management of hyperthermia. Aggressive fluid resuscitation is critical to maintain urine output.

Seizures may be treated with benzodiazepines as well (see Chap. 232); however, in status epilepticus, phenobarbital loading or neuromuscular blockade may be necessary to control motor activity and prevent hyperthermia, acidosis, and rhabdomyolysis. Computed tomography is recommended in all cases of stimulant-induced seizures because the finding of intracranial pathology creating a seizure focus is common.

The patient complaining of chest pain should be evaluated for possible myocardial ischemia, as well as for the common pulmonary etiologies already discussed. Patients suspected of acute coronary syndrome should be managed by standard protocol with nitrates, morphine, benzodiazepines and aspirin (see Chap. 51).^{18,20} **Adrenergic antagonist therapy is absolutely contraindicated** because unopposed stimulation of α -adrenergic receptors may worsen coronary and peripheral vasoconstriction, hypertension, and possibly ischemia.^{18,19} This recommendation is also emphasized in the most recent *Advanced Cardiac Life Support Guidelines*. Although labetalol (a mixed α - and β -adrenergic antagonist) has been suggested by some authors, labetalol increases seizures and mortality in an animal model of cocaine toxicity and does not decrease cocaine-induced coronary vasoconstriction in humans. Consultation may be helpful before administering thrombolytic therapy in cocaine-associated myocardial infarction. Despite the increased incidence of coronary atherosclerosis, thrombolytic agents should not be used when severe hypertension is present or vasospasm or coronary artery dissection are suspected.^{21,22} Emergent catheterization, when available, is a safer diagnostic and therapeutic alternative.

Wide-complex tachydysrhythmias and QRS prolongation secondary to the quinidine-like effects of cocaine may be treated by alkalinizing the serum to a pH of 7.45 to 7.5 with sodium bicarbonate. Although lidocaine has been used safely in this setting, some animal studies and theoretical evidence suggest that lidocaine may potentiate cocaine neurotoxicity and should be used with caution in patients with dysrhythmias who are not responsive to sodium bicarbonate.

Severe hypertension not responding to sedation may require treatment with nitroprusside infusion or phentolamine (phentolamine starting dose: 2.5 to 5 mg IV). Blood pressure may be lowered aggressively if the patient is not suspected to have chronic hypertensive disease. Treatment for refractory hypertension would be similar to that for hypertensive emergencies of any etiology (see Chap. 57).

The treatment of patients with cardiovascular or neurologic sequelae of amphetamine or other stimulant use is comparable to that outlined for cocaine. Acidification of the urine to increase amphetamine excretion was previously recommended but should not be done because of the increased risk of renal tubular precipitation of myoglobin in the presence of rhabdomyolysis. Dialysis has no value.

The management of an asymptomatic cocaine "body packer" brought in by police or customs officials constitutes a dilemma for the emergency physician. If the patient shows no signs of toxicity, we recommend a dose of activated charcoal followed by whole-bowel irrigation with polyethylene glycol electrolyte lavage solution (GoLYTELY or Colyte) to gently hasten elimination of the potentially lethal packets. If the patient begins to show signs of intoxication, such as agitation, hypertension, or tachycardia, benzodiazepines should be administered while immediate surgical consultation for emergent laparotomy and packet removal is made. Neither upper nor lower endoscopy should be routinely attempted because both routes are associated with packet rupture. Following passage of the "last" packet, a radiologic imaging procedure (a barium-enhanced upper gastrointestinal series with small bowel follow-through or abdominal computed tomography with contrast) should be performed to ensure that the gut has been purged of all containers. In contrast to "body packers," "body staffers" (people who ingest poorly packaged drugs while trying to avoid arrest) are more likely to be seen in the ED. These patients can be given a dose of activated charcoal, sedated (if indicated), and given supportive care if intoxicated, because the toxicity should be shorter-lived and often involves smaller amounts of drug.

Drug Interactions

There are a few potential drug interactions to be aware of in the treatment of the stimulant-poisoned patient. Because cocaine is metabolized by plasma cholinesterase, coadministration of other drugs such as succinylcholine and mivacurium, which are metabolized by plasma cholinesterase, may have a prolonged duration of effect as a result of decreased metabolism.

Both lidocaine and cocaine are local anesthetics and act as sodium-channel antagonists. It is thought that neurotoxic effects from both occur by similar mechanisms. Despite some theoretical risk of treating cocaine-induced dysrhythmias with lidocaine, it has been used safely to date in patients with cocaine-associated myocardial infarction.

Monoamine oxidase inhibitors block the degradation of catecholamines and lead to increased levels of presynaptic catecholamines. Amphetamines are indirect-acting sympathomimetic amines and weak inhibitors of monoamine oxidase as well. Thus, patients taking monoamine oxidase inhibitors who subsequently use amphetamines or phenylpropanolamine (and to a lesser extent cocaine) may precipitate an acute syndrome of excessive catecholamine release, resulting in severe hypertension, tachycardia, hyperthermia, agitation, tremors, and possible severe neurotoxicity.

Withdrawal

Cocaine withdrawal is characterized by irritability, paranoid ideation, and delayed depression. Symptoms are generally milder than for amphetamines. Psychological addiction may be particularly strong. Amphetamine withdrawal is characterized by drowsiness, lethargy, hunger, tremor, and chills. There is considerable potential for long-term depression and suicide.

DISPOSITION

Patient disposition depends on initial patient presentation, response to therapy, the stimulant involved, and expected duration of effect. Patients who present with adrenergic excess following recent cocaine use and who respond to sedation may be expected to improve completely during a period of observation in the ED secondary to the relatively limited duration of cocaine effect. In contrast, amphetamines have a longer duration of effect and may be expected to produce more prolonged toxicity, necessitating hospital admission or prolonged observation in some cases. Patients demonstrating resolution of toxicity and clear sensorium in the absence of focal complaints or end-organ dam-

age should be advised of the medical risks of their drug abuse and referred to appropriate detoxification, counseling, and social support services. In general, patients with significantly increased creatine phosphokinase levels, hyperthermia, myoglobinuria, or ECG changes consistent with myocardial ischemia should be hospitalized in an intensive care setting.

Disposition of patients who present with cocaine-associated chest pain is discussed in Chap. 51.

CAFFEINE

Caffeine is probably the most commonly used drug in the world. Its ubiquitous presence in coffee, tea, soda, and other drinks allows both for unperceived use and addiction. In addition, the use of large doses of caffeine in products designed to reduce weight or enhance arousal gives rise to the potential for substantial overdose and toxicity (Table 168-1). Although clearly an underestimation of true exposures and toxicity, U.S. poison centers received more than 5000 calls in 2001, including 1 fatality.²³

Pharmacologically, caffeine (1,3,7-trimethylxanthine) is best described as a methylxanthine, and as such, has properties very similar to theophylline (1,3-dimethylxanthine) and theobromine (3,7-dimethylxanthine) (see Chap. 173). Although caffeine can be administered IV, IM, SC, and PR, the most common route of absorption is PO. Whether in a pill or a liquid, it is rapidly and completely absorbed within approximately 30 to 60 min, depending on the presence of food. Once absorbed, caffeine's mechanism of effect is similar to theophylline, and includes p-adrenergic stimulation (largely through the release of endogenous epinephrine and norepinephrine) adenosine antagonism, and in overdose, phosphodiesterase inhibition.

There is no clearly defined toxic dose. At low doses (approximately 200 mg in adults), the literature is clearly supportive of caffeine's ability to enhance arousal and performance both of cognitive and psychomotor skills.²⁴ However, at higher doses (about 1 g) toxicity is indistinguishable from theophylline toxicity with severe gastrointestinal symptoms as the first manifestation. This is followed by tachycardia, tachypnea, agitation, and electrolyte abnormalities such as hypokalemia and hyperglycemia. As levels increase, seizures, dysrhythmias, and cardiovascular instability may occur. Ingestions of 100 to 150 mg/kg or blood levels of 100 p.g/mL are consistent with life-threatening toxicity.

Treatment begins with basic supportive care. Volume depletion results from vomiting, tachypnea, diuresis, and vasodilation. Therefore, patients with good cardiovascular function should be aggressively resuscitated with NS. Antiemetics, such as metoclopramide (5 to 10 mg IV or IM), will ease gastrointestinal symptoms and facilitate the administration of activated charcoal, which both prevents absorption and

TABLE 168-1 Caffeine Content of Various Products

Product	Caffeine Content, mg

enhances elimination. Seizures are best treated with benzodiazepines, followed by barbiturates or propofol (see Chap. 232). Phenytoin is ineffective in theophylline-induced seizures and by analogy should not be used for caffeine toxicity. For life-threatening toxicity such as recurrent seizures, ventricular dysrhythmias or cardiovascular instability hemodialysis or charcoal hemoperfusion is indicated.

NICOTINE

Nicotine is available in all tobacco products (cigarettes, cigars, pipe tobacco, snuff, and chewing tobacco), in smoking cessation products (gums, sprays, and patches), and in liquid form for use as a pesticide. Consequently, like caffeine, nicotine is pervasive in modern society with nearly one fourth of Americans smoking regularly. Although not specifically used or abused as a stimulant, on a pharmacologic level, nicotine is exactly that.

Nicotine is most commonly absorbed through the pulmonary system, but also demonstrates excellent transdermal, transmucosal (oral or nasal), and gastrointestinal absorption. The rate of absorption is highly dependent on the route of administration. For example, following inhalation, CNS levels are achieved in less than 10 s, whereas gastrointestinal absorption is delayed because of poor absorption in the acid stomach.

Once absorbed, nicotine binds to the nicotinic subset of muscarinic receptors in the autonomic, central nervous, and muscular systems. At typical doses used by smokers, an electroencephalogram (EEG) can demonstrate CNS stimulation of the reticular activating system.²⁵ Clinically, this corresponds to improved memory and attention.²⁵ As levels increase, nausea, vomiting, salivation, and tremor are common. Hypertension, tachycardia, and seizures may follow. Ultimately, overstimulation of receptors leads to blockade, with coma, hyporeflexia, muscle fasciculations, weakness, and paralysis resulting.²⁶

A typical cigarette may contain 13 to 30 mg of nicotine. Although it is generally accepted that a child who ingests more than one cigarette is likely to become symptomatic, life-threatening toxicity would only be expected with exposures to concentrated forms of nicotine such as the pesticides or smoking cessation products.²⁷ Nicotine levels can be obtained, and levels greater than 50 ng/mL are predictive of severe toxicity. However, levels are not available emergently.

Management begins with decontamination. Gastric emptying is rarely required, as most patients will have spontaneous emesis. Activated charcoal may help prevent absorption of remaining drug, but is typically difficult to administer because of consequential nausea and vomiting. Dermal decontamination with soap and water may be beneficial following topical exposures. Subsequent therapy is completely supportive, as there is no antidote. Benzodiazepines may be used for seizures and endotracheal intubation and mechanical ventilation may be required if significant neuromuscular weakness develops. Fortunately, because nicotine has a very short half-life (on the order of 1 to 4 h in nonsmokers) symptoms typical resolve rapidly.

HALLUCINOGENS

Karen N. Hansen
Katherine M. Prybys

INTRODUCTION

Over the centuries, humans have purposefully ingested naturally occurring mind-altering substances, such as psilocybin-containing mushrooms and peyote cactus, to achieve mystical or religious enlightenment. Modern interest in hallucinogenic drugs dates from Albert Hofmann's 1943 discovery of the properties of lysergic acid diethylamide (LSD) through inadvertent exposure.

The popularity of hallucinogens (Table 169-1) as recreational drugs peaked in the 1960s, but has undergone a resurgence among

TABLE 169-1 Characteristics of Hallucinogens

Drug	Chemical Classification	Mechanism of Action	Typical Dose	Duration of Action	Clinical Features	Complications	Specific Treatment
LSD	Indole alkylamine	5-HT ₂ agonist	50–300 µg	8–12 h	Mydriasis Sympathomimetic symptoms Nausea Muscle tension	Persistent psychosis Hallucinogen persisting perception disorder	Supportive Benzodiazepines
Psilocybin	Indole alkylamine	5-HT ₂ agonist	5–100 mushrooms, 4–6 mg of psilocybin	4–6 h	Mydriasis Sympathomimetic symptoms Nausea	Seizures (rare) Hyperthermia (rare)	Supportive Benzodiazepines
Mescaline	Phenylethylamine	5-HT ₂ agonist	3–12 “buttons,” 200–500 mg of mescaline	6–12 h	Mydriasis Abdominal pain Vomiting Dizziness Sympathomimetic symptoms	Rare	Supportive Benzodiazepines
MDMA (“Ecstasy”)	Phenylethylamine	5-HT release	50–200 mg	4–6 h	Mydriasis Sympathomimetic symptoms Bruxism Jaw tension Ataxia	Arrhythmias Hypertension Seizures Hyperthermia Rhabdomyolysis DIC Chronic neuropsychiatric problems	Benzodiazepines Hydration Active cooling
Phencyclidine (PCP)	Piperidine derivative	Glutamate antagonist at NMDA receptor	1–9 mg	4–6 h	Miosis or midsized pupils Nystagmus Hypertension Sympathomimetic, anticholinergic, and cholinergic symptoms	Coma Seizures Hyperthermia Rhabdomyolysis Hypoglycemia	Benzodiazepines Hydration Active cooling Multiple doses of activated charcoal Alkalinize urine (for rhabdomyolysis)
Marijuana	Cannabinoid	Binds cannabinoid receptor	5–15 mg of THC	2–4 h	Tachycardia Conjunctival injection Impaired motor coordination	Rare	Supportive Benzodiazepines

Abbreviations: DIC = disseminated intravascular coagulation; NMDA = N-methyl-D-aspartate; THC = tetrahydrocannabinol.

adolescents and young adults which started in the early 1990s.¹ According to data from the Monitoring the Future study,² use of LSD within the U.S. has declined over the past few years, while marijuana and MDMA ("ecstasy" or "Adam") have become increasingly popular. In 2001, 6.6 percent of high school seniors reported using LSD within the previous 30 days, and 10.9 percent had used it at least once in their life. In the same year, 37 percent of high school seniors reported recent use of marijuana, and a remarkable 49 percent admitted trying it at some time in their life.² Of particular concern is the increasing popularity of the psychoactive amphetamine derivative MDMA. In 2000, 11 percent of high school seniors reported recent use of MDMA.² According to a large national survey, the percentage of college students reporting use of MDMA within the previous year increased 69 percent (from 2.8 to 4.7 percent) between 1997 and 1999.³ Encouragingly, use of phencyclidine (PCP) has declined. In 2000, only 0.1 percent of Americans over age 12 reported using PCP during the previous year, and only 2.6 percent reported ever trying it.⁴

The term *psychedelic* is sometimes preferred to *hallucinogen*. Many of the drugs within this group rarely produce true hallucinations, which are sensory perceptions occurring in the absence of any external stimulus. Perceptual alterations based on some environmental cue are termed *illusions*, and are far more common. These effects may involve any sensory modality, but are most often visual. Users may also experience distortions of body image, and a distorted sense of the passage of time. Alterations in mood and heightened suggestibility are common.

The classic hallucinogens include agents from the indole alkylamine (LSD, psilocybin), and phenylethylamine (mescaline and others) chemical families. These drugs share a common proposed mechanism of action, and are capable of producing the profound psychological effects and sensory distortions characteristic of the psychedelic "trip." In addition to classic hallucinogens, a number of other drugs, such as MDMA ("ecstasy"), PCP, and marijuana possess the ability to alter sensory perceptions, and can be placed within the broader category of hallucinogens.

LSD

LSD (lysergic acid diethylamide) can be chemically synthesized or obtained by hydrolysis of ergot alkaloids from the fungus *Claviceps purpurea*. It is the most potent hallucinogenic compound known. Evidence suggests that the psychedelic effects of LSD are mediated through serotonergic (5HT) systems, and that LSD acts as an agonist at 5HT₂ receptors.

The typical LSD dose of 50 to 300 µg is most commonly delivered through ingestion of a small square of dried "blotter" paper saturated with a solution of the compound. Blotter acid is often imprinted with fanciful designs or cartoons, which may serve as trademarks for the manufacturer. Other forms of LSD include "microdots" (tiny tablets), "windowpane" (gelatin sheets), impregnated sugar cubes, and liquid LSD. LSD is relatively inexpensive; a dose typically costs less than \$15.

LSD is rapidly absorbed following ingestion. Onset of psychedelic effects occurs after about 30 min, peak effects occur within the first 4 h, and the total duration of an LSD "trip" is between 8 and 12 h. The serum half-life of LSD is approximately 3 h.⁵ Physiologic effects of LSD usually precede psychedelic effects, and are dominated by sympathomimetic symptoms. These include marked mydriasis, and mild elevations of pulse, blood pressure, and temperature. Facial flushing, mild gastric distress, piloerection, bruxism, increased muscle tension, and hyperreflexia may be seen. Severe or life-threatening complications are extremely uncommon. Seizures have been reported rarely. Massive overdose of LSD may produce coma, respiratory arrest, hyperthermia, and coagulopathy.⁶

The psychedelic effects of LSD may be perceived as pleasurable or horrifying, depending on the user's prevailing mood and expectations ("set"), and external environmental factors ("setting"). Acute adverse

psychological effects ("bad trip") include panic attacks, extreme paranoia, acute psychotic reactions, and depressive reactions. Potential physical trauma as a consequence of dangerous or impulsive behavior is a serious hazard. Occasional suicides have been reported. Prolonged and sometimes permanent psychosis following LSD use has been well described, and affects up to almost 5 percent of users.⁷ The term "flashback" has been replaced by *hallucinogen persisting perception disorder*,¹⁶ a debilitating malady in which patients experience chronic perceptual distortions reminiscent of the drug-induced state, often accompanied by anxiety or panic.

Patients who present to the ED due to effects of LSD are conscious and alert and will usually be able to give a history of the drug ingestion. Diagnosis is based on a history of use and the presence of sympathomimetic signs. Sensitive assays have been developed for the detection of LSD, but are not usually available or necessary in the emergent clinical setting. Routine toxicology screens available in most EDs will not usually detect LSD, but may be indicated if other intoxicants are suspected. If the history is clear, and in the absence of medical complications or possible coingestants, observation in a safe, quiet environment is appropriate. Reassurance and emotional support are generally the only interventions required to manage a patient experiencing a "bad trip." Oral or parenteral benzodiazepines may be given if the patient is extremely agitated or exhibiting significant sympathomimetic stimulation. Haloperidol may be used as a second choice if additional sedation is required, but may have a small theoretical risk of lowering the seizure threshold. Patients who are lucid and medically stable may be released into the custody of family or friends. Patients with paranoid or psychotic symptoms lasting longer than 8 to 12 h may require hospital admission. Rare patients with medical complications due to massive overdose may require hospital admission, but can be expected to recover quickly with supportive management.⁶

PSILOCYBIN

Psilocybin and the related compound psilocin are hallucinogens of the indole alkylamine class, and are structurally related to LSD. Psilocybin and psilocin are believed to act as 5-HT₂ agonists in a manner similar to LSD. They occur naturally in mushrooms of the *Psilocybe* genus, most notably *P. semilanceata* (liberty cap) and *P. cubensis*. Psilocybin-containing mushrooms grow naturally in many areas of the U.S. and Europe, and kits containing spores and the ingredients necessary for propagation are advertised in drug-oriented publications. Hallucinogenic mushrooms purchased on the street are often nonpsychoactive mushrooms which have been adulterated with LSD or PCP.⁹ Psilocybin-containing mushrooms may be dried or cooked without losing potency. Because mushroom size and the concentration of psychoactive compounds vary, there is little correlation between the number of mushrooms ingested and hallucinogenic effect. A user may ingest as few as 5 or as many as 100 mushrooms for a single "dose."

Symptom onset occurs about 30 min after ingestion of psilocybin-containing mushrooms, and the total duration of hallucinogenic effects is about 4 to 6 h. The hallucinogenic effects are similar to, but less powerful than, those produced by LSD. Other common effects include mydriasis, mild tachycardia, hyperreflexia, and nausea and vomiting. Serious medical side effects are extremely rare, but seizures and hyperthermia have occurred, and the death of a small child has been reported.

ED management of patients presenting with isolated hallucinogenic mushroom ingestion is largely supportive. Routine drug screens will not detect psilocybin or psilocin. However, a drug screen may be indicated if there is a possibility that the mushrooms ingested were adulterated with PCP. If the patient's symptoms are not consistent with psilocybin, the possibility that the mushrooms ingested were of another more toxic variety should be considered (see Chap. 204).

MESCALINE

Mescaline (3,4,5-trimethoxyphenylethylamine) is the hallucinogenic alkaloid found in the Mexican peyote cactus *Lophophora williamsii*, a small spineless cactus that grows throughout the southwestern U.S. and northern Mexico. Mescaline is a member of the phenylethylamine class of hallucinogens, and is structurally related to amphetamines. Like LSD, mescaline is believed to act as an 5-HT₂ agonist,¹⁰ but mescaline is a much weaker hallucinogen than LSD.

The small 8-mm crowns of the peyote cactus are dried and sold as peyote "buttons," each containing approximately 45 mg of mescaline. A typical dose of 200 to 500 mg will require 3 to 12 of these "buttons." Mescaline can be extracted from peyote or chemically synthesized, but these methods are expensive. Pills or capsules sold on the street as "mescaline" are unlikely to be genuine,⁹ and may instead contain LSD or PCP.

Peyote is bitter tasting, and causes significant uncomfortable physical side effects within an hour of ingestion. Initial signs and symptoms, which often include nausea and vomiting, abdominal discomfort, diaphoresis, dizziness, nystagmus, ataxia, and headache, generally resolve in about 2 h. Adrenergic stimulation causes mydriasis and mild elevations in pulse, blood pressure, and temperature. Hallucinogenic effects very similar to those produced by LSD begin several hours after ingestion and persist for 6 to 12 h. Death due to aberrant behavior while under the influence of the drug can occur, but reports of significant morbidity or mortality due to physiological effects of mescaline are absent from the literature. Patients presenting to the ED due to peyote ingestion can usually be managed supportively. Routine drug screens do not detect mescaline.

MDMA

MDMA (3,4-methylenedioxymethamphetamine, "ecstasy" or "Adam") is a synthetic phenylethylamine derivative, structurally related to both amphetamines and mescaline. MDA (3,4-methylenedioxymethamphetamine) and MDEA (3,4-methylenedioxyethamphetamine, "Eve") are related compounds with similar properties. MDMA is believed to act as an indirect monoamine agonist by causing release and inhibiting reuptake of 5-HT and dopamine.¹¹

MDMA is usually ingested in doses of 50 to 200 mg. Tablets are typically round and white, and are often imprinted with logos such as birds, butterflies, lightning bolts, or four-leaf clovers. At the turn of the century, the street price for a dose is approximately \$20 to \$30. The drug is colorless and tasteless, and has become notorious as a "date rape" drug. Acute effects last about 4 to 6 h. MDMA rarely causes actual hallucinations, but can produce sensory effects such as alterations in the intensity of colors or sensation of textures. Users often report feelings of euphoria, enhanced sociability, verbosity, and heightened sexual interest. Common physical manifestations of MDMA include sympathomimetic effects, particularly mydriasis and mild elevations of pulse and blood pressure, as well as nausea, jaw tension, bruxism, dry mouth, muscle aches, and ataxia.

The increase in popularity of MDMA has been accompanied by an increase in reports of serious complications and death related to its use. Fatal arrhythmias and death due to cardiac effects have been reported in patients with and without underlying cardiac disease.¹² Severe hypertension and intracranial hemorrhage have been reported.¹² A pattern of toxicity manifested by hyperthermia, seizures, disseminated intravascular coagulation (DIC), rhabdomyolysis, and renal failure is well recognized.¹³ This pattern shares many features of the serotonin syndrome.¹⁴ Acute liver damage has occurred, not always attributable to hyperthermia. Hyponatremia, due to excessive water consumption or possibly inappropriate antidiuretic hormone secretion,¹⁴ has been reported.

Serious concerns have arisen regarding the possibility of persistent neurotoxic effects from MDMA use. Mounting evidence indicates that

repeated use of MDMA may result in neurotoxic injury to serotonin axon terminals and long-term functional consequences.¹⁵ MDMA has been shown to cause significant reductions in both the number of serotonin transporters in the brain and levels of serotonin metabolites in the cerebrospinal fluid.¹⁵ A corresponding dramatic loss of serotonergic neurons was observed on examination of brain tissue from primates even 1 year after drug administration. Significant dopaminergic toxicity has also been found in a recent study using nonhuman primates.¹⁶ Neuropsychiatric studies performed on chronic MDMA users demonstrate long-lasting cognitive impairment and mood dysfunction, including memory impairment, diminished learning ability, and depression. More human clinical studies are necessary to definitively establish a link between MDMA use and permanent neurologic damage. Patients presenting to the ED with complications due to MDMA should receive activated charcoal if the ingestion was recent. Arrhythmias are managed with standard therapy. Hypertension and tachycardia will often respond to treatment with benzodiazepines. Rapid intravenous titration with very high doses of benzodiazepines may be required to control symptoms. If hypertension is severe, phentolamine or nitroprusside can be used. 3-Blockers such as propranolol should be avoided due to the risk of unopposed alpha stimulation.¹⁷ Hyperthermia should be managed aggressively with active cooling measures. Patients with temperatures exceeding 40°C (104°F) have increased morbidity and mortality, and may require rapid sequence intubation and paralysis using a nondepolarizing neuromuscular blocking agent. The use of dantrolene or specific serotonin antagonists¹³ has been suggested, but no prospective clinical studies support use of these agents in treatment of MDMA toxicity.

PHENCYCLIDINE

Phencyclidine (PCP) is a synthetic piperidine derivative. It is a dissociative anesthetic agent structurally related to ketamine. PCP is unlike the classic hallucinogens in that it causes clouding of the sensorium rather than heightened sensory awareness. PCP is believed to act as a glutamate antagonist at the NMDA (N-methyl-D-aspartate) receptor.¹⁸

PCP can be easily and inexpensively synthesized. Powdered drug ("angel dust") is most often combined with tobacco, marijuana, or other vegetable matter and smoked, but PCP can be ingested orally, sniffed intranasally, or injected intravenously. Unfortunately PCP is often sold as another drug, or used to adulterate another drug, and thus may be unknowingly ingested.⁹ The onset of action depends on the mode of administration, and is about 5 min if PCP is smoked. Acute effects generally last 4 to 6 h, but can persist much longer.

Because of the remarkable variability of clinical effects, recognition of PCP intoxication can be challenging. Patients may present with CNS stimulation or depression, and may be physically violent, catatonic, or comatose. A combination of cholinergic, anticholinergic, and sympathomimetic effects may be present. Many patients have taken a combination of drugs, compounding the clinical picture.¹⁹ In a series of 1000 PCP-intoxicated patients, nystagmus and hypertension were the most common findings, each occurring in 57 percent of patients.¹⁹ Hypertension was generally mild. Other prevalent manifestations were: acute brain syndrome (37 percent); violent (35 percent), agitated (34 percent), or bizarre (29 percent) behavior; hallucinations or delusions (19 percent); and tachycardia (30 percent).¹⁹ Diaphoresis, muscle rigidity, dystonic reactions, ataxia, and a decreased response to painful stimuli have also been described. Pupil size is variable; unlike classic hallucinogens, widely dilated pupils are not common.¹⁹

Medical complications due to PCP use occur frequently. Coma has been seen in 10.6 percent,²⁰ and seizures in 3.1 percent¹⁹ of PCP-intoxicated patients. Elevated serum creatine kinase (CK), due to increased muscle activity and/or a possible direct toxic effect of PCP, was found in 70 percent of patients in one study.¹⁹ Rhabdomyolysis may occur, sometimes resulting in renal failure requiring dialysis.²⁰ Hypoglycemia,¹⁹ hypertension causing intracerebral hem-

orrhage,²¹ and hyperthermia causing hepatic necrosis have also been reported. In addition, significant traumatic injury and even death may occur as a result of the violent or aberrant behavior characteristic of PCP use.

The ED evaluation of a patient with known or suspected PCP intoxication should include examination for occult trauma and evaluation for the possibility of hypoglycemia or rhabdomyolysis. A urine dipstick positive for occult blood when no red blood cells are seen on microscopic examination suggests myoglobinuria, and should prompt the physician to obtain a total CK level to screen for rhabdomyolysis. Results of toxicologic screening for PCP can be misleading. Tests can be falsely negative; also, chronic PCP users may test positive for weeks following their last use,²² so a positive test does not necessarily indicate acute PCP intoxication.

PCP is secreted into the stomach, so administration of multiple doses of activated charcoal could theoretically facilitate drug removal. In reality, patients intoxicated with PCP are often uncooperative or combative, and it may be impractical or impossible to administer this form of therapy. If possible, activated charcoal should be administered to patients known to have large or recent ingestions of PCP.

Violence and agitation are common features of PCP intoxication, and sedation and/or physical restraints are frequently required to prevent patients from harming themselves and to protect ED personnel. Pharmaceutical intervention is preferable to physical measures because the muscular activity caused by a patient fighting against restraints may contribute to the development of rhabdomyolysis. Parenteral benzodiazepines are recommended, but haloperidol can also be used.

Management of patients with PCP intoxication is generally supportive, but patients with severe CNS toxicity or who have specific medical complications require appropriate intervention. They should be evaluated for other causes of altered consciousness, including hypoglycemia and trauma. Seizures should be treated with benzodiazepines, and patients in status epilepticus may require endotracheal intubation and neuromuscular blockade. Hyperthermia is treated with rapid cooling measures, and if severe, endotracheal intubation with neuromuscular blockade should be considered. Hypertension usually responds to sedation, but severe hypertension can be treated with nitroprusside. Treatment of rhabdomyolysis includes aggressive hydration. Use of intravenous sodium bicarbonate to alkalize the urine is controversial but may help prevent acute tubular necrosis (see Chap. 279).

Patients with significant medical complications due to PCP, such as rhabdomyolysis, seizures, hyperthermia, or severe hypertension, require hospital admission. Patients exhibiting only minor clinical features of PCP intoxication (lethargy, bizarre behavior, violent behavior, or agitation) can often be discharged if improved following a period of observation.²⁰

MARIJUANA

Dried leaves and flowers from the hemp plant *Cannabis sativa* is called marijuana, and dried resin from the flower tops of this plant is known as hashish. The psychoactive ingredient of marijuana is Δ^9 -tetrahydrocannabinol (Δ^9 -THC). Δ^9 -THC binds to a specific brain receptor for which an endogenous ligand has been discovered.²³

Marijuana is most often smoked, but can be ingested. Symptoms persist for 2 to 4 h, or longer if ingested. Drowsiness, euphoria, heightened sensory awareness, paranoia, distortions of time and space, and feelings of unreality are described. Hallucinations do not normally occur at usual doses. Common physiologic effects of marijuana are mild tachycardia, injected conjunctiva, bronchodilation, orthostatic hypotension, and impaired motor coordination. Although significant medical complications occur rarely if at all, users may experience panic reactions, or even brief toxic psychoses due to Δ^9 -THC.

Acute psychiatric symptoms due to marijuana use can usually be managed with reassurance alone, but benzodiazepines can be used if

medication is warranted. **Urine tests are unreliable indicators of acute marijuana intoxication because it is detectable for days after use in novice users, and for weeks after the last use in chronic users.**²⁴

OTHER HALLUCINOGENS

Several drugs with hallucinogenic properties are enjoying increasing popularity due to information disseminated on the Internet. Numerous websites promote the use of psychoactive drugs that are "natural" and legal, such as *Salvia divinorum* and toad venom. *S. divinorum* is a plant in the mint family that can be chewed, smoked, or made into tea. The active ingredient, salvinorin A, is a potent κ opioid agonist,²⁵ and can cause profound hallucinations. It is currently legal in the U.S. and can be purchased through Internet sites. Possible adverse medical effects are largely unknown.

Bufotenin and related compounds are indolalkylamines with hallucinogenic properties that are present in venom from toads of the *Bufo* genus. Toads are "milked," or venom can be ingested through the practice of "toad-licking"; dried toad skins are also sold and smoked. Unfortunately toad venom may also contain toxic cardioactive steroids with digoxin-like properties, and can cause severe toxic reactions and death.²⁶ Digoxin-specific Fab fragments may be lifesaving for critically ill patients exposed to toad venom.²⁶

Seeds of the Morning glory plant (*Ipomoea violacea*, *Ipomoea tricolor*, and others) contain lysergic acid amide (ergine), a compound closely related to LSD. They are sometimes intentionally ingested for the hallucinogenic effects. Several hundred seeds may be taken as a "dose." Physical and psychologic manifestations closely resemble effects of LSD, and patients can be managed similarly.

Accidental or intentional ingestion of large amounts of nutmeg can cause delirium with hallucinations. Nutmeg is the dried seed from the tropical *Myristica fragrans* tree. The hallucinogenic properties of nutmeg may be due to a component, myristicin, but the mechanism is not well understood. Ingestion of 1 to 3 nutmegs or 5 to 15 g of the ground spice produces psychologic effects which begin in 3 to 6 h and last for 6 to 24 h. Uncomfortable physical symptoms are prominent, and may include tachycardia, flushing, dry mouth, nausea, and abdominal pain. Signs and symptoms may resemble anticholinergic poisoning, but pupils are usually small or midsized. Management is generally supportive.

Jimson weed (*Datura stramonium*) and Angel's trumpet (*Datura Candida*) are plants which grow naturally in the U.S., and contain the anticholinergic alkaloids atropine, scopolamine, and hyoscyamine. Seeds or other parts of the plant can be ingested or smoked, and cause the anticholinergic toxic syndrome. Delirium, hallucinations, and seizures can occur, along with other classic anticholinergic effects such as mydriasis, tachycardia, dry mouth and skin, blurred vision, urinary retention, and hyperthermia. Gastric emptying can be delayed, so gastric decontamination is an important part of the management of such patients. Whole bowel irrigation is recommended for patients who have ingested a large number of seeds. Medications with anticholinergic properties, such as phenothiazines, should be avoided. Physostigmine is effective treatment for severe anticholinergic symptoms.

Ketamine and dextromethorphan are chemically related to PCP, and have hallucinogenic properties. Like PCP, they are believed to act at the NMDA receptor. Ketamine, called "vitamin K" or "special K," is usually taken in powdered form, mixed in a drink, or snorted. Effects can be similar to those of PCP. Dextromethorphan is legal and readily available in over-the-counter cough suppressants, and has become increasingly popular among adolescent drug users. A large quantity must be ingested for the user to experience hallucinogenic effects. Dextromethorphan-containing preparations often include other ingredients such as acetaminophen, so the potential for toxic coingestion should be considered in any patient who has consumed a hallucinogenic dose of dextromethorphan.

DIFFERENTIAL DIAGNOSIS

Among the many conditions that may mimic hallucinogen intoxication are alcohol or benzodiazepine withdrawal, anticholinergic poisoning, thyrotoxicosis, central nervous system (CNS) infections, structural CNS lesions, and acute psychosis. Hypoglycemia should be considered in all patients with altered mental status. Numerous prescription and nonprescription medications can also cause hallucinations. Hallucinogens are usually taken intentionally, so in most cases a history of what was taken and the mode of administration will be available. However, the identity of street drugs is often misrepresented; the possibility that the substance used was adulterated or substituted by another more toxic drug, particularly PCP, should be considered. Drug testing is of limited utility since routinely available drug screens will not detect many hallucinogens. In addition, a positive test for PCP or marijuana can be misleading, as it may be indicative of use days or even weeks prior to testing.

GENERAL MANAGEMENT

The initial ED management of a patient presenting with hallucinations, bizarre behavior, or altered thought processes should be concentrated on assessing the patient's general medical condition and stabilizing the airway, breathing, and circulation as appropriate. Hypoxia and hypoglycemia should be recognized and treated promptly.

Most hallucinogens are rapidly absorbed. Patients experiencing adverse effects due to hallucinogen use do not usually present to the ED until several hours after the drug was administered. Therefore gastric decontamination is of limited utility in most cases of hallucinogen intoxication. Administration of oral activated charcoal is indicated for recent ingestions. Hemodialysis is not indicated, as it does not effectively remove hallucinogens from the body.

In many cases, calm reassurance in a supportive environment will sufficiently soothe the violent patient. In other cases, pharmacologic intervention, and possibly physical restraints, may be necessary in order to ensure the safety of the patient and the ED staff and to facilitate evaluation and treatment of the patient. Benzodiazepines are considered the mainstay of treatment. Diazepam 5 to 10 mg PO or IV, or lorazepam 1 to 2 mg PO, IM, or IV can be given depending on the severity of symptoms and the clinical situation. Repeated doses can be given as needed, provided the patient is monitored for the possibility of respiratory depression. Phenothiazines should not be used. Use of haloperidol, a butyrophenone, may be considered when a second sedating agent is required. However, haloperidol lowers the seizure threshold, has anticholinergic properties, and can cause dystonic reactions. Haloperidol's theoretical risk of reduction of the seizure threshold is often cited, but rarely experienced in practice. It should be avoided if the patient is exhibiting significant anticholinergic symptoms. Haloperidol can be administered intramuscularly or intravenously in 5-mg increments. Physical restraints are sometimes necessary, but their use should be minimized and avoided if possible. Physical restraints may cause injury, may exacerbate paranoia and agitation, and may contribute to the development of rhabdomyolysis in patients who struggle against them.

The management of patients with hallucinogen intoxication is largely supportive, but medical complications can occur and should be treated appropriately. Tachycardia and hypertension often respond to sedation with benzodiazepines alone. Significant arrhythmias are treated using standard protocols. Severe hypertension can be treated with nitroprusside. The dose of a nitroprusside infusion starts at 0.5 μ g/kg per min, and can be titrated to a maximum of 10 μ g/kg per min as needed. Propranolol should probably be avoided because many of the hallucinogens cause significant adrenergic stimulation, and use of a β -blocker may lead to paradoxical hypertension due to unopposed α stimulation.¹⁷ Rapid cooling measures should be initiated for patients with significant hyperthermia. Treatment of severe hy-

perthermia may require neuromuscular paralysis and endotracheal intubation. Seizures are treated with benzodiazepines and standard anticonvulsants. Patients with rhabdomyolysis require aggressive hydration and intravenous sodium bicarbonate to achieve a urinary pH of 6.5 to 8.

DISPOSITION

Most patients seen in the ED due to adverse reactions from hallucinogen use can be discharged into the custody of family or friends if they are lucid and medically stable after a period of observation. Patients with persistent psychotic symptoms or other significant psychiatric disturbance require psychiatric evaluation and possible hospital admission. Patients with significant medical complications of hallucinogen use, such as severe hypertension, hyperthermia, seizures, or rhabdomyolysis, should be admitted to the hospital for continued treatment and observation.

SALICYLATES

Luke Yip

EPIDEMIOLOGY

The widespread availability of aspirin [acetylsalicylic acid (ASA)] in prescription and over-the-counter (OTC) preparations, confusion between product names and brand names, and the ease with which incremental chronic dosing can cause toxicity make salicylism a common and sometimes fatal occurrence. Data from the American Association of Poison Control Centers Toxic Exposures Surveillance System showed that in 2000, aspirin was implicated in 20,892 exposures, with 12,658 cases (61 percent) treated in a health care facility; 45 deaths (0.2 percent of cases) were attributed to salicylate toxicity.¹ Many people use OTC medications without realizing that they may contain significant amounts of salicylate. For example, Pepto Bismol (261 mg salicylate per 30 mL) will deliver large amounts of salicylate in patients who misuse the product. Children may become salicylate-toxic from extensive application of keratolytic agents or other agents containing oil of wintergreen (methyl salicylate). **One milliliter of a 98% methyl salicylate solution contains 1400 nig of salicylate. Liniments and products used in hot vaporizers have high concentrations of methyl salicylate, and an ingestion of 5 to 10 mL can be lethal for an infant or a toddler.**

PATHOPHYSIOLOGY

Absorption of salicylate may be delayed or erratic depending on the product. After ingestion of large amounts of non-enteric-coated ASA, absorption from the gastrointestinal (GI) tract may be slowed because of the inhibitory effect of ASA on gastric emptying and the impaired dissolution of tablets in gastric fluids at high concentrations. Peak serum salicylate levels may not be reached for 18 to 24 h, although toxic levels usually are evident within 6 h. Methyl salicylate is a liquid that produces peak levels earlier, whereas peak levels following enteric-coated or sustained-release ASA overdose have been reported to occur 60 h after ingestion.² Some formulations of ASA may coalesce to form a gelatinous gastric mass after an intentional overdose, and this mass becomes a source for continued absorption.

After absorption, ASA is hydrolyzed to salicylic acid (salicylate) and is distributed throughout body tissues. Salicylate is responsible for both the therapeutic and the toxic effects of ASA. The severity of toxicity depends on the cellular salicylate concentration. At higher salicylate concentrations, a lesser percentage of the drug is protein bound, and more free drug is available to diffuse into tissues. The pK_a of salicylate is 3.0, and at physiologic pH (7.40), almost all salicylate molecules are ionized. If the systemic pH decreases, the change in equilibrium will form a greater portion of nonionized molecules. This is an important concept because nonionized molecules will cross cellular

membranes, such as the blood-brain barrier. Thus, for a given serum salicylate concentration, brain salicylate concentrations will be substantially higher in the presence of acidemia.³ Although the precise mechanism remains to be determined, the concentration of salicylate in the brain is correlated directly with mortality rate.³

The ionized state of salicylate can be used to enhance its elimination. If the urine pH is above 8.0, more salicylate molecules in the urine will be ionized compared with the renal tubular cell pH of 7.4, and reabsorption across the urinary tubule will be reduced.⁴

Acute salicylate overdose may produce nausea and vomiting as a result of local gastric irritation and stimulation of the chemoreceptor trigger zone. Vomiting may result in volume depletion, which reduces renal perfusion and urine flow, adversely affecting renal salicylate elimination and contributing to acid-base and electrolyte disturbances.

Salicylate initially increases respiratory rate through a direct stimulatory effect on the medullary respiratory center in the central nervous system (CNS),⁵ but very high salicylate concentrations depress respiration, a finding usually seen later in the course. Salicylate also stimulates skeletal muscle metabolism, which causes an increase in oxygen consumption and carbon dioxide production.⁵ The clinical manifestation of the initial respiratory center stimulation (the dominant component) and the increase in carbon dioxide production cause an increased respiratory rate, resulting in respiratory alkalosis.⁵ Initially, this will counter the enduring metabolic acidosis. If ventilatory compensation fails to keep pace with increased carbon dioxide production, respiratory acidosis will develop and will compound the metabolic acidosis. The loss of the respiratory buffering effect is detrimental because the kidneys, even under ideal conditions, cannot react with sufficient rapidity to counter the acidosis meaningfully. Also, the critical alkalemia seen early when respiratory alkalosis predominates causes the kidneys to increase bicarbonate and potassium excretion. The urinary bicarbonate loss eventually will decrease the body's bicarbonate stores and impair compensation for the metabolic acidosis of salicylism.

Salicylate enhances lipolysis, uncouples oxidative phosphorylation, and inhibits various Krebs cycle enzymes involved in energy production and amino acid metabolism, resulting in (1) increased catabolism that leads to increased carbon dioxide production, (2) increased heat production, (3) increased glycolysis and peripheral demand for glucose, and (4) production of metabolic intermediaries (i.e., organic acids, lactate, pyruvate, and keto acids) that contribute to the metabolic acidosis of salicylate toxicity.⁶ Overall, the acid-base disturbance associated with salicylate poisoning is mixed and includes respiratory alkalosis, metabolic alkalosis (due to volume contraction), and wide anion-gap metabolic acidosis.

Salicylate-induced noncardiogenic pulmonary edema has been observed in humans and studied in animals. Salicylate toxicity causes increased pulmonary vascular permeability, whereas pulmonary vascular pressures and cardiac performance are unaffected. This vascular injury also may involve the kidneys. Proteinuria is a prominent early finding in salicylate toxicity, starting at a serum salicylate concentration of greater than 30 mg/dL, and it is related directly to salicylate concentrations.

Salicylate also affects both central and peripheral glucose homeostasis. Salicylate causes mobilization of glycogen stores, resulting in hyperglycemia. However, salicylate is also a potent inhibitor of gluconeogenesis. Therefore, normoglycemia, hyperglycemia, or hypoglycemia may occur in salicylate toxicity. The brain involves a unique problem with glucose delivery. Animal studies demonstrate that toxic doses of salicylate produce a profound decrease in brain glucose concentration despite normal serum glucose levels.⁷ This finding suggests that the supply of glucose to the brain in salicylate poisoning may be inadequate, even though serum glucose levels are normal.

Antiplatelet activity is a well-known effect of ASA, but hemorrhage is a rare complication of acute, single, massive overdose of salicylate. *Chronic* administration of large doses of salicylate may cause

significant hypoprothrombinemia when the serum salicylate concentration exceeds 60 mg/dL.⁸

Salicylate ototoxicity is characterized by a reversible sensorineural hearing loss that is not idiosyncratic; it is related to serum salicylate concentrations.⁹ When serum salicylate concentrations exceed 40 mg/dL, hearing loss reaches its maximum of 40 dB.⁹

CLINICAL FEATURES AND DIAGNOSIS

Clinical manifestations of salicylism depend on the dose of salicylate ingested, duration of exposure, and age of the patient. In general, acute ingestion of less than 150 mg/kg may produce "mild" toxicity, with nausea, vomiting, and GI irritation, but significant toxicity is not expected. Acute ingestion of 150 to 300 mg/kg may produce "mild to moderate" toxicity, with vomiting, hyperpnea, diaphoresis, tinnitus, and acid-base disturbances. Acute ingestion of more than 300 mg/kg may produce "severe" toxicity.

Intoxication in Children

Acute pediatric salicylate intoxication is characterized by a known history of ingestion and onset of symptoms within a few hours of ingestion. Patients usually present soon after the ingestion. Symptoms are usually mild and the intoxication well tolerated.¹⁰ When the duration of salicylate intoxication is between 12 to 24 h, metabolic acidosis and acidemia (pH < 7.35) occur primarily in children younger than age 4, and nearly all children younger than age 1 have acidosis.¹¹ The acid-base disturbance in older children (age 4 or older) changes to a mixed disturbance with respiratory alkalosis and increased anion-gap metabolic acidosis; alkalemia (pH > 7.45) tends to be observed.

Chronic or "therapeutic" (repeated dose) pediatric salicylate poisonings generally are more serious and are associated with a higher mortality than acute salicylism.^{10,12} Often, several days elapse between the initial salicylate administration and the onset of symptoms.¹² There is frequently a coincidental illness that prompted salicylate administration, and children usually appear more ill than those with acute intoxication. The presenting signs are hyperventilation, volume depletion, acidosis, severe hypokalemia, and CNS disturbances.¹⁰ Chronic salicylism is often mistaken for an infectious process. Young children are prone to develop hyperpyrexia, which indicates a worse prognosis.¹² Renal failure may be a significant complication, but pulmonary edema is unusual in the pediatric population.¹² The delay in diagnosis may account for the more severe clinical picture with "therapeutic" salicylism.

Intoxication in Adults

Acute salicylate intoxication in adults is usually due to intentional ingestion, most often occurs in young women, and the patient frequently has a psychiatric or drug overdose history. The typical clinical presentation includes nausea, vomiting, tinnitus, sweating, and hyperventilation, which are reported to occur when the serum salicylate concentration is above 30 mg/dL.¹³ However, tinnitus may develop when the serum salicylate concentration exceeds 19.6 mg/dL.¹³ Most patients have a mixed acid-base disturbance of respiratory alkalosis and metabolic acidosis.¹⁴ However, when patients also have ingested sedative drugs that impair the hyperpneic response associated with salicylate toxicity, their acid-base profile is altered. Respiratory acidosis, rather than respiratory alkalosis, is more likely to occur.¹⁴ Patients with mixed ingestions have a normal anion-gap metabolic acidosis 40 percent of the time compared with patients who have a larger mean anion gap when salicylate was ingested alone.¹⁴ Therefore, salicylate intoxication in adults who present with a normal anion-gap metabolic acidosis should raise the suspicion that a coingestion including a CNS depressant has occurred. **A normal anion gap does not rule out salicylate toxicity in patients with an unknown ingestion.**

The complex triple-mixed acid-base disturbance of increased anion-gap acidosis, metabolic alkalosis, and respiratory alkalosis may not be seen frequently in salicylate toxicity, but when it is noted, the differential diagnosis is limited. The only other single entity that leads to increased anion-gap acidosis seen with the other two components is sepsis (lactic acidosis, contraction metabolic alkalosis, and respiratory alkalosis). The main contribution to the metabolic acidosis in sepsis is lactate. In contrast, any lactic acidosis associated with salicylate poisoning should be mild unless there is significant hypotension and impaired tissue perfusion. The presence of significant lactic acidosis should prompt a search for an alternate etiology (see Chap. 25).

Uncommon features of acute adult salicylism include fever, neurologic dysfunction, renal failure, adult respiratory distress syndrome (ARDS), noncardiogenic pulmonary edema, and hypoglycemia. Each of these uncommon manifestations indicates more severe poisoning, with associated greater morbidity and mortality rates. Hyperpyrexia appears to be an adverse prognostic indicator, and death is usually preceded by a predominant metabolic acidosis and neurologic deficits.¹⁴ Other rare complications may include rhabdomyolysis, gastric perforation, and GI hemorrhage. Risk factors for death from acute salicylate toxicity include unconsciousness on presentation, fever, severe acidosis, seizures, cardiac dysrhythmias, and advanced age. The development of respiratory acidosis is usually a premorbid event.

The diagnosis of chronic salicylate intoxication (chronic excessive dosing) in adults is different, particularly in the elderly. These patients are more likely to have underlying medical conditions that they are treating with salicylates. Signs and symptoms of chronic intoxication include hyperventilation, tremor, papilledema, agitation, paranoia, bizarre behavior, memory deficits, confusion, and stupor.¹⁵ Neurologic abnormalities are much more common in chronic salicylate poisoning and often mislead physicians. Chronic salicylism should be considered in any patient with unexplained CNS dysfunction, especially in the presence of a mixed acid-base disturbance, tachypnea or dyspnea, unexplained noncardiogenic pulmonary edema, or nonfocal neurologic or behavioral abnormalities. Adults with chronic salicylate toxicity have a higher morbidity rate, including pulmonary edema, seizures, and renal failure, as well as higher mortality rate. The distinction between acute and chronic salicylate toxicity may not always be clear. A patient may present many hours after an acute severe salicylate overdose, when altered mental status, acidosis, elevated prothrombin time, and serious toxicity with a "therapeutic" serum salicylate concentration are signs consistent with a chronically poisoned patient. Significant toxicity may be evident despite declining or "therapeutic" serum salicylate concentrations. In these situations, the patient's clinical status is most important when assessing the severity of toxicity.

Chronic salicylism may develop in patients taking carbonic anhydrase inhibitors for treatment of glaucoma.¹⁶ The normal anion-gap (hyperchloremic) metabolic acidosis produced by carbonic anhydrase inhibitors increases the volume of distribution for salicylate and facilitates its entry into the CNS, causing toxicity at a "therapeutic" serum salicylate concentration.

SPECIFIC ISSUES

The Done nomogram was created to assist in clarifying the level of salicylate intoxication that should prompt intervention: "... this [nomogram] provides only a rough guide to a single criterion of severity in previously well patients. ... it obviously does not supplant clinical judgment."¹⁷ Although widely taught and used for over 40 years, the Done nomogram typically is misunderstood and often is misused. Thus it is strongly recommended that the patient's clinical condition and early course, rather than the nomogram, guide clinical management. The nomogram was based primarily on previously healthy pediatric patients with acute single salicylate ingestion.¹⁷ The patients' presentations were graded clinically. The initial serum salicylate con-

centration was extrapolated based on toxicokinetic data. The clinical grade was then correlated with the extrapolated initial salicylate concentration. The potential usefulness of the nomogram is to assist in predicting the degree of toxicity after an acute single ingestion of ASA in patients who have not been taking salicylate recently. The nomogram is *not* useful when:

salicylate has been ingested over several hours or days, the preparation is an enteric-coated or a sustained-release tablet, the compound is oil of wintergreen, which is absorbed rapidly, the patient has renal insufficiency or failure, the time of ingestion is unknown or uncertain, the patient is acidemic, or a salicylate level drawn before 6 h after ingestion returns nontoxic.

In such situations, the degree of toxicity is determined by serial evaluation of a patient's clinical condition and serial salicylate levels. Evolution of a "nontoxic" salicylate level into severe salicylate intoxication has surprised many physicians. Failure to anticipate worsening intoxication is generally due to reliance on a single salicylate level, without regard for the formulation used or the time of ingestion. If the level was drawn before 6 h, it may underestimate the severity. It is prudent in most patients to obtain serial serum salicylate levels every 1 to 2 h until the levels are declining and the patient's clinical status stabilizes. Acidemia must alter estimation of the severity of the intoxication. Due to its limitations and deceptive utility, **use of the Done nomogram is not recommended**, and for this reason, a description of its use is not provided in this text.

The presence of salicylate may be determined with the ferric chloride test, which uses several drops of 10% ferric chloride added to 1 mL of urine. A purple color will be seen in the presence of salicylic acid, acetoacetic acid, or phenylpyruvic acid. This test is very sensitive to small quantities of salicylic acid, and a positive test result does not indicate salicylate poisoning or toxicity. False-negative results have not been reported. However, false-positive results may occur when a small quantity of urine that has been used for test-strip analysis with the N-Multistix or Bili Labstix is then used for ferric chloride testing. Presumably, some impregnated chemical from the dipstick dissolves in the urine and causes a false-positive reaction. Another bedside test for salicylic acid uses the Ames Phenistix, which turns brown when either salicylic acid or phenothiazines are present in the urine or serum. Adding one drop of 20 N sulfuric acid to the strip bleaches out the color in the case of phenothiazines but not in the case of salicylic acid. The color change is often difficult to interpret. Both the ferric chloride and Ames Phenistix tests are qualitative tests. All positive urine results must be confirmed with serum salicylate level. There are severe limitations associated with bedside detection techniques for salicylic acid, and I do not advocate their use in the clinical setting.

Assessing the condition of patients who have ingested enteric-coated or a sustained-release ASA preparation is difficult. These products are formulated to remain intact in the acidic gastric environment but to dissolve in the alkaline intestinal fluids. Drug release is therefore primarily a function of gastric emptying, and peak levels may not be apparent until 10 to 60 h after ingestion.² Another problem with enteric-coated and sustained-release tablets is their large size, which makes them difficult to remove from the stomach even through a no. 40 French gastric lavage tube. A plain radiograph of the abdomen has been recommended for enteric-coated medications, but not all are radiopaque.¹⁸ Thus a positive radiograph can confirm that pills are present, but a negative radiograph does not rule out enteric-coated or sustained-release ASA tablets in the GI tract. If a potentially lethal number of enteric-coated or sustained-release tablets has been ingested, the patient should be observed for at least 24 h and serial serum salicylate levels obtained until a declining level is ensured.²

Many standard texts assert that urinary alkalization is impossible until hypokalemia has been corrected.¹¹ The kidneys will attempt to excrete hydrogen ion in order to retain potassium, leading to paradox-

ical aciduria despite alkalemia. However, there seem to be little or no clinical data specifically regarding the role of potassium replacement in alkalization of urine during salicylate intoxication. In one human study, no correlation was found between serum potassium levels and urinary pH, and the patients' urines remained acidic despite alkalemia and normokalemia.¹⁹ Although it is important to administer supplemental potassium to hypokalemic patients, do not delay the administration of sodium bicarbonate until normokalemia is achieved. Potassium and sodium bicarbonate should be administered simultaneously. When aggressive management for ARDS with endotracheal intubation, mechanical ventilation, and sedation becomes necessary, hyperventilation must be maintained, or acute deterioration may occur as a result of iatrogenic respiratory acidosis, causing a rapid shift of salicylate into the CNS.

TREATMENT

There is no specific antidote for salicylate toxicity. The main goals of therapy are immediate resuscitation; maintenance of airway, breathing, and circulation; correction of volume depletion and metabolic derangements; GI decontamination; and reduction in body salicylate burden. The first step is to determine that clinically significant salicylate toxicity exists. This decision is made based on serial clinical assessment of the patient and serial serum salicylate concentrations. Essential laboratory tests include serum salicylate levels, electrolytes, glucose, blood urea nitrogen, and creatinine. Arterial blood gases, chest and abdominal radiograph, electrocardiogram, complete blood count, serum calcium level, and urinalysis with urine pH determination should be obtained as clinically indicated.

Reducing a patient's salicylate burden involves minimizing further absorption of salicylate from the GI tract and hastening elimination of salicylate already absorbed. Salicylate absorption is effectively reduced by the administration of activated charcoal (AC) both for regular and for sustained-release forms.²⁰ AC 1 to 2 g/kg should be administered to patients who have ingested potentially toxic amounts of salicylate. In contrast, no convincing data support the use of repeated or multiple doses of AC. Evidence supports the use of whole-bowel irrigation as a more effective means of GI decontamination when dealing with enteric-coated or sustained-release ASA in the GI tract.²¹

Patients with severe salicylate intoxication are usually volume depleted and have acid-base disturbances that require general supportive and specific measures to enhance elimination. Careful assessment of a patient's volume and electrolyte status is important, particularly in the elderly and in patients with a history of cardiac disease. Fluid replacement of volume deficits should be undertaken while preparations are made for other measures. Potassium (40 mEq/L) should be supplemented in the NS (may require central line administration) after adequate urine output has been established. Note that correction of acidemia might further exacerbate hypokalemia due to a shift of potassium into cells.

Urinary salicylate clearance is directly proportional to urine flow rate, but more important, it is logarithmically proportional to urine pH.¹⁹ Urine alkalization is more effective than forced diuresis or forced alkaline diuresis, and it avoids the potential complication of fluid overload that may result from forced diuresis, especially in those with marginal cardiac reserve or cardiac performance.¹⁹

Opinions differ on the approach to initial fluid resuscitation and alkalization of the urine. In practice, often both hydration and urine alkalization are initiated simultaneously. My approach has been to volume replete patients with NS with a target urine output of 1 to 2 mL/kg per h. Concurrently, in a second intravenous line, administer an intravenous bolus of sodium bicarbonate (1 to 2 mEq/kg), followed by a continuous infusion of D5W, to which 3 ampules (either 44 or 50 mEq/ampule) of sodium bicarbonate have been added, starting at 1.5 to 2.0 times the maintenance rate and then adjusted to maintain the urine pH above 7.5. Except for the fluids used for hydration, all

intravenous fluids administered should contain a minimum of 50 g/L of glucose (D5W) because hypoglycemia has been implicated in the pathophysiology of salicylate CNS injury.⁷ When hypoglycemia or neurologic symptoms are present, a minimum of 100 g/L glucose (D10W) has been suggested. It is important to diligently monitor the patient's clinical course. The patient's urine pH and serum salicylate concentration, as well as volume, acid-base and electrolyte status, and cardiopulmonary and neurologic status, should be evaluated at least every hour.

Patients with salicylate-induced (noncardiogenic) pulmonary edema should be managed as are patients with ARDS from other causes. Pulmonary edema begins to improve concomitantly with the lowering of serum salicylate levels. This would suggest that aggressive efforts toward rapid elimination by hemodialysis may be beneficial in this subset of patients. In addition, early hemodialysis enables removal of salicylate without the volume challenge that accompanies sodium bicarbonate administration, and it avoids the possibility of aggravating pulmonary edema.

Hemorrhagic complications are seen rarely in single massive salicylate overdoses. Chronic administration of large doses does cause significant hypoprothrombinemia when serum salicylate concentration exceeds 60 mg/dL.⁸ However, hemorrhage, even under this scenario, is seen rarely in clinical practice or in animal experiments. When bleeding does occur, it rarely appears to be a contributing factor in mortality from salicylate toxicity. Patients with clinically significant bleeding should be treated with fresh-frozen plasma. Observations in animals and humans indicate that administering large doses of vitamin K after the development of hypoprothrombinemia has little or no effect on the plasma prothrombin time when serum salicylate concentration is high. After discontinuing salicylate, the prothrombin time rapidly returns to normal.

Hemodialysis is considered the extracorporeal technique of choice for the treatment of serious salicylate toxicity because hemodialysis can correct acid-base and electrolyte abnormalities while rapidly reducing the body salicylate burden.²² Indications for hemodialysis include:

clinical deterioration or failure of improvement despite intensive supportive care and an alkaline diuresis, lack of success in establishing an alkaline urine, renal insufficiency or renal failure, severe acid-base disturbance, altered mental status, and patients with ARDS.

Serum salicylate concentration may be helpful but should not be the sole determinant in the decision to initiate hemodialysis. A level of 100 mg/dL after an acute ingestion in a healthy patient may not require hemodialysis, whereas a patient with a level of 30 mg/dL in a chronic ingestion may be moribund. One should err on the side of hemodialysis in patients who are elderly, have chronically ingested ASA, have altered mental status, have acidemia, or have a severe underlying disease (e.g., coronary artery disease or chronic obstructive pulmonary disease).

In significant ingestions, serum salicylate levels should be monitored at least every 2 h until a peak has been reached and then every 4 to 6 h until the peak falls into the nontoxic range. In severe ingestions, serum salicylate levels should be determined hourly, and clinical decisions should be based on the trend of the serum salicylate levels as well as the patient's clinical status.

DISPOSITION

A patient may be discharged following adequate GI decontamination if there is progressive clinical improvement, no significant acid-base disturbance, and a documented serial decline in serum salicylate lev-

els toward the therapeutic range. If there is any doubt, the patient should be admitted to an intensive care setting. Although the determination of serial salicylate levels offers valuable information regarding the effectiveness of the treatment implemented, it is a poor substitute for clinical evaluation of a patient. Management decisions are never based solely on a particular salicylate level. Early consultation with a clinical toxicologist is prudent.

ACETAMINOPHEN

Oliver L. Hung Lewis S. Nelson

Acetaminophen (7Y-acetyl-⁴-aminophenol, paracetamol, or APAP) is the most popular over-the-counter analgesic used in the United States, and is one of the most commonly reported toxic exposures reported to poison centers nationwide. Poisonings often occur because of the er-

roneous belief that this medication is benign or because the victim was unaware that it was an ingredient in the ingested preparation. According to the Toxic Exposure Surveillance System in 2000, acetaminophen accounted for 5 percent of all toxic exposures, but also accounted for 23 percent of reported fatalities.¹

PHARMACOLOGY

The recommended dosing of acetaminophen is 650 to 1000 mg every 4 to 6 h up to 4 g a day in adults and 10 to 15 mg/kg every 4 to 6 h in children. After ingestion, acetaminophen is rapidly absorbed from the gastrointestinal tract. In therapeutic doses, peak serum levels are usually achieved within 30 min to 2 h. Even in overdose, peak serum levels are usually achieved within 2 h. However, delayed absorption of acetaminophen is reported following overdoses of preparations in which acetaminophen is combined with propoxyphene (e.g., Darvocet) or diphenhydramine (e.g., Tylenol PM), as well as those with altered release kinetics (e.g., Tylenol Arthritis Pain Extended Relief).

Acetaminophen is primarily metabolized by the liver through sulfation (20 to 46 percent) and glucuronidation (40 to 67 percent). A small percentage (<5 percent) of acetaminophen undergoes direct renal elimination. A small percentage is also oxidized by cytochrome P450 (CYP2E1, CYP1A2, and CYP3A4) to a reactive metabolite

NAPQI (TV-acetyl-*p*-benzoquinoneimine), which is quickly detoxified by hepatic glutathione to a nontoxic acetaminophen-mercaptate compound that is renally eliminated (Figure 171-1).

However, following acetaminophen overdose, hepatic metabolism through glucuronidation and sulfation is easily saturated. A larger proportion of acetaminophen is therefore metabolized by cytochrome P450 to NAPQI, depleting glutathione. When hepatic stores of glutathione decrease to less than 30 percent of normal, NAPQI binds to other hepatic macromolecules and hepatic necrosis ensues (Figure 171-2).² Within the hepatic lobule, cytochrome P450 is concentrated within hepatocytes surrounding the terminal hepatic vein and least concentrated within hepatocytes surrounding the portal triad. As a result, acetaminophen-induced hepatic injury develops in the characteristic pattern of centrilobular necrosis.

Although the clinical manifestations of acetaminophen toxicity are classically delayed, hepatic injury actually occurs very early. In an animal model of acetaminophen hepatic toxicity, early signs of hepatocyte injury occurred within 12 h of exposure.³ This was based on microscopic evidence as well as immunofluorescent staining of NAPQI-hepatic protein adducts (3-Cys-A) within hepatocytes. Hepatocyte changes progressed until day 2, when cell lysis occurred, releasing hepatic enzymes, such as transaminases, and NAPQI-hepatic protein adducts into the circulation where they were detected in the

FIG. 171-1. A and B. Acetaminophen [*N*-acetyl-*p*-aminophenol (APAP)] metabolism.

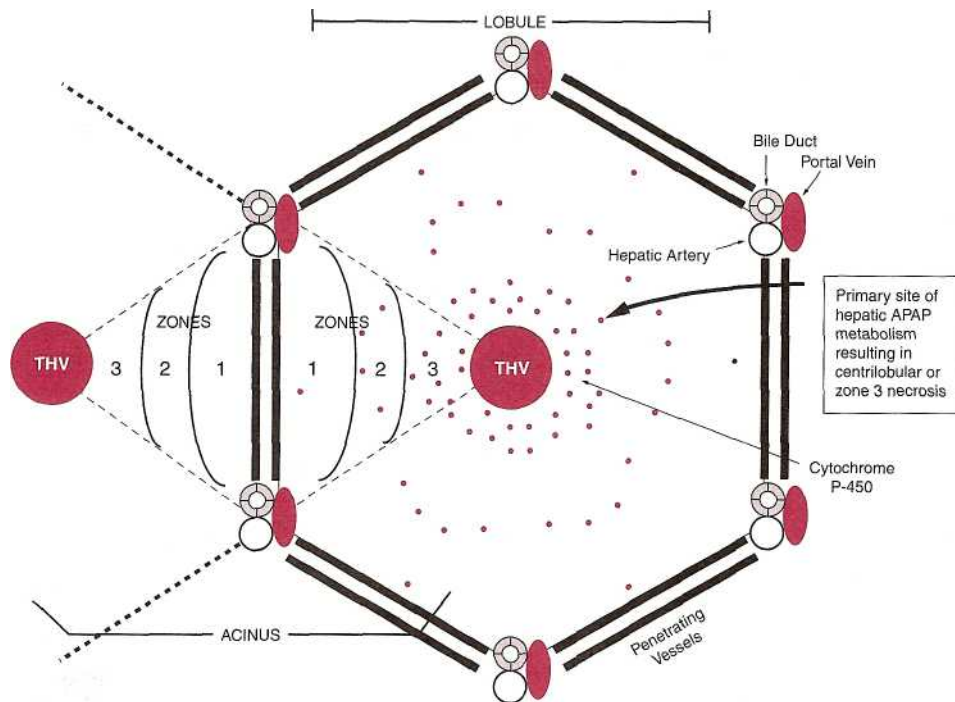

FIG. 171-2. Hepatic architecture. Although morphologically the liver is described by the lobule, it is better described functionally by the acinus. The acinus includes the tissue located between adjacent portal triads and it contains zones of differing metabolic function. Zone 3, located closest to the hepatic vein, contains the greatest concentration of cytochrome P450, accounting for the pathologic finding of centrilobular necrosis in patients with acetaminophen hepatotoxicity. THV = terminal hepatic vein.

serum. This corresponds generally to the development of overt clinical toxicity in humans.

CLINICAL PRESENTATION

The clinical presentation of human acetaminophen toxicity can be approximately divided into four stages. During the first 24 h after exposure (stage 1), patients often have minimal signs and symptoms of toxicity. Some may have minor, nonspecific signs and symptoms such as anorexia, nausea, vomiting, pallor, and malaise. By days 2 to 3 (stage 2), clinical signs of hepatotoxicity that may be discerned in hepatotoxic patients include right upper quadrant abdominal pain and tenderness, and abnormal laboratory tests, such as elevated serum aspartate aminotransferase (AST), alanine aminotransferase (ALT), and bilirubin. Even without treatment, most of these patients will recover without sequelae. By days 3 to 4 (stage 3), however, the conditions of some patients will progress to fulminant hepatic failure. Characteristic findings include metabolic acidosis, coagulopathy, renal failure, encephalopathy, and recurrent gastrointestinal (GI) symptoms. Those patients who survive the complications of fulminant hepatic failure will begin to recover over the next week (stage 4), with complete resolution of hepatic dysfunction in survivors.

Patients with insufficient glutathione stores (e.g., alcoholics and AIDS patients) and patients with induced cytochrome P450 enzymatic activity (e.g., alcoholics and those taking concurrent anticonvulsant or antituberculous medications) may be at greater risk for developing acetaminophen-induced hepatotoxicity following overdose.^{4,5} In contrast, children, because of their greater ability to metabolize acetaminophen through hepatic sulfation, may be at decreased risk for developing hepatotoxicity following a moderate overdose when compared to adults.^{6,7}

Acetaminophen may also cause acute, extrahepatic toxic effects, presumably because of the presence of cytochrome P450 present in other organs. Ingestion of massive doses of acetaminophen (4-h acetaminophen level >800 [ig/mL]) is associated with the acute development of altered sensorium (coma, agitation) and a metabolic (lactic) acidosis.⁸ Lactic acidosis can occur with extremely high levels of APAP in the absence of both liver failure or hypotension. Acetaminophen overdose is also infrequently associated with the development

of isolated renal insufficiency. In rare cases, cardiac toxicity and pancreatitis may occur.

DIAGNOSIS

A toxic exposure to acetaminophen is suggested when greater than 140 mg/kg is ingested in a single dose or when greater than 7.5 g is ingested within a 24-h period. The confirmation of acute acetaminophen poisoning depends solely on obtaining a serum acetaminophen level and estimating the time since ingestion. Unlike other types of poisoning, the initial clinical findings are nonspecific and delayed in onset; thus the reliance on laboratory evaluation. An acetaminophen level should be obtained for all patients presenting to the ED with a presumed intentional overdose of any type. In one study, 1 in 500 patients presenting to the ED after an overdose who denied ingesting acetaminophen was determined by laboratory testing to have a potentially toxic acetaminophen level.⁹ Empirical testing of all patients with intentional overdoses may be cost-effective. The cost of treating a single patient for complications of acetaminophen-induced hepatotoxicity is commonly estimated to outweigh the cost of laboratory testing for 500 patients who prove to have nontoxic acetaminophen levels.

The implication of a measured acetaminophen level is determined by plotting it on the Rumack-Matthew nomogram¹⁰ (Figure 171-3). This nomogram was empirically based on a retrospective analysis of previous acetaminophen overdose patients and their clinical outcomes. The original nomogram line was based on a 4-h acetaminophen level of 200 fJg/mL, but was subsequently modified in the United States by the Food and Drug Administration (FDA) to increase the safety margin by moving the line to a 4-h acetaminophen level of 150 fJg/mL. More importantly, the nomogram only applies to an acetaminophen level obtained after 4 h postingestion and before 24 h postingestion. It cannot be applied to acetaminophen levels obtained outside this 20-h window.

Obtaining multiple acetaminophen levels following acute overdose is rarely indicated in the absence of hepatotoxicity. An initial level below the nomogram line may rarely "cross the line" in patients who ingest acetaminophen preparations known to have prolonged absorption kinetics (see "Pharmacology" above). However, the clinical significance of crossing the line in this fashion is unknown. Similarly, be-

FIG. 171-3. Rumack-Matthew nomogram. (Reproduced with permission from Rumack BH, Matthew H: Acetaminophen poisoning and toxicity. *Pediatrics* 55:871, 1975.)

cause the nomogram was constructed and verified by using only a single serum level, the clinical implications of a level initially above the line that falls below it on repeat analysis are unknown.

Based on data obtained before the widespread use of antidotal therapy, patients with serum acetaminophen levels above the original 200 $\mu\text{g/mL}$, nomogram were observed to have a 60 percent risk of developing hepatotoxicity (defined as $\text{AST} > 1000 \text{ IU/mL}$), a 1 percent risk of renal failure, and a 5 percent risk of mortality." In addition, patients with extremely high serum acetaminophen levels (above a parallel line coinciding with a 300 $\mu\text{g/mL}$ 4-h level) were observed to have a greater risk (90 percent) of developing hepatotoxicity (Figure 171-4). The safety level below the U.S. nomogram line (4-h level corresponding to 150 $\mu\text{g/mL}$) was confirmed in a prospective study involving 11,195 patients.¹² The risk of hepatotoxicity in patients with acetaminophen levels below the nomogram was 1 percent. No patients received antidotal therapy, and all recovered without any complications (Figure 171-5).

TREATMENT

Treatment for acetaminophen toxicity consists of GI decontamination, the timely use of the antidote, iV-acetylcysteine (NAC), and supportive care. For most cases of acetaminophen poisoning, adequate GI decontamination consists of the early administration of activated charcoal orally or through nasogastric tube. Inducing emesis by administering syrup of ipecac is undesirable because it delays the administration of

FIG. 171-4. Outcome of acetaminophen poisoned patients without N-acetylcysteine; such therapy initiated prior to 8 h post-ingestion reduces adverse outcomes to that expected if the acetaminophen level was below the nomogram line. APAP = iV-acetyl-;?-aminophenol (acetaminophen); AST = aspartate aminotransferase.* Defined as $\text{AST} > 1000$. (Adapted with permission from Smilkstein MJ, Knapp GL, Kulig KW, et al: Efficacy of oral iV-acetylcysteine in the treatment of acetaminophen overdose. *New Engl J Med* 319:1557, 1988.)

the antidote. In addition, more aggressive forms of decontamination, such as orogastric lavage or whole-bowel irrigation with polyethylene glycol are unnecessary because of the rapid gastrointestinal absorption of acetaminophen and the great success of treating acetaminophen poisoning with NAC. However, aggressive gastrointestinal decontamination should be considered in cases of poly drug overdose in which a coingestant is likely to be life-threatening (e.g., a tricyclic antidepressant or a sustained-release calcium-channel blocker).

The mainstay for the prevention or treatment of acetaminophen toxicity is the administration of NAC. Although its mechanisms of action are not fully understood, NAC is thought to have two important beneficial effects. In early acetaminophen poisoning (less than 8 h after ingestion), NAC averts toxicity by preventing the binding of

FIG. 171-5. The effect of the delay to the initiation of antidotal therapy on patients presenting with an initial acetaminophen level above the nomogram line. Initiation of iV-acetylcysteine therapy prior to 8 h post-ingestion nearly prevents the development of hepatotoxicity, defined as an $\text{AST} > 1000$. Although the benefit of N-acetylcysteine is less pronounced when initiated more than 8 h post-ingestion, without antidotal therapy 60 percent of the patients in this group, based on historical controls, are expected to develop hepatotoxicity. AST = aspartate aminotransferase. (Adapted with permission from Smilkstein MJ, Knapp GL, Kulig KW, et al: Efficacy of oral NV-acetylcysteine in the treatment of acetaminophen overdose. *New Engl J Med* 319:1557, 1988.)

NAPQI to hepatic macromolecules. NAC may do this by acting as a glutathione precursor or substitute, a sulfate precursor, or it may directly reduce NAPQI back to acetaminophen. In established acetaminophen toxicity, or greater than 24 h after acetaminophen ingestion, NAC diminishes hepatic necrosis by acting as an antioxidant, decreasing neutrophil infiltration, improving microcirculatory blood flow, or increasing tissue oxygen delivery and extraction.

The standard 72-h oral NAC regimen used in the United States is a loading dose of 140 mg/kg followed by maintenance doses of 70 mg/kg every 4 h for 17 additional doses. If treatment is initiated within 8 h of acetaminophen ingestion, NAC is nearly 100 percent effective in preventing the development of hepatotoxicity.¹² The longer the initiation of NAC therapy is delayed beyond 8 h after ingestion, the greater the risk of developing hepatotoxicity. **Even by 24 h after acetaminophen ingestion, however, NAC treatment is associated with a lower risk of hepatotoxicity than occurred in historical controls¹¹** (see Figure 171-5).

The major complications of oral NAC therapy are nausea and vomiting, due in part to its foul rotten egg odor and taste. To hide these disagreeable characteristics, the standard 10 or 20 percent NAC solution should be diluted to a 5 percent concentration in a chilled beverage, such as fruit juice or a soft drink, prior to administration. NAC's disagreeable odor may be further minimized by having the patient sip the drink through a straw from a covered cup or by administering the dose by nasogastric tube. Some patients with persistent nausea and vomiting may require concomitant antiemetic treatment with agents such as intravenous metoclopramide (Reglan), 0.1 mg/kg up to 1.0 mg/kg, ondansetron (Zofran), 0.15 mg/kg, or granisetron (Kytril), 0.01 mg/kg.

Intravenous NAC regimens are routinely used in other countries and are being used successfully with increasing frequency in certain parts of the United States. Intravenous NAC is better tolerated by most patients, and the only major limitation is the development of rate-related anaphylactoid reactions that are easily treated.¹³ Intravenous NAC therapy is as effective as oral therapy for patients with early acetaminophen poisoning,^{14,15} although its efficacy in patients presenting more than 10 h postingestion is less clear. At this time, the clinical experience with intravenous NAC in the United States remains too limited to recommend it as a routine replacement in most regions for the traditional oral NAC regimen. However, intravenous administration of NAC may be required to treat patients with refractory vomiting and in patients with contraindications to oral therapy (e.g., caustic ingestions). In addition, intravenous NAC may be preferable to oral NAC for the treatment of acetaminophen-induced fulminant hepatic failure,¹⁶ because oral NAC has not been adequately studied in this setting. Currently, there is no intravenous NAC formulation available in the United States. If it is to be used, the oral NAC preparation, which is sterile, can be administered intravenously. The recommended dose varies by locale, but administering a dose identical to that given in the oral regimen is reasonable without other expert guidance. Although not an FDA-approved route of administration, there is sufficient support in both the literature and clinical practice to allow its use.

Clinical experience suggests that patients with poor glutathione reserves, such as alcoholics and the chronically ill, have similar excellent clinical outcomes when the standard treatment guidelines are applied to their care. As such, there is no need to alter the use of the acetaminophen treatment nomogram or modify the dosing of iV-acetylcysteine for these patients.

In many clinical situations, NAC therapy is often started in close temporal proximity to the administration of activated charcoal. **Although NAC is adsorbed by activated charcoal, there is no evidence that activated charcoal inhibits the clinical effectiveness of NAC.**¹⁷ This loss is likely unimportant in most situations because the current dosing of NAC is probably excessive. This may explain why NAC appears to be equally effective in preventing hepatotoxicity following even very large acetaminophen overdoses. Separating the first dose of NAC and activated charcoal by 1 to 2 h when possible is a rea-

sonable (but not necessary) method to minimize potential NAC and activated charcoal interaction.

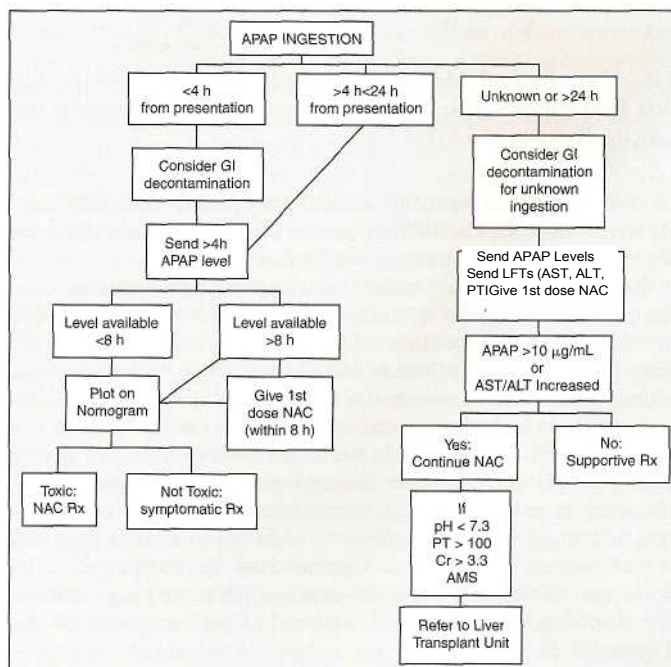

Finally, the weight of evidence suggests that NAC therapy is both safe and efficacious during pregnancy and that the approach to treating a pregnant patient following an acetaminophen overdose should remain the same. Although an ovine model demonstrated that NAC is unable to cross the placenta, there are data in humans establishing that it does.¹⁸ Still, NAC treatment has never been associated with fetal malformations in humans, but fetal demise and malformations have been described following delayed NAC treatment in first-trimester pregnant women after acetaminophen overdose.¹⁹

TREATMENT GUIDELINES

Treatment guidelines for acetaminophen poisoning are based on the time to presentation to the ED after ingestion: acetaminophen ingestions less than 4 h prior to presentation; acetaminophen ingestions greater than 4 h but less than 24 h ago; and acetaminophen ingestions of unknown time or greater than 24 h prior to presentation (Figure 171-6). No further acetaminophen serum measurements are necessary once the need for NAC therapy has been determined. Treatment with NAC should continue for the full 72-h course (18 doses).

For patients who present to the ED within 4 h and who are determined to likely have a significant overdose of their acetaminophen ingestion, treatment begins with GI decontamination (usually activated charcoal) and awaiting the determination of a 4-h postingestion acetaminophen level. If the hospital laboratory can report an acetaminophen level within 8 h postingestion, the clinician should wait for the serum acetaminophen level and plot it on the nomogram to determine whether NAC therapy is necessary. If the hospital laboratory cannot determine the acetaminophen level within 8 h, the clinician should empirically administer the first dose of NAC (within 8 h of acetamin-

FIG. 171-6. Treatment guidelines for acetaminophen ingestion. All

times noted are postingestion. Because the details of individual cases vary considerably, strongly consider calling the regional Poison Control Center (1.800.222.1222) for more specific or comprehensive assistance. ALT = alanine aminotransferase; AMS = altered mental status; APAP = N-acetyl-p-aminophenol (acetaminophen); AST = aspartate aminotransferase; LFTs = liver function tests, NAC = N-acetylcysteine; PT = prothrombin time; Rx = treatment.

open ingestion) without waiting for the measurement. Subsequently, when the acetaminophen level is determined, the need for additional NAC therapy should be determined with the use of the nomogram.

For patients who present longer than 4 h but less than 24 h following acetaminophen ingestion, the serum acetaminophen level should be determined by the laboratory as soon as possible. GI decontamination may be performed, particularly for suspected coingestants, but it may have limited effectiveness because of the delay in presentation. Similarly, if the hospital laboratory can determine the acetaminophen level within 8 h postingestion, the clinician should await the acetaminophen level and plot it on the nomogram to determine if NAC therapy is necessary. Otherwise, the first dose of NAC (within 8 h of acetaminophen ingestion, if possible) should be empirically administered. When the acetaminophen level is determined, it should be plotted on the nomogram to determine if additional NAC therapy is necessary.

Finally, for patients in whom the time of acetaminophen ingestion remains unknown or is >24 h, the clinician should consider whether GI decontamination is required. A serum acetaminophen level and liver function tests (AST, ALT) should be determined. In addition, the first dose of NAC therapy should be administered as soon as possible. In this scenario, a detectable acetaminophen level (greater than 10 J.g/ml) suggests that the patient may be at risk for developing hepatotoxicity. Similarly, elevated AST and ALT enzymes suggests the possibility of ongoing hepatic toxicity. Therefore, continued NAC therapy is indicated if the acetaminophen level is measurable or if the serum AST or ALT is elevated. If APAP <10 jxg/mL and the AST/ALT are not elevated, then NAC can be discontinued.

Standard supportive therapy should be initiated early for intravenous access, and a 12-lead electrocardiogram interpretation obtained to exclude cardiac toxins (e.g., cyclic antidepressants, digoxin, P-blockers, calcium channel blockers). Hypoxemia, hypoglycemia, and opiates should be quickly considered and excluded for all patients presenting with altered sensorium. All patients requiring NAC therapy should be admitted to the hospital until the completion of the therapy. In general, admission to a hospital floor bed is adequate unless the patient is hemodynamically unstable or the patient is suicidal and 24-h direct observation cannot be arranged. Patients who are not at risk for developing acetaminophen-induced hepatotoxicity (e.g., acetaminophen level below the nomogram, unmeasurable acetaminophen level with normal hepatic transaminase levels) should be observed in the ED for a minimum of a 4- to 6-h period to exclude potentially toxic coingestants. Psychiatric evaluation should be considered for patients with intentional acetaminophen overdoses.

FULMINANT HEPATIC FAILURE

Unfortunately, a small percentage of patients who overdose with acetaminophen will develop fulminant hepatic failure. The mortality rate for patients without NAC therapy is estimated at 58 to 80 percent. Most fatalities occur on days 3 to 5 after overdose and are attributed to hepatic complications such as cerebral edema, hemorrhage, shock, adult respiratory distress syndrome (ARDS), sepsis, and multiorgan failure. Patients who eventually survive from fulminant hepatic failure generally begin to show evidence of recovery by days 5 to 7. Eventually, all survivors will develop complete hepatic regeneration without any persistence of hepatic impairment.

NAC is beneficial in the treatment of acetaminophen-induced fulminant hepatic failure. When compared to controls, NAC therapy was associated with increased survival (48 vs 20 percent), decreased cerebral edema (40 vs 68 percent), and decreased vasopressor requirements (40 vs 80 percent).¹⁶ NAC also appears to be beneficial in the treatment of other forms of hepatic failure, too, including viral hepatitis and alcoholic cirrhosis.²⁰

Prognostic indicators exist to determine those patients with the highest risk of mortality from acetaminophen-induced fulminant hepatic failure. As a result, they also serve as early predictors of patients

who may subsequently require liver transplantation. A variety of laboratory and clinical markers are used including serum pH, prothrombin time (PT), serum creatinine, and mental status evaluation. The presence of a metabolic acidosis, pH <7.3, despite fluid and hemodynamic resuscitation, or a combination of coagulopathy (PT >100), renal insufficiency (creatinine >3.3 mg/dL), and grade III or IV encephalopathy is extremely useful in predicting poor outcome.²¹

Treatment for acetaminophen-induced fulminant hepatic failure includes NAC therapy, correction of coagulopathy and acidosis, monitoring for and aggressive treatment of cerebral edema, and early patient referral to a liver transplant center. Unlike the treatment of early acetaminophen toxicity, NAC therapy should be continued past the 72-h standard regimen until the patient recovers, receives a liver transplant, or dies. Because all clinical studies supporting the use of NAC for fulminant hepatic failure used the intravenous administration of NAC, intravenous NAC therapy may be preferable to oral NAC for the treatment of fulminant hepatic failure. Intravenous NAC should be administered at the same dosage as oral NAC. Because of the risk of anaphylactoid reaction, intravenous NAC infusions should be administered slowly and adjusted based on repeated blood pressure measurements to prevent hypotension.

SPECIAL CONSIDERATIONS: MULTIPLE-DOSE ACETAMINOPHEN INGESTIONS AND EXTENDED-RELEASE TYLENOL

Multiple closely-spaced acetaminophen ingestions and Tylenol Arthritis Pain Extended Relief ingestions represent two unique aspects of acetaminophen poisoning because the Rumack-Matthew nomogram cannot be readily applied. Tylenol Arthritis Pain Extended Relief (formerly Tylenol Extended Relief) is a formulation (McNeil Pharmaceuticals) that consists of a bi-layered formulation containing a total of 650 mg of acetaminophen. Theoretically, both of these situations could result in less toxicity than a single ingestion of the same total dose of acetaminophen because the time intervals between serum peaks may allow the liver to regenerate its supply of glutathione. Because there is little clinical data concerning both of these scenarios, treatment guidelines remain conservative.

The situation in which multiple ingestions of acetaminophen over a period of time occur cannot be interpreted on the nomogram because a single time of ingestion cannot be determined. One way to resolve this is to assume that a single ingestion occurred at the earliest possible time stated by the patient. An acetaminophen level is plotted on the Rumack-Matthew nomogram based on this artificial time, and treatment decisions are made accordingly. For example, if patient ingests 5 doses of 50 mg/kg of acetaminophen over a 4-h period beginning 8 h ago, a single acetaminophen ingestion is assumed to have occurred 8 h ago and the serum level is plotted on the nomogram.

Because of the uncertainty of potential toxicity of Tylenol Arthritis Pain Extended Relief, it is commonly recommended to obtain a second acetaminophen level 4 to 6 h later in those situations in which the first measured level (4 to 8 h postingestion) is elevated but below the nomogram line.²² A full course of NAC therapy should be instituted (or continued if already started) if the second acetaminophen level is above the nomogram line. If the initial level is above the nomogram line, standard therapy should be administered and there is no need to obtain a second level.

significant residual disability) and 38 deaths between 1997 and 2000. These cumulative data compare favorably to aspirin and acetaminophen, with fewer major outcomes and deaths per exposure (Table 172-1). The morbidity from NSAIDs in acute overdose is far overshadowed by complications of NSAIDs at therapeutic doses. It is estimated that NSAID-related gastrointestinal (GI) bleeding accounts for 16,500 deaths and 103,000 hospitalizations annually in the United States.² NSAIDs have also been reported to account for a substantial proportion of drug-induced renal failures.

PHARMACODYNAMICS

Overview

NSAIDs are structurally varied compounds with common therapeutic effects (Table 172-2). NSAIDs inhibit the enzyme cyclooxygenase (Cox), which is responsible for the production of prostaglandins from arachidonic acid. NSAIDs mediate inflammation through inhibition of prostaglandin production, but may also inhibit neutrophils via nonprostaglandin mechanisms. NSAIDs work as antipyretics through inhibition of prostaglandin E₂ (PGE₂) in the hypothalamus. NSAIDs appear to attenuate prostaglandin-mediated hyperalgesia and local pain-fiber stimulus.

Cyclooxygenase

There are at least two forms of cyclooxygenase: Cox-1 and Cox-2. Cox-1 is found predominantly in blood vessels, stomach, and kidneys at steady levels. Cox-2 is not usually found at significant levels in human tissue with the exception of possibly the brain and kidneys; rather, production of Cox-2 is induced by local inflammatory mediators.

There exist three general types of cyclooxygenase inhibitors: nonselective, partially selective, and selective (see Table 172-2). The vast majority of NSAIDs nonselectively inhibit both Cox-1 and Cox-2. It is the inhibition of Cox-1 that is believed to be responsible for many of the unwanted GI side effects of NSAIDs. There was a good deal of effort put forth to find more selective agents that would preferentially inhibit Cox-2. The partially selective agents (etodolac and meloxicam) are selective for Cox-2 at low doses, but become nonselective at higher doses. Recently, selective inhibitors of Cox-2 have been introduced with much anticipation and also some controversy. The new selective compounds do not appear to be more effective mediators of inflammation or analgesics, but they do appear to cause fewer GI side effects due to the lack of Cox-1 effects. The controversy surrounding these agents is the relative value of their GI sparing effects and less frequent dosing versus their significantly higher cost.

PHARMACOKINETICS

All NSAIDs are rapidly absorbed from the GI tract and are highly protein bound in the plasma. Most NSAIDs undergo at least partial me-

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS G.

Richard Bruno Wallace A. Carter

Nonsteroidal anti-inflammatory drugs (NSAIDs) are among the most widely used and prescribed drugs in the United States. They are effective antipyretics, nonnarcotic analgesics, and anti-inflammatory agents. There are between 35 and 70 million NSAID prescriptions written in the United States each year, and several agents are now available over the counter.¹ The world market for NSAIDs is reported to be a \$6 billion per year industry. Given the tremendous use and easy availability of NSAIDs, they are relatively safe agents with respect to acute ingestion and overdose. The American Association of Poison Control Centers (AAPCC) reports 290,031 NSAID exposures resulting in 997 major outcomes (life-threatening signs and symptoms or

TABLE T72-1 Outcome and Deaths

Cumulative AAPCC Data, 1997-2000	NSAIDs	Acetaminophen	Aspirin
Number of exposures	290,031	269,143	62,076
Major outcomes*	997	2,678	827
Deaths	35	287	175

*Major outcomes are defined as signs or symptoms that are life threatening or result in significant disability.

Abbreviations: AAPCC = American Association of Poison Control Centers; NSAIDs = nonsteroidal anti-inflammatory drugs.

TABLE 172-2 Classes of Nonsteroidal Agents Available in the United States

<i>Nonselective</i>
<i>Active NSAIDs</i>
Salicylates
Aspirin
Salsalate (Salflex, Disalcid)
Diflusal (Dolobid)
Acetic acids
Tolmetin (Tolectin)
Ketorolac (Toradol)
Diclofenac (Voltaren)
Indomethacin (Indocin)
Sulindac (Clinoril)
Xabumetone (Relafen)
Mefenamic acid (Ponstel)
Meclofenamate (Meclomen)
Propionic acids
Ibuprofen (Advil, Motrin, Nuprin)
Naproxen (Naprosyn, Aleve)
Ketoprofen (Onjdis)
Fenoprofen (Nalfon)
Flurbiprofen (Ansaide)
Oxaprozin (Daypro)
Pyrazolones
Phenylbutazone
Oxicams
Piroxicam (Feldene) <i>Partially selective Cox-2 inhibitors</i>
Eto dolac (Lodin)
Meloxicam (Mobic)
<i>Selective Cox-2 inhibitors</i>
Valdecoxib (Bextra)
Celecoxib (Celebrex)
Rofecoxib (Vioxx)

metabolism in the liver via glucuronic acid conjugation or oxidation in the microsomal enzyme system before elimination in the urine or feces. Plasma half-lives of NSAIDs range from 2 to 4 h for ibuprofen to longer than 50 h for the long-acting agents piroxicam and phenylbutazone. The new selective Cox-2 inhibitors have a plasma half life of approximately 15 h.

SIGNIFICANT DRUG-DRUG INTERACTIONS

Warfarin

Warfarin and NSAIDs have important interactions. Two NSAIDs (phenylbutazone and naproxen) have been reported to displace warfarin from plasma proteins, leading to increased warfarin levels in serum and elevated prothrombin times. The selective Cox-2 inhibitors at therapeutic doses have also been reported to slightly elevate prothrombin times. Phenylbutazone has been shown to decrease elimination of warfarin. Other NSAIDs have not been reported to change warfarin protein binding or elimination, but the use of nonselective NSAIDs is not recommended in warfarin users because they inhibit platelet aggregation, significantly increasing the risk for bleeding.

Diuretics and Other Antihypertension Agents

NSAIDs may decrease the effectiveness of some antihypertensives, including diuretics, α -adrenergic blockers, angiotensin-converting enzyme inhibitors, and β -adrenergic blockers. The blood pressure change when both NSAIDs and antihypertensives are used ranges from little effect to hypertensive urgencies. Inhibition of prostaglandin synthesis is believed to be central to the attenuation of antihypertensive effects. Lower prostaglandin levels result in decreased renal sodium clearance, water retention, changes in vascular tone, and alter-

ations in the renin-angiotensin system, all which may attenuate the effectiveness of antihypertensive agents.³

Decreased Renal Clearance of Drugs

NSAIDs may also decrease the renal clearance and elimination of certain drugs. **NSAID use inhibits renal clearance of lithium and leads to elevated serum lithium levels. Methotrexate elimination is also decreased with coadministration of NSAIDs and has resulted in fatal toxicity.**

CLINICAL PRESENTATION OF TOXICITY

Toxicity of NSAIDs at Therapeutic Doses

NSAIDs are relatively safe drugs that have a number of well-documented side effects at therapeutic doses. Morbidity and death from renal insufficiency and GI bleeding with chronic NSAID use far overshadow those of acute NSAID overdose. Other organ systems that may show toxicity at therapeutic doses include the central nervous system (CNS), and the cardiovascular, respiratory, hepatic, and dermatologic systems. It is generally believed that indomethacin and the long-acting agents phenylbutazone and piroxicam are responsible for a greater proportion of side effects, and that the propionic acid agents such as ibuprofen are responsible for fewer side effects.

Central Nervous System

Toxic CNS side effects of NSAIDs are far less frequent than GI or renal toxicity; however, various CNS effects include headache, cognitive difficulties, behavioral change, and aseptic meningitis. Acute psychosis has been reported with indomethacin and sulindac use and is hypothesized to result from the structural similarity of these NSAIDs to serotonin.

One of the most interesting side effects of NSAID use is aseptic meningitis. The literature reports cases in which patients repeatedly present with symptoms of headache, fever, neck stiffness, and fever within hours of taking NSAIDs. Cerebrospinal fluid analysis in these patients reveals elevated white blood cell and protein levels, and normal or decreased glucose levels. Symptoms resolve after NSAID use is stopped and can be elicited with repeat NSAID challenges. This phenomenon is most often seen with patients who have underlying autoimmune diseases, such as systemic lupus erythematosus. The phenomenon is thought to be a hypersensitivity reaction. Infectious meningitis must be excluded before the diagnosis of NSAID-induced aseptic meningitis is entertained.⁴

Pulmonary System

NSAIDs have been responsible for various adverse pulmonary reactions, including hypersensitivity pneumonitis, bronchospasm in asthmatics, and pulmonary edema. Patients with NSAID-related hypersensitivity pneumonitis present with symptoms of fever, cough, shortness of breath, pulmonary infiltrates on chest x-ray, leukocytosis, and often peripheral eosinophilia. Cessation of NSAID use results in the resolution of symptoms, whereas readministration causes a recurrence of symptoms. NSAIDs implicated in hypersensitivity pneumonitis include naproxen, diflusal, piroxicam, sulindac, and diclofenac. The mechanism of NSAID-mediated pneumonitis is believed to be an immune-mediated hypersensitivity reaction.

NSAID-induced bronchospasm is a well-described phenomenon in patients with reactive airway disease. The spectrum of hypersensitivity reaction varies from rhinitis to severe bronchospasm with laryngeal edema. Patients with underlying reactive airway disease and nasal polyps appear to be at greater risk for these complications. Aspirin is

most often involved in hypersensitivity reactions. Aspirin-induced bronchospasm occurs in 8 to 20 percent of all asthmatics and in 14 to 23 percent of asthmatics with nasal polyps.⁵ **Cross-sensitivity between aspirin and other NSAIDs is believed to be as high as 90 percent.** The mechanism of hypersensitivity to NSAIDs in asthmatics does not appear to be IgE mediated anaphylaxis; rather, it is an anaphylactoid reaction resulting from excessive leukotriene production.⁶

Gastrointestinal System

Gastrointestinal adverse effects result in the greatest morbidity from the therapeutic use of NSAIDs. These undesired effects range from dyspepsia to life-threatening bleeding from gastric or duodenal ulcerations. At therapeutic doses, nonselective NSAID inhibition of cytoprotective gastric prostaglandins (PGI₂ and PGE₂) increases the risk of gastric erosion, gastritis, and GI bleeding. There is a two- to five-fold increased risk of perforation or hemorrhage in NSAID users over the non-NSAID-using population. Data suggest that the risk for life-threatening bleeding is between 1.3 and 4 percent per year among NSAID users. It is estimated that NSAID-related GI bleeding contributes to 16,500 deaths and 103,000 hospitalizations annually in the United States.² Patients specifically at risk for GI bleeding include those who are elderly, those with a previous history of ulcers, those on high doses of NSAIDs, and those on corticosteroids.⁷

This significant risk for GI-related morbidity from the nonselective NSAIDs lead to the development of the newer selective Cox-2 inhibitors. These agents have been shown in multiple studies to have significantly reduced rates of gastric erosions and bleeding at therapeutic doses compared to nonselective NSAIDs.⁸

Liver

Both selective and nonselective NSAIDs may cause a spectrum of hepatic dysfunction, from asymptomatic elevation of transaminases to fulminant hepatic failure. NSAIDs that have caused idiosyncratic fulminant hepatic failure include diclofenac, bromfenac, ibuprofen, sulindac, naproxen, phenylbutazone, and oxaprozin. Hepatic toxicity can occur at any time during NSAID administration and is most common in patients with underlying liver disease, in the elderly, and in patients with preexisting autoimmune diseases.

Kidneys

The inhibition of prostaglandin synthesis by NSAIDs has specific effects on the kidneys. It appears that many of the renal effects of NSAIDs are mediated through Cox-2 inhibition.⁹ These effects range from mild changes in fluid and electrolyte homeostasis to acute renal insufficiency. NSAIDs promote sodium and water retention by attenuating prostaglandin-mediated inhibition of chloride reabsorption. NSAIDs may lead to hyperkalemia, either by increased potassium reabsorption secondary to decreased sodium concentration at the distal tubule, or by decreased secretion of renin. There is at least one report in the literature of cardiac arrest secondary to NSAID-induced hyperkalemia.¹⁰

Prostaglandins have a vasodilatory effect on the renal vasculature. The most important of these renal vasodilatory prostaglandins are PGI₂ and PGE₂. Prostaglandin-mediated vasodilatation is probably of little importance in euvolemic patients with normally functioning kidneys. However, prostaglandins appear to attenuate the vasoconstricting effects of the renin-angiotensin system and sympathetic nervous system during times of stress, during periods of decreased intravascular volume (sepsis, hemorrhage, and diuretic therapy), and in disease states that predispose patients to sodium retention (congestive heart failure, cirrhosis, and nephrotic syndrome).¹¹ The lack of these va-

sodilatory prostaglandins due to Cox inhibition by NSAIDs may put stressed kidneys at risk for azotemia and renal insufficiency. Similar precautions must be used when using both nonselective and selective Cox-2 inhibitors in patients predisposed to intravascular volume depletion, preexisting renal insufficiency, diabetes, and the aforementioned comorbid states.

Hematologic System

Nonselective NSAIDs inhibit platelet formation of thromboxane A₂, a potent stimulator of platelet aggregation. This leads to qualitative platelet deficiencies. The new Cox-2 inhibitors have far fewer antiplatelet effects than traditional NSAIDs. This may explain why there may be an increase in cardiac and neurovascular events in patients taking the Cox-2 inhibitor rofecoxib versus the nonselective Cox-1 inhibitor naproxen.¹

Most NSAIDs decrease platelet aggregation only when significant concentrations of the drug are present. Increased bleeding tendencies secondary to NSAIDs are not widely reported in the literature. However, patients taking aspirin are at risk for increased bleeding during surgery, and patients maintained on coumadin are advised to avoid all NSAIDs.

NSAIDs may cause other blood disorders. Bone marrow suppression is a rare but reported hematologic complication with use of NSAIDs. Aplastic anemia has been reported with almost all classes of NSAIDs, but phenylbutazone, indomethacin, and diclofenac are responsible for most cases.¹² NSAID use has also resulted in agranulocytosis, red cell aplasia, thrombocytopenia, and hemolytic anemia.

Skin

NSAIDs account for approximately 10 percent of cutaneous drug reactions.¹³ Agents most frequently involved in dermatologic complications include phenylbutazone, piroxicam, and benoxaprofen.¹⁴ Drug reactions to NSAIDs range from benign maculopapular rashes to the severe Stevens-Johnson syndrome and toxic epidermal necrolysis. NSAIDs are some of the most often-implicated drugs in cases of toxic epidermal necrolysis, accounting for up to one-third of drug-related cases in one series.¹⁵ NSAIDs of all types (oral and topical) can cause photosensitivity reactions, including increased sensitivity to sun exposure (phototoxic) and true photoallergic reactions. Piroxicam and ketoprofen are the NSAIDs most frequently involved in photoallergic reactions. One NSAID of the oxicam family, isoxicam, was removed from the U.S. market after fatal skin reactions.

Pregnancy

Prostaglandins are found in high concentration in the term uterus and have a stimulatory effect on normal labor. NSAIDs inhibit uterine motility through Cox-mediated inhibition of prostaglandin synthesis. Indomethacin is sufficiently effective at slowing uterine contractions that it has been used to treat preterm labor. Although NSAIDs are not believed to be teratogenic in humans, they do cross the placenta later in pregnancy. **One of the most significant effects of fetal exposure to NSAIDs is premature constriction of the ductus arteriosus, which may result in pulmonary hypertension.** Other reported effects of in utero exposure to NSAIDs include oligohydramnios, renal dysfunction, necrotizing enterocolitis, and CNS hemorrhage.

NSAID-induced inhibition of platelet aggregation may place the fetus and the mother at increased risk for bleeding. Mothers who take NSAIDs during the latter part of pregnancy appear to be at risk for increased peripartum hemorrhage. **The safest recommendation is to avoid NSAID use during pregnancy, especially during the third trimester.**

ACUTE OVERDOSE

Most patients with acute overdoses suffer little morbidity, but patients with significant overdoses may present with CNS, metabolic, hemodynamic, GI, or renal dysfunction.¹⁶ It is generally accepted that patients taking NSAIDs of the pyrazolone (phenylbutazone and oxyphenylbutazone) and the fenamic acid (mefenamic acid) families may present with the most severe clinical symptoms. It does not appear that NSAID metabolism is changed after acute overdose, and symptoms of acute overdose are usually apparent within 4 h of ingestion. There is little data about acute overdose of the relatively new Cox-2 inhibitors, but they are assumed to have similar safety profiles as the traditional NSAIDs.

Central Nervous System

CNS manifestation of acute NSAID overdose is usually minimal, but patients with significant overdose may present with altered mental status. Other CNS manifestations of acute overdose have included diplopia, nystagmus, and headache. Seizures have been reported after large overdoses and appear to be of special concern after ingestion of mefenamic acid.

Cardiovascular System

Acute NSAID overdose has resulted in hypotension and bradydysrhythmia. NSAIDs are not known to be primary causes of dysrhythmias, but fluid and electrolyte abnormalities may place patients at risk. Cardiovascular dysfunction is responsive to conventional critical care management.

Electrolytes

Electrolyte and acid-base abnormalities have been reported in acute NSAID overdoses. Alterations in serum electrolytes may occur secondary to decreased prostaglandin synthesis or from NSAID-induced renal failure. Sodium and water retention may lead to volume overload in patients having preexisting renal failure, cirrhosis, or congestive heart failure. Hyperkalemia, hypocalcemia, and hypomagnesemia have been reported in NSAID overdoses complicated by acute renal failure.¹⁷

Increased anion-gap acidosis has been observed with large overdoses of the propionic acid NSAIDs ibuprofen and naproxen. Prostaglandin inhibition is not directly responsible for the anion-gap acidosis; rather, acidosis is likely to be related to lactic acidosis. Case reports of large overdoses suggest that the acidosis may be related to large quantities of these mildly acidic NSAIDs and their metabolites in serum.¹⁸ However, these studies neither measured nor considered lactate as the possible mechanism. Concurrent lactic acidosis in the setting of NSAID-induced seizures may worsen the acidosis in some cases.

Gastrointestinal-Hepatic System

Patients presenting after acute NSAID overdose may have abdominal pain, nausea, and vomiting. Life-threatening GI hemorrhage is not a typical finding after acute overdoses. Overdose may also result in hepatic injury, as witnessed by elevated transaminase levels and cholestasis.

Renal Failure

Acute renal failure is rare after NSAID overdose, but NSAID overdose may place a stressed renal system at risk for failure. Clinical presentation may include hematuria, elevations in blood urea nitrogen/creatinine, and oliguria. The mechanism of renal insufficiency in acute overdose

is believed to be renal vascular changes secondary to Cox-mediated prostaglandin inhibition. Patients with underlying renal insufficiency appear to be at greatest risk for acute renal failure. Most patients have recovery of renal function, but the need for long-term dialysis has been reported.

TREATMENT

Most patients who present with NSAID overdose will be asymptomatic. Patients who present with symptomatic ingestions (altered mental status, seizure, electrolyte disturbances, anion-gap acidosis, or renal insufficiencies) should be treated with supportive care using emergency medicine and toxicology principles. Airway management should be initiated in obtunded or apneic patients, hypotension should be managed with fluid boluses or vasopressor agents when refractory, and seizures should be treated initially with intravenous benzodiazepines.

Patients who present as hemodynamically stable with a report of acute ingestion should have a directed history and physical examination with attention focused on mental status, GI symptoms, and any signs of renal dysfunction (Figure 172-1). The history should include amount and type NSAID ingested and questions about coingestants. Ibuprofen is the most common NSAID encountered in acute ingestion, and it is generally accepted that an ingestion of less than 100 mg/kg is unlikely to result in toxicity and that greater than 400 mg/kg places the patient at greatest risk for toxicity. Most authorities believe that patients with acute ingestions will show symptoms within 4 h.

Laboratory Evaluation

Laboratory evaluation of patients with acute ingestions should focus on acid-base status, electrolyte level, and renal function. Hepatic profile, complete blood count, coagulation profile, and aspirin and acetaminophen levels should also be sent. Evaluation of drug levels for specific NSAIDs are not indicated. **A nomogram for ibuprofen intoxication does exist but is not clinically useful.** NSAID levels do not correlate well with observed toxicity or outcomes.¹⁹

Decontamination and Enhanced Elimination

Gastric decontamination should be initiated in all patients with suspected NSAID overdoses. Activated charcoal with the cathartic sorbitol should be given orally or through a nasogastric tube. Repeated doses of activated charcoal without sorbitol are indicated in symptomatic patients. Dialysis and charcoal hemoperfusion are not effective in enhancing elimination, because NSAIDs are highly protein bound. Manipulation of serum and urine pH through alkalization is not helpful in enhancing elimination.

DISPOSITION OF PATIENTS WITH ACUTE OVERDOSES

Most patients with asymptomatic NSAID ingestions can be safely discharged after screening for coingestants and a 4- to 6-h period of observation. Any patient with symptomatic overdose (altered mental status, abnormal vital signs, electrolyte abnormalities, or acute renal failure) should be admitted for observation and supportive care. The psychosocial situation within which the overdose occurred requires careful evaluation.

Prognosis

The majority of NSAID overdoses will not cause significant sequelae. Even patients with major symptoms have a good prognosis if they overcome the initial insult (see Table 172-1).

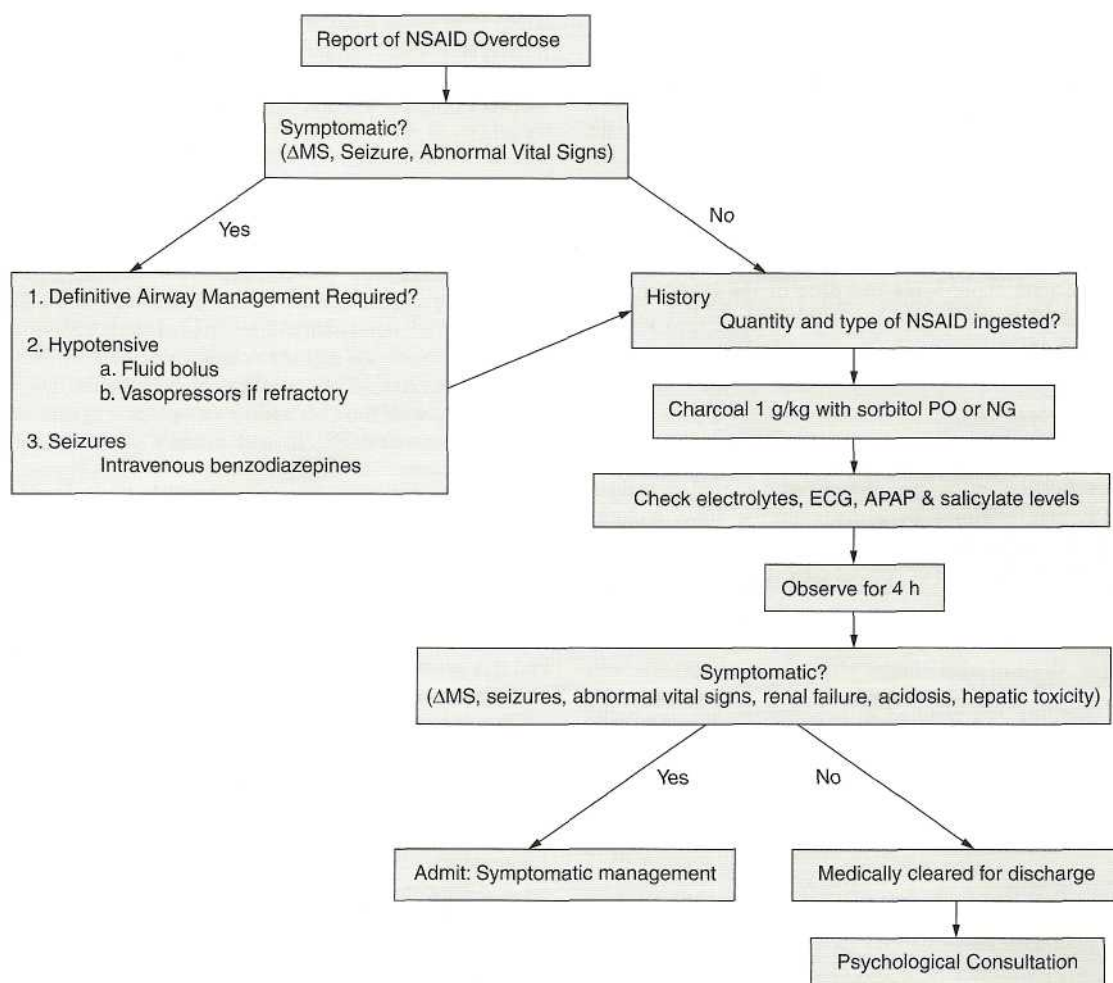

FIG. 172-1. Approach to treatment of acute NSAID overdose. APAP = acetaminophen.

THEOPHYLLINE

Heather Marshall
Charles L. Emerman

Theophylline use is complicated by its narrow therapeutic window, with a metabolism that depends on the patient's coincident medical problems and use of other medications. The 2000 Annual Report of the American Association of Poison Control Centers Toxic Exposure Surveillance System reported 1146 exposures to aminophylline or theophylline, resulting in 18 deaths.¹ This represents a decrease in the number of exposures from 5 years ago, but a similar number of fatalities and incidents with major toxicity. Most theophylline exposures are unintentional overdoses occurring in adults. A theophylline level greater than 20 (ig/mL (110 μ mol/L) is generally considered in the toxic range, although side effects may be seen at lower levels and some patients may remain asymptomatic at higher levels.² Recent changes in the U.S. Food and Drug Administration dosing guidelines are aimed

at reducing the likelihood of developing toxic levels. Life-threatening toxicity from theophylline poisoning can result in significant cardiac, neurologic, and metabolic abnormalities. Several modalities are available for treating theophylline toxicity, but indications for their use in patients without life-threatening symptoms is controversial.

PHARMACOLOGY

Theophylline and related products (Table 173-1) have a complex mechanism of action that has not been entirely elucidated. Although traditional teaching is that theophylline acts by inhibiting the action of phosphodiesterase, the concentration required for effective *in vivo* inhibition far exceeds the concentration usually produced by clinical dosages. Others have suggested that theophylline may act by affecting the binding of cyclic adenosine monophosphate, cyclic glucose monophosphate phosphodiesterase inhibition, prostaglandin antagonism, modification of intracellular calcium, stimulation of catecholamine release, or adenosine antagonism. In addition to its bronchodilatory effect, theophylline affects both the immune and inflammatory mechanisms.³ Crossover studies have found that theophylline blunts the late asthmatic response.⁴ Theophylline is readily absorbed after oral administration, with peak levels occurring 90 to 120 min after ingestion. Oral absorption is enhanced by fasting or Digestion of large volumes of fluid and is decreased following ingestion of certain foods. Enteric-coated tablets and sustained-released preparations reach peak plasma levels between 6 and 8 h. The newer, once-daily preparations have an erratic absorption rate, particularly after eating, which may lead to drug "dumping" (rapid absorption) and elevated theophylline levels. Peak levels are reached within 30 min after intravenous administration of aminophylline. The absorption of IM and PR administered drug is erratic and unpredictable. Consequently, these routes should not be used.

Theophylline is approximately 60 percent protein bound, with less binding in neonates and patients with cirrhosis. The volume of distribution ranges from 0.3 to 0.7 L/kg, with an average of 0.5 L/kg. Theophylline is primarily (85 to 90 percent) eliminated by the hepatic cytochrome P450 system, and the remaining 10 to 15 percent is eliminated by urinary excretion. Metabolism generally follows first-order elimination. The half-life is 4 to 8 h in young, healthy, nonsmoking adults, and shorter in children and smokers. Most bronchodilation occurs by serum concentrations of 15 (jig/mL, leading to recommendations to lower the target for dosing from 20 |xg/mL. The use of aminophylline in the management of acute asthma is controversial. Several reviews conclude that **intravenous administration of aminophylline is not effective in adults for the management of acute exacerbations of chronic obstructive pulmonary disease (COPD) or asthma.**^{3,5,6} **There may, however be some utility to its use in children with acute asthma.**⁷ Theophylline products may be useful for outpatient management, particularly for patients who cannot or will not use inhalers, patients with prominent nighttime symptoms, or those who have maximized or cannot tolerate other asthma controlling agents such as long acting (3-agonists or corticosteroids. A number of factors affect theophylline's half-life, including cigarette use, diet, cardiac and liver disease, and medications that interfere with the cytochrome P450 pathway (Table 173-2). The effect of fluoroquinolone antibiotics is variable, with levofloxacin causing little change in theophylline clearance. Passive smoke exposure increases theophylline

clearance, as does the use of St. John's wort. Theophylline acts as an adenosine antagonist. It markedly inhibits the coronary vasodilating effects of adenosine and may interfere with the usefulness of pharmacologic stress tests. Theophylline has been reported to reverse adenosine-induced bronchoconstriction. Few studies have examined the effects of theophylline on the therapeutic use of adenosine to reverse supraventricular tachycardia. One study reported on the successful conversion from supraventricular tachycardia in two patients with therapeutic theophylline levels. A few case reports describe the use of adenosine in theophylline-induced arrhythmias, but experience on which to base recommendations is inadequate. Aminophylline has been reported to reverse toxicity caused by overdose of multiple antihypertensive agents. There are some reports that aminophylline reduces the incidence of contrast-induced nephropathy, although other reports do not confirm this.^{8,9}

TOXIC EFFECTS

Theophylline has a range of toxic effects from minor gastrointestinal symptoms to life-threatening dysrhythmias. Although it is commonly thought that symptom severity is serum-level dependent, in fact, life-threatening adverse effects may occur with little warning and before minor symptoms are evident. Many patients with elevated levels are asymptomatic and the type of symptom is not predictive of the theophylline level.¹⁰

Cardiovascular

Even at therapeutic levels (10 to 20 |xg/mL), theophylline can cause cardiac side effects. Sinus tachycardia may occur after administration, and increased atrial automaticity, with premature atrial contractions, atrial tachycardia, multifocal atrial tachycardia, atrial fibrillation, and atrial flutter, occurs more frequently with levels above 20 |xg/mL. Ventricular

dysrhythmias with premature ventricular contractions and self-limited runs of ventricular tachycardia may also occur. Sustained ventricular tachycardia may occur in older patients with chronic overdose at levels of approximately 40 to 60 $\mu\text{g/mL}$. Younger patients with acute intentional overdose may tolerate levels above 100 $\mu\text{g/mL}$ without developing life-threatening cardiac effects. Patients with a history of dysrhythmias may experience a recurrence of dysrhythmias with levels less than 40 $\mu\text{g/mL}$. Patients who are reported to poison control centers are more likely to have cardiac complications than any other serious manifestation of toxicity.¹¹ Hypotension has also been associated with acute ingestion but may also occur with chronic overmedication.

Neurologic

Even with therapeutic levels, theophylline use can be associated with agitation, headache, irritability, sleeplessness, tremors, and muscular twitching. Seizures, including both generalized tonic-clonic and focal motor, have been reported in patients with therapeutic levels. Patients with a history of epilepsy are particularly susceptible to aminophylline-induced seizures. Animal data indicates that chronic cocaine use may increase the susceptibility to theophylline induced seizures. There are human case reports of nonconvulsive status epilepticus with bizarre posturing associated with cocaine use. The incidence of seizures increases as toxic levels increase.¹² Status epilepticus resistant to treatment can occur as the level rises above 25 $\mu\text{g/mL}$. When seizures occur at only mildly elevated levels, there are usually underlying neurologic deficits. The occurrence of seizures does not appear to correlate with prognosis. Theophylline toxicity is also associated with hallucinations and psychosis.

Metabolic

Theophylline produces a dose-dependent increase in circulating catecholamines. There is a concomitant increase in glucose, free fatty acid, insulin levels, and white blood cell count. Hypokalemia may occur, with the fall in serum potassium level inversely related to the theophylline concentration. Hypokalemia appears to be a particular problem in patients with acute overdose or acute overdose superimposed on chronic use. Administration of a β -agonist may also be associated with hypokalemia and, with the hypokalemia produced by theophylline overdose, may lead to cardiac dysrhythmias. Lactic acidosis may also be present.

Gastrointestinal

Theophylline has a direct central nervous system effect, leading to nausea and vomiting (the most frequent and usually the earliest symptom). In addition, theophylline increases gastric acid secretion. Nausea and vomiting can be seen with therapeutic levels, although the incidence of nausea and vomiting increases markedly with levels above 15 $\mu\text{g/mL}$. Approximately 25 percent of patients with levels greater than 20 $\mu\text{g/mL}$ have nausea or vomiting. Gastrointestinal bleeding, with epigastric pain, may also occur. Esophageal reflux has also been reported.

TREATMENT

Gastric emptying with gastric lavage may be considered for patients who have a potentially toxic ingestion occurring within the previous 1 to 2 h. Gastric lavage is probably not indicated for patients whose dose is calculated to have raised their levels to less than 30 $\mu\text{g/mL}$ (approximately 10 mg/kg), unless coingestion of other medications is suspected. Ipecac may complicate the use of other therapies for enhancing the elimination of theophylline and, given the seizure potentiation, probably should be avoided. In addition, vomiting is usually a prominent symptom in theophylline toxicity.

Theophylline undergoes hepatobiliary enteric circulation leading to recommendations for multiple-dose oral-activated charcoal administration. Treatment begins with activated charcoal administered in a dose of 1 g/kg. The use of repeated doses (1 g/kg, up to 50 g) of activated charcoal at 2- to 4-h intervals significantly decreases the half-life of theophylline. Charcoal may also be administered as a continuous nasogastric infusion at rates of 0.25 to 0.5 g/kg per h. Cathartics can enhance the passage of ingested theophylline through the gastrointestinal tract. Some investigators have found magnesium citrate not to be effective in lowering the theophylline level. However, there have been reports of magnesium toxicity after the use of magnesium cathartics and thus sorbitol may be a better choice. A 70 percent sorbitol solution (100 mL) is used in combination with activated charcoal for patients with potentially toxic ingestions. Caution should be used since cathartics may cause fluid and electrolyte imbalances.

The treatment of theophylline toxicity is often hindered by the gastrointestinal disturbances produced by toxic levels. Antiemetic therapies noted to be effective in controlling theophylline-induced emesis are ranitidine (50 mg IV) or metoclopramide (high-dose, 0.5 to 1.0 mg/kg). Ondansetron has also been shown to be efficacious.¹³ The control of nausea and vomiting permits the use of repeated doses of activated charcoal to enhance drug elimination.

There are reports of successful use of whole-bowel irrigation with polyethylene glycol solution, although one study showed no additional benefit over activated charcoal.¹⁴ The use of whole-bowel irrigation as an adjunct therapy to activated charcoal remains controversial.

Recent prospective studies, however, indicate that hemoperfusion is associated with a higher complication rate without any significant increase in clinical efficacy over hemodialysis.¹⁵ The clearance rate induced by hemodialysis is approximately 200 mL/kg per h. Charcoal hemoperfusion with resin or charcoal filters produces extraction ratios above 0.85, with clearance rates of up to 300 mL/kg per h. Recent case reports also show the use of continuous venovenous hemofiltration as an effective alternative to hemoperfusion, especially because it is available in most hospitals and because it is well tolerated in the hemodynamically unstable patient.¹⁶ The guidelines for extracorporeal drug removal (hemoperfusion/hemodialysis) remain controversial (Table 173-3). In the view of some investigators, hemoperfusion or hemodialysis is not absolutely indicated at any theophylline level in the absence of life-threatening symptoms, such as status epilepticus or resistant ventricular dysrhythmias. Others have felt that patients with increased half-lives, advanced age, or theophylline levels above 80 $\mu\text{g/mL}$ may be candidates for early hemoperfusion or hemodialysis as a preventive intervention. Young, healthy patients with an acute ingestion may be able to tolerate levels over 100 $\mu\text{g/mL}$ without adverse incident. The decision to use hemoperfusion or hemodialysis should be made considering the potential for life-threatening toxicity.

Hypotension or cardiac arrhythmias are another indication of severe theophylline toxicity requiring aggressive supportive care. If the hypotension is refractory to fluids and conventional vasopressor ther-

TABLE 173-3 Indications for Hemoperfusion/Hemodialysis

Clinical Conditions	Recommendation
Life-threatening toxicity (i.e., seizures, tachydysrhythmias) not responsive to other therapy	Indicated
Acute overdose with level $\geq 100 \mu\text{g/mL}$	Possibly indicated
Chronic overdose with level $>60 \mu\text{g/mL}$	Possibly indicated
Elderly patient with known prolonged theophylline half-life, severe liver or severe cardiac disease, or level $>40 \mu\text{g/mL}$	Controversial
Theophylline level $\geq 30 \mu\text{g/mL}$	Not indicated

apy, α -adrenergic agents such as phenylephrine may be considered. (3-Blocker therapy, particularly with propranolol, also reverses the theophylline-induced vasodilation, thereby improving hypotension and tachyarrhythmias. (3-Blockers should be administered cautiously in low doses and monitored for adverse effect. Alternatively, esmolol, an agent with cardioselectivity and a short duration of action, has been successfully used.¹⁷

In addition to being treated with 3-blockade, cardiac arrhythmias may be treated with other antiarrhythmics. Verapamil has been effective in animal studies. The use of digoxin, lidocaine, and phenytoin has been reported for treatment of ventricular dysrhythmias (see Chaps. 28 and 29). Adenosine is effective in the treatment of theophylline-induced supraventricular arrhythmias, although it has been associated with bronchospasm. The contributory effect of hypokalemia should be considered in treating patients with resistant ventricular dysrhythmias, and correction of serum electrolyte abnormalities may be effective in terminating recurrent dysrhythmias.

Seizures may be difficult to control with standard anticonvulsant therapy. Benzodiazepines (diazepam, 10 mg iv or lorazepam) remain the first-line anticonvulsants of choice and may require high doses. Second-line therapy is with a barbiturate such as phenobarbital. The airway should be protected in patients with theophylline-induced status epilepticus, especially following the administration of oral activated charcoal. Patients with status epilepticus resistant to traditional therapy may require general anesthesia with electroencephalographic monitoring and more aggressive measures to lower the serum theophylline level.

INDICATIONS FOR TREATMENT AND ADMISSION

Although theophylline toxicity can lead to life-threatening side effects, elevated theophylline levels are common and most patients tolerate them with only minor toxic manifestations.¹⁸ Serum theophylline concentrations do not correlate well with severity of toxicity in chronic exposures. However, serum levels for acute exposures are more valuable in predicting toxicity and clinical course. No well-conducted studies have demonstrated that prophylactic use of antiarrhythmics or antiepileptics decreases morbidity or mortality rates. Similarly, while hemodialysis, hemoperfusion, and oral activated charcoal therapy enhance theophylline clearance, there is no compelling evidence that their use lowers morbidity or mortality rates for patients with only mild toxic symptoms or minimally elevated levels.

Ventricular dysrhythmias or seizures may occur in patients before the manifestation of other minor toxic effects, leading some authors to advocate aggressive therapy. Older patients with concomitant medical problems are more susceptible to life-threatening theophylline toxicity following chronic overmedication than are younger patients with an acute overdose.¹⁹ The prophylactic use of hemoperfusion has been reported to decrease rates of major morbidity in elderly patients.

In general, patients with a history of seizures or ventricular dysrhythmias should be monitored until their theophylline level returns to normal. Patients with levels below 25 fig/mL and minor symptoms do not require specific therapy other than discontinuation or modification of theophylline administration. Such patients generally do not require hospitalization. Patients with levels above 30 fig/mL should be treated with oral activated charcoal (repeated) and monitored for toxic side effects. Hemoperfusion or hemodialysis use is controversial but may be indicated for older patients with levels above 40 jig/mL, especially with chronic intoxications or for younger patients with acute intentional overdose with levels above 100 [ig/mL.

PREVENTION

Theophylline toxicity is only rarely a result of intentional overdose. Patients being started on certain medications, in particular cimetidine and macrolide or fluoroquinolone antibiotics, should have their the-

ophylline dose decreased by approximately 25 percent, with monitoring of the effect on levels. Aminophylline infusions should be started using standard guidelines with close monitoring of serum levels. Because the history of outpatient theophylline use has been found to be a poor guide to the serum concentration, loading doses of aminophylline should be calculated using the initial theophylline level. The initial dose of oral theophylline should not exceed 900 mg/d. Starting patients at a much lower dose (400 mg/d) helps to avoid the nausea and vomiting frequently accompanying initial theophylline use. Levels should be determined in order to monitor therapy.

The presence or absence of mild side effects is not a good predictor of drug levels.¹⁰ Patients should be cautioned not to alter their medication regimen without physician guidance.

DIGITALIS GLYCOSIDES

William Dribben Mark A. Kirk

EPIDEMIOLOGY

For centuries, digitalis glycosides have been recognized for their medicinal benefits and potential toxicity. Digitalis preparations are used most commonly in the treatment of supraventricular tachydysrhythmias and congestive heart failure. In addition to their availability as Pharmaceuticals, cardiac glycosides are also found in plants such as foxglove, oleander, and lily of the valley. It is important that physicians recognize digitalis toxicity because potentially fatal cardiac dysrhythmias can be reversed with prompt administration of a highly specific antidote, digoxin-specific Fab fragments.¹ According to the American Association of Poison Control Centers (AAPCC), 2977 exposures to cardiac glycosides were reported in 2001. Of these exposures, 652 (22 percent) patients demonstrated moderate or major morbidity, with 13 (0.4 percent) deaths.² Even though digitalis use has declined due to newer modes of therapy for supraventricular tachydysrhythmias and congestive heart failure, reported exposures and morbidity and mortality have remained constant over the past 10 years.

PHARMACOLOGY AND PATHOPHYSIOLOGY

Digoxin is currently the most widely used digitalis preparation. It is absorbed rapidly from the gastrointestinal tract and is eliminated primarily through renal excretion. It has a volume of distribution of 6 L/kg. The half-life of a therapeutic dose is 36 to 48 h.

Digitalis has a narrow therapeutic-toxic margin. Toxicity results from an exaggeration of its therapeutic actions. Digitalis binds to a specific receptor site on the cardiac cell membrane, inactivating the $\text{Na}^+\text{K}^+\text{ATPase}$ pump.³ This pump concentrates sodium extracellularly and potassium intracellularly to maintain the electrochemical membrane potential vital to conduction tissues. When $\text{Na}^+\text{K}^+\text{ATPase}$ is inhibited, the sodium-calcium exchanger removes accumulated intracellular sodium in exchange for calcium. This exchange increases sarcoplasmic calcium and is the mechanism thought to be responsible for the positive inotropic effect of digitalis. Inhibition of the $\text{Na}^+\text{K}^+\text{ATPase}$ pump also results in an increase in extracellular potassium.³ Other potential mechanisms accounting for increased cytosolic calcium resulting in increased inotropic and/or toxic effects may be due to actions directly at calcium channels on the sarcoplasmic reticulum or via activation of the ryanodine receptor.⁴ Digitalis increases vagal tone and decreases conduction through the atrioventricular (AV) node. In toxic doses, these effects result in various bradydysrhythmias. Automaticity is increased due to slowing of conduction in the electrical system along with a shortened refractory period in the myocardium. Intracellular calcium overload can create delayed afterdepolarizations, causing electrical oscillations in cell membranes that give rise to triggered dysrhythmias.⁵

CLINICAL FEATURES

Determine if toxicity is due to an accidental ingestion, massive intentional ingestion, or chronic toxicity from therapeutic use of digitalis. If the ingestion is intentional, historical information may be inaccurate or incomplete, and coingestants should be suspected. The time of ingestion is extremely helpful in interpreting laboratory information. Because various plants contain digitalis glycosides and cause similar toxicity to medicinal forms, an attempt should be made to accurately identify any ingested plants.

Preexisting medical conditions and current medications may identify risk factors that potentiate digitalis toxicity. Increased susceptibil-

ity is seen in patients who are elderly, have coexisting diseases (e.g., heart disease, renal dysfunction, hepatic dysfunction, hypothyroidism, and chronic obstructive pulmonary disease), electrolyte disturbances (e.g., hypokalemia, hypomagnesemia, and hypercalcemia), and hypoxia.⁶ Drug interactions, most notably class IA antidysrhythmics, calcium channel blockers, and (3-blockers, potentiate digitalis toxicity.

Cardiac dysrhythmias in digitalis toxicity are nonspecific and may be life-threatening. Suspect digitalis toxicity in patients with any dysrhythmia or junctional escape rhythms and AV block. The most common dysrhythmia is frequent premature ventricular beats, especially in a diseased heart. Bidirectional ventricular tachycardia, a tachycardia with an alternating axis and QRS complex, is rare but relatively specific for digitalis toxicity⁷ (see Chap. 28 for examples of dysrhythmias).

In addition to cardiac manifestations, gastrointestinal distress, dizziness, headache, weakness, syncope, and seizures may occur. Reported psychiatric symptoms include confusion, disorientation, delirium, and hallucinations. Any elderly patient taking digitalis who presents with mental status changes should be evaluated for toxicity. Patients with toxicity have reported seeing yellow-green halos around objects.⁸

DIAGNOSIS

The history, physical examination, and laboratory studies provide important clues, with no single element that excludes or confirms the diagnosis.

Laboratory Evaluation

Serum potassium and digoxin levels will assist in providing information necessary to make adequate therapeutic decisions. Acute poisoning of the $\text{Na}^+\text{K}^+\text{ATPase}$ pump may result in markedly elevated serum potassium levels.³ A high incidence of hyperkalemia has been noted in patients with severe acute poisoning. The serum potassium level may be a better indicator of end-organ toxicity and a better prognostic indicator than the serum digoxin level in the acutely poisoned patient. Hyperkalemia is less common in chronically poisoned patients. Potassium status may be less predictive in patients with renal insufficiency or volume depletion or in those who are receiving diuretic therapy.

Accepted therapeutic digoxin levels are 0.5 to 2.0 ng/mL. In most laboratories, the serum digoxin level is not part of the routine toxicologic screen and must be specifically requested. Serum digoxin levels in both acute and chronic toxicity should be interpreted in the overall clinical context and not relied on as the sole indicator of the presence or absence of toxicity. In acute exposures, digoxin is absorbed into the plasma compartment and then redistributed slowly into the tissue compartment. Hence high digoxin levels are not always associated with clinical signs and symptoms of poisoning. Serum levels are most reliable when obtained 6 h after ingestion, when distribution is complete. In patients with clinical evidence of chronic digitalis toxicity, a "therapeutic" level does not exclude toxicity, especially when predisposing factors are present. Conversely, levels above the upper limits of normal do not always cause symptoms. Given the preceding limitations, it is still most common that the higher the serum level, the greater is the likelihood of toxicity.⁹

A positive serum assay is diagnostic of acute ingestion if the patient has not received digitalis glycosides therapeutically. The rare exception is in the presence of a digoxin-like immunoreactive substance that has been detected in neonates and patients with renal insufficiency or hepatic dysfunction. In addition, naturally occurring digitalis glycosides from plants and animals may cross-react with the digoxin assay. The degree of cross-reactivity is unknown, and no correlation has been established between serum levels of these glycosides and toxicity.

Additional laboratory evaluation includes a determination of adequate oxygenation, renal and hepatic function, and electrolyte deter-

minations in addition to potassium. Continuous electrocardiographic monitoring is essential to detect dysrhythmias.

Differences in the Presentation of Acute and Chronic Toxicity

A distinct clinical presentation exists for both acute and chronic digitalis glycoside toxicity (Table 174-1). Acute poisoning most often results from accidental or intentional ingestion. There may be an asymptomatic period of several hours prior to development of symptoms. Gastrointestinal symptoms are often the earliest manifestation of toxicity. In the early period of toxicity, increased central vagal tone produces cardiac dysrhythmias that are typically bradydysrhythmias or supraventricular dysrhythmias with AV block; however, life-threatening ventricular dysrhythmias may develop at any stage in an acute massive ingestion.⁷ Acute toxicity correlates most closely with hyperkalemia and correlates poorly with the serum digoxin level.¹⁰

Chronic toxicity occurs most typically in the elderly cardiac patient taking digoxin and diuretics. Signs and symptoms may mimic more common illnesses such as influenza and gastroenteritis. An altered mental status or psychiatric symptoms may not be recognized as signs of digitalis toxicity. Almost any cardiac dysrhythmia may be seen, but ventricular dysrhythmias occur more frequently in chronic than in acute poisonings.⁷ The serum digoxin level is not an accurate predictor of toxicity, and the serum potassium level is usually decreased or normal, but may even be elevated in the setting of renal failure.

Differential Diagnosis

Other toxins causing bradydysrhythmias include calcium channel blocker and β -blocker overdoses, class IA antidysrhythmics (procainamide and quinidine) overdoses, clonidine overdoses, organophosphate insecticide poisoning, and cardiotoxic plants (e.g., rhododendron, monkshood, tobacco, false hellebore, and yew berry). Sinus node disease also can mimic digitalis toxicity.

Factors Enhancing Toxicity

A number of factors increase susceptibility to digitalis toxicity. True end-organ sensitivity is seen with myocardial disease or ischemia and metabolic or electrolyte abnormalities. **Hypokalemia, hypomagnesemia, and hypercalcemia all predispose to increased toxicity.**³ The elderly are more susceptible to toxicity. Decreased renal function, hepatic disease, hypothyroidism, chronic obstructive pulmonary disease,

TABLE 174-1 Clinical Presentation of Digitalis Toxicity

Acute toxicity	
Clinical history	Intentional or accidental ingestion
GI effects	Nausea and vomiting
CNS effects	Headache, dizziness, confusion, coma
Cardiac effects	Predominately supraventricular tachydysrhythmias with AV block, bradydysrhythmias
Electrolyte abnormalities	Hyperkalemia
Digoxin level	Marked elevation
Chronic toxicity	
Clinical history	Typically in elderly cardiac patients taking diuretics; may have renal insufficiency
GI effects	Nausea, vomiting, diarrhea, abdominal pain
CNS effects	Fatigue, weakness, confusion, delirium, coma
Cardiac effects	Almost any ventricular or supraventricular dysrhythmia can occur; ventricular dysrhythmias are common
Electrolyte abnormalities	Normal or decreased serum potassium, hypomagnesemia
Digoxin level	Minimally elevated or "therapeutic" range

TABLE 174-2 Treatment of Digitalis Glycoside Poisoning

Asymptomatic patients	Obtain accurate history
Continuous cardiac monitoring	Intravenous access
Gastrointestinal decontamination:	Activated charcoal (1 g/kg)
Frequent reevaluation	Fab fragments at bedside (Calculate dose; Table 174-3)
Symptomatic patients	ABCs
Intravenous access	Continuous cardiac monitoring
Treat altered mental status	Oxygen
Glucose (if indicated)	Naloxone (if indicated)
Dysrhythmias	Bradydysrhythmias
Atropine (0.5-2.0 mg IV)	Pacemaker (external or transvenous)
Fab fragments (IV infusion)	Ventricular dysrhythmias
Fab fragments (IV infusion or bolus)	Magnesium sulfate (2-4 g IV)
Lidocaine (1 mg/kg) or fosphenytoin (15 mg PE/kg) infuse at 150 mg PE/min	Electrocardioversion (10-25 J; last resort)
Cardiac arrest	CPR
ACLS protocols	Fab fragments (IV bolus; give 5-10 vials if amount ingested is unknown)
Electrolyte abnormalities	Hyperkalemia
Avoid calcium chloride or calcium gluconate	Glucose-insulin (See Chap. 27)
Sodium bicarbonate (See Chap. 27)	Fab fragments (IV infusion or bolus)
Potassium resin binder (See Chap. 27)	Hemodialysis
Hypomagnesemia	Evaluate renal status prior to replacement
Magnesium sulfate (2-4 g IV)	Gastrointestinal decontamination
Activated charcoal (1 g/kg; then 0.5 g/kg q4-6 h)	

and drug interactions all can augment toxic effects.⁶ Drug interactions potentially resulting in digitalis toxicity include quinidine, procainamide, (3-blockers, calcium channel blockers, amiodarone, spironolactone, indomethacin, claritromycin, and erythromycin.

EMERGENCY DEPARTMENT CARE

Management of any poisoned patient includes general supportive care, treatment of specific complications of toxicity, prevention of further drug absorption, enhanced drug elimination, antidote administration, and safe disposition (Table 174-2). Patients with intentional or accidental ingestions may present with no symptoms. Still, life-threatening complications of toxicity should be anticipated. Management of the asymptomatic patient should focus on preventing drug absorption and closely monitoring for the development of toxicity. Continuous cardiac monitoring, intravenous access, and frequent reevaluations should be provided for any patient with a potentially toxic ingestion of digitalis. Toxicity may not develop for several hours after an acute ingestion; therefore, extended observation (12 h) is required for anyone with a confirmed ingestion.⁹ Admission to the intensive care unit and frequent reassessment are required for any patient developing signs of toxicity.

Treatment of Life-Threatening Conditions

For the patient with life-threatening dysrhythmias, ensure a patent airway, adequate ventilation, and effective circulation. Rapidly correct conditions such as hypoxia, hypoglycemia, hypovolemia, and electrolyte abnormalities.

Conventional and antidote therapies are available to treat digitalis-induced dysrhythmias. Atropine and cardiac pacing (external and transvenous) have been used successfully in treating bradydysrhythmias. Both phenytoin and lidocaine depress ventricular automaticity and increase the fibrillation threshold. Because of phenytoin's ability to accelerate conduction at the AV node, it has been considered the antidysrhythmic of choice by some for digitalis-induced ventricular dysrhythmias. Bretylium has effectively suppressed dysrhythmias in the clinical setting, although in a digitalis-toxic animal model it was found to enhance dysrhythmias.¹¹ Class IA antidysrhythmics, such as quinidine and procainamide, are contraindicated because they depress AV nodal conduction, which in turn may enhance digitalis-induced cardiac toxicity. Intravenous magnesium has been reported to counteract ventricular irritability in digitalis toxicity.¹² Electrocardioversion may induce intractable ventricular fibrillation and should be considered only as a last resort. If necessary, use a low setting (10–25 J), and prepare to treat resulting ventricular fibrillation. In severe toxicity, conventional treatment may be unsuccessful. When available, digoxin-specific Fab fragments are the treatment of choice for dysrhythmias that are life-threatening and do not respond immediately to conventional therapy.¹³

Hyperkalemia secondary to acute exposures also may be life-threatening and needs immediate treatment. Treatment includes intravenous administration of glucose, insulin, and sodium bicarbonate and enteral administration of a potassium-binding resin (see Chap. 27).¹³ Calcium chloride or calcium gluconate administration in the face of digitalis-induced hyperkalemia may promote cardiac toxicity and should be avoided. If digitalis-induced hyperkalemia is not corrected rapidly by conventional therapy, then Fab fragments are indicated for reversal (see below).¹³

Gastrointestinal Decontamination and Enhanced Elimination

Ipecac clearly has no role in the emergency department management of digitalis glycoside poisoning. After initial stabilization, administer activated charcoal to prevent further drug absorption.¹⁴ Gastric lavage is not recommended as asystole has been reported in a digoxin-toxic patient, presumably from vagal stimulation during lavage. If lavage is contemplated, pretreatment with atropine prior to performing gastric lavage has been suggested. Cathartics, forced diuresis, hemodialysis, or hemoperfusion have no role in enhancing elimination of digitalis.

Digoxin-Specific Fab Antibody Therapy

Digoxin-specific Fab antibody fragments (Digibind, GlaxoSmithKline; DigiFab, Savage Laboratories) are derived from ovine IgG antibodies to digoxin. Fab fragments distribute widely throughout tissues and remove digitalis from tissue binding sites¹³ as well as the plasma. According to AAPCC data from 2001, 314 patients received antidotal therapy with digoxin-specific Fab antibody fragments.² In a series of 150 severely poisoned patients, 90 percent showed reversal or significant improvement in life-threatening dysrhythmias and hyperkalemia after Fab fragment administration.¹³ In most cases, clinical improvement in cardiac rhythm occurs within 1 h of antidote administration. Patients developing cardiac arrest prior to Fab administration had a 50 percent survival, which is significantly improved from survival by treatment with conventional therapies.¹³ Fab fragments also have been reported to be beneficial in treating digitoxin and oleander poison-

ings.¹⁵ Although Digibind was used in most of the studies regarding the effectiveness and safety of Fab fragments, in 2001, the Food and Drug Administration (FDA) approved DigiFab for use in cardiac glycoside poisoning.¹⁶ Indications for digitalis-specific Fab fragments are ventricular dysrhythmias, hemodynamically significant bradydysrhythmias unresponsive to standard therapy, and hyperkalemia in excess of 5.5 mEq/L¹³ associated with a toxic digitalis level or a presumptive diagnosis of overdose. Elevated serum digoxin levels should not be the sole indication for Fab fragment administration. DigiFab is indicated for the same conditions as Digibind and has similar pharmacokinetic and pharmacodynamic properties.¹⁶

Fab fragment administration has resulted in few adverse effects.¹³ Cardiogenic shock has been reported in patients dependent on digoxin for inotropic support.¹⁷ In addition, ventricular response to atrial fibrillation may be increased. Hypokalemia may develop rapidly as digitalis toxicity is reversed. Only mild, acute hypersensitivity reactions including rash, flushing, and facial swelling have been reported. No incidences of serum sickness or anaphylaxis have been observed, even in patients with repeated administration.¹⁷ Skin testing has not proven to be useful in predicting allergic responses and may delay urgently needed treatment.¹⁸ Failures to Fab fragment therapy have been attributed to inadequate dosing, moribund state prior to administration, and incorrect diagnosis of digitalis toxicity.¹⁷

The Fab fragment dosage is based on an estimation of total-body load of digoxin.¹³ This can be determined from the serum digoxin level or based on the estimated dose ingested (Table 174-3). Clinical series have reported that an average of 200 to 480 mg (5–12 vials) were required to effectively treat severely digitalis-toxic patients.¹³ When the ingested dose is unknown, 5 to 10 vials are recommended as initial treatment in life-threatening situations. Fab fragments are administered IV through a 0.22-µm filter over 30 min, except in a cardiac arrest, where it may be given as a bolus.

The serum digoxin level has no correlation with clinical toxicity following Fab administration because most laboratories use assays that measure both bound and unbound digoxin, although there are some laboratories that measure only free digoxin levels. Minutes after Fab fragment administration, the free digoxin level falls to zero, but the total serum digoxin level (bound to Fab fragments) increases 10- to 20-fold.¹³ The Fab-digoxin complex is eliminated by renal excretion.¹⁹ In

TABLE 174-3 Calculating Digoxin-Specific Fab Fragment Dosage

Calculate total-body load: Based on history of amount ingested:
$\text{Total body load} = \text{amount ingested (mg)} \times 0.80 \text{ (bioavailability)}$
Based on serum digoxin concentration: Total body load
$= \text{serum digoxin level (ng/mL)} \times 5.6 \text{ L/kg} \times \text{patient's weight (kg)} \times 1000$
Calculate number of vials of digoxin-specific Fab fragments needed to neutralize the calculated total-body load:
It is assumed that an equimolar dose of Fab fragments is required for neutralization; one vial (40 mg) of Fab fragments binds 0.6 mg of digoxin.
$\text{Number of Digibind vials required} = \frac{\text{total-body load}}{0.6}$
$\text{Number of DigiFab vials required} = \frac{\text{total-body load}}{0.5}$
A simple and accurate variation of the above calculations: Number of vials of Fab = serum digoxin level (ng/mL) X patient's weight (kg)
$\frac{\text{.....}}{100} \text{}$

the case of renal failure, the complex may persist in the circulation for several periods. Recurrent toxicity can occur up to 10 days after Fab fragment administration in patients with renal failure. Hemodialysis does not enhance the elimination of the digoxin-Fab complex,¹⁹ although plasma exchange may be of benefit.²⁰

DISPOSITION

Patients with signs of toxicity or a history of a large ingested dose, especially if coexisting risk factors increase susceptibility to digitalis toxicity, should be admitted to a monitored unit. Contacting the local poison center and medical toxicologist can facilitate difficult management and treatment decisions regarding when to administer Fab fragments. Any patient receiving Fab fragments requires intensive care unit observation for at least 24 h. All suspected suicidal patients should have a psychiatric evaluation prior to discharge. Accidental exposures with no signs of toxicity after 12 h can be discharged home.

175 P-BLOCKER TOXICITY

Teresa M. Carlin

P-Blockers are commonly prescribed drugs in clinical practice. They have a multitude of therapeutic indications that include the treatment of myocardial infarction, angina, arrhythmias, obstructive cardiomyopathy, diastolic dysfunction, migraine headaches, thyrotoxicosis, anxiety, tremor, glaucoma, and hypertension. Accidental and intentional ingestions are not uncommon presentations in the ED. According to the American Association of Poison Control Centers, during 2001, there were over 12,000 exposures to p-blockers.¹ Of these, three quarters were unintentional and more than a quarter were among children less than 6 years of age. Almost 20 percent resulted in serious toxicity and there were 39 deaths.

PHYSIOLOGY

The p-receptor is a glycoprotein within the cell membrane coupled to an intracellular second messenger, cyclic adenosine monophosphate (cAMP), by a regulatory protein called the *G protein*. When catecholamines bind to beta receptors, the G protein undergoes a conformational change that activates adenylyl cyclase. Adenylyl cyclase catalyzes the formation of cAMP. cAMP stimulates protein kinase, which phosphorylates calcium channels, leading to calcium entry into cells. Additional calcium is released into the cytosol from cellular storage organelles. The expression of this reaction depends on which beta receptor is activated.²

At least three types of (3-adrenergic receptors exist. The P₁ subunit is located in the myocardium, kidney, and eye, while the P₂ subunit is found in smooth muscle, skeletal muscle, the liver, pancreas, and adipose tissue. The P₃ subunit is located in adipose tissue. P₁ activation promotes cardiac inotropy and chronotropy. Additionally, it causes the kidney to release renin and the eye to produce aqueous humor. Stimulation of the P₂-receptors causes smooth muscle relaxation, which results in vasodilatation, bronchodilation, and uterine relaxation. P₂ activation also increases metabolic substrate availability needed for stress by stimulating lipolysis and glycogenolysis. The P₃ subunit alters lipid metabolism.²

PHARMACOLOGY AND PATHOPHYSIOLOGY

P-Blockade blunts the production of cAMP via P-receptor stimulation. If the P₁ subunit is preferentially antagonized, the effect is negative inotropy and negative chronotropy, the hallmark of p-blocker toxicity. Vasoconstriction, bronchospasm, and hypoglycemia may occur when the P₂-receptor is blocked.

Other mechanisms may contribute to p-blocker toxicity. Membrane-stabilizing activity of several beta blockers causes cardiovascular depression, similar to quinidine, and is associated with QRS complex widening.³

The pharmacologic properties of various p-blockers influence their spectrum of toxicity³ (Table 175-1). These properties include cardioselectivity (P₁ antagonist activity), membrane-stabilizing activity, lipid solubility, and partial agonist activity. For example, lipid-soluble agents such as propranolol rapidly cross the blood-brain barrier and achieve high concentrations in brain tissue. Additionally, propranolol has a membrane-stabilizing activity similar to quinidine. These properties may contribute to the central nervous system (CNS) manifestations of propranolol overdose, namely, depression of mental status and seizures.^{3,4} Membrane-stabilizing activity makes drugs such as propranolol potentially more cardiotoxic. Since propranolol is not cardioselective, it is theoretically more likely to present with P₂ effects such as wheezing than a cardioselective drug such as atenolol. Cardioselective

TABLE 175-1P-Blocker Pharmacologic Profile

Agent	Beta-Selective	Partial Agonist	Membrane-Stabilizing Activity	Lipophilic
Acebutolol	Yes	Yes	Yes	Weak
Atenolol	Yes	No	No	Weak
Esmolol	Yes	No	No	Weak
Labetolol	No	No	No	Moderate
Metoprolol	Yes	No	Weak	Moderate
Nadolol	No	No	No	Weak
Oxprenolol	No	Yes	Yes	Moderate
Pindolol	No	Yes	Yes	Moderate
Propranolol	No	No	Yes	High
Sotalol	No	No	No	Weak
Timolol	No	No	No	Weak

P-blockers, however, may lose specificity for the β_1 receptor at toxic doses. Several p-blockers have partial agonist activity, and thus weak stimulation of the beta receptor occurs concurrently with blockade. Bradycardia is initially less pronounced with these agents. Experimental evidence implicates calcium and potassium homeostasis as a contributing mechanism of toxicity.⁵

Clinically relevant pharmacokinetic characteristics include drug formulation (regular versus sustained release), rate of drug absorption, lipid solubility, and volume of distribution (Vd). Absorption of normal-release p-blockers occurs rapidly, with peak effects in 1 to 4 h. For this reason, toxic symptoms begin soon after ingestion. The high degree of protein binding, the large Vd, and the lipid solubility predict that extracorporeal drug removal will not be useful for most P-blockers. Hemodialysis may be effective for atenolol, nadolol, and sotalol because these agents have lower binding, are hydrophilic, and have Vd values similar to that of water.

CLINICAL PRESENTATION

Patients who ingest P-blockers manifest a spectrum of clinical presentations ranging from minimal symptoms to profound bradycardia and hypotension, the hallmark of toxicity (Table 175-2). Conduction abnormalities, dysrhythmias, and cardiogenic shock also occur. Wide-complex bradyarrhythmias are seen rarely. Symptoms typically develop within 2 to 4 h of acute ingestion.⁶ Sudden deterioration with cardiovascular collapse may occur.⁷ Most individuals ultimately requiring treatment for cardiovascular depression after exposure with propranolol, metoprolol, or atenolol develop symptoms by 6 h after ingestion.^{4,6} Sotalol is an exception to this rule. Sotalol, unlike other p-blockers, is classified as a Vaughan Williams class III antiarrhythmic. Class III antiarrhythmic drugs cause a prolonged QT interval, which may degenerate into a ventricular dysrhythmia for as long as the QT interval remains abnormal. Premature ventricular contractions, bigeminy, ventricular tachycardia, ventricular fibrillation, and torsades de pointes have been reported. It is unclear whether other p-blockers, particularly sustained-released preparations, can present with delayed toxicity.⁶ There is no report in the literature of delayed onset of symptoms (e.g., outside a 6-h window) with sustained-released products.

Slowing of the heart rate due to sinus node suppression or conduction abnormalities occurs in all significant p-blocker intoxications except overdoses of p-blockers with partial agonist activity. In fact, ingestion of P-blockers with partial agonist activity such as pindolol may present with hypertension and tachycardia.^{3,4} QRS complex

widening is associated with the membrane-stabilizing activity of some p-blockers, such as propranolol.

The single most important predictive factor associated with cardiovascular morbidity in p-blocker exposure may be the coingestion of another cardioactive drug, such as calcium channel blockers and tricyclic antidepressants.⁸ In the absence of a coingestion, the most important predictive factor is whether the β_1 -blocker possesses membrane-stabilizing activity.⁸ Examples of (3-blockers that possess membrane-stabilizing activity include propranolol, acebutolol, and pindolol. Atenolol, sotalol, timolol do not possess membrane-stabilizing activity. Metoprolol has membrane-stabilizing effects only at high doses^{3,8} (see Table 175-1).

The CNS is another target of (3-blocker toxicity. CNS manifestations include depressed mental status, coma, psychosis, and seizures. These symptoms may occur secondary to poor perfusion or direct neuronal toxicity. It is postulated that the more lipophilic (3-blockers such as propranolol cause greater CNS and cardiac toxicity compared with less lipophilic agents.⁴ Studies suggest a significant association between a QRS complex duration of greater than 100 ms and seizure activity. However, a normal QRS complex does not exclude the risk of seizure.⁴ Status seizures are rare but may be refractory to treatment.

Noncardioselective (3-blockers may antagonize the (3₂ subunit. Bronchospasm with wheezing and metabolic derangements such as hypoglycemia have been reported but are infrequent occurrences. Case reports suggest that hypoglycemia in children may have a delayed presentation. ■ Rare complications of poisoning include esophageal spasm, mesenteric ischemia, and acute renal failure.

DIAGNOSIS

A limited number of other medications, chemicals, and natural toxins potentially result in bradycardia and hypotension. Common drugs include calcium channel antagonists, centrally acting alpha agonists, and digoxin. Many plants (e.g., oleander, digitalis, and rhododendron) contain cardiac glycosides that may cause symptoms following ingestion of plant parts or consumption of teas brewed from the plant. Chinese medicinal preparations and aphrodisiacs often contain animal-derived cardiac glycosides (e.g., bufotoxin) that may cause bradycardia and hypotension. Such chemicals as organophosphate insecticides, cyanide, or hydrogen sulfide cause bradycardia.

The diagnosis of p-blocker toxicity is made on clinical grounds. Drug levels correlate poorly with clinical presentations.¹¹ However, specific drug levels, if available, may help confirm an exposure. A 12-lead electrocardiogram and continuous rhythm monitoring are essential in evaluation and ongoing assessment. Laboratory testing is directed at supportive monitoring of renal function, glucose level, oxygenation, and acid-base status. Radiographs to detect P-blocker pills

in the gastrointestinal tract are not useful because these drugs are not radiopaque.¹²

TREATMENT

Standard approach to poisoning should be initiated (see Chap. 156). For serious cases, treatment begins by establishing adequate airway patency, ventilation, and oxygenation. Multiple intravenous access sites, as well as central venous access, may be required.

The goal of specific cardiovascular drug therapy is to restore perfusion to critical organ systems by improving myocardial contractility, increasing heart rate, or both. Current therapy (Table 175-3) is derived from reports of case studies and includes glucagon, adrenergic agonists, atropine, and phosphodiesterase inhibitors. Overall, these therapies have met with variable success.

Syrup of ipecac should never be used to decontaminate the gastrointestinal tract after p-blocker overdose. Enhanced vagal tone associated with vomiting may be detrimental after p-blocker exposure because of its association with cardiovascular collapse.¹³ Additionally, β -blocker-intoxicated patients may experience a rapid decline in mental status, which increases the risk of aspiration during vomiting.

Gastrointestinal decontamination with 1.0 g/kg plain activated charcoal should be initiated unless oral intake is contraindicated. Gastric lavage may be beneficial prior to instillation of charcoal if it can be accomplished within 1 to 2 h of ingestion.

Glucagon is a first-line agent in the treatment of acute β -blocker overdose. Glucagon is thought to activate myocardial adenylyl cyclase by a mechanism independent of (3-receptor stimulation. Adenylyl cyclase generates cAMP, which causes positive inotropic and chronotropic effects.¹⁴ An intravenous bolus of glucagon achieves maximum serum concentration within 1 min and has a half-life of 6.6 min. Therefore, a bolus dose of glucagon should be followed by a continuous infusion. The bolus dose of glucagon is .05 to .15 mg/kg (3-10 mg for the average 70-kg adult) followed by a continuous infusion of 1 to 10 mg per h. There is no defined maximum therapeutic dose. Of note, the positive inotropic and chronotropic effects of glucagon may not be maintained for a prolonged period due to possible tachyphylaxis. How long the myocardial effects will last over time is not known.¹⁴

Nausea and vomiting are commonly reported side effects of high-dose glucagon therapy that may be related to esophageal sphincter relaxation. Patients should be monitored during therapy for hypoglycemia and hypokalemia secondary to reflex release of insulin. The

manufacturer uses a glycerin diluent with a phenol preservative. Excessive phenol exposure can cause thrombophlebitis, seizures, hypotension, or dysrhythmias. To avoid these unwanted effects, **the supplied diluent should be discarded and the glucagon reconstituted with NS solution to a concentration not to exceed 1 mg/mL.**^{14,15} The dose needed to treat p-blocker overdose could exceed the amount available at a hospital pharmacy.¹⁶

(3-Adrenergic receptor agonists (catecholamines) are used routinely for p-blocker toxicity. However, results have been variable. The most effective therapy may be glucagon followed by epinephrine. Isoproterenol and dopamine may be the least effective.¹⁷ Clinical improvement has been noted with isoproterenol used in high doses (160-200 μ g per min).¹⁸ Canine models of propranolol overdose also support the use of high-dose catecholamines such as isoproterenol and dopamine.¹⁹

Phosphodiesterase inhibitors also have been used to treat P-blocker toxicity. In theory, drugs such as amrinone inhibit the ability of phosphodiesterase to break down cAMP, thereby facilitating maintenance of intracellular calcium levels. In original models, amrinone demonstrated positive inotropic effects without increasing myocardial oxygen demands in propranolol-induced heart failure.²⁰ However, in other animal studies, amrinone and milrinone increased cardiac output but had no appreciable effect on heart rate. When administered with glucagon, neither amrinone nor milrinone provided any additional benefit over glucagon.²¹ Thus phosphodiesterase inhibitors have no advantage over glucagon. However, if glucagon is not available, phosphodiesterase inhibitors can be reasonable alternatives. The dosage of amrinone used in adults is an initial bolus of 0.75 mg/kg over 2 min, followed by a continuous infusion of 5 to 10 μ g/kg per min. Atropine is unlikely to be effective in the management of (3-blocker-induced bradycardia and hypotension.

Canine studies and case reports suggest that calcium chloride therapy may improve the depressed hemodynamic status, mainly by positive inotropic action.^{22,25} Serum calcium improves transport of extracellular calcium into the cell and release of calcium from intracellular storage organelles, which supports myofibril contraction and promotes positive inotropy.^{22,25}

Insulin may prove to be a novel therapy in (3-blocker toxicity. In a canine model, high-dose insulin-dextrose therapy improved survival in severe overdoses when compared with glucagon or epinephrine. Further trials are needed to confirm beneficial effects in humans before therapy can be recommended routinely.^{24,26}

Treatment of ventricular dysrhythmias due to sotalol requires pharmacologic measures different from those required for other P-blockers. Isoproterenol, lidocaine, and overdrive pacing have been used successfully. Magnesium also may be of benefit.²⁷

Extrinsic pacing may be required to maintain heart rate.²⁸ However, electrical capture is not always successful, and if capture does occur, blood pressure is not always restored.¹⁷ Cardiac pacing may be most beneficial in treating torsades de pointes associated with sotalol.²⁷ Occasionally, extreme means of resuscitation, including extracorporeal circulation and aortic balloon pump, have been successful.^{29,30} Intra-aortic balloon pump should be considered when glucagon and high-dose catecholamines fail to reverse drug-induced cardiogenic shock.³⁰ Based on previously described pharmacokinetic properties, hemodialysis would not be expected to effectively remove lipophilic P-blocker drugs that have a large volume of distribution or extensive protein binding. Hemodialysis may be useful for atenolol, nadolol, and sotalol overdose because these drugs have a lower volume of distribution and less protein binding than do other p-blockers.

DISPOSITION

Patients who develop altered mental status, bradycardia, conduction delays, or hypotension should be managed in the intensive care unit. Patients with cardioactive coingestants or with ingestions of sustained-released

TABLE 175-3 Treatment Algorithm for Cardiovascular Effects of (J-Blocker Ingestions

Standard initial interventions*
Fluid bolus (NS)
Atropine trial for symptomatic bradycardia
Glucagon
Bolus: .05—.15 mg/kg (3-10 mg for average size adult) followed by infusion: 1-5 mg per h (repeat bolus as necessary)
Epinephrine
Infusion: 1 μ g/kg per min and titrate to effect (doses up to 30-100 μ g per min have been used successfully)
Isoproterenol
Infusion: 2 μ g per min and titrate to effect (doses up to 160-200 μ g per min have been used successfully)
Consider other inotropic drugs
Dopamine infusion: 5 μ g/kg per min and titrate to 20 μ g/kg per min
Norepinephrine infusion: 0.5 μ g per min and titrate to 4.0 μ g per min
Amrinone
Bolus: 0.75 mg/kg over 2 min followed by infusion: 5 (μ g/kg per min and titrate
Cardiac pacing for refractory bradycardia Intra-aortic balloon pump for refractory shock

* ABC's, two large bore IVs, cardiac monitor, glucose check, activated charcoal.

(3-blocker formulations probably warrant inpatient monitoring because the risk of delayed toxicity is unclear.⁸

Patients with probable 3-blocker overdoses who remain asymptomatic and demonstrate no signs of hemodynamic instability for 6 h after ingestion appear to be at little risk of subsequent deterioration.^{6,8} Sotalol deserves special consideration because it has class III antiarrhythmic activity and has a long half-life. One group of authors suggests that the need for observation of a sotalol ingestion beyond 6 h depends on the QT_c interval.^{6,8}

CALCIUM CHANNEL BLOCKERS

Kennon Heard Jeffrey A. Kline

EPIDEMIOLOGY

Emergency physicians are familiar with the use of calcium channel blockers (CCBs) for the treatment of hypertension, angina pectoris, and for control of ventricular rate in supraventricular dysrhythmias. Less common uses include prophylactic treatment of migraine headaches, treatment of arterial vasospasm from Raynaud disease, treatment of esophageal spasm, and treatment of pulmonary hypertension.¹ For the last 5 years, CCBs have accounted for more poisoning deaths than any other cardiovascular drug, and are the second most common cause of prescription drug poisoning death. More than 4500 cases of CCB poisoning are treated in health care facilities annually.²

PHARMACOLOGY AND PATHOPHYSIOLOGY

Intracellular calcium is the primary stimulus for smooth and cardiac muscle contraction and for impulse formation in sinoatrial pacemaker cells. At therapeutic concentrations, CCBs bind to the a subunit of the L-type calcium channel, causing the channel to favor the closed state, thereby decreasing calcium entry during phase II depolarization. At very high concentrations, some CCBs (notably, verapamil) may occupy the channel canal and completely block calcium entry through the L-channel. The result is profound smooth muscle relaxation, weakened cardiac contraction, blunted cardiac automaticity, and intracardiac conduction delay.¹ Clinically, these effects are recognized as hypotension and bradycardia. Animal data suggest that verapamil overdose also impairs myocardial carbohydrate intake, which contributes to the negative cardiac inotropy.³

Table 176-1 reviews the therapeutic effects of three major CCB classes that are widely used in the clinical setting: the phenylalkylamines (verapamil), the benzothiazepines (diltiazem), and the dihydropyridines (nifedipine and most newer agents). Verapamil is the most potent negative inotrope of all CCBs, causing at least equal depression of heart contraction compared with smooth muscle dilatation at any concentration.⁴ This cardiotoxic effect may be one reason that verapamil overdose causes more deaths than all other CCBs combined. Dihydropyridines bind more selectively to vascular smooth muscle calcium channels compared with cardiac calcium channels, and therefore relax smooth muscle at concentrations that produce almost no negative inotropy. Dihydropyridines have been structurally modified to make them more lipid soluble in an effort to prolong their durations of action. These modified dihydropyridines are known as *second-generation dihydropyridines*. They cause more gradual smooth-muscle relaxation, producing less reflex baroreceptor activation and less reflex tachycardia than is observed with first-generation dihydropyridines.

The older agents—verapamil, nifedipine, and diltiazem—all have relatively short serum half-lives. Consequently, sustained-release formulations have been developed for all of these agents. As sustained-

TABLE 176-1 Relative Negative Inotropic Effect versus Vascular Smooth Muscle Relaxing Effect of Calcium Channel Antagonists in Humans

Class	Trade Name	Vascular Selectivity*
Phenylalkylamines:		
Verapamil	Calan, Verelan, Isoptin	1.0
Benzothiazepines:		
Diltiazem	Cardizem, Dilacor	1.0
Dihydropyridines:		
Nifedipine	Procardia, Adalat	0.1
Amlodipine	Norvasc	0.1
Nicardipine	Cardene	0.01
Isradipine	DynaCirc	0.01
Felodipine	Plendil	0.01
Nisoldipine	Baymycard (in U.K.)	0.0001

*Ratio of percent negative inotropy to percent vasodilation at 10^{-7} M. Note: An index number closer to 1.0 indicates that the drug causes an equal degree of reduction in cardiac function compared with vasodilation.

release formulations prolong drug absorption, onset of symptoms may be delayed and toxicity may be prolonged. Several of the second-generation dihydropyridines have prolonged duration of action, and therefore are generally not formulated as sustained-release products. While clinical data on overdose of these agents is limited, pharmacokinetic data suggest that delayed onset of toxicity is less likely. As newer formulations are released frequently, it is often helpful to contact a Regional Poison Control Center for help in determining if a given product is formulated as a sustained-release preparation.

CLINICAL FEATURES

Calcium channel blocker poisoning is associated with many clinical effects. The most prominent and life-threatening effects are an extension of the therapeutic effects on the cardiovascular system. Patients with moderate verapamil or diltiazem poisoning often have sinus bradycardia, varying degrees of atrioventricular block, and hypotension.⁵ Mild or moderate dihydropyridine overdoses usually cause peripheral vasodilatation with resultant hypotension and reflex tachycardia.⁵ In severe overdose, any of these agents may cause complete heart block, depressed myocardial contractility, and vasodilatation that ultimately results in cardiovascular collapse.

Hyperglycemia and lactic acidosis are also common manifestations of severe overdoses. These effects are caused by antagonism of calcium channels on pancreatic (3 cells, leading to decreased serum insulin levels, decreased myocardial glucose metabolism and increased anaerobic metabolism resulting from circulatory impairment associated with negative inotropy and vasodilation produced by the drug. The net effect is a metabolic profile similar to diabetic ketoacidosis. Hypokalemia may also be observed.

Pulmonary and central nervous system effects are generally secondary to decreased myocardial function and impaired organ perfusion. Cardiogenic pulmonary edema is sometimes observed in severe overdoses, especially if large volumes of crystalloid are infused during resuscitation. Noncardiogenic pulmonary edema has also been reported.⁶ Seizures, delirium, and coma have been reported, and are presumed to be secondary to cerebral hypoperfusion. Alteration in consciousness in patients with adequate mean arterial pressure should not be attributed to CCB toxicity, and should prompt an evaluation for other causes.

DIAGNOSIS

From a large series of CCB overdoses, the lowest dose that produced toxicity in adults is shown in Table 176-2. A history of ingestion that

TABLE 176-2 Single Ingestion Toxicity from Calcium Channel Blockers

Agent	Lowest Dose	Mean Toxic Dose
Verapamil	720 mg	16 mg/kg
Diltiazem	420 mg	5.7 mg/kg
Nifedipine	50 mg	8 mg/kg

Source: Adapted from Romoska EA et al.⁵

is near these doses should be considered potentially toxic. Doses in excess of the mean toxic dose (see Table 176-2) should be expected to produce toxicity.⁵

Many clinicians now prescribe verapamil, diltiazem, nifedipine, and some of the second-generation dihydropyridines as extended-release preparations. Compared with standard-release preparations, extended-release preparations have delayed and prolonged toxicity. Therefore, it is important to determine the exact formulation of the ingested agent to guide management decisions. If the history cannot identify the exact formulation, the clinician should assume it is sustained release and modify treatment in a conservative way. Further critical history should include the possibility of coingestants. The time of ingestion should be determined. **The onset of symptoms can be delayed as much as 12 h with significant overdose.** Thus, the conclusion that toxic manifestations will not occur should not be based solely on a questionable remote time of ingestion.

The physical examination of a patient with CCB poisoning is frequently unremarkable other than cardiovascular findings of a slow heart rate relative to the arterial blood pressure. Following dihydropyridine ingestion, patients will usually have systemic vasodilatation leading to flushed skin, tachycardia and mild to moderate hypotension. Peripheral edema is commonly seen as a side effect of chronic nifedipine therapy.

Toxicity from diltiazem or verapamil will frequently cause profound bradycardia and hypotension. Systemic hypoperfusion may cause secondary findings such as alteration in mental status, signs of pulmonary edema, or decreased urine output.

Electrocardiographic findings include sinus bradycardia, varying degrees of heart block, and slowing of intraventricular conduction. Reflex tachycardia is commonly seen with mild to moderate ingestion of dihydropyridines. Junctional rhythms and ventricular escape rhythms are frequently noted in severe overdoses with verapamil or diltiazem.

No laboratory findings are critical to the acute management of CCB toxicity. Hyperglycemia is often noted following CCB ingestion, differentiating CCB toxicity from β -blocker toxicity that may cause hypoglycemia. Lactic acidosis will manifest as an elevated anion gap and low serum bicarbonate. Hypokalemia is also noted in severe overdoses. Serum calcium levels are usually normal. Ionized serum calcium levels may be followed when calcium chloride is administered as therapy, but the optimum serum calcium level for patients with severe CCB poisoning is not known. Finally, a screening serum acetaminophen level should be performed for patients that present following suicidal overdose.

DIFFERENTIAL DIAGNOSIS

Table 176-3 shows the critical differential diagnosis for bradycardia, heart block, and hypotension. Hypothermia should be detected during vital sign assessment. Myocardial infarction may be evident on the initial or subsequent electrocardiogram. Hyperkalemia should be suspected in patients with renal failure.

Differentiation of CCB toxicity from cardiac glycoside toxicity is difficult but critical. These drugs may be used for the same indications, and patients are frequently taking both. While calcium salts are standard therapy for CCB poisoning, they may cause cardiovascular

TABLE 176-3 Differential Diagnosis

collapse when given to a patient with digoxin poisoning. Unfortunately, patient acuity may not allow serum digoxin measurement, and treatment decisions must be made on clinical impression. In general, patients with chronic digoxin poisoning will have more ventricular ectopy than patients with CCB toxicity. However, as the main manifestation of acute cardiac glycoside poisoning is heart block and bradycardia, bedside differentiation may be difficult. **If the diagnosis of acute digoxin poisoning cannot be excluded, administration of digoxin Fab should precede calcium administration.** Alternatively, other treatments for CCB toxicity should be initiated.

(3-Adrenergic antagonist toxicity may be clinically indistinguishable from CCB toxicity. In general, (3-blocker toxicity is not as severe and patients tend to have hypoglycemia and normal to elevated serum potassium concentrations. However, these findings are not consistent enough to have diagnostic value. Fortunately, the treatment for these two poisonings is similar. Calcium, (3-adrenergic agonists, glucagon, and pacing are considered useful therapy for both.

MANAGEMENT

Decreased level of consciousness following CCB ingestion is a result of cerebral hypoperfusion or coingestion. During the initial resuscitation, patients with altered mental status should be considered for treatment with an opiate antagonist and have a serum glucose level determination. Early airway management should be implemented in patients with any degree of mental status impairment or hemodynamic instability. Decontamination with the associated risk of aspiration will be required for all but the most trivial ingestions. Endotracheal intubation may minimize this risk. In addition to the vomiting associated with decontamination, glucagon often will precipitate vomiting. Finally, early airway management will allow the physician to concentrate on treating the often-precipitous cardiovascular collapse without having to perform a "crash airway."

Following airway management, patients will generally require cardiovascular stabilization. Therapies directed at improving heart rate should be directed at increasing end-organ perfusion rather than restoring a specific heart rate. For example, some patients with heart rates in the 30 to 40 beats/min range will maintain adequate blood pressure and perfusion, and therefore will only require monitoring rather than a specific intervention. Conversely, patients may respond to cardiac pacing with an increase in heart rate to 90 to 100 beats/min but no improvement in blood pressure or perfusion. These patients obviously require additional therapy to increase myocardial function.

Therapies directed specifically at increasing heart rate include several medications and cardiac pacing. Atropine alone is rarely effective for CCB-induced bradycardia, but administration is commonly recommended. Isoproterenol may be useful (2 to 10 μ g/min intravenous infusion) to increase heart rate, but peripheral vasodilation may worsen hypotension. Calcium salts may improve both heart rate and blood pressure, but the response is variable. External and transvenous pacing may be attempted, and are often successful at restoring an acceptable rate, but blood pressure frequently will improve minimally or not at all. However, pacing is indicated for patients with severe bradycardia (heart rate <30).

In general, it is reasonable to administer crystalloid during the initial resuscitation of a hypotensive CCB-poisoned patient. However, overaggressive fluid administration may worsen pulmonary edema.

Therefore, consider pulmonary artery catheterization prior to continued fluid resuscitation beyond 2 L.

Specific treatments of the hemodynamic effects of CCB toxicity are well described, but the therapies are untested in controlled human trials. The recommendations given below are based on animal data and human case reports/series. Case reports often document the use of multiple therapies simultaneously. Severely toxic patients responding to calcium (repeated boluses or infusions), multiple adrenergic agonists, and glucagon have been documented. Given the complexity of managing these cases, pulmonary artery catheterization should be considered in patients requiring more than one vasopressor.

Calcium Salts

Administration of calcium salts improves blood pressure in animal models and in human case reports.^{7,9} Effects on heart rate are variable. Calcium chloride is preferred to calcium gluconate as it provides triple the amount of calcium on a weight-to-weight basis. However, calcium chloride must be administered through secure intravenous access as extravasation may result in tissue necrosis. Calcium chloride is usually given as a 1 to 3 gm intravenous bolus. The effects of calcium administration may be transient, and repeat dosing is commonly required, and continuous infusions of 2 to 6 g/h may also be used. Serum calcium levels may become markedly elevated, which may lead to reluctance toward subsequent dosing. However, for patients who do not respond to other therapies, it is reasonable to continue calcium administration even when serum calcium levels are markedly elevated. Animal studies of severe verapamil toxicity report response to an infusion of 5 mg/kg per min of calcium chloride. One human case report documents survival following administration of 30 g of calcium chloride over 12 h resulting in a serum calcium level of 5.94 mmol/L (23 mg/dL).⁷

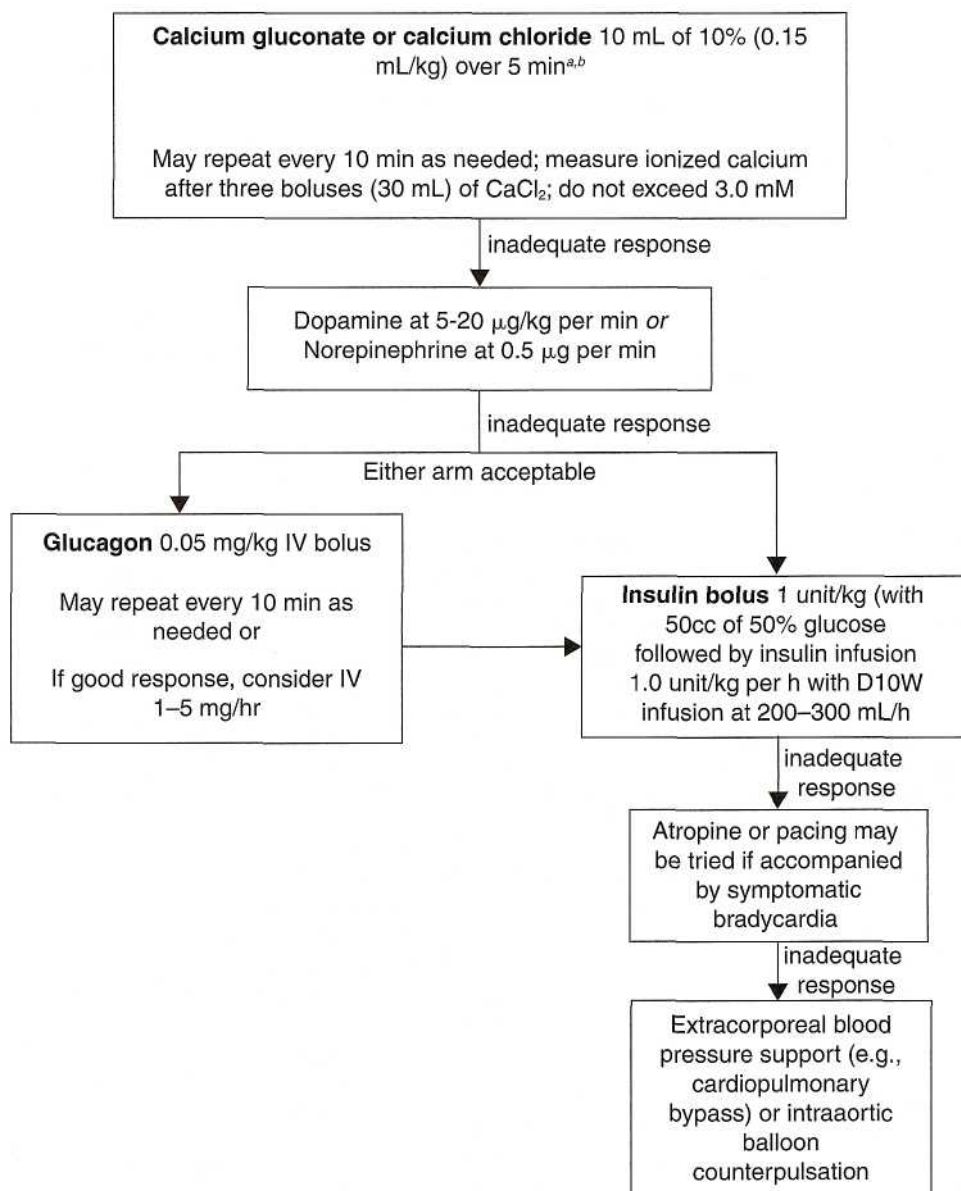

Adrenergic Agents

Patients who do not respond to calcium administration or who require repeated doses are usually given adrenergic agonists. While animal data suggest that other therapies may offer improved metabolic function and improved survival in severe poisonings, adrenergic agonists have several advantages over more specific therapies. Physicians and nurses are familiar with these agents. Therapy can be initiated quickly and most patients will respond favorably. This prevents a period of nontreatment while the supplies for more esoteric therapies are gathered. Given the availability of these therapies and the familiarity of clinicians with their use, adrenergic agonists should be considered the first line of treatment for persistent hypotension following CCB ingestion. Cases of CCB poisoning responding to dopamine, epinephrine, and norepinephrine have been reported.¹⁰ When standard doses are inadequate, it is reasonable to use high doses titrated to a systolic blood pressure of >90 mm Hg, although addition of another agent (such as insulin/glucose or glucagon) should also be considered. Phosphodiesterase inhibitors such as amrinone and milrinone have also been reported to improve blood pressure in animal studies and human case reports.^{11,12} Figure 176-1 outlines the authors' suggested choices and dosing of (3-adrenergic agents.

Insulin

Over the last 5 years, hyperinsulin/euglycemia (HIE) has emerged as a promising new treatment for the myocardial suppression associated with CCB poisoning. Several well-designed animal studies have demonstrated improved cardiac metabolic and mechanical function and improved survival when HIE is compared to glucagon, epinephrine, or placebo for treatment of verapamil poisoning.^{3,13} Several human case reports have also suggested that HIE therapy improves perfusion in cases of CCB poisoning unresponsive to other therapies.^{14,15} Unlike glucagon, insulin is readily available and inexpensive. Finally, the main adverse effect is hypoglycemia, a condition that may be eas-

FIG. 176-1. Proposed protocol for treatment of moderate to severe CCB poisoning.

^a Calcium chloride provides three times as much free calcium as calcium gluconate.⁶
Use with caution if digoxin toxicity is possible.

ily detected with appropriate monitoring and responds rapidly to treatment. While failures are not unknown, most reports document a therapeutic response within 15 to 30 min. Current insulin dosing recommendations vary between 0.1 and 1 unit/kg. One anecdotal report noted a rapid response following a tenfold dosing error that resulted in administration of 1000 units of insulin to a patient that had failed to respond to dopamine, norepinephrine, glucagon, and calcium therapy. The patient's blood pressure increased dramatically within 15 min and the patient was off all vasopressors within 5 h, and no supplemental glucose was required. Given the success of HIE in animal models and recent clinical reports, HIE should be considered as a second line to vasopressors, and on a level with glucagon. Table 176-4 provides a suggested protocol for HIE.

Glucagon

Glucagon has been considered the treatment of choice for moderate to severe CCB toxicity. Glucagon improves blood pressure in animal models, and several case reports have also noted improvement in hemodynamics following glucagon therapy.^{16,17} However, failures of

therapy have also been reported.¹⁵ The current recommended dose in adults is 0.05 mg/kg as a bolus. A response is usually seen within 15 min. If there is no response, doses should be repeated every 10 min up to 0.15 mg/kg. Patients that respond should be started on an infusion of 0.075 to 0.15 mg/kg per h. Similar dosing may be used for pediatric patients. Glucagon should be reconstituted using saline rather than the provided diluent, as this diluent contains phenol, which may cause toxicity when administered in high doses. The main adverse effects of glucagon are vomiting and hyperglycemia. Therefore, endotracheal intubation should be strongly considered prior to initiation of glucagon therapy. Finally, supplies of glucagon are often limited. Hospital glucagon supplies are often rapidly depleted and it may be necessary to contact other institutions for additional supplies. When these factors are considered, it is likely that HIE will replace glucagon as standard treatment for CCB toxicity in the near future.

Patients who do not respond to the above therapies may benefit from extraordinary measures. Hemodynamic support devices, such as intraaortic balloon pumps, left ventricular assist devices, and even extracorporeal circulatory devices, may provide adequate blood pressure to allow clearance of the drug and resolution of symptoms.¹⁸

TABLE 176-4 Suggested Protocol for Insulin Therapy of Severe Calcium Channel Blocker Overdose

Administer 50 mL of 50% glucose IV Administer insulin, 1 unit/kg IV bolus. Begin insulin infusion at 0.5—1 unit/kg per h and D10W at 200–300 mL per h (adult) or 15—20 mL/kg per h (pediatric). Monitor serum glucose every 20 min. Titrate glucose infusion rate to maintain serum glucose between 150 and 300 mg/dL. Once infusion rates have been stable for 60 min, glucose monitoring may be decreased to hourly. Monitor serum potassium and start intravenous potassium infusion if serum potassium is below 3.5 mEq/L.

Abbreviation: D50 = glucose 50% (0.5 g/mL) in water.

DECONTAMINATION

While routine gastric lavage has fallen out of favor with many toxicologists, CCB overdoses are often life-threatening and may not respond to therapy. Given these considerations, the authors recommend gastric lavage for any patient that presents within 60 min of a potentially life-threatening CCB ingestion, and for any patient who requires intubation following CCB ingestion.

Calcium channel blockers are well bound to charcoal, and should be administered to adults following any potentially significant ingestion. In addition, charcoal should be routinely administered following accidental ingestion of verapamil in children, as life-threatening toxicity has been reported following ingestion of a single tablet.

Whole-bowel irrigation (WBI) is frequently advocated for ingestion of sustained-release calcium channel blockers. While prospective data are lacking, anecdotal case reports note that a large amount of medication may be recovered. Given the potential for severe toxicity, WBI should be strongly considered for patients who present following large ingestions of sustained-release products.

DISPOSITION

In general, patients will show manifestations of toxicity within 6 h of ingestion of non-sustained-release products. Patients who are asymptomatic, who have received charcoal decontamination, and who have normal vital signs following a 6-h observation period can be discharged after appropriate psychiatric evaluation. Toxicity may be delayed for up to 12 h following ingestion of sustained-release products.¹⁹ In general, patients that ingest potentially toxic doses of sustained-release products should be admitted to a monitored setting for at least 24 h.

**ANTIHYPERTENSIVE
AGENT TOXICITY** Arjun
Chanmugam Keith Thomasset

Hypertension is one of the most common diseases in the United States, affecting almost 24 percent of the population.¹ Medications used to control hypertension are among the most commonly prescribed drugs. As a result, the potential for overdose, inadvertent or intentional, is quite high. In 2001, according to the Toxic Exposure Surveillance System, cardiovascular drugs, including antihypertensive medications, accounted for nearly 4 percent of all adult toxic exposures. There are many classes of antihypertensive medications available for use, with new agents introduced into the market frequently.

The initial management of patients with an acute overdose of antihypertensive medication remains relatively uniform. Airway, breathing, and circulation remain the initial priorities. Thus, oxygen, cardiac monitoring, and intravenous access remain the key initial interventions. If mental status changes are present, glucose and naloxone should also be considered as initial interventions. If no contraindications are present, antihypertensive-induced hypotension should be treated initially with volume expansion, using NS or an equivalent crystalloid solution (such as LR solution). In most adults, initial fluid therapy should consist of bolus challenges of 500 mL or 10 to 20 mL/kg over 10 to 15 min. If hypotension persists despite fluid challenges, the use of a vasopressor may be warranted. In most cases, dopamine is the vasopressor of choice, with infusion rates started at 2 to 5 μ g/kg per min and increased as appropriate.

Supportive measures and appropriate monitoring should be instituted as early as possible. The use of activated charcoal is indicated in most overdose situations, but gastric decontamination should be considered only in appropriate patients (discussed below). The management of patients with antihypertensive poisonings rarely relies on

serum levels of medications but instead depends on symptoms. However, a key to managing these patients is to determine the medication involved and to target interventions specific for that class of antihypertensive agent (Table 177-1). In the following discussion, antihypertensive toxicology is divided into sections based on the class of medications. (3-Blockers, monoamine oxidase inhibitors, and calcium-channel blockers are discussed in separate chapters.

DIURETICS

Diuretics are among the most commonly prescribed of all antihypertensives because they are recommended as a first-line medication in the treatment of hypertension.¹ Diuretics can be subdivided into several groups based on their mechanism of action.

Thiazide and Loop Diuretics

Thiazide and loop diuretics are two classes of diuretics commonly used. The classic thiazide diuretic is hydrochlorothiazide, which can be used as single-drug therapy or as part of a multidrug regimen. Combination products are becoming more common in the treatment of hypertension, and hydrochlorothiazide is often used as a component of these fixed-combination medications. In general, toxicity associated with thiazide diuretics is rare.

The pharmacologic action of thiazide diuretics (e.g., chlorthalidone, hydrochlorothiazide, and metolazone) is a result of their ability to inhibit reabsorption of sodium and chloride at the distal convoluted tubule. This results in a greater excretion of water and other essential electrolytes, including potassium and bicarbonate. At higher doses,

TABLE 177-1 Common Antihypertensive Medications

Agent	Mechanism of Action	Therapeutic Range	Oral LD ₅₀	Dialysis	Maximum Tolerated Exposure	Therapeutic Interventions and Comments
Hydrochlorothiazide	Inhibits reabsorption of Na ⁺ and Cl ⁻ in the distal convoluted tubule of the kidney	12.5–100mg qd (in divided doses)	10 g/kg in mice/rats	Partially	1 g	IV fluids, correct electrolytes, vasopressor if necessary
Furosemide	Decreases reabsorption of Na ⁺ and Cl ⁻ in the loop of Henle	20–600 mg qd	1000 mg/kg in rats/dogs	No	Not established	IV fluids, correct electrolytes, vasopressor if necessary
Spirolactone	Specific antagonist of aldosterone	25–400 mg qd		Yes	Not established	IV fluids, correct electrolytes
Triamterene	Inhibits the reabsorption of sodium ions in exchange for potassium and hydrogen ions at the distal tubule	100–150 mg bid	380 mg/kg in mice	Yes	Not established	IV fluids, correct electrolytes, vasopressor if necessary
Acetazolamide	Inhibits carbonic anhydrase in the kidney	Up to 1000 mg qd in divided doses	No deaths reported	Possibly	Not established	IV fluids, correct electrolytes, pH, vasopressor if necessary
Mannitol	Osmotic diuresis	0.5–2 g/kg	Not known	Yes	Not established	IV fluids, correct electrolytes, vasopressor if necessary
Clonidine	Central α ₂ -adrenergic agonist	0.1–2.4 mg/d	465 mg/kg	No	11.25 mg	IV fluids, vasopressor, naloxone, tolazoline
Captopril	Angiotensin-converting enzyme inhibition	6.25–150 mgqd	o deaths reported	Yes	7.5 g	IV fluids, vasopressor, naloxone
Enalapril	Angiotensin-converting enzyme inhibition	5–40 mg qd	2000 mg/kg in mice/rats	Yes	300 mg	IV fluids, vasopressor, naloxone
Lisinopril	Angiotensin-converting enzyme inhibitor	2.5–80 mg qd	ot well established	Yes	400 mg	IV fluids, vasopressors (dopamine), naloxone
Losartan	Angiotensin-receptor inhibitor	12.5–100 mg qd	000 mg/kg in rats	No	Not well established	IV fluids, vasopressors (dopamine)
Valsartan	Angiotensin-receptor inhibitor	80–320 mg qd	ot well established	No	Not well established	IV fluids, vasopressors (dopamine)
Candesartan	Angiotensin-receptor inhibitor	2–32 mg in one or two divided doses daily	ot well established	No	Not well established	IV fluids, vasopressors (dopamine)
Methyl dopa	Central inhibition of α-adrenergic receptors, false neurotransmission, and/or reduction of plasma rennin activity	250–3000 mg qd	>1.5 g/kg in mice/rats	Yes	Not established	IV fluids, vasopressor

(continued)

TABLE 177-1 Common Antihypertensive Medications (Continued)

Agent	Mechanism of Action	Therapeutic Range	Oral LD ₅₀	Dialysis	Maximum Tolerated Exposure	Therapeutic Interventions and Comments
Hydralazine	Direct relaxation of arteriolar smooth muscle	10–50 mg qid	173 mg/kg in rats	No	Not established	IV fluids; vasopressor therapy should be avoided secondary to potential dysrhythmias
Minoxidil	Direct peripheral vasodilation	5–100 mg qd in divided doses	1321–3492 mg/kg in rats	Partially	Not established	IV fluids; vasopressor therapy should be avoided secondary to potential dysrhythmias
Sodium nitroprusside	Relaxation of arteriolar and venous smooth muscles	0.5+10 µg/kg per min	—	Yes, for thiocyanate toxicity	Unknown	Prolonged use can result in cyanide and/or thiocyanate toxicity; for cyanide toxicity, treat with cyanide antidote kit (see Chap. 188)
Prazosin	Competitive blockade of α ₁ -adrenergic receptors	1–20 mg qd in divided doses	Not known	No	200 mg	IV fluids, vasopressor
Doxazosin	Arteriolar dilator, competitive blockade of postsynaptic α ₁ -adrenergic receptors	1–16 mg qd	1000 mg/kg in mice and rats	No	70 mg	IV fluids, vasopressors (dopamine)
Terazosin	Arteriolar dilator, competitive blockade of postsynaptic α ₁ -adrenergic receptors	1–20 mg in one or two divided doses daily	Not well established	No	Not well established	IV fluids, vasopressors (dopamine)
Fenoldopam	Postsynaptic dopamine 1 receptor agonist	0.1–1.6 µg/kg per min	Not established	Yes	Not established	IV fluids, vasopressors

thiazide diuretics can function similar to carbonic anhydrase inhibitors. Calcium regulation is also affected by thiazide diuretics by two separate mechanisms: 1) inhibition of vitamin D synthesis and thus, decreased calcium absorption from the gastrointestinal tract; 2) increased renal absorption of calcium. The net result, however, is calcium retention and possibly hypercalcemia.

Loop diuretics include drugs such as furosemide, bumetanide, ethacrynic acid, and torsemide. These agents act on the ascending limb of the loop of Henle to decrease reabsorption of sodium, chloride, and water. They act similarly to the thiazide diuretics in that they alter the regulation of other essential electrolytes, particularly potassium and calcium. Unlike thiazide diuretics, the loop diuretics increase the excretion of calcium. Loop diuretics also increase venous capacitance and are used in acute situations with elevated cardiac filling pressures.

The toxicity associated with thiazide and loop diuretics involves two basic processes: volume contraction and electrolyte derangements. Findings associated with intravascular volume depletion include hypotension (sometimes only orthostatic hypotension), tachycardia, and altered mental status. Common electrolyte derangements include hyponatremia, hypokalemia, hypocalcemia (loop diuretics), hypomagnesemia, hyperuricemia (thiazide diuretics), and hypochlor-emic metabolic alkalosis. Occasionally, an increased anion gap without acidosis is noted because of concentration of unmeasured anions in the serum. Other adverse reactions from thiazide and loop diuretics may include rash, pruritis, hearing loss, leukopenia, and thrombocytopenia.

Normal saline administration is the preferred therapy for hypovolemia, hyponatremia, and alkalosis. The use of vasopressors is rarely indicated for hypotension. Potassium replacement should be instituted early, although renal function should be assessed and monitored during therapy to avoid inducing iatrogenic hyperkalemia in

acute or chronic renal failure. In general, if comorbid conditions are not present, most asymptomatic individuals can be medically cleared after therapy and observation. Poisonings sufficient to cause significant electrolyte abnormalities are likely to be associated with total body deficits of various elements and may require prolonged therapy.

Potassium-Sparing Diuretics

The most common medications of this subclass are spironolactone, triamterene, and amiloride. Spironolactone, a competitive inhibitor of aldosterone, acts to allow potassium retention while inducing sodium and water excretion. Triamterene has direct effects on the renal tubule to inhibit sodium exchange for potassium and hydrogen. Amiloride's mechanism of action, also independent of aldosterone, is to promote potassium retention in exchange of sodium and water. Volume depletion, hyperkalemia, hyponatremia, and hypochloremia are common manifestations of toxicity for this class of medication. Treatment for potassium-sparing diuretic toxicity is directed at maintaining intravascular volume, repleting sodium, and reversing the hyperkalemia. Hypotension is best initially treated with intravenous fluids, usually normal saline. If hypotension is persistent, a vasopressor such as dopamine is warranted. The most serious manifestations of hyperkalemia include neurologic and cardiovascular dysfunction. Treatment of hyperkalemia should remain a priority, and can be serious enough to warrant dialysis.

Carbonic Anhydrase Inhibitors

The prototype for this subclass of diuretic is acetazolamide, which is a nonbacteriostatic sulfonamide whose adverse reactions include se-

vere allergic reaction and Stevens-Johnson syndrome. The primary action of this class of diuretic is to inhibit carbonic anhydrase in the kidney to prevent the reversible reaction of carbon dioxide and water to form carbonic acid. This results in loss of bicarbonate ions in the urine, along with sodium, potassium, and water. Overdose with this class of medication can lead to volume depletion and electrolyte disturbances, as well as non-anion-gap metabolic acidosis. Treatment is directed at reversing volume depletion, monitoring electrolytes, and restoring normal pH balance.

Osmotic Agents

Osmotic agents, such as mannitol, are not absorbed by the nephron. Rather, they induce diuresis by raising the osmolarity of the glomerular filtrate, thereby attracting more water in the tubules to increase urine volume. The main effect of osmotic agents is to decrease intravascular volume, but toxicity can result in pulmonary edema, anaphylaxis, and acute renal failure. Overdoses can cause profound volume loss, accompanied by electrolyte imbalances. Treatment is aimed at replenishing the intravascular volume and correcting any electrolyte imbalances. Other adverse reactions—such as pulmonary congestion, acidosis, electrolyte loss, dryness of mouth, thirst, marked diuresis, urinary retention, edema, headache, blurred vision, convulsions, nausea, vomiting, rhinitis, skin necrosis, thrombophlebitis, chills, dizziness, urticaria, dehydration, fever, and angina-like chest pains—have been reported during or following mannitol infusion.

CENTRALLY ACTING ANTIHYPERTENSIVE AGENTS

A number of centrally acting antihypertensive agents are available for use. Examples include clonidine, guanabenz, guanfacine, and methyl-dopa. Clonidine is the most used agent in this class and has long been a favorite for the acute management of hypertension. Two forms of clonidine are commonly prescribed, an oral version and a transdermal patch. Clonidine has gained prominence in recent years because of its ability to mitigate opiate and alcohol withdrawal symptoms. Although it has not been approved by the Food and Drug Administration for this use, clonidine has been used in clinical practice for the treatment of narcotic withdrawal for almost two decades.³ With the advent of the clonidine patch in 1986, drug delivery could be reliably maintained for 7 days at a variety of doses, which increased its attractiveness for prescribers. However, plasma concentrations of clonidine remain high enough to maintain a hypotensive effect for approximately 8 h after the removal of the patch. Regardless of the route of administration, clonidine's most common adverse effects are dry mouth and drowsiness.

Clonidine

Clonidine is an imidazoline whose principle site of action is on the α_2 receptors in the lower brainstem. Stimulation of the central α_2 receptor decreases norepinephrine release in the central nervous system (CNS), resulting in a lower heart rate and blood pressure. Although clonidine acts as a central α_2 -adrenergic receptor agonist, it has other effects. For example, it reduces noradrenergic output in the locus ceruleus, which is stimulated by the cessation of narcotic use, thereby mitigating the symptoms of opioid withdrawal. At higher doses, clonidine can act as a partial peripheral α -agonist, resulting in a paradoxical increase in blood pressure and heart rate. However, this effect is relatively short-lived and the antihypertensive effects usually predominate.

Clonidine exposure appears particularly prevalent in children. During a recent 6-year period there were over 10,000 clonidine exposures in children (<19 years), with a majority among those less than 6 years. Most were of little to no consequence, but about 10 percent were moderate to serious. There was only one death.⁴

The primary symptoms associated with clonidine toxicity include hypotension and bradycardia, which can lead to cardiac ischemia and

congestive heart failure. Mental status changes range from agitation and hallucinations to sedation and coma. Respiratory depression and recurrent apnea can occur, especially in children. The other symptoms of clonidine toxicity include seizures, diarrhea, hypothermia, and miosis.

Treatment of clonidine overdoses is centered on maintaining adequate blood pressures. In the acute phase of toxicity, a brief episode of blood pressure elevation may occur. This paradoxical hypertensive response is due to peripheral α_1 -adrenergic receptor stimulation but usually evolves rapidly into hypotension as central α_2 -agonist stimulation predominates. Treatment is rarely indicated for transient blood pressure elevation, but if aggressive intervention is warranted, nitroprusside is the drug of choice because of its rapid onset and dissipation. The peak effects of clonidine usually occur in 1 to 3 h. Intravenous fluids are usually adequate for the treatment of hypotension, but in cases of persistent hypotension, a dopamine infusion beginning at a midlevel dose rate of 2 to 5 $\mu\text{g/kg}$ per min can be initiated.

The other serious cardiovascular condition caused by clonidine toxicity—sinus bradycardia—must be monitored closely. Symptomatic bradycardia should be treated with repeated doses of atropine sulfate. The other toxic effects of clonidine occur less commonly but may be serious. Respiratory depression is rare, but recurrent apnea, especially in children, may require intubation. Seizures require supportive measures and usually respond to standard anticonvulsant therapy. Hypothermia associated with clonidine toxicity also responds to standard interventions.

In cases of severe refractory hypotension or CNS depression, the use of naloxone has been suggested, although its mechanism of action is not well understood. Tolazoline 10 mg IV titrated every 15 min to a maximum of 40 mg, is only recommended after intravenous fluids, dopamine, atropine, and naloxone have failed to reverse the cardiovascular effects of clonidine.⁵ There is also a single case report of clonidine toxicity being successfully treated with yohimbine, a CNS α_2 -adrenergic antagonist.⁶

Clonidine's range of toxicity has not been well established. Severe toxicity has been reported in children at doses as low as 0.1 mg, whereas adults have survived with levels exceeding 15 mg. Symptoms of clonidine toxicity can persist for up to 72 h, so admission should be considered for any patient suspected of clonidine overdose.

Similar to clonidine, the following agents also exert their effects by decreasing norepinephrine release from the distal nerve terminals in the CNS. The additional agents should also be considered in this group include guanabenz, guanethidine, guanfacine, and methyl-dopa. Reserpine is also a centrally acting agent that exerts its action by depleting norepinephrine and other catecholamine stores in the central nervous system. Overdoses of these medications results in effects similar to the α_2 -adrenergic receptor agonists, which include hypotension, symptomatic bradycardia, dry mouth, and potential mental status changes.

Hypotension should be treated with intravenous crystalloid; if necessary, vasopressors such as norepinephrine or dopamine should be considered. Bradycardia can be treated with atropine. Methyl-dopa can be dialyzed, but there is no clear evidence that dialysis of the other agents is beneficial. A rebound hypertensive condition, similar to that of clonidine withdrawal, may occur with the abrupt cessation of any centrally acting antihypertensive medication.

PERIPHERAL α_1 -ADRENERGIC RECEPTOR ANTAGONISTS

Agents in this class exert their hypotensive effects by antagonism of peripheral α_1 -adrenergic receptors. The result is a decrease in systemic vascular resistance. Agents in this class can be administered PO and IV. The oral agents include doxazosin, prazosin and terazosin. Intravenous agents used in this class include phenoxybenzamine and phentolamine. Reported toxicity associated with this drug class is relatively uncommon. A first-dose phenomenon has been reported with the use of these agents that results in an unanticipated sudden

hypotensive episode, potentially leading to syncope. Inadvertent hypotension generally occurs within 30 to 60 min after the first dose has been given and is usually preceded by tachycardia. The first-dose phenomenon usually occurs in individuals with impaired hepatic function or congestive heart failure.

Other toxic symptoms include headache, vertigo, paresthesias, gastrointestinal discomfort, and weakness. Case reports have indicated that priapism, pulmonary edema, and acidosis can also occur as a result of overdose with these agents. However, the most common manifestation of α -adrenergic receptor antagonist overdose remains hypotension and tachycardia. Treatment is supportive with intravenous fluids, careful monitoring, and vasopressors, if necessary.

DIRECT VASODILATORS

Hydralazine

Hydralazine, a smooth muscle vasodilator whose mechanism of action is poorly understood, is available both in tablet form and in parenteral form. Acute toxicity with hydralazine is uncommon, and no fatalities as a result of acute poisoning have been reported. Chronic use does lead to a hydralazine-induced systemic lupus erythematosus syndrome, but this generally occurs in individuals who have slow hepatic acetylation. Treatment is supportive; the hypotension associated with hydralazine responds well to intravenous fluids. Vasopressors should be used with caution in order to avoid precipitating dysrhythmias. If a vasopressor is necessary, dopamine should be used judiciously. Symptomatic tachycardia can be cautiously treated with (3-blockers.

Minoxidil

Minoxidil is a direct-acting peripheral vasodilator that lowers systolic and diastolic blood pressure without much effect on the CNS. It also has the advantage of not interfering with vasomotor reflexes and therefore does not induce orthostatic hypotension.

In tablet form, minoxidil is usually reserved for the treatment of severe or refractory hypertension, and reported toxicity has been rare. A common side effect of minoxidil is hirsutism. In 1988, a 2 percent topical solution of minoxidil was approved for the treatment of baldness. At least one case report exists involving ingestion of the topical solution. Regardless of the preparation, the most common symptoms of toxicity include hypotension and tachycardia.⁷ In patients with renal failure, fluid retention, and pericardial effusion have been reported. Treatment is supportive and includes intravenous fluids. If the hypotension is persistent, dopamine or phenylephrine should be considered. Vasopressors with β -adrenergic activity, such as epinephrine, should be avoided because of the potential for excessive cardiac stimulation. P-Blockers can be used for symptomatic tachycardia.

Sodium Nitroprusside

This is the drug of choice for most true hypertensive emergencies. It is a rapidly absorbed and rapidly dissipated drug whose principle action is to lower blood pressure by relaxing smooth muscle in arteries and veins. Sodium nitroprusside causes toxicity by three primary mechanisms: 1) the most common adverse effect is direct vasodilation resulting in hypotension and dysrhythmias; 2) thiocyanate toxicity occurs infrequently, resulting in tinnitus, altered mental status changes, nausea, and abdominal pain; 3) in rare cases, cyanide toxicity can occur, resulting in coma, metabolic acidosis, or respiratory arrest. In very rare cases, and in susceptible patients, methemoglobinemia can occur, which, if levels reach greater than 15 percent, can result in symptomatic cellular hypoxia. Toxicity associated with sodium nitroprusside is usually related to prolonged administration or occurs in patients with renal or hepatic failure.

Nitroprusside reacts with hemoglobin to form cyanomethemoglobin and cyanide. Methemoglobin is derived from hemoglobin and will bind cyanide until the intraerythrocyte methemoglobin has been saturated. Thiosulfate will react with the remaining cyanide to form thiocyanate, which is excreted in the urine. A limiting factor in cyanide metabolism is the amount of thiosulfate in the body, and that limit is usually achieved at a nitroprusside infusion rate of 5 μ g/kg per min.

The direct vasodilatation effects of nitroprusside can result in excessive hypotension, resulting in mental status changes and dysrhythmias. Thiocyanate toxicity causes anorexia, fatigue, and mental status changes, including psychosis, weakness, seizures, tinnitus, and hyperreflexia. Cyanide toxicity is often associated with the odor of almonds on breath and can result in acidosis, tachycardia, mental status changes, and death.

Excessive vasopressor secondary to nitroprusside administration can be avoided by careful monitoring using an arterial line and frequent clinical evaluations. In general, blood pressure reduction should not exceed a 25 percent reduction in mean arterial pressure. Should hypotension occur, stopping the infusion is usually effective since the half-life of nitroprusside is only a few minutes.

Thiocyanate toxicity can be minimized by avoiding prolonged administration of nitroprusside and by limiting drug use in patients with renal insufficiency. If necessary, thiocyanate can be removed by dialysis. Cyanide toxicity can be avoided by the coadministration of sodium thiosulfate or by limiting the administration of nitroprusside. Details of the treatment of cyanide toxicity are discussed in Chap. 188.

DOPAMINE AGONISTS

Fenoldopam is an agent used in the management of acute severe hypertension. It is used as a nitroprusside alternative in patients with renal dysfunction, negating the risk of cyanide/thiocyanate toxicity.⁸ Lack of experience and the associated expense of this agent have resulted in minimal use to date. This agent exerts its effects by agonism of the dopamine 1 receptor. The result is peripheral vasodilation and a reduction in blood pressure. Toxicity with fenoldopam is theorized to result in hypotension. These effects of fenoldopam are short lived based on its relatively short half-life (5 to 10 min). Treatment involves discontinuation of the agent and the administration of intravenous crystalloid. If hypotension persists, vasopressor therapy with agents such as dopamine or norepinephrine is warranted.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Angiotensin-converting enzyme inhibitors (ACEIs) come in two basic forms: an active drug form, best represented by captopril, and a pro-drug form, represented by enalapril. Recently, enalaprilat, the active form of enalapril, became available for intravenous use. However, there are many ACEIs available today, and all work to inhibit the conversion of the prohormone angiotensin I to the potent endogenous vasoconstrictor angiotensin II. Besides being a vasoconstrictor, angiotensin II stimulates aldosterone release to increase sodium and water retention. Aside from these two effects, ACEIs have other mechanisms of action to decrease total peripheral resistance without increasing heart rate or cardiac output. For example, by inhibiting ACE (also known as bradykininase), the degradation of the vasodilator peptide bradykinin is prevented.

Adverse effects of ACEIs include hypotension, angioedema, rash, anaphylactoid reactions, cough, drug fever, proteinuria, glomerulopathy, neutropenia, and agranulocytosis. With overdoses of ACEIs, the most important concern is hypotension, which can be profound. The preferred therapy to reverse the hypotension is the administration of normal saline (NS), and, if necessary, vasopressors, such as intermediate- or high-dose dopamine, can be added. Although ACEIs are dialyzable, peritoneal dialysis and hemodialysis are not recommended at

this time. Naloxone has been reported to be useful in reversing the hypotension induced by captopril, although its mechanism is unclear.⁹ The mechanism is theorized to involve the ACEIs ability to inhibit the metabolism of enkephalins and potentiate their opioid effect, including a decrease in blood pressure.¹⁰

ANGIOTENSIN II RECEPTOR ANTAGONISTS

This class of agents exerts its antihypertensive effects via inhibition of the angiotensin II receptor. Common agents in this class include, but are not limited to, losartan, valsartan, and candesartan. Experience with toxic effects of these agents appears to be limited in humans to date. Symptoms experienced are primarily extensions of the agents' therapeutic effects and are similar to those of ACE inhibition. Hypotension and reflex tachycardia are the commonly seen effects of these agents. Bradycardia may be seen as a result of excess vagal stimulation. Hyperkalemia can also be seen in patients receiving these agents. Supportive measures, including intravenous NS, adequate monitoring (including electrolytes-potassium). Close observation is indicated for anyone who may have ingested an overdose of an angiotensin II receptor antagonist.

ting of digoxin toxicity, but it is no longer considered a first-line agent. Morbidity or mortality is unusual after intentional phenytoin overdose if good supportive care is provided. Most phenytoin-related deaths have been caused by rapid intravenous administration or hypersensitivity reactions.

Data with regard to exposures from the American Association of Poison Control Centers are almost certainly underestimates. Major toxicity is more likely to be reported from adverse parenteral events, and minor drug reactions are more common with oral preparations. Nevertheless, in 2001, 3941 exposures were reported, 53 percent of which were unintentional, 35 percent were intentional, 8 percent were adverse reactions, and the rest were "other." Among these exposures, 23 percent were considered inconsequential, 24 percent were considered minor, 13 percent were considered moderate, and fewer than 3 percent were considered major. Only six deaths were reported.²

MECHANISM OF ACTION

Phenytoin exerts its anticonvulsant effect by blocking voltage-sensitive and frequency-dependent sodium channels in the neurons. Phenytoin stabilizes sodium channels in an inactive state, and this inhibitory effect, similar to the action of local anesthetics, depends on the voltage and frequency of firing of the neuron. Phenytoin has no effect on the amplitude or duration of the action potential. Rather, it limits the ability of the neuron to fire trains of action potentials at high frequency by delaying recovery. In this fashion, it suppresses repetitive neuronal activity and prevents the spread of a seizure focus. At higher concentrations, phenytoin delays activation of outward potassium currents in nerves and prolongs the neuronal refractory period. It also may exert an anticonvulsant effect by influencing calcium channels or 7-aminobutyric acid receptors (GABA), although this has not been fully established.

PATHOPHYSIOLOGY

The toxic effects of phenytoin vary with route administration, duration of exposure, and dosage used. Of these determinants of toxicity, the most important is the route of administration. The intravenous administration of phenytoin carries the greatest risk, in large part due to the other constituents of the parenteral vehicle (see "Effects of Propylene Glycol and Ethanol Diluents"). The most serious reactions after intravenous administration are cardiovascular (bradycardia, hypotension, and asystole), although tissue necrosis and sloughing after extravasation have been described.³ Major cardiac toxicity occurs only after parenteral administration; in general, oral overdose does not lead to cardiovascular morbidity.⁴ It is more common in the elderly and those with underlying cardiac disease but has been described in young healthy patients.

Many of the side effects of the oral preparation are dose related and are predictable at higher plasma concentrations. Nevertheless, different individuals have different tolerance profiles, and adverse effects can be evident in some at seemingly therapeutic doses, whereas others may only display untoward effects well beyond the therapeutic range. Early toxicity is manifested by vestibular, ocular, or cerebellar signs: nystagmus, dysdiadochokinesia, and ataxia. At higher levels, central nervous system (CNS) depression and other cognitive effects (confusion, dizziness, and loss of concentration and memory) are seen. Only two areas of the brain normally exhibit spontaneous neuronal burst discharge: the hippocampus and the cerebellum. The ability of phenytoin to suppress these areas may result in impaired memory and balance, respectively. Paradoxically, very high levels of phenytoin may be associated with seizures, although this is, at best, a rare occurrence. Acute oral overdose is usually manifested by nystagmus, nausea and vomiting, ataxia, dysarthria, choreoathetosis, opisthotonos, and CNS depression or excitation.⁵ Deaths from oral ingestion of phenytoin are extremely rare and occur in association with the ingestion of other

PHENYTOIN AND FOSPHENYTOIN TOXICITY

Harold H.

Phenytoin (3-hydroxymethyl-5,5-diphenylhydantoin) is a primary anticonvulsant for all types of epilepsy except absence. It is useful in the treatment of status epilepticus in conjunction with other more rapidly acting anticonvulsants.¹ Phenytoin has been used prophylactically in a variety of clinical settings characterized by acute symptomatic seizures (head trauma, alcohol withdrawal, and drug overdose) but thus far has proven useful only in the setting of head trauma and then only in the immediate posttraumatic period. Phenytoin has been employed in the management of chronic pain syndromes. Historically, it has also been used as an antidysrhythmic agent, especially in the set-

substances. The chronic administration of phenytoin is associated with numerous side effects that involve a variety of organ systems. Many of these effects depend on dose and duration, but some are idiosyncratic. Hypersensitivity reactions to phenytoin usually occur within the first few months of therapy and include fever, skin rashes, blood dyscrasia, and, rarely, hepatitis. Deaths due to Stevens-Johnson syndrome have occurred, and anyone with this syndrome should never receive phenytoin again.

PHARMACOKINETICS

Phenytoin is a weak acid with a pK_a of 8.3. Thus, in the acid milieu of the stomach and even at physiologic pH, its aqueous solubility is limited. The parenteral form of phenytoin is adjusted to pH 12 to keep the drug in solution, but it is very irritating to the tissues, and intramuscular injection results in local precipitation of phenytoin with erratic absorption and therefore is not recommended. Absorption after oral ingestion is slow, variable, and often incomplete, especially after an overdose. Consequently, it may be necessary to obtain serial levels in suspected overdose to determine peak levels. Significant differences in bioavailability exist among different phenytoin preparations. Peak levels typically occur from 3 to 12 h after a *single* oral dose.

After absorption, phenytoin is distributed throughout the body, with a volume of distribution of 0.6 to 0.8 L/kg. Brain tissue concentrations equal those in plasma within about 10 min of intravenous infusion and correlate with therapeutic effects, whereas cerebrospinal fluid and myocardium equilibrate within 30 to 60 min. At steady state, concentrations are higher in neural tissue than in the serum. Within the CNS, concentrations are higher in the brainstem and cerebellum than in the cerebral cortex.

PROTEIN BINDING AND FREE PHENYTOIN FRACTIONS

Phenytoin is extensively (90 percent) bound to plasma proteins, especially albumin. The free, unbound, form is the biologically active moiety responsible for the drug's clinical effect and toxicity. The free phenytoin fraction normally constitutes 10 percent of the plasma level. The unbound fraction of the drug is greater in the following groups of patients: neonates; the elderly; pregnant women; individuals with uremia, hypoalbuminemia (cirrhosis, nephrosis, malnutrition, burns, trauma, or cystic fibrosis), and hyperbilirubinemia; and individuals taking drugs that displace phenytoin from binding sites (salicylate, valproate, phenylbutazone, tolbutamide, and sulfisoxazole).

Although patients with decreased protein binding may have higher levels of free phenytoin and a greater biologic effect, they may have lower levels of total phenytoin, because more of the drug is available for metabolism. Theoretically, such patients may become toxic with total phenytoin levels in the therapeutic range. Patients who exhibit toxic signs in the therapeutic range and those with decreased protein binding should have free phenytoin levels measured.

Phenytoin concentrations are most commonly measured by an enzyme-mediated immunoassay technique, which is specific and sensitive to less than 1 $\mu\text{g/mL}$. If available, free phenytoin concentrations are more useful to predict toxicity. Corrected serum phenytoin levels can be calculated in hypoproteinemic patients with a known serum albumin level. To calculate the phenytoin concentration (C_{normal}) that would be present if a patient's serum albumin were normal, the following equation is used:

$$C_{\text{normal}} = \frac{C_{\text{measured}} \times 4.4}{\text{albumin concentration}}$$

where the phenytoin concentration is in micrograms per milliliter and the albumin concentration is in grams per deciliter.

METABOLISM

After absorption and distribution, only 4 to 5 percent of phenytoin is excreted unchanged in the urine. The remainder is metabolized by hepatic microsomal enzymes. The drug is primarily hydroxylated to a series of inactive compounds. The major metabolite (60 to 70 percent) is the parahydroxyphenyl derivative. It is processed by glucuronidase, secreted in the bile, reabsorbed, and subsequently excreted in the urine. Phenytoin is not appreciably removed by hemodialysis or hemoperfusion. The metabolism of phenytoin is capacity limited (dose dependent). At plasma concentrations below 10 $\mu\text{g/mL}$, elimination is first order (a fixed percentage of drug metabolized per unit of time). However, at higher concentrations, including those in the therapeutic range (10 to 20 $\mu\text{g/mL}$), the metabolic pathways may become saturated, and the elimination may change to zero-order kinetics (a fixed amount metabolized per unit of time). This change in kinetics can markedly prolong the half-life of phenytoin, which is normally 6 to 24 h. An understanding of capacity-limited kinetics is essential to the proper dosing of phenytoin, the avoidance of side effects with chronic therapy, and the management of overdoses. At higher levels in the therapeutic range, any increase in the daily dose may result in a disproportionate increase in the plasma level. Thus, incremental doses should be limited to 30 mg at a time, and levels should be carefully monitored when it is necessary to raise phenytoin doses above 300 mg (about 5 mg/kg) per day.

Because the half-life of phenytoin is 24 h or less, once-a-day regimens may result in erratic levels and become problematic for patients requiring tight seizure control. Only one phenytoin preparation (Phenytoin Kapseals) is approved by the Food and Drug Administration for once-a-day use. Concomitant use of drugs that inhibit or enhance hepatic microsomal activity may result in an increase or decrease of phenytoin level, respectively. Phenytoin also affects the metabolism of various other agents (Table 178-1).

EFFECTS OF PROPYLENE GLYCOL AND ETHANOL DILUENTS

The acute cardiovascular toxicity seen with intravenous phenytoin infusion has frequently been ascribed to its diluent. The vehicle for the older parenteral formulation of phenytoin (Dilantin) is 40 percent propylene glycol and 10 percent ethanol, adjusted to a pH of 12 with sodium hydroxide. The glycol component has been shown to cause coma, seizures, circulatory collapse, ventricular dysrhythmias, atrioventricular node depression, and hypotension in human and animals.⁶ Propylene glycol is a strong myocardial depressant and vasodilator and increases vagal tone. Other toxic effects of propylene glycol include hyperosmolality, hemolysis, and lactate-associated metabolic acidosis. Louis and Kutt compared the acute toxicities of intravenous phenytoin and propylene glycol alone and in combination in a feline model.⁷ Phenytoin alone did cause hypotension but did not cause significant electrocardiographic effects; rather, it partly reversed the toxic effects that occurred when propylene glycol was given.⁷ Acute toxic effects of propylene glycol are also strongly related to the rate of infusion. This is further evidence for its role in intravenous phenytoin toxicity, a phenomenon that is almost always related to infusion rate. The ethanol diluent fraction of parenteral phenytoin also may precipitate a reaction in patients taking disulfiram. The glycol preparation is still available in the United States (although the original manufacturer no longer makes it). With intravenous infusion pumps controlling the rate of administration, use of cardiac and blood pressure monitors, and dilution with normal saline, adverse effects are not as common, and phenytoin is less expensive than the alternative (see "Fosphenytoin" below).

The limitations of this parenteral form of phenytoin (incomplete aqueous solubility, irritating nature of the vehicle, and tendency to precipitate in intravenous solutions) have prompted a search for a more suit-

able preparation. Recently, a prodrug of phenytoin, *fosphenytoin*, has been synthesized that is more soluble and less irritating to the tissues.

FOSPHENYTOIN

Fosphenytoin is the disodium phosphate ester of phenytoin. It is freely soluble in aqueous solutions and is formulated with Tris buffer only at a pH of 8.8. Fosphenytoin is a pro-drug and is converted to phenytoin by phosphatases in the blood and various organs. **For simplicity, the concentration and dose of fosphenytoin are expressed in phenytoin equivalents (150 mg fosphenytoin = 100 mg phenytoin).** The conversion half-life is 10 to 15 min.⁸ Fosphenytoin is tolerated IV and IM, and patients can be successfully loaded within 30 min with one or more intramuscular injections without significant side effects.⁹

Given IV, fosphenytoin can cause pruritus and hypotension. Due to the time delay while conversion takes place, it is not clear whether fos-

phenytoin administered IV can result in therapeutic levels more quickly and with fewer side effects than intravenous phenytoin. Blood pressure and cardiac monitoring are recommended when loading with fosphenytoin IV but not IM. The adverse and toxic effects of fosphenytoin are the same as with phenytoin, except that the effects of glycol and ethanol are not present with fosphenytoin. The ability to administer fosphenytoin intramuscularly offers a clear advantage over phenytoin and is especially useful in the prehospital and non-acute care settings and in those patients lacking venous access.

In clinical trials fosphenytoin administered IV has caused hypotension in 8 percent of subjects. Borderline heart block has been observed, and bradycardia, seizures, and asystole have been reported in a patient given 225 mg IV who had undiagnosed mitral valve prolapse.^{10,11} Negative inotropic effects have been documented in a guinea pig left atrium model. Phlebitis and pain at the injection site are much less common than with phenytoin. Paresthesias have been reported in 21 percent of epileptic patients treated with fosphenytoin.¹²

SERUM LEVELS AND RANGE OF TOXICITY

Therapeutic phenytoin levels are described as being 10 to 20 [xg/mL (40 to 80 mmol), with a free phenytoin level of 1 to 2 [jLg/mL.¹³ Although 50 percent of seizure patients achieve reduction of seizure frequency with amounts below these levels, some patients require levels above 20 [xg/mL for adequate seizure control. The therapeutic range for phenytoin is rather narrow. However, some patients have a greater propensity for side effects than others. Individual variation in toxicity is a function of baseline neurologic status, individual response to the drug, and free drug fraction. Patients with underlying brain disease are predisposed to toxicity and may become toxic at low levels. Long-term therapy must be individualized and based on clinical response, drug levels, and signs of toxicity. In general, toxicity correlates fairly well with increasing plasma levels (Table 178-2), but this is not a universal tenet, because some patients tolerate levels above 40 (xg/mL quite well. Nystagmus usually appears first at a phenytoin level of 20 [xg/mL but may occur at lower or higher levels. Almost all patients with phenytoin-induced seizures will have levels well above 30 [xg/mL. Signs of toxicity occur at free phenytoin levels of 2.0 [Lg/mL and are consistently severe above 5.0 [xg/mL.

CLINICAL FEATURES

As toxic phenytoin levels are reached, inhibitory cortical and excitatory cerebellar and vestibular effects begin to occur. The usual initial sign of toxicity is nystagmus, which is seen first on forced lateral gaze and then becomes spontaneous. Vertical, bidirectional, or alternating nystagmus may occur with severe intoxication. A decreased level of consciousness is common with initial sedation, lethargy, ataxic gait,

TABLE 178-2 Correlation Side Effects of Plasma Phenytoin Level and

Plasma Level ((xg/mL)	Side Effects
<10	Usually none
10-20	Occasional mild nystagmus
20-30	Nystagmus
30~0	Ataxia, slurred speech, nausea and vomiting
40-50	Lethargy, confusion
>50	Coma, seizures

and dysarthria progressing to confusion, coma, and even apnea in a large overdose. Chronically impaired cognitive function or acute encephalopathy may occur. Nystagmus may disappear at levels sufficient to cause coma, and complete ophthalmoplegia and loss of corneal reflexes may occur. Therefore, absence of nystagmus does not exclude severe phenytoin toxicity. Nystagmus then returns as serum drug levels decrease and coma lightens.

Phenytoin-induced seizures are usually brief and usually generalized. They are quite rare and almost always are preceded by other signs of toxicity, especially in acute overdose.¹⁴ Cerebellar stimulation and alterations in dopaminergic and serotonergic activities may be responsible for acute dystonias and movement disorders, such as opisthotonos and choreoathetosis. Depressed or hyperactive deep tendon reflexes, clonus, and extensor toe responses also may be elicited. Some signs of neurologic toxicity may outlast the presence of drug by months, especially mild peripheral neuropathy or acute reversible cerebellar degeneration with ataxia.

Cardiovascular Toxicity

Cardiac toxicity after oral phenytoin overdose in an otherwise healthy patient has not been reported and, if observed, requires assessment for other causes (e.g., hypoxia and other drugs). Cardiovascular complications have been almost entirely limited to cases of intravenous administration. Complications include hypotension with decreased peripheral vascular resistance, bradycardia, conduction delays progressing to complete atrioventricular nodal block, ventricular tachycardia, primary ventricular fibrillation, and asystole. Electrocardiographic changes include increased PR interval, widened QRS interval, and altered ST segments and T waves. Bradycardia, hypotension, and syncope in healthy volunteers have been reported even after small undiluted intravenous doses. Some of these complications can be attributed to rapid intravenous administration of the preparation containing propylene glycol and are avoidable with cautious administration (Table 178-3). Even slowly administered intravenous phenytoin (<25 mg/min) has been reported to cause cardiac arrest in critically ill patients receiving dopamine infusions to support blood pressure.

Fosphenytoin lacks propylene glycol but nevertheless has been associated with cardiovascular toxicity. Thus, we have come full circle in

our understanding of phenytoin toxicity. Having first attributed all the toxic cardiovascular effects to phenytoin and then to the vehicle, we now realize that phenytoin, fosphenytoin, and propylene glycol can cause significant cardiovascular toxicity.

Vascular and Soft Tissue Toxicity

Intramuscular injection of phenytoin results in localized crystallization of the drug and hematoma, sterile abscess, and myonecrosis at the injection site. Complications after intravenous infusion have included skin and soft tissue necrosis requiring skin grafting, compartment syndrome, gangrene, amputation, and death. Delayed bluish discoloration of the affected extremity (the "purple glove syndrome") followed by erythema, edema, vesicles, bullae, and local tissue ischemia also have been described.¹⁵ The propylene glycol diluent, strong alkalinity of the intravenous solution, administration of the preparation undiluted, and crystallization of the drug contribute to tissue toxicity. Fosphenytoin, in contrast, is better tolerated when given IV or IM.

Hypersensitivity Reactions

Hypersensitivity reactions usually occur within 1 to 6 weeks of beginning phenytoin therapy and can include fever, systemic lupus erythematosus, erythema multiforme, toxic epidermal neurolysis, Stevens-Johnson syndrome, hepatitis, rhabdomyolysis, acute interstitial pneumonitis, lymphadenopathy, leukopenia, disseminated intravascular coagulation, and renal failure. One should always ask about a history of previous hypersensitivity reactions before deciding to restart phenytoin in the ED setting.

Miscellaneous Effects

Other side effects from phenytoin include gingival hyperplasia, hirsutism, hypocalcemia, megaloblastic anemia responsive to folate administration, pseudolymphoma, and hemorrhagic disease of the newborn responsive to vitamin K (Table 178-4). Gingival hyperplasia is so common, its absence should suggest poor compliance. Another clinically significant effect in some patients is hyperglycemia, felt to be secondary to inhibition of insulin release, which can lead to diabetic

TABLE 178-3 Guidelines for Safe Phenytoin or Fosphenytoin Loading

Intravenous	
Loading dose is 18 mg/kg phenytoin or fosphenytoin in PE*	
Mix total dose of phenytoin in 150-200 mL of NS (keep concentration 6.7 mg/mL); mix fosphenytoin in NS (keep concentration 1.5-25 mg PE/mL)	
Administer phenytoin through Millipore filter by using an infusion pump	
Rate of administration should not exceed 25 mg/min of phenytoin or 150 mg/min PE fosphenytoin (less in patients with cardiovascular disease)	
Monitor the blood pressure and cardiac rhythm continually during the infusion	
In the event of complications, immediately stop the infusion and administer isotonic crystalloid and other treatment as indicated	
Intramuscular	
Administer 15 mg/kg fosphenytoin PE preparation in one or multiple intramuscular sites	
Oral†	
Loading dose is 20 mg/kg	
Phenytoin tablets or suspension may be used	
Patient must be conscious with an intact gag reflex and not actively seizing or vomiting	
Administer the total amount in one dose	

*PE = phenytoin equivalents (150 mg fosphenytoin = 100 mg phenytoin)

†Unlike intravenous loading, not all patients orally loaded will reach a therapeutic level.

TABLE 178-4 Toxicity of Phenytoin

Central nervous system	
Dizziness, tremor (intention), visual disturbance, horizontal and vertical nystagmus, diplopia, miosis or mydriasis, ophthalmoplegia, abnormal gait (bradykinesia, truncal ataxia), choreoathetoid movements, vomiting, dysphagia, respiratory distress, irritability, agitation, confusion, hallucinations, fatigue, coma, death (rare), encephalopathy, pseudodegenerative disease, dysarthria, meningeal irritation with pleocytosis, seizures (rare)	
Peripheral nervous system	
Peripheral neuropathy, urinary incontinence	
Hypersensitivity reactions	
Eosinophilia, rash, pseudolymphoma (diffuse lymphadenopathy), systemic lupus erythematosus, pancytopenia, hepatitis, pneumonitis	
Gastrointestinal	
Nausea and vomiting, hepatotoxicity	
Skin	
Hirsutism, acne, rashes (including Stevens-Johnson syndrome)	
Other	
Fetal hydantoin syndrome, gingival hyperplasia, coarsening of facial features, hemorrhagic disease of the newborn, hyperglycemia, hypocalcemia	
Parenteral preparations	
May cause hypotension, bradycardia, conduction disturbances, myocardial depression, ventricular fibrillation, asystole, and sloughing of tissues	

ketoacidosis or nonketotic hyperosmolar coma in diabetics. The teratogenic fetal hydantoin syndrome is well described, so oral phenytoin therapy in a pregnant patient should never be initiated or continued by an emergency physician without consultation and close follow-up from an attending neurologist and obstetrician.

DIFFERENTIAL DIAGNOSIS

Intoxication with almost any CNS active or sedative hypnotic drug, especially ethanol, carbamazepine, benzodiazepines, barbiturates, and lithium, may mimic early phenytoin intoxication. Disease states resembling phenytoin toxicity include hypoglycemia, Wernicke's encephalopathy, and posterior fossa hemorrhage or tumor. Although seizures may be caused by phenytoin at toxic levels, other epileptogenic drug overdoses and seizures due to trauma, drug and alcohol withdrawal, and infection should be considered first.

TREATMENT

Initial general treatment of severe oral phenytoin overdose, including intravenous access and airway management, is similar to that for other ingested drugs. Acidosis (respiratory or metabolic) should be corrected to decrease the active free phenytoin fraction. Multiple doses of oral activated charcoal (1 g/kg) within the first 24 h may be of benefit, given the known poor solubility and resultant extended absorptive phase of oral phenytoin in overdose.¹⁶ Hemodialysis and hemoperfusion are of no clinical benefit in phenytoin poisoning. Seizures may be treated with intravenous benzodiazepines or phenobarbital, with the caution that seizures are not common in phenytoin overdose and other causes must be ruled out. Cardiovascular toxicity is extremely rare in oral overdose and should suggest other etiologies.

Cardiac monitoring after oral ingestion is unnecessary. Atropine and temporary cardiac pacing may be used for symptomatic bradydysrhythmia associated with intravenous phenytoin. Hypotension that occurs during intravenous administration of phenytoin or fosphenytoin usually responds to discontinuation of the infusion and the administration of isotonic crystalloid. Hospital admission and appropriate orthopedic or plastic surgery consultation should be obtained for patients with any significant extravasation of intravenous phenytoin or other signs of local vascular or tissue toxicity after infusion. To minimize complications due to infusion, intravenous phenytoin and fosphenytoin should be administered under close observation, with constant cardiac and blood pressure monitoring. The infused solution should be given slowly (≤ 25 mg phenytoin, or ≤ 150 mg fosphenytoin phenytoin equivalents/min) through a large, well-positioned catheter. Phenytoin should never be administered intravenously without first diluting it in normal saline.

ADMISSION CONSIDERATIONS

Patients with serious complications after an oral ingestion (seizures, coma, altered mental status, ataxia, etc.) should be admitted for further evaluation and treatment. Others with only mild symptoms may be treated with activated charcoal in the ED and discharged after their levels have returned to normal, provided they are not actively suicidal. Prolonged observation and frequent assessment of levels are not practical in many EDs. Thus, patients with continuing symptoms may need to be admitted or their case followed in an observation unit. Given the long and erratic absorption phase of phenytoin after oral overdose, the decision to discharge or medically clear a patient for psychiatric evaluation cannot be based on one serum level. Patients with symptomatic chronic intoxication should be admitted for observation unless signs are minimal, adequate care can be obtained at home, and patients are 8 to 12 h from their last therapeutic dose. Phenytoin therapy should be stopped in all cases, and, if toxicity continues to resolve, a serum level may be reassessed in 2 to 3 days to guide resumption of therapy.

Patients with significant or persistent complications after the intravenous administration of phenytoin or fosphenytoin should be admitted. Those with transient effects need not be.

IRON

Joseph G. Rella Lewis

S. Nelson

INTRODUCTION

There were approximately 30,000 calls related to iron supplement ingestion made to U.S. poison control centers in 2000.¹ Iron is widely available, particularly in homes with small children, and for this reason many of the exposures involve children younger than age 6 years. Fortunately, most children remain asymptomatic or develop only minimal toxicity. Alternatively, children with large overdoses, or adults with intentional overdose, risk dying without aggressive supportive and antidotal therapy. Recent changes in the available iron formulations, as well as in current supplemental iron dispensing practices, may reduce the incidence and consequences of iron poisoning.

PHYSIOLOGY

A 70-kg (154-lb) male has a total body iron store of about 4 g, two-thirds of which is incorporated into hemoglobin. The remainder is found in other iron-containing molecules such as myoglobin, cytochromes,

and other enzymes and cofactors, or stored as ferritin. Because excess iron is toxic, the body uses several mechanisms to maintain appropriate iron availability while preventing toxicity. These mechanisms include serum protein binding, intracellular storage, and, most importantly, regulation of gastrointestinal (GI) absorption.

The oral bioavailability of inorganic iron is less than 10 percent and ferrous iron (Fe^{2+}) is better absorbed than ferric (Fe^{3+}). Most dietary iron is in the ferric form, and this is reduced to ferrous by a brush border ferrireductase. Chelated iron, most readily found in heme, is best absorbed, suggesting one beneficial effect of eating meat. Fe^{2+} is transported into enterocytes by a membrane proton-coupled metal transporter called DMT1. Once absorbed, iron is bound by poorly understood chaperone molecules that sequester the iron in ferritin. In times of iron need, the body produces transferrin, which moves iron from the enterocytes into the body. Alternatively, the stored iron in the intestinal cell is eventually eliminated when the mucosal cell is sloughed. This is the principal mechanism for limiting absorption, and failure of this mechanism occurs in iron overdose.

Transferrin, the carrier protein that binds Fe^{3+} , is the major mechanism for safe iron transport through the body. The total iron-binding capacity (TIBC) primarily measures the amount of serum transferrin. The TIBC is generally two to three times the normal serum iron concentration. Ferritin is a large intracellular storage protein that can reversibly bind as many as 4500 molecules of iron. When an iron deficit exists, iron is transported from ferritin and the GI tract to the liver, spleen, and bone marrow, where it is incorporated into appropriate molecules.²³ It is noteworthy that, under normal conditions, unbound iron, or free iron, does not exist within the body.

PATHOPHYSIOLOGY

Iron is a potent catalyst for the production of oxidants such as free radicals. Through this mechanism, iron is a direct GI irritant and causes vomiting, diarrhea, abdominal pain, mucosal ulceration, and bleeding soon after a significant ingestion. As the mucosal surface is injured, iron passes unimpeded into the blood. When the ability of transferrin to combine with iron is exhausted, free iron becomes available. Free iron enters the mitochondria where it inhibits oxidative phosphorylation resulting in metabolic (lactic) acidosis. Iron also participates in the production of toxic hydroxyl free radicals and subsequent membrane lipid peroxidation of various organ systems. Clinical effects of free iron include coagulopathy through inhibition of serum proteases,⁴ hepatotoxicity, myocardial and vascular dysfunction,⁵ and encephalopathy.

Chelated sources of supplemental iron, such as Ferrochel, are less toxic in overdose because the ligand sterically limits the iron from participating in redox reactions.⁶ Similarly, carbonyl iron is a nonionic iron molecule that does not participate in redox reactions.

TOXIC DOSE

It is the amount of ingested elemental iron that determines a patient's potential for experiencing toxicity. The fraction of elemental iron in various preparations ranges from 12 to 33 percent. Ferrous sulfate, the most commonly available form, contains 20 percent elemental iron (e.g., a 325-mg tablet of ferrous sulfate contains 65 mg of elemental iron). Pediatric multivitamins typically contain 10 to 18 mg of elemental iron per tablet. Toxic effects are reported following oral doses as low as 10 and 20 mg/kg elemental iron.

In general, moderate toxicity occurs at doses of 20 to 60 mg/kg of elemental iron, and severe toxicity can be expected following ingestion of greater than 60 mg/kg elemental iron.⁷

LABORATORY ASSESSMENT

Serum iron levels used to determine toxicity and to direct management must be used with caution. In general, serum iron levels between 300

and 500 $\mu\text{g/dL}$ correlate with significant GI toxicity and mild systemic toxicity, and serum iron levels between 500 and 1000 $\mu\text{g/dL}$ correlate with moderate systemic toxicity. Levels greater than 1000 $\mu\text{g/dL}$ are associated with significant morbidity. However, **low levels do not necessarily mean absence of toxicity.** Serum levels may be low because of variable times to peak level following ingestions of different iron preparations,^{8,9} and deferoxamine can artificially lower serum iron levels.

Leukocytosis and hyperglycemia have also been examined for their ability to predict iron toxicity. One early study found that a white blood cell (WBC) count of greater than 15,000/ μL with glucose level of greater than 150 mg/dL correlated with an iron level of more than 300 $\mu\text{g/dL}$.¹⁰ This study, however, assumed that a serum iron level of greater than 300 $\mu\text{g/dL}$ denoted toxicity, which is not always true. Subsequent studies were unable to validate the association between these laboratory values and also did not correlate these laboratory values with clinical illness.^{11>12}

TIBC has little value in the assessment of iron-poisoned patients. It becomes falsely elevated in the presence of elevated serum iron levels or deferoxamine.¹³ Additionally, the relationship of the TIBC to the serum iron level is not useful, because in conditions of chronic iron overload (e.g., thalassemia and hemochromatosis), significant organ pathology occurs despite a TIBC that exceeds the serum iron level.

Radiopaque iron tablets are visible on x-ray and can guide GI decontamination when visualized. However, many iron preparations are not routinely detected, including pediatric chewable and liquid preparations, and negative radiographs do not exclude iron ingestion.¹²

CLINICAL FEATURES

Although five stages of toxicity are traditionally described, more practically, acute iron toxicity manifests in two clinical stages: local GI toxicity and systemic toxicity.

Abdominal pain, vomiting, and diarrhea characterize *stage 1* of iron poisoning. Iron is directly irritating and corrosive to the GI tract and typically induces vomiting within the first few hours following ingestion. The absence of GI symptoms within 6 h of ingestion essentially excludes a diagnosis of significant iron ingestion. Vomiting is the clinical sign most consistently associated with acute iron toxicity.^{10,12} Patients with symptoms of gastric irritation may either recover over several hours or progress to the development of systemic toxicity.

Stage 2, or the "latent" stage, of iron poisoning does not always occur. Manifesting within the 6- to 24-h period following ingestion, GI symptoms may resolve, so a patient may have few, if any, symptoms, which may falsely reassure a physician. However, this is not a truly quiescent phase. Patients who have significant toxicity will have ongoing clinical illness and progressive systemic deterioration because of volume loss and worsening metabolic acidosis, despite the absence of GI symptoms. Alternatively, the resolution of GI findings may signal the end of mild poisoning, and in such a scenario, patients should have normal vital signs, a normal physical examination, and normal laboratory studies.

Systemic toxicity characterizes *stage 3* of iron toxicity. During this stage, intracellular iron disrupts cellular metabolism with resultant shock and lactic acidosis. Iron-induced coagulopathy may worsen bleeding and hypovolemia. The coagulopathy may be biphasic, with prolonged prothrombin time and partial thromboplastin time within the first 24 h that appear reversible with chelation therapy as free iron initially interferes with the activity of factors in the coagulation cascade.⁴ Later, as iron poisoning causes hepatic injury, factor production decreases, potentially worsening the coagulopathy. During this stage renal failure, cardiomyopathy, and failure of other critical organ systems may also occur.

Stage 4, the hepatic stage of iron poisoning, develops 2 to 5 days following ingestion. It results from iron uptake by the reticuloen-

dothelial system with local lipid peroxidation and manifests as elevation of aminotransferases and may progress to hepatic failure.

Stage 5 of iron poisoning refers to delayed sequelae, including gastric outlet obstruction secondary to the corrosive effects of iron on the pyloric mucosa. These changes are rare and occur 4 to 6 weeks after ingestion.

TREATMENT

Evaluation and Supportive Care

Iron poisoning is a clinical diagnosis. Patients who arrive at an ED asymptomatic, who have not ingested a toxic amount, with normal findings on physical examination, and who remain so for 6 h following ingestion, do not require specific medical treatment for iron poisoning. Patients who vomit once or twice from the gastric irritant effects of iron, but who are otherwise asymptomatic, can also be observed and may require no specific treatment. Patients who are symptomatic should first be stabilized with attention to airway, breathing, and circulation, after which GI decontamination and chelation therapy with deferoxamine may proceed (Table 179-1). Dialysis is not effective in clearing iron. Antiemetics such as metoclopramide (10 mg IV in adults; 0.1 mg/kg in pediatric patients) or ondansetron (4 mg IV over 2 to 5 min, or IM in adults; 0.1 mg/kg to a maximum of 4 mg in pediatric patients ages 2 to 12 years) should be used for repetitive vomiting.

Patients with persistent vomiting and abnormal vital signs or other signs of poor perfusion or shock should be aggressively fluid resuscitated and treated with deferoxamine. Coagulopathy should be treated with parenteral vitamin K₁ (5 to 25 mg SC) and fresh-frozen plasma (10 to 25 mL/kg in adults; 10 mL/kg in pediatric patients). Significant blood loss may require transfusion.

Laboratory tests should include complete blood cell count and determination of serum electrolyte levels, renal and liver function studies, coagulation parameters, and serum glucose and serum iron levels, with the understanding that the importance of these values may be limited.

Arterial blood gas (ABG) and serum lactate determination is usually unnecessary in mild cases because determination of serum electrolytes (anion gap evaluation) will yield all the important information. However, in the moderately to severely toxic patient, or in those with respiratory compromise, ABG determination, often more rapidly available, will yield vital information regarding the patient's acid-base status. Blood typing, screening, and cross-matching should be requested from the blood bank in anticipation of potential need.

Gastrointestinal Decontamination

In general, syrup of ipecac is not used, because it may obscure the initial signs of clinical toxicity and it is not thought to be more effective at gastric emptying than is iron-induced vomiting. **Activated charcoal does not adsorb significant amounts of iron, and its use is not recommended.** Furthermore, it may complicate endoscopy, should that be necessary. Cathartics should not be used. Orogastric lavage may not be effective if the ingested tablets are large or if several hours have elapsed since ingestion, but it may be useful within 60 min after ingestion. There are no data to support the efficacy of sodium bicarbonate or phosphosoda to form insoluble iron salts. Pills located on radiograph may indicate a potential for progressive toxicity and may guide decontamination. Whole-bowel irrigation with a polyethylene glycol solution has demonstrated efficacy in children with large iron ingestions. Administration of 250 to 500 mL/h in children, and 2 L/h in adults, by nasogastric tube may clear the GI tract of iron pills before absorption can occur. Endoscopy has been used to remove large iron loads but may not be practical where there are large numbers of pills requiring multiple endoscope insertions. Gastrotomy may rarely be an option in profoundly ill patients where other measures are unsuccessful or impractical.¹⁴

Deferoxamine

Deferoxamine is a specific chelating agent derived from *Streptomyces pilosus*; it has been used to treat iron toxicity since the 1960s. Deferoxamine binds primarily to free iron and secondarily to iron from ferritin, hemosiderin, and non-protein-bound ferric salts, as well as to intracytoplasmic and mitochondrial free iron, to form the complex ferrioxamine, which is renally excreted. It is safely administered to children and pregnant women. Complete complexation of ingested iron is not the goal of therapy. Indeed, only a small fraction of the total amount of ingested iron is found in the urine following chelation. Deferoxamine administration may prove clinically effective by removing a critical amount of intracellular iron from its target, thus restoring cellular function.

Patients without hypotension or dehydration are treated with intramuscular administration of deferoxamine 90 mg/kg up to 1 g in children and 2 g in adults. The dose may be repeated every 4 to 6 h as clinically indicated (see below). This route of administration, however, can become difficult because of the volume of injected material required when used in children.

In patients with severe iron poisoning in whom fluid loss and hypovolemia are significant, and who require aggressive fluid resuscitation, deferoxamine should be administered intravenously. Intramuscular deferoxamine is not reliably absorbed in hypotensive patients. Rate-related hypotension is the limiting factor in intravenous administration, and it is recommended to begin the infusion slowly (5 mg/kg per h). A second intravenous access may be required so as not to impede volume resuscitation.

Deferoxamine can be increased to 15 mg/kg per h within the first hour of treatment, as tolerated. In fact, much higher doses have been used safely. However, it is generally not recommended to exceed a total daily dose of 6 to 8 g, although there are no specific data supporting this limit in acutely iron-poisoned patients. Administering deferoxamine at this rate will achieve a total of 6 g in about 6 h in an average-sized adult. Once this amount is reached, it is prudent to decrease the rate of deferoxamine administration, because of several associated risks. Adverse effects may include mucormycosis infection,¹⁵ renal insufficiency,¹⁶ pulmonary toxicity,¹⁷ and sepsis from *Yersinia enterocolitica*, which may be related to duration of therapy.

The determination of the efficacy and duration of deferoxamine therapy involves acquisition of serial urine samples. As ferrioxamine is excreted, the urine color changes to what is classically called vin rose, but may actually appear brown or rusty. Theoretically, the disappearance of the vin rose means that a patient no longer has significant toxicity. It is important to obtain a urine sample prior to initiating treatment because patients who are hypovolemic will likely produce concentrated urine, which may also be somewhat dark and may be confused with the vin rose appearance. False-negatives, color-change latency, and difficulty visualizing a color change can limit the utility of this test.

There is some controversy surrounding the duration of deferoxamine therapy. Recommended end points range from clinical recovery and normal iron levels, to measurement of iron-to-creatinine ratios,¹⁸ to clinical recovery with normal iron level in conjunction with normal urine color.⁷ Because measured iron levels are artificially depressed by the presence of deferoxamine and urine color change can be unreliable, and because iron toxicity is a clinical diagnosis, clinical recovery of the patient is probably the most important factor in terminating therapy. For patients who continue to exhibit severe iron toxicity after 24 h of deferoxamine therapy, the therapy should continue carefully at a decreased dose, for reasons mentioned earlier.

Previously advocated was the *deferioxamine challenge test*, a half-dose of 50 mg/kg intramuscular injection of deferoxamine followed by examination of urine samples for change in color that would indicate the presence of chelated free iron and therefore confirm iron toxicity. More recently, a first dose of 90 mg/kg IM has been used, also using

TABLE 179-1 Treatment of Iron Ingestion

Gastrointestinal decontamination	No
ipeccac, no activated charcoal	Consider
gastric lavage in first hour	Consider
whole-bowel irrigation	Consider
endoscopy to remove pills	Local gastric irritation only
Fluid resuscitation	
Antiemetics	
Metoclopramide	0.1 mg/kg IV in children, 10 mg IV in adults
or Ondansetron	0.1 mg/kg IV to a maximum of 4 mg in children, 4 mg IV
	over 2—5 min in adults
Mild systemic toxicity	
Fluid and metabolic resuscitation	
Deferoxamine	90 mg/kg IM or IV (up to 1 g in children) q4-6 h as clinically indicated, not to exceed total daily dose of 6 g
Moderate or severe systemic toxicity	Fluid and metabolic resuscitation
Deferoxamine	90 mg/kg IV at a rate of 5 mg/kg per h, can increase to rate of 15 mg/kg per h if there is no rate-related hypotension; not to exceed total daily dose of 6 g

change in urine color to verify toxicity. There may be several problems with this management strategy. Single-dose deferoxamine can be unreliable in eliciting a visible color change in urine, especially if a pre-deferoxamine urine sample was not obtained, and should not be the sole factor in deciding toxicity.⁷

HYDROCARBONS AND VOLATILE SUBSTANCES Paul M. Wax Michael B. Beuhler

INTRODUCTION

Hydrocarbons are a diverse group of organic compounds consisting primarily of carbon and hydrogen atoms arranged in various aliphatic and aromatic configurations. Products containing hydrocarbons are found in many household and occupational settings. Examples include fuels, lighter fluids, lamp oil, paints, paint removers, pesticides, medications, cleaning and polishing agents, spot removers, degreasers, lubricants, and solvents. Volatile liquid chemicals or gases are substances sometimes abused for their euphoric effects. Examples of commonly abused volatiles include many hydrocarbon-containing substances such as glue (which contains toluene), propellants (e.g., butane, trichloroethylene, Freon), and gasoline. Other volatile chemicals not generally classified as hydrocarbons, such as nitrites (e.g., isobutyl nitrite) and nitrous oxide, are also subject to abuse. Hydrocarbon and volatile substance exposure may cause life-threatening toxicity and, in some cases, sudden death.

Classification

Most hydrocarbons are produced from petroleum distillation, which results in predominantly aliphatic (open-chain) mixtures of hydrocarbons of different chain lengths. Gasoline, for instance, consists of approximately 80 percent saturated and unsaturated aliphatic hydrocarbons of chain length C₄ to C₁₀ and 20 percent aromatic hydrocarbons. Chain length and branching determines the phase of the hydrocarbon at room temperature. Short-chain aliphatic compounds, such as methane, propane, or butane, are gases; long-chain aliphatic compounds, such as waxes, are solids. Intermediate-chain (C₅ to C₁₅) aliphatic compounds are in liquid form and account for most hydrocarbon exposures seen in the ED (Table 180-1). Pulmonary toxicity secondary to aspiration is the most common complication from ingesting liquid aliphatic hydrocarbons.

The wood distillates (e.g., turpentine and pine oil) are derived from pine, consist mainly of cyclic terpene derivatives, and comprise another class of hydrocarbons. Gastrointestinal (GI) absorption of wood distillates tends to be greater than that of aliphatic petroleum distillates, increasing the risk for central nervous system (CNS) depression.

Aromatic hydrocarbons (containing a benzene ring; Table 180-2) and halogenated hydrocarbons (aliphatics with at least one substituted

TABLE 180-1 Substances that Predominantly Contain Aliphatics

Xylene	Solvent, cleaning agent, degreaser

halogen group; Table 180-3) are widely used industrial solvents. Freon is the trade name for a group of halogenated hydrocarbons that contain fluoride. Although many of these chlorofluorocarbons (CFCs) are thought to cause atmospheric ozone changes and are being replaced by more environmentally friendly compounds, Freon may still be found as a refrigerant gas and component of fire extinguishing systems. Inhalational exposure is the usual route of toxicity for aromatic and halogenated hydrocarbons, although ingestion of these chemicals may also be problematic. Substance abusers and workers in certain occupational settings are most often affected. Such exposures may result in significant systemic toxicity. Along with their potent CNS effects, specific cardiovascular, hepatic, renal, and hematologic toxicity are attributed to aromatic and halogenated hydrocarbons.

Finally, some compounds have toxicity related to an additive, such as lead in gasoline (greatly decreased in the United States) and pesticides in a hydrocarbon base. With these, **the toxic additive usually dictates the clinical approach.**

Epidemiology

Exposures to hydrocarbons and volatiles most commonly occur in one of two settings: ingestion or inhalation. Hydrocarbon ingestions account for approximately 3 to 10 percent of all unintentional childhood poisonings in the United States. Ingestions of gasoline, kerosene, lighter fluid, mineral seal oil, and turpentine are most frequent. In less-developed countries kerosene ingestion accounts for 33 to 59 percent of unintentional childhood poisonings.¹ It is estimated that 3.5 to 10 percent of young people have experimented with volatile substance inhalation to produce inebriation.

Most hydrocarbon exposures have a benign clinical course. The 2001 American Association of Poison Control Centers Toxic Exposure Surveillance System revealed that 79,608 potential hydrocarbon exposures were reported to poison control centers (3.5 percent of all reported exposures). Of the 3793 (4.8 percent) persons who developed moderate to major toxicity 12 died.² An epidemiologic study of volatile substance abuse in the United Kingdom revealed that 605 people younger than age 18 years died from volatile substance abuse during the period 1981 to 1990.³ The most commonly implicated volatiles were butane (39 percent), aerosols (26 percent), cleaners (16 percent), and glue (10 percent).

TABLE 180-3 Common Halogenated Hydrocarbons

Substance	Commercial Use
Carbon tetrachloride	Solvent, refrigerant, aerosol propellant
Chloroform	Solvent, chemical intermediate
Methylene chloride	Paint stripper, varnish remover, aerosol paint, degreaser
Trichloroethylene (TCE)	Spot remover, degreaser, typewriter correction fluid
Trichloroethane (TCA)	Spot remover, degreaser, typewriter correction fluid
Tetrachloroethylene (perchloroethylene)	Dry cleaning agent, degreaser

PATHOPHYSIOLOGY AND CLINICAL FEATURES

Determinants of Toxicity

The toxic potential of hydrocarbons depends on physical characteristics (volatility, viscosity, and surface tension), chemical characteristics (aliphatic, aromatic, or halogenated), presence of toxic additives (pesticides or heavy metals), route of exposure, concentration, and dose.

Viscosity, defined as the resistance to flow, and surface tension, denoting "creeping" ability, plays a major role in determining the aspiration potential. Viscosity is measured in Saybolt Universal Seconds (SUS). **Patients ingesting substances with viscosities less than 60 SUS (e.g., gasoline, kerosene, mineral seal oil, turpentine, and aromatic and halogenated hydrocarbons) are at greater risk for aspiration than are those ingesting substances with viscosities greater than 100 SUS (e.g., diesel oil, grease, mineral oil, paraffin wax, and petroleum jelly).** Low surface tension also increases the risk of aspiration. Volatility denotes the ability of a substance to vaporize. A compound with high volatility evaporates easily and usually has low viscosity and low surface tension. Inhalation of volatile agents, such as aromatic hydrocarbons, halogenated hydrocarbons, or gasoline, results in systemic absorption and the potential for significant toxicity.

Dermal exposure to hydrocarbons causes local toxicity, and occasionally leads to systemic absorption. Dermal toxicity secondary to intravenous administration of hydrocarbons has also been reported. When used intravenously, hydrocarbons may cause pulmonary toxicity by their first-pass exposure through the lungs (first capillary bed encountered).

Toxicity from hydrocarbon exposure can be divided into different clinical syndromes based on the organ system(s) predominately affected. Characteristic presentations usually affect one or more of the following systems: pulmonary, neurologic (central and/or peripheral), GI, cardiac, hepatic, renal, hematologic, or dermal.

Pulmonary Toxicity

Pulmonary complications, especially aspiration, are the most frequent adverse effects of hydrocarbon exposure. Typically, this involves the unintentional childhood ingestion of small amounts of aliphatic hydrocarbon mixtures commonly stored in the household. Aliphatic hydrocarbons have a limited GI absorption; toxicity usually results from aspiration of the low-viscosity compounds or inhalation (with resulting systemic absorption) of compounds with high volatility. Although ingestion of aromatic or halogenated hydrocarbons may also result in aspiration, GI absorption is greater. Hence, CNS and other systemic toxicity secondary to GI absorption often predominate after aromatic and halogenated hydrocarbon ingestion. High-viscosity compounds such as lubricants, mineral oil, or tar, are not aspirated readily and tend to be less toxic when ingested. Occasionally, however, aspiration occurs that results in the development of lipid pneumonia. Deaths from hydrocarbon lipid pneumonia have been reported.

The risk and degree of aspiration is not dependent on volume ingested. Experimentally in rats, as little as 0.2 mL instilled intratracheally has caused pneumonitis. Pulmonary toxicity does not result from GI absorption but occurs from direct aspiration of the hydrocarbon into the pulmonary tree. This occurs at the time of ingestion when the hydrocarbon migrates from the hypopharynx into the airway. There is no evidence that hydrocarbons reflux from the stomach into the airway. Spontaneous vomiting, however, does increase the risk of aspiration.⁴ Pulmonary toxicity manifested as acute bilateral pneumonitis has also been reported from the inhalation of an aerosolized aliphatic hydrocarbon such as gasoline or kerosene as well as from pyrrolized fluorinated compounds.⁵

Hydrocarbon aspiration causes chemical pneumonitis by direct toxic injury to the pulmonary parenchyma and altered surfactant function. Destruction of alveolar and capillary membranes results in

increased vascular permeability and edema. Early distal airway closure and alveolar collapse produces clinical bronchospasm and ventilation/perfusion mismatch. The CNS manifestations seen after ingestion of a poorly GI-absorbed aliphatic hydrocarbon are thought to be from hypoxia secondary to the hydrocarbon induced pneumonitis and/or direct CNS toxicity following the pulmonary absorption of a volatile hydrocarbon. Pneumatoceles, pneumothoraces, and/or pneumomediastinum are occasionally associated with hydrocarbon aspiration. Other complications include bacterial superinfection, acute respiratory distress syndrome, and death. Long-term pulmonary dysfunction may occur.

In one study of 950 children who ingested products containing hydrocarbons and who were brought to the hospital, 19 percent had clinical or radiographic evidence of pulmonary aspiration.⁶ In another study of 184 pediatric hydrocarbon ingestions called to a poison center, 35 percent had initial symptoms, but only 3 percent had progressive pulmonary symptoms.⁷

The clinical manifestations of pulmonary aspiration are usually apparent almost immediately on ingestion. The early effects result from irritation of the oral mucosa and tracheobronchial tree. Symptoms include coughing, choking, gasping, dyspnea, and burning of the mouth. Patients with these symptoms should be assumed to have aspirated until proven otherwise. Physical examination may reveal grunting respirations, retractions, tachypnea, tachycardia, and cyanosis. An odor of the hydrocarbon may be noted on the patient's breath. An elevated temperature of 39°C (102.2°F) or greater is common and may occur upon initial presentation or be delayed for 6 to 8 h. Auscultation may be normal, or reveal wheezing and decreased or absent breath sounds. Arterial blood gas analysis may demonstrate a widened alveolar-arterial oxygen gradient or frank hypoxemia. The development of a necrotizing pneumonitis and hemorrhagic pulmonary edema usually occurs within hours in severe aspiration. Most fatalities from these complications occur within 24 to 48 h. With less-severe damage, symptoms usually subside within 2 to 5 days, except with pneumatoceles and lipid, pneumonias whose symptoms may persist for weeks to months.

Although most patients with clinically significant aspiration have abnormal chest x-rays, the time course of radiographic changes varies and correlation with physical examination may be poor. Changes may be seen as early as 30 min after aspiration, but **the initial radiograph in the symptomatic patient may be deceptively clear.** Radiographic changes usually appear by 2 to 6 h and are almost always present by 18 to 24 h, if they are to occur. The infiltrates range in appearance from streaking to flocculent to homogeneous, and are usually located in the dependent lobes. Multilobar involvement is more common than single-lobe involvement and right-sided involvement is more common than left-sided involvement. Radiographic changes limited to bilateral perihilar regions with clear lung bases are also common, however mild radiographic changes do not automatically mean the patient will become symptomatic.

Central Nervous System Toxicity

CNS toxicity may result from either a direct toxic response to the systemic absorption of the hydrocarbon, as an indirect result of severe hypoxia secondary to aspiration, or as a result of simple asphyxiation due to either loss of ventilatory drive, or the use of a plastic bag or other device during "bagging." Systemic absorption occurs through GI absorption, the inhalation of highly volatile petroleum distillates, or by direct dermal penetration, usually by prolonged contact with chlorinated hydrocarbons. GI absorption resulting in CNS toxicity is common with ingestion of terpene containing hydrocarbons (Pine-sol), especially in the elderly.⁸

Exposure to volatile hydrocarbons may occur inadvertently or deliberately when associated with solvent abuse. Volatile solvent abuse most often occurs in teenagers and younger adults, especially from lower socioeconomic backgrounds and in particular cultures (e.g., Na-

tive Americans). These patients are described as "huffers" or "baggers" depending on whether they inhale through a rag soaked with the hydrocarbon held to the mouth or rebreathes into a plastic bag containing the hydrocarbon. The act of rebreathing to facilitate inhalation may also contribute to toxicity by producing significant hypercarbia and hypoxia. Table 180-4 lists many of the most commonly abused volatiles.

Many of the hydrocarbons that affect the CNS have a natural affinity for the lipid-rich neural tissue. They behave similarly to the inhalational anesthetic agents. Hydrocarbon intoxication may be confused with ethanol inebriation. CNS depression ranges in severity from dizziness, slurred speech, ataxia, and lethargy to obtundation, coma and apnea. These effects are usually dose-dependent. Although hydrocarbons are CNS depressants, they often have an initial excitatory effect manifested as euphoria, exhilaration, and giddiness, effects sought by those who abuse them. More severe excitatory features include tremor, agitation, and convulsions. Perceptual changes, such as confusion, hallucinations, and psychosis, may occur.

Chronic CNS sequelae may result from recurrent inhalational exposure to hydrocarbons in the workplace or with solvent abuse.⁹ These sequelae are seen among house painters and solvent abusers exposed to toluene-containing substances. Recurrent headaches, cerebellar ataxia, and a chronic encephalopathy consisting of tremors, emotional lability, mental status changes, cognitive impairment, and psychomotor impairment, characterize the syndrome. These effects may be transitory or permanent. The development of encephalopathy, ataxia, tremor, chorea, and myoclonus also is associated with the habitual sniffing of leaded gasoline. In this case, symptoms are thought to be secondary to the effects of tetraethyl lead and its toxic metabolites.

Peripheral Nervous System Toxicity

Exposure to n-hexane, methyl t-butyl ketone, and other six-carbon aliphatic hydrocarbons is associated with the development of a characteristic peripheral polyneuropathy caused by demyelination and retrograde axonal degeneration.¹⁰ Onset of symptoms may be delayed for months to years after initial exposure. Toxicity is attributed to a metabolite, 2,5-hexanedione, produced by the cytochrome P450-mediated biotransformation of the parent compounds. This neurotoxic metabolite is thought to inhibit glutaraldehyde-3-phosphate dehydrogenase, which supplies energy for axonal transport. Long, distal nerves seem to be most vulnerable, characteristically producing foot

TABLE 180-4 Commonly Abused Volatile Substances

Product	Volatile Agent
Acrylic spray paint	Toluene
Adhesives/glue	Toluene, trichloroethylene
Aerosol propellants	Propellants and butane
Cigarette lighter refills	Butane
Degreasing agents	Trichloroethylene
Dry-cleaning agents	Tetrachloroethylene
Fire extinguishers	Bromochlorodifluoromethane
Inhalational anesthetics	Nitrous oxide, halothane
Lighter fluid	Naphtha
Nitrites (poppers)	Isobutyl nitrite, amyl nitrite
Paint stripper	Methylene chloride
Petrol	Gasoline
Plastic modeling cement	Methyl ethyl ketone, toluene
Spot removers	Trichloroethylene, trichloroethane
Typewriter correction fluid	Trichloroethane, trichloroethylene

and wrist drop with numbness and paresthesias. Unleaded gasoline sniffing has produced a similar clinical picture as well.¹¹

Gastrointestinal Toxicity

Most hydrocarbons act as intestinal irritants, resulting in burning in the mouth and throat, abdominal pain, belching, nausea, vomiting, and diarrhea. Vomiting, which occurs in approximately one-third of the patients with aliphatic hydrocarbon ingestions, is particularly troublesome because of the increased risk of pulmonary aspiration. Corrosive GI injury, as well as pancreatitis, has been reported with ingestion of some chlorinated hydrocarbons.¹²

Cardiac Toxicity

Life-threatening dysrhythmias, such as ventricular tachycardia and ventricular fibrillation, may occur with systemic absorption (gastrointestinal or inhalational) of a variety of hydrocarbon compounds. Most commonly, dysrhythmias occur after exposure to halogenated hydrocarbons and aromatic hydrocarbons. Exposures to predominantly aliphatic mixtures, such as gasoline or mineral spirits, and exposure to butane have also been reported to cause dysrhythmias and sudden death.¹³ The mechanism of toxicity is believed to be secondary to a sensitization of the heart to catecholamines. The term "sudden sniffing death" describes solvent abusers who die suddenly after exertion, panic, or fright. The sudden release of catecholamines in these situations is thought to induce these fatal dysrhythmias.¹³ Cardiac dysrhythmias as a consequence of industrial exposure to volatile hydrocarbons have also been described. Other mechanisms for sudden death include asphyxia, respiratory depression, and vagal inhibition. The use of exogenous catecholamines, such as epinephrine, may precipitate sudden dysrhythmias and should be avoided except if required for cardiac resuscitation. Decreases in myocardial contractility and peripheral vascular resistance as well as bradycardia and atrioventricular conduction blocks have also been associated with volatile solvent abuse.

Hepatic Toxicity

Hydrocarbon-induced hepatic damage resulting from halogenated hydrocarbons is well described. Carbon tetrachloride toxicity has been used as a model for toxin-induced hepatic dysfunction. As little as 3 mL of carbon tetrachloride has been associated with the development of fatal liver injury.¹⁴ Other halogenated hydrocarbons, such as chloroform and methylene chloride, are also associated with liver dysfunction.¹² Free-radical metabolites of these agents that cause lipid peroxidation are apparently responsible for hepatocellular destruction. Pathologic examination reveals acute fatty degeneration of the liver with areas of centrilobular necrosis. The time-course of hepatic dysfunction with acute exposures appears similar to acetaminophen hepatotoxicity. Liver function tests may be elevated within 24 h after ingestion, with the development of liver tenderness and jaundice in 48 to 96 h. Chronic exposure to carbon tetrachloride may be associated with the development of cirrhosis and hepatomas.

Renal and Metabolic Toxicity

Solvent abuse and occupational exposure to hydrocarbons may result in renal dysfunction. Exposure to hepatotoxic halogenated hydrocarbons, such as carbon tetrachloride, trichloroethylene, and chlorinated paraffins, have caused acute renal failure, as well as centrilobular hepatic necrosis.¹⁵ In large ingestions, occasionally unchanged renal excretion of aliphatic hydrocarbons may occur, resulting in visible hydrocarbon droplets in the urine. Hemorrhagic cystitis has also been reported for some hydrocarbon ingestions.

Renal tubular acidosis may occur in patients who abuse toluene-containing substances. Patients present with a non-anion gap meta-

bolic acidosis, hypokalemia, and hypophosphatemia. The serum potassium may be so low (<2 mEq/L) that severe muscle weakness develops, occasionally resulting in quadriplegia. Once treatment begins, the serum potassium may significantly plummet, resulting in severe muscle weakness and occasionally apnea. Significant rhabdomyolysis may also result. Toluene toxicity may also cause a high anion gap metabolic acidosis as a result of the accumulation of hippuric acid and benzoic acid metabolites. Proteinuria and renal insufficiency can occur in patients who abuse toluene.

Hematologic Toxicity

Chronic exposure to benzene, the prototypical aromatic hydrocarbon, is associated with an increased incidence of hematologic disorders including aplastic anemia, acute myelogenous leukemia, and multiple myeloma.¹⁶ This association has received much attention because of the extensive use of benzene in the workplace. The etiology of these blood dyscrasias is probably not benzene itself but rather a toxic metabolite. Although aplastic anemia is associated with glue sniffing, this is most likely a result of the benzene fraction of the glue, and not the toluene. Hydrocarbon-induced hemolysis has occurred following the acute ingestion of gasoline, kerosene, and tetrachloroethylene, and inhalation of mineral spirits. Consumptive coagulopathy has also been reported. Significantly delayed methemoglobinemia has been reported after exposure to hydrocarbons containing amine functional groups such as aniline ($-\text{NH}_2$), and hemolytic anemia has been reported from ingestion of naphthalene.

A peculiar complication of methylene chloride exposure is the endogenous production of carbon monoxide.¹⁷ This is unlike ordinary carbon monoxide exposure from exogenous sources where maximum carboxyhemoglobin level occurs at the time of the exposure. **With methylene chloride exposure, carbon monoxide formation may continue after cessation of exposure caused by slow release of methylene chloride from the tissues prior to its metabolism to carbon monoxide.** When patients exposed to methylene chloride present with CNS and cardiac symptoms, impairment caused by significant carbon monoxide production must be considered.

Dermal Toxicity

Dermal exposure to hydrocarbons may also result in toxicity. Cutaneous injury is most often associated with the short-chain aliphatic, aromatic, and halogenated hydrocarbons. These agents act as primary irritants and as sensitizers. Clinically, skin findings can range from local erythema, papules, and vesicles to a generalized scarlatiniform eruption and an exfoliative dermatitis. A "huffer's rash" may be noted over the face of patients who chronically abuse the volatile hydrocarbons. Pruritus may also be present. A defatting dermatitis, similar to a chronic eczematoid dermatitis, may occur. Frostbite of the face may develop during the inhalational abuse of fluorinated agents. Cellulitis and sterile abscesses have been associated with the injection of hydrocarbons, and even a small amount of injected hydrocarbon can cause significant injury.¹⁸ Extensive partial-thickness and full-thickness burns following immersion in hydrocarbons may also occur. Occasionally, highly permeable hydrocarbons can penetrate the skin, resulting in systemic toxicity. Exposure to heated high-viscosity, long-chain aliphatics, such as tar, asphalt, or bitumen, present a particularly challenging problem because of their association with burns and hyperthermia, and difficulty with decontamination.¹⁹

TREATMENT

Prehospital

Not all patients who have ingested hydrocarbons require emergency department evaluation. In a retrospective study of 211 patients with

hydrocarbon ingestions called to a poison center, fewer than 1 percent required physician intervention.⁷ This data suggests that patients who are asymptomatic or who quickly become asymptomatic after ingestion can be watched safely at home. This approach of home observation for asymptomatic patients can be supported when the ingestion is accidental, the ingredients are known and do not cause significant systemic toxicity when ingested, and reliable follow-up can be ensured.

All symptomatic patients and intentional exposures should be referred to the hospital for further evaluation. Patients who ingest hydrocarbons that may cause significant systemic toxicity (e.g., aromatic, halogenated hydrocarbons, or toxic additives), whether or not symptomatic, should also be referred to the hospital. Volatile substance abusers and others exposed to volatiles should have immediate cardiac monitoring and advanced life support transport, if available, because of the potential for life-threatening dysrhythmias.

Emergency Department

General principles of poison management apply to the initial approach to patients once they reach the hospital. Establishing the airway and maintaining ventilation is the critical first maneuver in any patient who presents with respiratory depression and/or significant CNS depression. The detection of a sweet odor may be associated with certain halogenated hydrocarbon exposures (especially chloroform or trichloroethylene) while a petrol odor suggests gasoline or some other petroleum derivative. Continuous cardiac monitoring should be initiated, and an electrocardiogram should be obtained. Hydrocarbon-induced dysrhythmias, if present, would generally occur shortly after the exposure, especially with inhalational use. Hypotension should be treated with aggressive fluid resuscitation. **Catecholamines, such as dopamine, norepinephrine, or epinephrine, should be avoided to prevent precipitating dysrhythmias, especially following exposure to halogenated hydrocarbons and aromatic hydrocarbons.** The administration of glucose, thiamine, and naloxone should be considered in cases of altered mental status (see Table 180-5).

The patient needs to be fully undressed to prevent ongoing contamination from hydrocarbon-soaked clothes. Dermal decontamination with soap and water, and eye decontamination with saline irrigation, should be performed. Prehospital decontamination is preferable. It is unlikely that a patient contaminated with a simple hydrocarbon will generate enough vapors to affect the staff, but it is important for staff to wear protective gloves and aprons to prevent possible secondary exposure, especially for organophosphate containing mixtures.

Useful diagnostic tests include the chest x-ray and arterial blood gas to detect pulmonary aspiration and hypoxemia. Abdominal radiographs may show evidence of chlorinated hydrocarbon ingestions, such as carbon tetrachloride, because of the radiopaque nature of these polyhalogenated substances.¹⁸ Tests of liver and renal function should be obtained in all aromatic and halogenated hydrocarbon exposures to check for the development of hepatic and renal injury. A carboxyhemoglobin level is useful to evaluate the extent of endogenous carbon monoxide production following methylene chloride exposure. Pulse oximetry will not differentiate between oxyhemoglobin and carboxyhemoglobin. Routine drug screens are not useful for the detection of hydrocarbons, but as in all intentional ingestions, an acetaminophen level, ethanol level, anion gap, and osmolality may be helpful in assessing for the presence of other coingestants.

Gastrointestinal Decontamination

For most hydrocarbon ingestions, gastrointestinal decontamination would provide little benefit; supportive care and appropriate treatment of coexisting ingestions are all that is required. The necessity for GI decontamination depends on the type of hydrocarbon and route of exposure. The risk of systemic toxicity by intestinal absorption has to be weighed against the risks of aspiration associated with gastric empty-

TABLE 180-5 ED Management of Hydrocarbon Exposures

Find out what type of hydrocarbon and route of exposure
Utilize MSDS (material safety data sheets) and Regional Poison Control Center as resources Ingestion: aliphatic mixtures (gasoline, kerosene, lamp oil, etc.; see Table 180-1)
GI decontamination: usually unnecessary.
Skin decontamination: if spilled on clothes or skin, soap and water
Diagnostic: observe for evidence of aspiration and CNS symptoms (CXR, pulse oximetry)
Treatment
If evidence of aspiration-respiratory support (oxygen, inhaled P-agonists, ventilatory support) No need for steroids, no need for antibiotics unless documented
infection Disposition: admit if symptomatic, discharge home with follow-up if
unintentional ingestion and asymptomatic after 6 h Ingestion: aromatics, halogenated, other volatiles (see Tables 180-2,180-3, 180-4) GI decontamination: consider activated charcoal, gastric aspiration if
highly toxic (e.g., CCl ₄ , chloroform, benzene) Skin decontamination: if spilled on clothes or skin, soap and water Diagnostic adjuncts
Observe for evidence of aspiration and CNS symptoms (CXR, pulse oximetry)
Continuous cardiac monitoring for dysrhythmias Abdominal radiographs to evaluate suspected chlorinated hydrocarbon
ingestions Methylene chloride: check COHB level, serial levels may be necessary,
O ₂
Toluene: check potassium, anion gap, CPK Benzene: follow CBC Potent halogenated hydrocarbons (CCL ₄ , chloroform, TCE, TCA) follow LFTs
Nitrites and amines: check methemoglobin level
Treatment Oxygen
Avoid exogenous catecholamines if possible (dopamine, norepinephrine)
Consider [3-adrenergic antagonists to treat dysrhythmias Consider NAC therapy for potent halogenated hydrocarbon exposure Consider HBO if markedly elevated COHB level from methylene
chloride Disposition: admit symptomatic exposures or hydrocarbons with delayed
toxicity (CCl ₄) Inhalation: aliphatic mixtures, aromatics, halogenated, other volatiles
Treat as aromatics above but no need for GI decontamination
Dermal: tar and asphalt Immediate cooling with water
Debridement of blistered skin
Remove adherent substance with petroleum based solvent (e.g., De-Solv-It, Tween 80, Polysporin)

Abbreviations: CBC = complete blood count; CCL₄ = carbon tetrachloride; COHB = carboxyhemoglobin; CPK = creatine phosphokinase; CXR = chest x-ray; HBO = hyperbaric oxygen; LFT = liver function test; NAC = TV-acetyl-L-cysteine; TCA = trichloroethane; TCE = trichloroethylene.

ing. The majority of hydrocarbon ingestions, which consist of aliphatic hydrocarbons mixtures (see Table 180-1), do not require GI decontamination. These agents have poor GI absorption and their toxicity is limited primarily to pulmonary aspiration. In the typical childhood accidental ingestion, the actual amount ingested is usually one swallow or about 5 mL. Suicidal ingestions, which involve larger amounts of hydrocarbons, frequently are associated with spontaneous emesis, and further decontamination is usually not required.

GI decontamination may be warranted when the ingested hydrocarbon is known to have good GI absorption and may cause significant systemic toxicity (e.g., toluene, chloroform, wood distillates) or an additive in the toxic agent (e.g., organophosphate pesticides are often mixed in petroleum distillates). The CHAMP

mnemonic (camphor, halogenated hydrocarbons, aromatic hydrocarbons, metals, pesticides) is helpful in remembering most situations where GI decontamination should be considered. Unfortunately, little data is available that evaluates the clinical benefits of gastrointestinal decontamination in these settings. If the patient presents to the ED shortly after the ingestion of these toxic hydrocarbons, aspiration with a small nasogastric tube may be useful. In patients who present with an altered mental status, the airway should be protected with a cuffed endotracheal tube, although in smaller children younger than 8 years of age, the cuff should be kept inflated only during the period of lavage because of cuff-related injury from prolonged inflation. Ipecac-induced emesis is contraindicated as its risks appear to outweigh any potential benefits. Although activated charcoal may adsorb some hydrocarbon compounds, its use is not recommended for most hydrocarbon ingestions. Charcoal instillation may distend the stomach increasing the risk for vomiting and aspiration. The use of charcoal should only be considered if one of the CHAMP-type hydrocarbons has been ingested, and extreme caution should be exercised because of aspiration risk.

The use of cathartics to hasten GI transit and facilitate decontamination has no proven efficacy in hydrocarbon ingestions. Many patients will already have diarrhea from the hydrocarbon, and further catharsis is not required. Oil-based cathartics, which had been used in the past to thicken the ingested hydrocarbon to increase its viscosity and decrease the subsequent risk of aspiration, are contraindicated. They may actually increase GI absorption and are associated with an increased risk of lipid pneumonia when aspirated.

Pulmonary Treatment

Nebulized oxygen is helpful in the treatment of pulmonary aspiration. Inhaled (O_2 -agonists may also be useful, especially in the setting of bronchospasm, but their role in the treatment of hydrocarbon pneumonitis has not been studied. Positive end-expiratory pressure (PEEP) or continuous positive-airway pressure (CPAP) may sometimes be required, but because of the potential for further injury from barotrauma, one should observe for the development of pneumatoceles or pneumothorax. In cases of severe pulmonary aspiration resulting in refractory hypoxemia, treatment with extracorporeal membrane oxygenation and high-frequency jet ventilation has proved successful.^{20,21} Consensus that corticosteroids are contraindicated because they impair the cellular immune response and increase the chance of bacterial superinfection remains. Antibiotics have no proven role in prophylaxis and are usually not required except in cases of continued pulmonary deterioration because of the risk of a superimposed bacterial pneumonitis.

Other

There are few antidotes to counteract the actions of hydrocarbons. *N*-acetylcysteine and hyperbaric oxygen may have a role in preventing hepatic toxicity after carbon tetrachloride (and possibly chloroform) exposure, but more studies are needed. Hyperbaric oxygen therapy may be indicated for patients who develop significant carbon monoxide toxicity after exposure to methylene chloride, but has not been studied. (3-blockers may be useful in the treatment of hydrocarbon-induced malignant dysrhythmias. Although extracorporeal removal with hemodialysis, hemoperfusion, or peritoneal dialysis has been attempted for severe intoxications, clinically controlled evidence of efficacy is lacking. Specific antidotal treatment directed at the complications of toxic additives, such as organophosphates, pyrethrins or heavy metals, may also be needed.

The treatment of tar and asphalt injuries is a particular problem because of the difficulty in removing these substances without causing further tissue injury. Immediate prehospital cooling with cold water to limit injury is important. Debridement of blistered skin can aid

in the removal of adherent substances. De-Solv-It, a surface-active petroleum-based solvent, is both nonirritating and effective in removing these agents; however, it should only be applied briefly and personal protection should be employed (gloves, eyewear).¹⁹ Poly-oxyethylene sorbitan-containing ointments, such as Polysorbate 80 or Tween 80, are also useful. Petrolatum-containing preparations, such as Neosporin (although occasionally sensitizing) or Polysporin, may also work and are readily available. It is possible to apply the ointment (not De-Solv-It) under an occlusive dressing and allow the patient to go home, having them return for follow up in 24 h after it has solubilized the tar to wash it off. It is not necessary to remove all tar during the first visit, and close follow up is recommended. In some instances, excision and skin grafting are required to treat the more significant hot tar burns.

DISPOSITION

A medical toxicologist or regional poison control center should be consulted on most symptomatic hydrocarbon exposures and asymptomatic exposures that involve halogenated, aromatic, and hydrocarbon exposures with toxic additives. Hospitalization is required for patients who have ingested aliphatic hydrocarbons who are symptomatic at the time of evaluation, and patients exposed to significant amounts of methemoglobinemia-producing hydrocarbons. After a 6-h observation period, asymptomatic patients with a normal chest x-ray may be discharged home, but follow up should be assured as delayed toxicity (18+ h) has been reported.^{6,23} Similar disposition of asymptomatic patients, with abnormal chest x-rays has also been suggested if reliable follow-up can be ensured. Some physicians, however, prefer to observe these patients for 24 h in the hospital. Hospitalization is recommended for those who ingest hydrocarbons capable of producing delayed complications (e.g., halogenated hydrocarbons causing hepatic toxicity) and those with toxic additives (organophosphates and organic metal compounds). All patients taking ingestions with suicidal intent or presenting with complications of solvent abuse should have psychiatric evaluation.

CAUSTICS

G. Richard Bruno
Wallace A. Carter

The American Association of Poison Control Centers (AAPCC) reports approximately 103,000 potentially caustic exposures in the United States annually (Table 181-1),¹ including dermal and ocular exposure and oral ingestions. Most exposures are unintentional, with many occurring in children younger than age 6. In 2000, there were approximately 387 exposures that resulted in significant morbidity and 20 in death. Intentional adult ingestions with suicidal intent account for a greater percentage of serious injuries than unintentional oral ingestions by curious children.

Many chemicals used in industry have caustic potential. Alkali substances used in industry include sodium hydroxide and potassium hydroxide in cleaning fluids, calcium hydroxide in concrete, lithium hydroxide in photography, and ammonium hydroxide in fertilizers (Table 181-2). Common acids used in industry include hydrochloric acid and

sulfuric acids as cleaners, hydrofluoric acid in etching and metal cleaning, chromic acid in metal plating, and formic acid in leather/textile tanning. Industrial strength cleaners and chemicals accounted for 3,129 alkali exposures and 1,519 acid exposures in the 2000 AAPCC data (see Table 181-1).¹

Household caustics are common, and many are less-concentrated forms of industrial-strength cleansers. Alkali caustics found in the home include sodium hydroxide in drain cleaners, oven cleaners, and Clinitest tablets (see Table 181-2). Caustic ammonium compounds are found in glass, tub, and tile cleaners. Household bleach (sodium hypochlorite) is the most common alkali exposure reported in AAPCC data, accounting for more than 49,000 exposures per year.¹ Most bleach exposures are benign, but 53 patients suffered major morbidity and 3 deaths were reported in the 2000 AAPCC data. Common household acids include sulfuric acid in drain cleaners and automobile batteries, hydrochloric acid in cleaners, formic acid in airplane glue, and hydrofluoric acid in rust removers.

PATHOPHYSIOLOGY OF CAUSTIC INJURIES

Alkali

Alkali injuries can induce deep tissue injury from liquefaction necrosis. After caustic alkali exposures, proteins are rapidly denatured and lipids undergo saponification. Initially, there is direct cellular destruction from contact with the alkali. This is followed by thrombosis of local microvasculature that leads to further tissue necrosis. Solid or granular alkali caustics often injure the oropharynx and proximal esophagus. Liquid alkali ingestions are characterized by esophageal injuries. Severe intentional alkali ingestion may cause multisystem organ injuries, including gastric perforation and necrosis of abdominal viscera. Severe injuries to the pancreas, gallbladder, and small intestine after intentional ingestion have been reported.

The most common household alkali is bleach, a 3 to 6 percent sodium hypochlorite solution with a pH of approximately 11. Household liquid bleach is not corrosive to the esophagus, but ingestion may cause emesis secondary to gastric irritation or pulmonary irritation related to chlorine gas production in the stomach or when mixed with other substances.² Industrial-strength bleach may contain much higher concentrations of sodium hypochlorite, and ingestion may result in esophageal necrosis. Other injuries reported with bleach include pneumonitis after aspiration and sight-limiting ocular injuries.

TABLE 181-1 Epidemiology of Caustic Ingestions Reported to the American Association of Poison Control Centers, 2000

	No. Exposures	Age <6	Unintentional	Intentional	Major Outcome*	Death
Alkalis						
Chemicals	26,959	14,039	26,062	546	117	1
Rust remover	20	3	19	0	0	0
Drain cleaners	3,890	630	3,614	232	61	3
Industrial cleaners	3,129	869	2,958	100	20	0
<i>Total alkali exposures</i>	<i>33,998</i>	<i>15,541</i>	<i>32,653</i>	<i>878</i>	<i>198</i>	<i>4</i>
Acids						
Chemicals	14,576	2,466	14,028	373	108	10
Rust remover	315	64	303	9	4	2
Drain cleaner	1,099	106	968	27	9	1
Industrial cleaner	1,519	534	1,476	32	9	0
<i>Total acid exposures</i>	<i>17,509</i>	<i>3,170</i>	<i>16,778</i>	<i>441</i>	<i>130</i>	<i>13</i>

TABLE 181-2 Common Caustic Compounds

	Found In
Alkali	
Sodium hydroxide	Industrial chemicals, Clinitest tablets, drain cleaners, oven cleaners
Potassium hydroxide	Drain cleaners, batteries
Calcium hydroxide	Cement
Ammonium hydroxide	Hair straighteners, skin peels, toilet cleaners, glass cleaners, fertilizers
Lithium hydroxide	Photographic developer, batteries
Sodium tripolyphosphate	Detergents
Sodium hypochlorite	Bleach
Acids	
Sulfuric acid	Automobile batteries, drain cleaners, explosives, fertilizer
Acetic acid	Printing and photography, disinfectants, hair neutralizer
Hydrochloric acid	Cleaning agents, metal cleaning, chemical production
Hydrofluoric acids	Rust remover, petroleum industry, glass etching, jewelry cleaners
Formic acid	Model glue, leather and textile manufacturing, tissue preservation
Chromic acid	Metal plating, photography
Nitric acid	Fertilizer, engraving, electroplating
Phosphoric acid	Rustproofing, metal cleaners, disinfectants

Solid alkali ingestions may have greater potential for proximal esophageal tract injury and less for distal injury.

Acids

Injuries by strong acids produce coagulation necrosis. Tissue destruction and cell death result in eschar formation, which is believed to protect against deeper injury. Ingested acids settle in the stomach, where gastric necrosis, perforation, and hemorrhage may result. It was previously thought that acids were esophagus-sparing, with most tissue injury concentrated in the stomach, but a study by Zargar and colleagues³ reported a similar incidence of gastric and esophageal injury (85.4 percent gastric and 87.8 percent esophageal) after acid ingestion. Despite relatively less tissue destruction, strong acid ingestion results in a higher mortality rate than does strong alkali ingestion. This higher mortality rate after acid ingestion is hypothesized to result from complications of systemic absorption of acid (metabolic acidosis, hemolysis, and renal failure).

CLINICAL FEATURES

Patients who present after caustic ingestion may have severe pain, odynophagia, dysphonia, oral and facial burns, respiratory distress, and/or abdominal pain, and may be drooling, coughing, or vomiting. Dysphonia, stridor, and respiratory distress may indicate laryngotracheal injury, whereas dysphagia, odynophagia, epigastric pain, and vomiting may indicate esophageal and gastrointestinal (GI) injury.

Conflicting data exist on the reliability of presenting signs and symptoms to predict upper GI injuries. An early retrospective study of caustic ingestions by Gaudreault and colleagues⁴ reported 12 percent of patients who presented without initial signs or symptoms of upper GI injury were subsequently found to have serious esophageal injuries of grade 2 or higher (Table 181-3). A subsequent prospective study by Gorman and coworkers found that no single symptom, or group of symptoms, had 100 percent positive or negative predictive value for esophageal injury.⁵ All patients with serious esophageal injuries (grade 2 or 3) in the study by Gorman and colleagues had some initial sign or symptom (drooling, abdominal pain, etc.).

TABLE 181-3 Endoscopic Grading of Upper Gastrointestinal Caustic Injuries

Grade 0	Normal examination findings
Grade 1	Edema and hyperemia of mucosa
Grade 2a	Friability, hemorrhages, erosions, blisters, whitish membrane, exudates, and superficial ulcerations
Grade 2b	Grade 2a plus deep discrete or circumferential ulceration
Grade 3a	Small scattered necrosis
Grade 3b	Extensive necrosis

MANAGEMENT

Initial Assessment

During the initial and subsequent evaluations, the ED staff should take precautions to prevent personal injury secondary to caustic exposure.

The first step is immediate airway evaluation. Patients with respiratory distress may have significant oral, pharyngeal, and/or laryngotracheal injury, and may require emergency airway management. Ideally, patients with potential airway injuries should have fiberoptic evaluation of the airway prior to intubation to determine the extent of the damage, but this may not always be possible. **Blind nasotracheal intubation is contraindicated** secondary to the potential for exacerbating airway injuries. Oral intubation with direct visualization is the first choice for definitive airway management, but surgical cricothyrotomy may be required if oral intubation is not possible. When in doubt, it is prudent to establish an airway early rather than risk greater difficulty later as secondary effects of injury, such as edema, complicate the situation.

A directed history and physical examination should be performed to determine the type and amount of caustic ingested. It should also be determined whether the ingestion was intentional or unintentional. Patients should be assessed for hemodynamic instability. Etiologies for shock in these patients include GI bleeding, complications of GI perforation, and volume depletion. Patients should be examined for peritoneal signs from hollow viscus perforation, and mediastinitis should be considered in patients complaining of chest discomfort. Carefully examine eyes and skin to detect dermal and ocular caustic exposures.

Laboratory and Ancillary Tests

Laboratory evaluation should include arterial blood gas level, electrolyte panel, hepatic profile, complete blood count, and coagulation profile. Strong acid ingestions may cause severe acid-base disorders, and an arterial line may be indicated if serial blood gas determinations are required. Obtain serum calcium and magnesium levels after hydrofluoric acid exposures. All patients should have an upright chest radiograph to detect peritoneal and mediastinal air. After intentional ingestions, an ECG should be done and aspirin and acetaminophen levels should be obtained to screen for potential coingestants.

Gastric Decontamination

Charcoal should not be given to caustic ingestions, because caustics do not bind well to activated charcoal and charcoal will impede visualization when endoscopy is performed. Ipecac should not be given because vomiting could precipitate perforation, and vomiting will result in repeat exposure of the airway and gastrointestinal mucosa to the caustic agent. The risk of inserting a nasogastric tube generally outweighs the benefits. A nasogastric tube should not be inserted in the ED for alkali ingestions because the risk of perforation is considered great. For acid injuries, a nasogastric tube may be inserted by the endoscopist to aspirate residual material.

Neutralization and Dilution

Dilution or neutralization are not recommended at this time, because the risks outweigh the benefits. Potential dangers of such therapy include vomiting, airway injury, and perforation.

Benefits of dilution or neutralization have not been clearly demonstrated in the clinical setting. However, in animal models, dilution can decrease tissue destruction.^{6,8} Prior concerns that neutralization therapy (neutralization of strong bases with acids and the reverse) can produce harmful exothermic reactions have been questioned.^{7,8} Still, until more clinical data are available, dilution or neutralization should not be done in the ED or the prehospital setting.

Endoscopy

Endoscopy is an important tool used to evaluate the location and severity of injury to the esophagus, stomach, and duodenum after caustic ingestion. Indications for endoscopy vary, so the endoscopist should be consulted in all cases of caustic ingestion. Some authorities recommend endoscopy in all cases of caustic ingestions, whereas others advocate endoscopy based on signs and symptoms.⁹ Recent data supports the latter idea (i.e., patients with endoscopically significant lesions all had signs or symptoms of oral pharyngeal injury).¹⁰ Currently, endoscopy is indicated in the presence of any signs or symptoms of serious injury (vomiting, drooling, dyspnea, or stridor), in the presence of oral-pharyngeal burns, and after intentional ingestions.

Zargar and colleagues³ developed the most commonly referenced system for endoscopic staging of upper GI tract caustic injuries and prospectively demonstrated the safety of using the endoscope in caustic ingestions. Injuries are divided into four grades (see Table 181-3).¹¹ Patients with grade 2b and 3 injuries are at risk of long-term sequelae, including stricture formation. Patients with grade 3 lesions are at greatest risk of perforation, fistula, and hemorrhage.

Traditionally, endoscopists have terminated their examination at the first sign of severe esophageal injury (grade 2b or 3). However, a more complete examination to document all injuries to the esophagus, stomach, and duodenum may outweigh the risk of perforation. Most experts agree that **the timing of the endoscopy should be within the first several hours after ingestion** and that follow-up exams should be avoided between days 5 and 15. Other noninvasive diagnostic means to evaluate and follow caustic GI injuries include abdominal computed tomography (CT) and ultrasonography. For patients not requiring emergent laparotomy, CT may be used to screen for intraabdominal necrosis outside the GI tract or in areas not reachable with the endoscope. Sonographic evaluation, both transabdominal and endoscopic, has been advocated for evaluation and follow-up of gastric injury after caustic ingestion.^{12,13}

Steroids

One of the most controversial aspects of caustic ingestion management is the use of steroids. The ability of steroids to inhibit the inflammatory response led to the hypothesis that steroids may decrease stricture formation after caustic ingestion. The largest study of steroid use in human caustic ingestions was not able to demonstrate such a benefit from steroids.¹⁴ Opponents of steroid use believe that steroids may increase the risk of infection, perforation, and hemorrhage, but no compelling data support these assertions.^{15,16}

Steroid use has never been recommended in acid ingestions, because the risk of esophageal stricture formation is believed to be lower. Recommendations vary for steroid use after alkali caustic ingestions, from not using steroids at all to using them only in endoscopic grade 2b lesions (circumferential deep ulcerated lesions). Steroids are not indicated in grade 1 and grade 2a lesions because these lesions do not form strictures and grade 3 lesions are probably best handled by surgical resection. If used, steroids should be used early for alkali inges-

tions, within the first 6 h, at a dose approximately equivalent to 2 mg/kg per 24 h of prednisolone for 3 weeks, followed by a taper.

Antibiotics

There is no good data to support use of prophylactic antibiotics after caustic ingestions. However in cases in which steroids are utilized, addition of penicillin or another antibiotic that covers oral flora appears to be prudent.

Systemic Toxicity

Morbidity or death from alkali injuries usually results from the complications of direct tissue necrosis, but acid ingestions may result in systemic toxicity from absorption of the acid in addition to local tissue destruction. Acid-base disorders, hemolysis, and renal failure may result. In cases of systemic toxicity, traditional critical care principles should be applied to optimize the patient's hemodynamics. Manipulation of serum pH with sodium bicarbonate may be required if the serum pH is consistently below 7.10 due to metabolic acidosis.

Ocular Exposures

Ocular injuries after caustic exposures can be devastating to vision. The Eye Bank Association of America reports that 300 of the 1000 corneal transplants in the United States in 1995 were secondary to eye injuries caused by chemicals.¹⁷ Caustic alkali injuries to the eye are generally more severe than acid-related eye injuries. Alkali injuries penetrate deep into ocular tissue and continue to be destructive after superficial removal, whereas acid injuries are usually superficial. The coagulation necrosis after acid injury limits the penetration of acid into ocular tissue. Ocular injuries should be immediately treated with copious irrigation. Patients should have continuous irrigation with at least 2 L of NS per affected eye. Nitrazine (pH) paper should be utilized to ensure that the offending acid or base is eliminated. The expected pH after irrigation should be between 7.5 and 8.0, and irrigation should continue until this pH range is achieved. A waiting period of 10 min before checking the pH will more accurately reflect the pH of the eye and not the irrigation fluid. After irrigation, all patients should have a complete eye examination, including fluorescein staining, and all except the most superficial exposures should have ED ophthalmology consultation.

Treatment of Dermal Exposures

Caustic injuries to the skin most frequently occur on the extremities. Most acid injuries, excluding hydrofluoric acid, respond well to local copious saline irrigation. Alkali dermal exposures may appear deceptively superficial, yet burn more deeply and for extended periods. Management of these injuries should include copious irrigation and local wound debridement to remove residual compound. In cases of lime exposure and other caustic powders, patients should brush off the dry compound and remove contaminated clothing before irrigating.

Portland or ready-mix cement is an alkali mixture of lime that warrants special mention. When water is added to the dry mixture, calcium, sodium, and potassium hydroxide are produced. Patients may initially present with severe pain without obvious injury, but eventually develop blisters and skin necrosis if the affected area is not irrigated early. All cutaneous caustic injuries require close follow-up or early referral to a plastic surgeon to ensure the injuries are not progressing.

Experimental Therapies

Many different therapies have been tried to decrease the toxic effects of caustic ingestions. Most experiential therapies have been aimed at

preventing esophageal strictures after caustic alkali ingestion. Animal data have showed decreased stricture formation with drugs that affect collagen deposition, including interferon- α -2b, octreotide, [3-aminopropionitrile, iV-acetylcysteine, and D-penicillamine.¹⁸ Pentoxifylline, a local inflammatory and microcirculation mediator, has also been used experimentally. Oral agents to coat and protect the GI tract from insult, including sucralfate, bismuth subsalicylate, and sodium polyacrylate, have been tried experimentally with some success. None of these agents have been evaluated in controlled clinical trials in humans, and more data are needed before a recommendation with respect to their use can be made.

Surgery/Stents/Dilation

Major ingestions of caustic agents may result in immediate perforation of the GI tract and require emergency surgery. The indications for emergency laparotomy include peritoneal signs or free intraperitoneal air. Esophageal perforation diagnosed by mediastinal air on plain films or by endoscopy is also an indication for emergency surgery. More controversial is the management of severe esophageal injuries, grade 2b and 3, without obvious perforation. Some authorities recommend early dilation therapy (in the first 3 weeks) with or without stenting, whereas others report good results with early surgical resection.

DISPOSITION

All patients with symptomatic caustic ingestions should be admitted to the hospital. Patients with grade 1 and 2a lesions will do well, but warrant hospitalization to ensure that symptoms do not progress. The majority of ocular injuries will require ophthalmology consultation in the ED and follow-up. Mild to moderate dermal injuries can be safely discharged after local wound irrigation, aseptic dressings, and close follow-up. The following dermal exposures may warrant admission: injuries that cross flexor or extensor surfaces, facial injuries, injuries to the perineum, partial-thickness injuries to greater than 10 to 15 percent of body surface area, all full-thickness injuries, and less severe injuries in patients at the extremes of age.

SPECIAL SITUATIONS

Disc Batteries

Disc batteries are a common, potentially caustic ingestant. Each year, there are approximately 2000 disc battery ingestions in the United States, mostly by children younger than age 6 (see Table 181-1). Batteries may contain manganese dioxide, zinc, mercuric acid, silver oxide, or lithium in an alkaline medium. Most disc batteries pass through the GI tract without incident. Batteries have the potential for alkali injury if they leak secondary to casing damage or from hydroxide production related to external current from intact batteries. Pressure necrosis may also play a role in injury if the disc battery becomes lodged in the GI tract. Heavy-metal toxicities, while a theoretical consideration in disc battery ingestion, have not been documented.¹⁹

Chest and abdominal radiographs should be obtained to determine the position of the battery. Batteries in the airway or esophagus should be removed by endoscopy/bronchoscopy immediately. If a battery has passed the gastroesophageal junction and appears to be in the stomach, then a follow-up film should be obtained in 24 to 48 h to ensure that the battery has passed through the pylorus. Batteries in the intestines should pass without difficulty, but checking the stools and follow-up film are used to ensure passage. See Chap. 76 for more discussion.

Hydrofluoric Acid

Hydrofluoric acid is a relatively weak acid ($pK_a = 3.8$) used in industry for glass etching, metal cleaning, and petroleum processing. It may

also be found in household products such as chrome wheel cleaner and rust remover. Despite being a relatively weak acid, hydrofluoric acid has great potential for causing morbidity and death. The major mechanism of injury with hydrofluoric acid is not coagulation necrosis; rather, the free fluoride ion complexes with body calcium and magnesium, resulting in cellular death. Most injuries are to the upper extremities. Patients often present with benign-appearing wounds but complain of a tremendous amount of pain. These wounds often have a slight white discoloration but may become black and necrotic as cellular damage results. Severe injuries may result in hypocalcemia, hypomagnesemia, hyperkalemia, acidosis, and ventricular dysrhythmias. Ventricular fibrillation and death have been reported with dermal exposure of between 2.5 and 22 percent of body surface area.

Treatment of minor hydrofluoric acid injuries consists of first thoroughly irrigating the affected area with water and then placing the area in a paste of calcium gluconate or benzalkonium chloride solution. The paste can be made with surgical lubricant and calcium gluconate powder (2.5 percent wt/vol) or alternately with a commercially-available preparation of benzalkonium chloride (Zephiran). The affected area is soaked in the gel, with pain relief being used as the end point for therapy. Other effective treatments include intradermal injections of 5 percent calcium gluconate or magnesium sulfate around the affected area (not to exceed 0.5 mL/cm²). For distal upper extremity injuries that do not respond to the aforementioned treatments, intraarterial infusion of calcium gluconate has been used. It is recommended that 10 mL of 10 percent calcium gluconate diluted in 40 mL of NS be infused over 4 h or until pain resolves. The use of **calcium chloride should be avoided** for fear of skin necrosis if extravasation occurs.²⁰ Oral ingestion of hydrofluoric acid has a high mortality rate. NG tube placement and gastric lavage with NS are recommended. Oral magnesium or calcium should be given in hydrofluoric ingestions on a milliequivalent-for-milliequivalent basis. If the amount of hydrofluoric acid ingested is not known, then 300 mL of magnesium citrate or calcium salts should be given. In serious exposures of any type, attention should be focused on hemodynamic monitoring for dysrhythmias. Serum calcium and magnesium levels should also be followed closely. Intravenous supplementation with large amounts of calcium and magnesium may be required.

Airbag-Related Burns

Recently reported caustic injuries that ED clinicians should be aware of are chemical burns related to airbag deployment. A small amount of aerosolized sodium hydroxide and sodium carbonate is released during airbag deployment. These caustic alkalis may burn skin or enter the eye and cause significant injury in the form of a chemical keratitis. Skin injuries are usually minor, related to direct contact with aerosolized alkalis or heat from melted clothing. Skin exposure usually requires only basic burn care. Caustic ocular exposures should be managed with copious irrigation, pH testing, and ophthalmology consultation.²¹

LONG-TERM MORBIDITY

Most long-term sequelae from caustic exposure are related to injuries to the GI tract. Acid ingestions may scar the pylorus and result in gastric outlet obstruction. Caustic alkali ingestions may result in esophageal strictures, which may result in dysphagia, odynophagia, and malnutrition. Controversy exists about the appropriate treatment—long-term dilation therapy versus surgery—or strictures.²²

Patients with caustic injuries to the esophagus are at risk for cancer of the esophagus. Increased risk for esophageal malignancy is up to 1000 times greater in patients with a history of caustic ingestion and is often seen decades after the initial ingestion and resulting esophageal injury. Some authorities advocate prophylactic esophagectomy in grade 3 lesions to decrease risk of potential future malignancy.

Pesticide intoxication results from intentional, accidental, and occupational exposures. Because of the number of chemical compounds marketed as multiple formulations and brand names and the complex clinical syndromes that result from exposure to their active ingredients, management often necessitates using a resource such as the Poison Index or consultation with a poison center. Pesticides contain inert ingredients such as petroleum distillates that also can be toxic to humans. Pesticides have class-specific toxicities. Many have both local and systemic effects. Supportive care is of utmost importance in pesticide poisonings, but for some compounds, the use of antidotes may be lifesaving.

INSECTICIDES

Chemical insecticides are toxic to the nervous system. Toxicity may include acute, chronic, and delayed sequelae of acute exposure. The four major classes of insecticides used today are the organophosphorous compounds, carbamates, organochlorines, and pyrethrins. Another compound, A[^]A[?]-diethyl-3-methylbenzamide (DEET), is marketed as a personal insect repellent. Organophosphorous and carbamate pesticides are cholinesterase inhibitors that have replaced organochlorine insecticides because of their improved effectiveness and lack of persistence in the environment and human tissues. In 2001, 47,777 insecticide exposures were reported to TESS, with 19,437 exposures to children younger than 6 years of age. Six fatalities were reported. There were 150 cases of major toxicity, 74 of which involved organophosphorous pesticides. Insecticide poisonings occur worldwide.²

Organophosphorous Compounds

EPIDEMIOLOGY Commonly used organophosphorous chemicals include diazinon, orthene, malathion, parathion, and chlorpyrifos. In addition to their use as insecticides, they have been used as chemical warfare agents since World War II. Recently, Sarin was used in the terrorist attack on the Tokyo subway in 1995.³ Organophosphorous and carbamate compounds are the most common insecticides associated with systemic illness. Potency does vary, however. Highly potent compounds such as parathion are used primarily in agriculture. Those of intermediate potency include coumaphos and trichlorfon, which are used in animal care. Diazinon and chlorpyrifos were restricted recently from household use in the United States due to concerns about human neurotoxicity. Poisoning results primarily from accidental exposure in the home, in recently sprayed or fogged areas using pesticide applicators, in agriculture, in industry, and in the transport of these products. Exposure to flea-dip products has been reported in pet groomers and children. Widespread food contamination and the potential for mass toxic exposure are always a risk.⁴ In addition, these chemicals are involved in intentional poisonings including homicides. Systemic absorption of organophosphates occurs by inhalation and by mucous membrane, transdermal, transconjunctival, and gastrointestinal exposure. When a patient presents with a pesticide exposure, the clinician should ask questions about first aid, prehospital intervention and decontamination, product name, manufacturer, product concentration and formulation, circumstances of exposure, amount, onset of symptoms, and patient age and medical history. In patients with Alzheimer disease, taking donepezil, tacrine, or rivastigmine can potentiate seizures and other toxic effects of organophosphorous and carbamate exposures.

PATHOPHYSIOLOGY Organophosphorous and carbamate compounds inhibit the enzyme cholinesterase in the nervous system, leading to an accumulation of the neurotransmitter acetylcholine in the central nervous system (CNS), the autonomic nervous system, and at neuromuscular junctions.

Acetylcholinesterase (true, or red blood cell acetylcholinesterase) is found primarily in erythrocyte membranes, nervous tissue, and

INSECTICIDES, HERBICIDES, RODENTICIDES Walter C. Robey III William J. Meggs

Pesticides include insecticides, herbicides, and rodenticides. In the United States, over 90,000 pesticide exposures were reported to the Toxic Exposure Surveillance System (TESS) of the American Association of Poison Control Centers in 2001,¹ with 46,929 exposures to children under 6 years of age. There were 17 deaths.

skeletal muscle. Plasma cholinesterase (pseudocholinesterase, butyrylcholinesterase) is found in the serum, liver, pancreas, heart, and brain. Inhibition of cholinesterase leads to acetylcholine accumulation at nerve synapses and neuromuscular junctions, resulting in overstimulation of acetylcholine receptors. This initial overstimulation is followed by paralysis of cholinergic synaptic transmission in the CNS, in autonomic ganglia, at parasympathetic and some sympathetic nerve endings (e.g., sweat glands), and in somatic nerves. A *cholinergic crisis* results in a central and peripheral clinical toxidrome.

Organophosphorous compounds bind irreversibly to cholinesterase, thus inactivating the enzyme through the process of phosphorylation. *Aging* is a term describing the permanent, irreversible binding of the organophosphorous compound to the cholinesterase. The time to aging is slightly variable with different agents. It can take minutes to a day or more. The interval after exposure during which administration of an antidote can reverse the process is initial. **Once aging occurs, the enzymatic activity of cholinesterase is permanently destroyed,** and new enzyme must be resynthesized over a period of weeks before clinical symptoms resolve and normal enzymatic function returns. Therapeutic agents must be given before aging occurs to be effective.

C: "EATURES Clinical presentations depend on the specific agent involved, the quantity absorbed, and the type of exposure. Most acutely poisoned patients are symptomatic within the first 8 h and nearly all within the first 24 h. However, highly fat-soluble compounds may cause recurrent or delayed symptoms and signs on redistribution from adipose tissue. Organophosphorous agents such as malathion are associated with local irritation of the skin and respiratory tract with resulting dermatitis and wheezing, respectively, without evidence of systemic absorption. A few cases of persistent reactive airways disease independent of cholinesterase inhibition have been reported.⁵

Acute systemic organophosphorous poisoning results in a variety of clinical CNS, muscarinic, nicotinic, and somatic motor manifestations. In mild to moderate poisoning, symptoms occur in various combinations. Time to onset of symptoms is variable, most often within 8 h, but can be delayed up to 24 h for compounds requiring metabolic activation. Onset is most rapid with inhalation and least rapid with transdermal absorption; however, dermatitis or skin excoriation may hasten this. Symptoms can occur within minutes with massive ingestion.

CNS symptoms of cholinergic excess include anxiety, restlessness, emotional lability, tremor, headache, dizziness, mental confusion, delirium, hallucinations, and seizures. Coma with depression of respiratory and circulatory centers may result. Aggressive behavior has been described. Inhibition of acetylcholinesterase in the parasympathetic branch of the autonomic nervous system has been described with two pneumonics, *DUMBELS* and *SLUDGE*, plus the "killer bees," as given in Table 182-1.

Muscarinic receptor stimulation by acetylcholine leads to salivation, lacrimation, diaphoresis, urinary incontinence, diarrhea, gastrointestinal distress, emesis, and bradycardia. Bradycardia or tachycardia may occur with severe poisoning.⁶ Bronchospasm and bronchorrhea resulting from acetylcholine excess can lead to hypoxia and tachycardia. Miotic pupils and blurred vision are due to cholinergic effects on the pupillary constrictors and ciliary body.

Acetylcholine is the presynaptic neurotransmitter at nicotinic receptors in the sympathetic ganglia and adrenal medulla. Overstimulation results in pallor, mydriasis, tachycardia, and hypertension. Parasympathetic stimulation usually predominates, but mixed autonomic effects are common. Nicotinic stimulation at neuromuscular junctions results in muscle fasciculations, cramps, and muscle weakness. This syndrome may progress to paralysis and areflexia. Respiratory muscle paralysis results in acute respiratory failure and death. Miosis and muscle fasciculations are considered reliable signs of toxicity.

An *intermediate syndrome* (IMS) may occur 1 to 4 days after an acute organophosphorous poisoning.⁷ Paralysis of neck flexor muscles, muscles innervated by the cranial nerves, proximal limb, and respiratory muscles occurs, and respiratory support may be needed. Electromyography (EMG) may assist in making the diagnosis. Aggressive, early antidote therapy and supportive measures may prevent this syndrome. Symptoms usually resolve within 4 to 18 days.

Organophosphate-induced delayed neuropathy occurs 1 to 3 weeks after acute poisoning. This mixed sensorimotor syndrome is due to the inhibition of neuropathy target esterase. This may mimic Guillain-Barre syndrome.

Irreversible neurologic and neurobehavioral sequelae after acute organophosphate poisoning include neuropsychiatric deficits and paralysis.⁸ More lipid-soluble organophosphates may not produce immediate symptoms of toxicity, and symptoms may persist for several weeks. Low-grade chronic organophosphorous exposures occur among farm workers, pesticide manufacturing plant workers, exterminators, and patients taking cholinergic ophthalmologic preparations. Symptoms and signs are often less dramatic and nonspecific, with varying degrees of headache, nausea, weakness, diarrhea, or fatigue and a subtle cholinergic syndrome. Neuropsychiatric effects have been described with chronic exposure and include cognitive dysfunction, impaired memory, and psychiatric illnesses such as depression.

Special Considerations Children are at greater risk of toxicity when exposed, due to size and lower baseline levels of cholinesterase activity. Chemical warfare nerve agents such as Soman, Sarin, Tabun, and VX are organophosphorous compounds that inactivate acetylcholinesterases. They are rapid acting and extremely potent, and death can occur within minutes of inhalation or dermal exposure. Soman ages within minutes, giving little time to administer antidotes.

DIAGNOSIS Suspicion of exposure to organophosphorous agents is based on history, the presence of a suggestive toxidrome, laboratory cholinesterase assays, and reference laboratory testing for specific compounds. Diagnosis is often difficult owing to a constellation of clinical findings that can be variable in both acute and chronic poisonings. Misdiagnoses such as flu and viral syndromes have occurred. Degree of toxicity may be based on the presence of specific signs and symptoms.

Noting a characteristic hydrocarbon or garlic-like odor may assist in diagnosis. The cholinergic toxidrome may vary depending on the predominance of muscarinic, nicotinic, and CNS manifestations of the toxin and the severity of the intoxication. An initial test dose of intravenous atropine that does not result in the expected improvement in signs and symptoms in the case of poisoning may assist in making a

diagnosis (see "Treatment" below). Differential diagnosis of CNS alterations includes all nontoxic causes of mental status changes, coma, and seizures. Muscarinic manifestations may imitate asthma, exacerbation of chronic obstructive pulmonary disease, cardiogenic pulmonary edema, acute gastroenteritis, mushroom toxicity, and primary cardiac bradycardia or hypotension. Miosis may appear late, whereas the presence of mydriasis may indicate hypoxia. Ocular exposure may cause persistent miosis. Nicotinic manifestations may imitate other causes of striated muscle dysfunction and respiratory failure. Sympathomimetic toxins and other causes of sympathetic hyperactivity such as withdrawal syndromes should be considered when signs and symptoms of nicotinic stimulation predominate. Exposure to medicinal cholinergic agents used in the treatment of glaucoma, myasthenia gravis, and Alzheimer disease should be considered.

Functional assays of plasma and red blood cell (RBC) cholinesterases are helpful for diagnosis and as a guide for therapy but may not be readily available. RBC cholinesterase enzymatic activity is a more accurate indicator of synaptic cholinesterase inhibition, but plasma cholinesterase is easier to assay and more available. The degree of cholinesterase inhibition necessary to produce symptomatic illness is variable, but symptoms generally occur when the enzyme is depressed below 50 percent baseline values. In theory, cholinesterase levels should correlate with toxicity, but **false-negative results occur, with symptomatic patients having determinations in the normal range.** Standardization among laboratories is poor. There is a large individual variability in baseline measurements, and deviation from baseline may be significant when laboratory values are in the normal range.

Unless pralidoxime is given before aging occurs, plasma cholinesterase takes up to 4 to 6 weeks and RBC acetylcholinesterase as long as 90 to 120 days to return to baseline after exposure. Plasma cholinesterase **levels have little prognostic value** in patients with acute organophosphate poisoning. Levels do not correlate with the amount of atropine required or the need for mechanical ventilation.⁹ When the rate of cholinesterase falls gradually, as in chronic exposure, clinical symptoms may be subtle. Plasma cholinesterase levels may be depressed in genetic variants, chronic disease states, liver dysfunction, cirrhosis, malnutrition and low serum albumin states, neoplasia, infection, and pregnancy. RBC acetylcholinesterase is affected by factors that influence the circulating life of erythrocytes such as hemoglobinopathies.

Routine laboratory test abnormalities are nondiagnostic but may include evidence of pancreatitis, hypo- or hyperglycemia, leukocytosis, and liver function abnormalities. A chest radiograph may show pulmonary edema in severe cases. The electrocardiogram may be abnormal and correlate with the degree of toxicity and outcome. Common abnormalities include ventricular dysrhythmias, torsade de pointes, and idioventricular rhythms. Heart blocks and prolongation of the QT_C interval are common.¹⁰ EMG may identify and quantify acetylcholinesterase inhibition at neuromuscular junctions.

TREATMENT Treatment consists of airway control, intensive respiratory support, general supportive measures, decontamination, prevention of absorption, and the administration of antidotes. *Therapy should not be withheld pending determination of cholinesterase levels.*

Protective clothing must be worn to prevent secondary contamination of health care workers. Neoprene or nitrile gloves must be used instead of latex. Patients with suspected exposure must be removed from the contaminated environment. All clothes and accessories must be removed completely, placed in plastic bags, and disposed of as hazardous materials. The patient is immediately decontaminated externally with copious amounts of soap and water and possibly a second washing with dilute ethanol. Decontamination includes the scalp, hair, fingernails, skin, conjunctivae, and skin folds. Body fluids are contaminated. Abrasion or irritation of the skin should be avoided. Contaminated runoff water should be contained and dis-

posed of as hazardous materials. Instruments can be decontaminated using chlorine bleach.

The patient is placed on 100 percent oxygen, a cardiac monitor, and pulse oximeter. A 100 percent nonrebreather mask will optimize oxygenation in the patient with excessive airway secretions and bronchospasm, and may reduce the chance of ventricular dysrhythmias during antidote therapy. Gentle suction will assist in clearing airway secretions from hypersalivation, bronchorrhea, or emesis. Coma, seizures, respiratory failure, excessive respiratory secretions, or severe bronchospasm may necessitate endotracheal intubation. **A nondepolarizing agent should be used when neuromuscular blockade is needed. Succinylcholine is metabolized by plasma cholinesterase, and therefore, prolonged paralysis may result.** An intravenous line is established, and baseline blood sampling and determination of cholinesterase levels should be done. Hypotension may necessitate initial fluid boluses of NS. Gastric lavage should be considered in recent or large ingestions. Activated charcoal is recommended for all ingestions. Protection of the airway must be ensured before lavage due to the risk of aspirating a hydrocarbon vehicle. When there is significant diarrhea due to cholinergic effects, catharsis is withheld. Hemodialysis and hemoperfusion are of no proven value.

Atropine and pralidoxime are antidotes for significant organophosphorous poisonings. Atropine, a competitive antagonist of acetylcholine at CNS and peripheral muscarinic receptors, is used to reverse muscarinic and central effects secondary to excessive parasympathetic stimulation. The dose is titrated until copious tracheobronchial secretions attenuate. Large amounts may be necessary. Pupillary dilatation is not a therapeutic end point. Atropine should not be withheld in the face of a tachycardia that may be the result of hypoxia due to secretions, respiratory muscle paralysis, or ganglionic stimulation. If secretions are present, an initial dose of 1 mg or more of atropine is given IV in the adult and 0.01 to 0.04 mg/kg in children (but never less than 0.1 mg). Intramuscular administration up to 6 mg is possible, if not ideal. Normally, this dose should produce antimuscarinic symptoms; therefore, failure to respond to a trial dose is indicative of organophosphorous poisoning. The dose may be repeated every 5 min until muscarinic symptoms subside. The dose necessary to dry secretions may be on the order of hundreds of milligrams in massive overdoses, and prolonged therapy may be necessary. Atropine infusion for as long as several weeks has been reported. Inadequate atropinization may lead to treatment failure. Alternate anticholinergic agents include high-dose diphenhydramine. Nebulized atropine or ipratropium may improve pulmonary symptoms. Ipratropium and glycopyrrolate do not cross the blood-brain barrier and are ineffective in treating CNS symptoms. Atropine does not reverse muscle weakness.

Compounds called *oximes* are used to displace organophosphates from the cholinesterases. Pralidoxime (2-PAM) is a specific antidote that restores acetylcholinesterase activity by regenerating phosphorylated acetylcholinesterase and appears to prevent toxicity by detoxifying the remaining organophosphorous molecules. Clinically, pralidoxime ameliorates muscarinic, nicotinic, and CNS symptoms. Pralidoxime reverses muscle paralysis if given early, before aging occurs. If possible, blood samples for cholinesterase levels are obtained before administration of pralidoxime, but it is important that pralidoxime be administered as soon as possible before permanent and irreversible binding, or aging, occurs. It is recommended for use even more than 24 to 48 h after exposure. Pralidoxime is more effective in acute than in chronic intoxications. The dose is 1 to 2 g for adults and 20 to 40 mg/kg up to 1 g in children, and it is infused in NS over 5 to 10 min. It also can be given by the intramuscular route. A continuous infusion of 500 mg per h in adults (5-10 mg/kg per h in children) is preferable to repeated bolus dosing if paralysis does not resolve after the initial dose or if paralysis returns. Pralidoxime should be continued for 24 to 48 h while monitoring cholinesterase levels. Combination therapy reduces atropine requirements. **Pralidoxime is not administered to asymptomatic patients or to patients with known carbamate exposures presenting with minimal symptoms.**

Response to pralidoxime therapy with a decrease in muscle weakness and fasciculations and relief of muscarinic effects with atropine usually occurs within 10 to 40 min of administration. Use of pralidoxime may prevent later subacute or chronic sequelae.

Seizures are treated with airway protection, oxygen, benzodiazepines, and antidote therapy. Use of diazepam has been described to decrease CNS effects and increase survival in animal studies of nerve gas poisoning.¹¹ Pulmonary edema and broncho spasm are treated with oxygen, intubation, positive-pressure ventilation, atropine, and pralidoxime. Altered heart rate is treated with supportive therapy and antidotes, and atropine should be given for both bradycardia and tachycardia secondary to brochospsasm or bronchorrhea with hypoxia. Management of dysrhythmias follows advanced cardiac life support guidelines. Succinylcholine, ester anesthetics, and β -blockers may potentiate poisoning and should be avoided.

DISPOSITION Minimal exposures may require only decontamination and 6 to 8 h of observation in the ED. Reexposure must be avoided because sequential exposures can have cumulative toxicity. Patients returning to work should be limited from further exposure risk. All clothing, including shoes and belts, should be discarded properly as hazardous materials and not returned to the patient. Poisonings have occurred from contaminated clothes and leather. Admission to the intensive care unit is necessary for significant poisonings. Most patients respond to 2-PAM therapy with an increase in acetylcholinesterase levels within 48 h. If toxins are fat-soluble, the patient may be symptomatic for prolonged periods of time and dependent on 2-PAM.¹² During a period of weeks while awaiting resynthesis of new enzyme, supportive care and respiratory support may be needed. The end point of therapy is determined by the absence of signs and symptoms on withholding pralidoxime therapy. Following an acute exposure, the patient may have a variety of neurologic sequelae and nonspecific symptoms lasting days to months that may be lifelong. Chronic exposure may necessitate serial enzyme determinations to identify a trend. Death from organophosphorous poisoning usually occurs in 24 h in untreated patients. If there is no posthypoxic brain damage, and if the patient is treated early, symptomatic recovery occurs in 10 days. Respiratory failure secondary to paralysis of respiratory muscles, CNS depression, or bronchorrhea is the usual cause of death.

Carbamates

EPIDEMIOLOGY TV-Methyl carbamates (Sevin, Baygon, Lannate, Carbaryl, Aldicarb) are cholinesterase inhibitors that are structurally related to the organophosphorous compounds. Medicinal forms include physostigmine, pyridostigmine, and neostigmine.

PATHOPHYSIOLOGY Carbamates transiently and reversibly inhibit the cholinesterase enzyme through carbamylation. Regeneration of enzyme activity by dissociation of the carbamyl-cholinesterase bond occurs within minutes to a few hours. This involves rapid, spontaneous hydrolysis of the carbamate-cholinesterase bond. Therefore, aging does not occur. Unlike organophosphorous poisoning, it is not necessary for new enzyme to be synthesized before normal function is restored after carbamate poisoning.

CLINICAL FEATURES Symptoms of acute intoxication are similar to the cholinergic crisis observed with organophosphorous agents but are of shorter duration. Because carbamates do not effectively penetrate the CNS, less central toxicity is seen, and seizures do not occur. Presentation of carbamate poisoning in childhood, with a predominance of CNS depression and nicotinic effects, differs clinically from that of adults.¹³

DIAGNOSIS Cholinesterase levels and thus enzymatic activity may return spontaneously to normal 4 to 8 h after a carbamate exposure. Measurement of cholinesterase activity generally is not useful in that it will be relatively normal because of rapid decarbamylation.

TREATMENT Initial treatment of carbamate poisoning is the same as for organophosphorous compounds. Atropine is the antidote of choice and is administered for muscarinic symptoms. This is usually all that is necessary while waiting for the carbamylated acetylcholinesterase complex to dissociate spontaneously and recover function, usually within 24 h. Therapy usually is not needed for more than 6 to 12 h. The use of pralidoxime in carbamate poisoning is controversial. The carbamate-binding half-life to cholinesterase is approximately 30 min, and irreversible binding does not occur, therefore there is little need for pralidoxime. Human case reports and some but not all animal studies suggest that pralidoxime may potentiate the toxicity of monomethylcarbamate, the carbamate carbaryl.¹⁴ It should be avoided in known single-agent carbaryl poisonings. Pralidoxime should be used in mixed poisonings with an organophosphorous compound and a carbamate or if the type of insecticide is unknown.

DISPOSITION Morbidity and mortality generally are limited in carbamate poisonings because of the transient cholinesterase inhibition and rapid enzyme reactivation. Carbamates are less toxic than organophosphorous compounds, and the clinical course is more benign. Most patients recover completely within 24 h. In mild poisonings, observation suffices, and the patient may be discharged with follow-up. Moderate poisonings necessitate 24 h of observation that includes ruling out concomitant exposure to or toxicity from inactive ingredients or vehicles such as hydrocarbons.

Organochlorines

EPIDEMIOLOGY Dichlordiphenyltrichloroethane (DDT) is the prototype insecticide of these chlorinated hydrocarbons. Chlordane and heptachlor are compounds that were used for termite and roach control. Dieldrin and adrin also were used commonly. Most have been restricted or banned in the United States because of their persistence in the environment, long half-life in the human body, and toxicity. Worldwide, chlorinated hydrocarbons continue to be used. Hexachlorocyclohexane (lindane) is a general garden organochlorine insecticide that is also used to treat scabies and head lice infestations. This compound is well absorbed by ingestion and inhalation. Dermal absorption occurs particularly if the skin is abraded or repeated applications are used. Children and the elderly can develop CNS toxicity and seizures with therapeutic use.

PATHOPHYSIOLOGY Organochlorines are CNS stimulants that can be toxic after dermal, inhalation, and gastrointestinal exposures. The physical state, whether a liquid or a solid, and the type of vehicle affect transdermal absorption. Toxicity results from repetitive neuronal discharges following the action potential due to a decrease in membrane sodium channel permeability. Organochlorines are highly lipid-soluble and accumulate in human tissues. Most are capable of inducing the hepatic microsomal enzyme system. Therefore, therapeutic efficacy of other chemicals and drugs that use this system is reduced in the presence of organochlorines.

CLINICAL FEATURES Neurologic symptoms predominate in acute organochlorine intoxication. Mild poisoning presents with dizziness, fatigue, malaise, headache, neurologic stimulation with hyperexcitability, irritability, and delirium, apprehension, tremulousness, myoclonus, and facial paresthesias. Fever is common. More severe exposure may result in seizures, coma, respiratory failure, and death. Seizures may occur early, without prodromal syndromes, and are usually short-lived.

Organochlorines are delivered dissolved in hydrocarbon solvents that can cause sedation, coma, and pneumonitis from aspiration. Sensitization of the myocardium to endogenous catecholamines with cardiac dysrhythmias can occur from both organochlorines and the solvents. Chronic neurotoxic effects from low-level exposure to the organochlorine compound chlordane include deficits in tests of balance, reaction time, and verbal recall.¹⁵

DIAGNOSIS History is important, and valuable information can be obtained from the package label regarding the product and vehicle involved. Differential diagnosis includes other causes of CNS stimulation and other insecticides. Laboratory evaluation generally is not helpful, but organochlorines can be detected in the serum and urine by specialty laboratories.

TREATMENT Treatment includes administration of oxygen, with intubation indicated to treat hypoxia secondary to seizures, aspiration, and respiratory failure. Benzodiazepines are indicated for seizure control. Dysrhythmia control may be indicated, but atropine and epinephrine should be avoided because both organochlorines and organic solvents can sensitize the myocardium to endogenous catecholamines. Hyperthermia must be managed by cooling techniques. Removal of clothing and skin decontamination with soap and water are important. Avoid using oils on the skin because they promote absorption. Activated charcoal and possibly gastric lavage in large, recent ingestions are indicated. The exchange resin cholestyramine should be administered to symptomatic patients exposed to Chlordane.

DISPOSITION Patients may be observed for 6 h and admitted to the hospital if signs of significant toxicity develop or if ingestion involved a hydrocarbon.

Pyrethrins

EPIDEMIOLOGY Pyrethrins are naturally occurring botanic substances found in the chrysanthemum plant. They are less toxic and considered safer than other compounds. Pyrethroids are synthetic analogues of pyrethrins. They are used commonly as aerosols in automated insect sprays in public areas; therefore, inhalation is the most common source of exposure. These agents are available as dusts and liquids in a hydrocarbon base. Both are common ingredients in over-the-counter household insecticides, pediculicides, and scabicides.

PATHOPHYSIOLOGY Pyrethroids block the sodium channel at the neuronal cell membrane, causing repetitive neuronal discharge. There is an additional effect on 7-aminobutyric acid receptors. Other effects include increased nicotinic cholinergic transmission, norepinephrine release, and interference with sodium-calcium exchange across membranes.

CLINICAL FEATURES These compounds are responsible for dermal, pulmonary, gastrointestinal, and neurologic findings. Allergic hypersensitivity reactions are the most common effects of pyrethrins. These manifest as dermatitis, asthma, allergic rhinitis, hypersensitivity pneumonitis, or anaphylaxis. Pyrethrin antigens are cross-antigenic with ragweed pollen. Dermal absorption is minimal, but these compounds are well absorbed from the gastrointestinal tract. Skin contact may lead to tingling and burning within 30 min of exposure that usually dissipates within 24 h. Contact dermatitis syndromes and allergic rhinitis result from both compounds. Allergic reactions including fatal asthma attacks have been reported. Upper and lower airway irritation occurs with local inhalation exposure. When absorbed, these compounds are metabolized rapidly in the liver, thus resulting in minimal systemic toxicity. Pyrethroids are responsible for occasional systemic occupational poisonings. Systemic symptoms of paresthesias, hyper-

excitability, tremors, incoordination, seizures, muscle weakness, respiratory failure, dizziness, headache, and nonspecific nausea, vomiting, diarrhea, and fatigue are seen with significant intentional ingestions. Alteration of consciousness, muscle fasciculations, pulmonary edema, and seizures may occur in severe poisonings.

DIAGNOSIS Differential diagnosis includes allergic and neurologic diseases. Laboratory tests are of little value.

TREATMENT Treatment includes removal from exposure; dermal, ocular, and gut decontamination; treatment of allergic manifestations; and supportive care. Hydrocarbon aspiration must be avoided.

DISPOSITION Disposition is usually related to the severity of asthmatic and allergic manifestations. The clinical course is usually benign, and hospitalization is not necessary.

AyV-Diethyl-3-Methylbenzamide(DEET)

DEET (OFF! Skintastic, Deep Woods OFF!) is used extensively as an over-the-counter insect repellent that comes in a variety of product formulations ranging in concentrations from 5 to 100 percent. When used as directed, they have a large margin of safety. DEET is absorbed through the skin and is a neurotoxin that causes seizures in large ingestions and extensive dermal exposures of high-concentration products in small children. Skin absorption occurs within 2 h of topical application. Systemic toxicity manifests as restlessness, insomnia, altered behavior, confusion, CNS depression, slurred speech, ataxia, tremors, muscle cramps, hypertonia, and seizures occurring with or without prodrome. DEET-induced hypotension and bradycardia have been reported.¹⁶ Treatment includes benzodiazepines for seizures, skin decontamination with soap and water, and activated charcoal for ingestions. Most patients recover with supportive care.

HERBICIDES

Herbicides are chemicals used to kill weeds. There are several classes that pose a health hazard despite their low acute toxicity in mammals. Toxicity in plants is due to inhibition of photosynthesis, respiration, protein synthesis, or growth stimulation mimicking plant hormones called *auxins*. Herbicidal formulations contain multiple ingredients such as organic solvents, surfactants, and preservatives that may have their own toxic effects. These may or may not be disclosed on the product label. There were 9378 exposures to herbicides reported by the American Association of Poison Control Centers in 2001.¹ Of these, 127 were intentional, with 2594 occurring in children younger than 6 years of age. About 2060 patients were treated in health care facilities, and 310 exposures resulted in moderate to major morbidity, including 4 deaths from paraquat.

Chlorophenoxy Herbicides

EPIDEMIOLOGY The most commonly used compounds are 2,4-dichlorophenoxyacetic acid (2,4-D) and 4-chloro-2-methylphenoxyacetic acid (MCPA). 2,4,5-Trichlorophenoxy acetic acid (2,4,5-T) has been banned in the United States because of its contamination with 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD). The aerially applied defoliant Agent Orange used during the Vietnam War was a mixture of 2,4-D and 2,4,5-T. These compounds are effective against broadleaf plants and are used as weed killers on lawns and grain crops.

PATHOPHYSIOLOGY The metabolic pathway or mechanism related to toxicity is unknown. Skeletal muscle toxicity can result in respiratory failure or rhabdomyolysis. Toxicity results from dermal contact, inhalation, or ingestion. Local exposure results in dermal and gastrointestinal irritation.

CLINICAL FEATURES Local exposure leads to eye and mucous membrane irritation. After ingestion, nausea, vomiting, and diarrhea occur. Tachypnea may indicate pulmonary edema. Cardiovascular findings include hypotension, tachycardia, and dysrhythmias. Muscle toxicity manifests as muscle tenderness, fasciculations, myotonia, and rhabdomyolysis. The patient may become hyperthermic. Peripheral neuropathy has been described in the recovery phase and in chronic exposure.

DIAGNOSIS Diagnosis is based on the history of exposure. Ancillary tests generally are nonspecific but may demonstrate a metabolic acidosis and evidence of hepatorenal dysfunction. Toxin levels are not immediately available. Myoglobinuria and an elevated creatine phosphate level indicate rhabdomyolysis. Differential diagnosis includes other causes of acute myopathy.

TREATMENT Treatment is supportive, including decontamination measures and respiratory support for myopathic-related respiratory failure. Alkalinization is suggested but not proven to increase the elimination of these compounds. Rhabdomyolysis should be monitored and treated.

DISPOSITION Severe toxicity and serious complications are not common. Since toxic effects usually appear within 4 to 6 h, patients with mild symptoms can be observed and discharged after that time. Significant toxicity warrants admission.

Bipyridyl Herbicides

These compounds, paraquat and diquat, are nonselective contact herbicides. Both are still used widely and are responsible for significant morbidity.

PARAQUAT

Epidemiology Paraquat is manufactured as a liquid, granules, or an aerosol and is commonly combined with diquat and other herbicides. Most products contain a blue dye, a stenchant, and an emetic. Ingestion is responsible for the majority of paraquat deaths.¹⁷ Deaths have been reported after transdermal exposure, ingestion, and inhalation. The inhalation of sprays is unlikely to cause systemic toxicity.

Pathophysiology Paraquat is a severe local irritant and devastating systemic toxin. There is minimal transdermal absorption of paraquat in the absence of preexisting skin lesions that increase systemic absorption. Ingested paraquat is absorbed rapidly, particularly if the stomach is empty. Plasma concentration peaks within minutes to 2 h after ingestion. Paraquat is then distributed to most organs, with the highest concentration found in the kidneys and lungs. Acute exposure causes liver and renal necrosis that is followed within a few weeks by pulmonary fibrosis.

Paraquat actively accumulates in the alveolar cells of the lungs, where it is transformed into a reactive oxygen species, the superoxide radical. This anion is responsible for lipid peroxidation that leads to degradation of cell membranes, cell dysfunction, and death. A redox reaction results in two phases of lung injury. An initial destructive phase is characterized by loss of type I and type II alveolar cells, infiltration by inflammatory cells, and hemorrhage. These changes may be reversible. The later, proliferative phase is characterized by fibrosis in the interstitium and alveolar spaces. Paraquat and oxygen enhance each other's toxicity by sustaining the redox cycle. Myocardial injury and necrosis of the adrenal glands may occur.

Clinical Features Paraquat's severe caustic effects produce local skin irritation and ulceration of epithelial surfaces. Severe corrosive corneal injury may result from eye exposure. Upper respiratory tract

exposure may result in mucosal injury and epistaxis. Inhalation may lead to cough, dyspnea, chest pain, pulmonary edema, epistaxis, and hemoptysis. Respiratory symptoms may persist for several weeks after inhalation exposure.

Ingestion causes gastrointestinal mucosal lesions and ulcerations. An acute burning sensation of the lips or mouth may be followed by ulceration 1 to 2 days later. Buccopharyngeal, esophageal, and abdominal pain and vomiting occur. Caustic lesions of lips, oral cavity, and gastrointestinal tract can occur within a few minutes to hours. Hypovolemia occurs from gastrointestinal fluid losses and decreased oral intake. Cardiovascular collapse may occur early in intoxication. Multisystem effects then result, including gastrointestinal tract corrosion, acute tubular necrosis, and extensive pulmonary injury. Ingestion of greater than 30 mg/kg leads to pulmonary edema, congestive heart failure, and renal failure within hours. Seizures, gastrointestinal perforation and hemorrhage, and hepatic failure may occur. Massive ingestion may lead to multisystem failure with death within a few days. Clinical manifestations of renal failure and hepatocellular necrosis develop between the second and fifth days, with pulmonary fibrosis leading to refractory hypoxemia 5 days to several weeks later. Metabolic (lactic) acidosis is common as a result of pulmonary effects (hypoxemia) and multisystem failure.

Diagnosis Early diagnosis and therapy are important. The history may be indicative of an accidental or intentional poisoning and of the route of exposure. The differential diagnosis includes exposure to other corrosive agents and herbicides. Qualitative and quantitative analyses for paraquat in urine and blood can assist in the diagnosis.¹⁸ Nomograms have been presented for predicting survival based on plasma paraquat concentration and time of ingestion.^{18,19} A 10-h level greater than 0.4 mg/L carries a high probability of death. Serial pulmonary function tests, chest radiographs, and arterial blood gas determinations, including alveolar-arterial gradient, may be used to monitor toxicity.

Chemistry abnormalities reflect multiorgan necrosis. Hypokalemia may be present. Chest radiographs may show pneumomediastinum or pneumothorax in the case of corrosive rupture of the esophagus. Radiographic abnormalities of diffuse consolidation indicating parenchymal injury on the chest radiograph may not parallel the severity of clinical symptoms. Upper gastrointestinal endoscopy should be performed to identify the extent and severity of mucosal lesions.

Treatment The goal of early and vigorous decontamination is to prevent pulmonary toxicity. Any exposure to paraquat is a medical emergency, with hospitalization indicated even if the patient is asymptomatic. Early treatment is mainly supportive but is an important determinant of survival. An attempt should be made to prevent superoxide radical formation by using low inspired oxygen to produce a therapeutic hypoxemia with the goal of reducing pulmonary injury. The use of low oxygen mixtures (Fio₂ <21 percent) with positive-pressure ventilation reduces pulmonary toxicity in experimental models and may be of therapeutic benefit. Supplemental oxygen should be avoided except for severe respiratory failure. Clothing is removed, and the skin should be decontaminated with soap and water without causing abrasions that may increase absorption. Ocular irrigation with copious amounts of water or saline must take place. Fluid and electrolytic losses from gastrointestinal tract damage, vomiting, and cathartics need to be replaced. Maintaining intravascular volume and urine output is important in preventing prerenal failure. Pain associated with oropharyngeal lesions should be treated with opioids. Emesis is common, but gastric lavage via orogastric tube is recommended despite the risk of perforation.

Immediate gut decontamination with absorbents that bind paraquat is indicated. Activated charcoal (1-2 g/kg), diatomaceous Fuller's earth (1-2 g/kg in 15% aqueous suspension), or bentonite (1-2 g/kg in a 7% aqueous slurry) should be used and repeated every 4 h. A 70% sorbitol

2 mL/kg cathartic should be administered initially. **Charcoal hemoperfusion is known to remove paraquat and should be instituted as soon as possible** and continued for 6 to 8 h. Other proposed therapies are not of proven efficacy. Corticosteroids have been used traditionally and should be considered.

Supportive care includes airway protection, maintaining intravascular volume, monitoring of vital signs and arterial blood gases, pain relief, treatment of renal failure and complications, and treatment of infection. Maintaining renal function will assist in avoiding toxic accumulation in other tissues.

Disposition An attempt to determine prognosis should be made. The mortality rate from ingestion is as high as 75 percent.¹⁷ Outcome is determined by the amount ingested; therefore, intentional ingestions tend to have a worse prognosis. A poor prognosis is seen when paraquat is ingested in a highly concentrated formulation¹⁸ on an empty stomach, thus increasing absorption, and when ingestion results in upper gastrointestinal ulcerations and renal failure.²⁰ Ingestion of a concentrated liquid solution is usually fatal. Dilute solid formulations rarely cause death. Three categories of toxicity have been described. Ingestion of less than 20 mg/kg of paraquat ion or 28 mg/kg of paraquat dichloride produces no or only moderate gastrointestinal symptoms. Recovery is usually without sequelae. Ingestion of 20 to 40 mg/kg usually results in death 5 days to several weeks after ingestion. Early development of gastrointestinal corrosion, acute renal tubular necrosis, and symptoms of systemic toxicity predominate, with subsequent extensive pulmonary injury and pulmonary fibrosis causing death in most patients. Death may be delayed 2 to 3 weeks. Patients who ingest more than 40 mg/kg of paraquat usually die in 1 to 5 days. Mortality from multiorgan failure and corrosive gastrointestinal effects is 100 percent in this group.

If more than a mouthful (50 mg/kg) is ingested, death occurs within 72 h and is due to multiorgan failure, renal tubular necrosis, myocarditis, liver necrosis, adrenal necrosis, and corrosive lesions of the gastrointestinal tract. If less than a mouthful (20-50 mg/kg) is ingested, death may be delayed up to 70 days and usually results from pulmonary fibrosis.²¹ Cardiogenic shock is the usual cause of death in patients with very high plasma concentrations. Death from lower levels is due to pulmonary fibrosis and respiratory failure.

DIQ U AT Diquat has a similar structure and mechanism as paraquat but is less toxic. For identification purposes, formulations containing diquat do not contain the dye, stenching agent, or emetic added to paraquat. The lethal dose is similar to that of paraquat, but severe poisoning and death are less common. The extent of pulmonary injury and fibrosis is less due to diquat's lower affinity for pulmonary tissue. Diquat is caustic to the skin and gastrointestinal tract, and primary effects result in renal and liver necrosis. Treatment is similar to that for paraquat poisoning. Mortality approaches 50 percent despite diquat's lower toxicity.

Urea-Substituted Herbicides

Urea-substituted herbicides such as chlorimuron, diuron, fluometron, and isopturon are inhibitors of photosynthesis and have low systemic toxicity. In humans, methemoglobinuria may occur with ingestion. Treatment includes decontamination, supportive care, and treatment with methylene blue.

Organophosphorous Herbicides

In addition to their use as insecticides, some organophosphorous compounds are effective herbicides. Butiphos (Def) is used commonly as a cotton defoliate prior to mechanical harvesting. Treatment is identical to that for insecticides.

Glyphosate (Roundup) is a widely used herbicide that is often combined with other herbicides, including diquat. Severe toxicity is lim-

ited to ingestions of concentrated solutions. Surfactant in glyphosate formulations may be responsible for toxicity. Dermal absorption is poor, and excretion is primarily renal. Clinical effects include mucous membrane irritation and erosions, widespread organ dysfunction, and refractory cardiovascular collapse. Treatment options are limited to activated charcoal and supportive care.

RODENTICIDES

Epidemiology

A number of agents with distinct toxicities are used as rodenticides. They may be classified based on whether they are anticoagulants or nonanticoagulants, time of onset of signs and symptoms, and degree of toxicity. According to the American Association of Poison Control Centers, in 2001, there were 19,294 rodenticide exposures reported to TESS.¹ Long-acting superwarfarin anticoagulants accounted for 16,423 of these exposures, most of which were in children younger than 6 years of age. There were only 815 intentional exposures. A total of 6983 patients were treated at health care facilities, and there were 2 deaths, with none involving superwarfarins, which are now combined with a bittering agent. Moderate to major morbidity occurred in 171 exposures. Individuals at risk are suicide victims, attempted homicide or abuse victims, exterminators, the intoxicated, the impaired elderly, and psychiatric patients. Intentional ingestions are often associated with significant morbidity and mortality. Most unintentional exposures occur in young children and result in minimal or no toxicity.¹

NONANTICOAGULANTS Nonanticoagulant rodenticides are listed by toxicity in Table 182-2.

High Toxicity Arsenic (Rough on Rats, Red Seal Rodenticide, Paris Green) is a heavy metal in the form of a white crystalline powder. It is no longer used because of its high toxicity. After ingestion, this compound combines with sulfhydryl groups and interferes with enzymatic reactions. Symptoms may occur as early as 1 h after ingestion, with death from cardiovascular collapse occurring within 24 h. Clinical presentation includes dysphagia, muscle cramps, nausea and vomiting, bloody diarrhea, cardiovascular collapse, altered mental status, seizures, and late peripheral neuropathies. Treatment consists of lavage, activated charcoal, catharsis, and chelation therapy using dimercaptosuccinic acid (DMSA, succimer), dimercaprol, or penicillamine.

Barium carbonate and other soluble forms such as barium chlorides, hydroxides, and sulfides are highly toxic compounds. This is a white powdery substance. Toxic mechanism is depolarization, stimulating all types of muscle and resulting in neuromuscular blockade,

paralysis, and hypokalemia. Onset occurs within 1 to 8 h with nausea, vomiting, diarrhea, abdominal pain, dysrhythmias, respiratory failure, muscular weakness, paresthesias, and paralysis. Treatment includes orogastric lavage with sodium or magnesium sulfate added to lavage solution to convert carbonate to less toxic sulfate and potassium replacement.

Elemental or yellow phosphorus (J-0 Paste, Rough on Rats, Steam's Electric Brand Paste) is a yellow or brown, waxy, fat-soluble rat or roach paste that has a garlicky odor. It is easily mixed with molasses or peanut butter or spread on bread for rodents to eat. It ignites on contact with moisture. Skin contact causes local irritation and severe burns within minutes to hours. Toxicity is related to its ability to uncouple oxidative phosphorylation. It appears to have direct toxic effects on the myocardium, kidney, and peripheral vessels. Clinical manifestations after ingestion consist of an initial stage of oral burns, abdominal pain, hematemesis, possible "smoking" luminescent vomitus and stool, a garlicky odor, and possible early death from cardiovascular collapse. The second stage, lasting a few weeks, may be relatively asymptomatic. Finally, CNS depression with multisystem toxicity including a hepatorenal syndrome may occur.

Gastric lavage with dilute potassium permanganate solution may convert phosphorus to less toxic phosphates. Activated charcoal and sorbitol catharsis, with aggressive supportive care and monitoring, is needed. Emesis should be avoided. Early cardiac and CNS toxicity is a poor prognostic sign.

N-3-Pyridylmethyl-N'-p-nitrophenylurea (PNU, Vacor, DLP-787) was withdrawn from the market several years ago because of its ability to interfere with nicotinamide metabolism in the pancreas, destroying (3 cells within hours of ingestion. It still may be found as a yellow cornmeal-like compound or yellow-green powder in bait and has a peanut-like odor. Toxicity manifests within 24 h of ingestion as acute gastrointestinal symptoms including perforation, autonomic nervous system dysfunction, insulin-deficient hyperglycemia or diabetic ketoacidosis, dysrhythmias, and neuropathies. Treatment consists of lavage, activated charcoal, cathartics, and intravenous or intramuscular administration of nicotinamide (niacinamide) and insulin.

Sodium monofluoroacetate (SMFA, Ratbane 1080, Compound 1081) is a white crystalline, odorless, tasteless, water-soluble powder licensed only by commercial exterminators. It is toxic when absorbed through broken skin, ingested, or inhaled. The active component, fluoroacetate, is converted to fluorocitrate, which interferes with the Krebs cycle. Aerobic glycolysis is thus blocked. As a result, glucose metabolism, cellular respiration, and energy production are blocked, resulting in anaerobic metabolism and lactic acidosis. Fluorocitrate binding of calcium causes hypocalcemia. Onset of toxicity is usually delayed from 2 to 20 h after ingestion. This lag time results from the delay in conversion to fluorocitrate. Signs of toxicity are nausea or vomiting, apprehension, and then lactic acidosis, seizures, coma, respiratory depression, cardiac dysrhythmias, and pulmonary edema. Electrocardiographic abnormalities such as ST-T wave changes, tachycardia, premature ventricular contractions, ventricular tachycardia, and fibrillation are seen. Hyperkalemia and hypocalcemia are common. Hypotension, an elevated serum creatinine level, and decreased blood pH are prognostic indicators of death.²²

Treatment includes activated charcoal, sorbitol cathartic, seizure and dysrhythmia control, and supportive care. Experimental regimens include glycerol monoacetate and a combination of calcium gluconate and sodium succinate and ethanol loading, which necessitates consultation with a toxicologist.

Strychnine is a highly toxic, naturally occurring alkaloid that comes from the seeds of the tree *Strychnis nux-vomica*. Strychnine is used rarely as a rodenticide. However, it may be a component of homeopathic tonics and cathartic pills. It is an odorless, colorless crystal or white, bitter-tasting powder that can be absorbed through the gastrointestinal tract or nasal mucosa. Toxicity results from its competitive antagonism of the inhibitory neurotransmitter glycine at the postsynaptic brain stem and spinal cord motor neuron. Signs and symptoms of

CNS stimulation begin approximately 15 to 20 min after ingestion but can be delayed for up to 2 h after ingestion. Toxicity manifests by restlessness, muscle twitching, painful extensor spasms, opisthotonos, trismus, inability to swallow, and facial grimacing. Medullary paralysis and death can follow.

Of diagnostic importance is that **the patient remains conscious during episodes of painful muscle spasm and what appear to be "seizures"** and that there is no postictal phase. Differential diagnosis includes tetanus, neuroleptic malignant syndrome, encephalitis, seizure disorders, and INH or PCP toxicity. Ancillary testing is not useful for diagnosis.

Treatment includes aggressive airway control, a quiet environment (because any sensory stimulation or manipulation may precipitate contractions), and activated charcoal. Gastric lavage may precipitate convulsions. Benzodiazepines and pain medications are administered to control painful spasms, but barbiturates and neuromuscular blocking agents may be needed. Rhabdomyolysis may ensue and is treated. Recovery is usually complete if therapy is aggressive.

Thallium sulfate (*Zelio Paste*, *Gizmo Mouse Killer*) is a heavy metal with moderate to high acute toxicity that is used by industry, found in homeopathic remedies, and is a common poisoning responsible for suicides and homicidal deaths. It is a white, crystalline, odorless, and tasteless powder. It is a cumulative poison that distributes in almost every tissue of the body. Thallium combines with mitochondrial sulfhydryl groups, interfering with oxidative phosphorylation. It is absorbed readily through the skin, by inhalation, and through the gastrointestinal tract.

Gastrointestinal symptoms including hemorrhage develop acutely within 12 to 48 h. A latent period with constipation is then followed in 2 to 5 days by neurologic sequelae, painful lower extremity paresthesias, myalgias, muscle weakness, headache, lethargy, tremors, ataxia, delirium, seizures, and coma. Respiratory failure and dysrhythmias may cause death in severe cases. Chronic sequelae include various neurologic syndromes, neuropathies, and alopecia. Urine sediment may be abnormal, showing RBCs and protein. Liver function tests may be abnormal. Thallium can be measured in the hair, serum, and urine.

Thallium ingestion is treated by multiple doses of activated charcoal, sorbitol initially, and supportive care. Potassium chloride infusion increases renal secretion but also may facilitate entry into cells. Multiple doses of activated charcoal or Prussian blue (potassium ferric hexanocyanate) may interrupt enterohepatic circulation and increase secretion in stool.

Zinc phosphide (Celphos, Phosfume, Acme Mole and Gopher Killer) is a dark-gray, crystalline, water-insoluble powder. It has a characteristic phosphorus or rotten fish odor. Zinc and phosphine gas are released on contact with water and acid. Toxicity is due to the phosphine formed following hydrolysis in the stomach. This gas may be inhaled and absorbed secondarily. Exposure causes widespread cellular toxicity and necrosis to the gastrointestinal tract, kidney, and liver if ingested and to the lungs if inhaled. The exact mechanism is unclear, but it appears to inhibit cytochrome oxidase and the electron transport system.²³

Onset of clinical syndromes may begin within hours to days of ingestion and may be delayed following inhalation. Nausea, vomiting, and epigastric pain may ensue within 10 to 15 min. Signs and symptoms include a phosphorous or fishy breath, black vomitus, and signs of gastrointestinal irritation or ulceration. There is myocardial toxicity, shock, and noncardiogenic pulmonary edema with nonprominent CNS manifestations such as agitation, coma, and seizures. Hepatorenal injury is common. Metabolic acidosis and hypocalcemic tetany may occur.

Treatment includes preventing gastric conversion to toxic substances by intragastric alkalization with sodium bicarbonate, dilution with water or milk, activated charcoal, a cathartic, treatment of hypocalcemia, and supportive therapy. Those who survive 3 days usually recover.

Moderate Toxicity *a-Naphthyl-thiourea* (ANTU, Bontu Prep Rat Powder, Nott's Rat-TU) is very selective for target species, with humans being relatively resistant. This compound is a fine, blue-gray powder that is odorless, water-insoluble, and slightly bitter. The mechanism of action is unknown, but this toxin does appear to increase alveolar capillary permeability, causing pulmonary edema. Patients present clinically with dyspnea, cyanosis, cough, pleuritic chest pain, noncardiogenic pulmonary edema, and pleural effusion. Treatment is supportive and includes activated charcoal and catharsis.

Cholecalciferol (vitamin D₃, Quintox Rat and Mouse Bait, Rampage, Ortho Mouse-B Gon) is used by professional exterminators and the general public. It is a white, odorless crystalline substance. In rodents, toxic doses result in the mobilization of calcium from bones, producing hypercalcemia, osteomalacia, and systemic metastatic calcifications. No severe human toxicity or deaths have been reported. Small amounts probably are nontoxic and do not require therapy.

Signs and symptoms are those associated with vitamin D intoxication and hypercalcemia. Onset of toxicity is from hours to days. Clinically, patients present with weakness, nausea, vomiting, abdominal pain, constipation, and CNS depression. Nerve and muscle dysfunction and dysrhythmias may be seen. Serum calcium, magnesium, and electrolyte levels should be monitored. Normal levels obtained 48 h after acute ingestion probably exclude significant toxicity. Therapy after acute massive ingestion includes lavage, activated charcoal, and sorbitol. Treatment of moderate to severe hypercalcemia involves intravenous infusion of normal saline, furosemide, steroids, calcitonin, and biphosphates.

Low Toxicity *Bromethalin* (Assault, Vengeance, Rat Place Packs) is a newer agent, with the first toxic exposure described in 1996. It is a pale-yellow crystalline solid that is odorless. This compound produces neurotoxicity by uncoupling oxidative phosphorylation in the mitochondria of the CNS, thus interrupting nerve conduction. Clinical experience in humans is limited, but toxicity presents as muscle tremors, myoclonic jerks, contractions of flexor muscles, ataxia, and focal motor seizures, personality changes, confusion, and coma. Treatment includes decontamination, benzodiazepines for seizures, and observation.

Norbormide or dicarboximide (Shoxin, Raticide) is a yellow cornmeal bait. There is no known human toxicity, but it causes irreversible smooth muscle vasoconstriction and resulting tissue hypoxia and ischemia in rats. Treatment is supportive and includes decontamination.

Red squill (Rat Snax, Rat's End, K-R-O-Powder and Bix Kit) is a bitter-tasting botanic cardiac glycoside derived from the plant *Urginea maritima*, or sea onion. Toxicity is related to the ability to block sodium-potassium adenosine triphosphatase and is similar to digoxin poisoning. Duration of onset is from 30 min to 6 h. Because of its potent emetic properties, patients present with nausea, protracted vomiting, diarrhea, and abdominal pain. Massive ingestion causes hyperkalemia, atrioventricular block, ventricular irritability with dysrhythmias, and death. This substance may crossreact with digoxin assays.

Treatment is similar to that for digoxin toxicity using antiarrhythmics and atropine as indicated. In severe poisoning, an infusion of of digitalis-specific antibody (Fab) is recommended. Activated charcoal should be given.

ANTICOAGULANTS *Warfarin-type* (*ia*-*acetonylbenzyl-4-hydroxycoumarin*) anticoagulants (Kill-Ko, Rat Busters) were the first anticoagulant rodenticides. They are commonly disguised as yellow corn meal or rolled oats. It is important to differentiate these short-acting anticoagulants from the more toxic long-acting superwarfarins. **Most one-time warfarin ingestions are insignificant accidental poisonings and do not cause any bleeding problems. Toxicity requires large amounts in a single exposure or a repetitive exposure over several days.** The toxic oral dose is estimated at greater than 5 to 20 mg per d for more than 5 days. Lipid solubility of the individual anticoagulant determines its elimination half-life. Onset of effect takes

place from 12 to 48 h after ingestion. Warfarin's biologic half-life is approximately 42 h. These anticoagulants inhibit, almost immediately, the synthesis of vitamin K₁-dependent clotting factors II, VII, IX, and X. Coagulopathy develops when the level of at least one critical coagulation factor falls to 25 percent of normal.²⁴ This time interval is approximately 12 to 18 h.

Therapy is not necessary for ingestion of a single mouthful of warfarin. For potentially toxic ingestion, therapy consists of activated charcoal and a cathartic, with a baseline International Normalization Ratio (INR) determination and repeated in 12 to 24 h. If the INR is greater than twice normal and the risk of bleeding exists, vitamin K₁ (phytonadione) administration is indicated. The suggested oral dose is 1 to 5 mg in children and 20 mg in adults administered two to four times daily due to its short half-life, and the INR is checked every 4 h initially and then every 24 h until stable.

Second-generation superwarfarins and the indandione derivatives were introduced when rodent resistance to warfarin began to appear. They are responsible for approximately 80 percent of human rodenticide exposures reported in the United States.¹ Their mechanisms are the same as those of the warfarins, but they are more potent, have more prolonged anticoagulant activity, and therefore have the potential to be highly toxic. Poisonings involving the indandione derivatives pindone, diphacinone, chlorophacinone, and valone have toxic and clinical characteristics similar to those of the superwarfarins.

The *superwarfarins* include the 4-hydroxy-coumarins brodifacoum, diphenacoum, coumafuryl, and bromadiolone. These are readily available over the counter as grain-based bait. **Since the biologic half-life of brodifacoum is approximately 120 days, a single ingestion may result in marked anticoagulation effects for weeks to months.** Acute intentional or repeated ingestions can cause severe bleeding. After intentional ingestions, adults often develop a coagulopathy within 24 to 48 h.

A single ingestion usually does not result in immediate toxic effects, and an ingestion may or may not be identified by history. Small children and depressed patients having an unexplained coagulopathy should elevate the index of suspicion. Clinical findings of toxicity consist of ecchymoses, hematuria, uterine or gastrointestinal bleeding, gingival hemorrhage and epistaxis, hematomas, and hemoptysis. Their onset, however, may be delayed for several days, and they may persist for several days.

If an ingestion is suspected, a baseline complete blood count, INR, and specific analysis of coagulation factors II and VII are done.

An abnormal INR or decreased factors may identify repetitive ingestions of a short-acting warfarin or patients who present hours or days after a large, single ingestion of a long-acting superwarfarin. While prothrombin time (PT) is usually monitored, large doses of warfarin can also cause prolongation of the activated partial thromboplastin time (aPTT) also. **Specific serum assays for superwarfarins are available in reference laboratories. Superwarfarins are not detected by warfarin assays.** The initial differential diagnosis in a patient with an elevated INR and PT includes disseminated intravascular coagulation, liver failure, pathologic inhibitors of coagulation, acquired vitamin K deficiency, or ingestion of a vitamin K antagonist. Warfarin abuse must be suspected when no other cause of vitamin K deficiency can be found.

Resuscitation of patients with acute hemorrhage consists of oxygen administration and repletion of volume losses with normal saline or transfusion. Fresh-frozen plasma should be used if bleeding is severe or unresponsive to vitamin therapy. Vitamin K₁ can be diluted and administered by slow intravenous infusion, at less than 1 mg per min, to minimize the risk of an anaphylactoid reaction and cardiovascular collapse. Oral absorption takes approximately 2 to 3 h. Because of the extended half-life of the anticoagulant, prolonged therapy with high doses of vitamin K₁ may be required to maintain hemostasis. Doses of vitamin K₁ should be titrated to effect. Initial doses of 1 to 5 mg in children and 20 mg in adults have been recommended, but doses up to

100 mg per d for 10 months have been reported. The INR is followed every 4 h and then every 24 h.

Treatment of acute ingestion consists of gastrointestinal decontamination. Recent ingestion of amounts greater than 0.1 mg/kg necessitates activated charcoal and a cathartic. Some recent studies suggest that there is no need for gastric decontamination or coagulation studies due to lack of significant toxicity of acute, unintentional superwarfarin ingestions in the pediatric patient.²⁵⁻²⁷ INR determinations are recommended 24-48 h postingestion.²⁸ If the INR is elevated, high-dose vitamin K₁ is initiated for at least 6 weeks. Discontinuation of vitamin K₁ therapy is followed by serial INR determinations to ensure that further therapy is not needed. After initial parenteral therapy, prolonged oral administration for several months may be required as the INR normalizes.

Clinical Approach

Patient evaluation is similar to that described in Chap. 156. Identifying product name is essential for appropriate management, but actual active ingredients need to be known over the commercial name. It must be recognized that similar brand names are used for more than one agent and that some agents are no longer on the market but remain on consumers' shelves. It must be recognized that chemicals can be mistakenly termed rodenticides when obtaining a history and that ingestion may involve coingestants. Specific odors or CNS, cardiopulmonary, gastrointestinal, skeletal muscle, metabolic, or hemorrhagic manifestations or electrocardiographic and radiologic findings may suggest a specific toxin.

Disposition

Given the low frequency of individual physician experience with these types of exposures, poison center or toxicology consultation may assist in recommending a plan for managing the patient based on presentation and toxin. When a patient has been exposed to a rodenticide having a rapid effect, symptoms usually manifest within 4 to 6 h of ingestion. Patients who have ingested a highly toxic rodenticide and are symptomatic are admitted after initial ED therapy. Symptoms related to agents with delayed onset typically begin 12 h or more after exposure.

The threshold for hospital admission should be low for intentional ingestions. For asymptomatic patients who have accidentally ingested a superwarfarin, baseline INR and PTT determinations are done, follow-up is ensured, and coagulation studies are repeated at 24 and 48 h. Prevention measures should be emphasized.

ANTICHOLINERGIC TOXICITY

Paul M. Wax

Anticholinergic poisoning should always be considered in patients who present to the ED with unexplainable mental status changes. Significant anticholinergic toxicity is manifested by a dramatically altered sensorium, hallucinations, and, at times, severe agitation. A large number of agents, both pharmaceuticals and plants, have anticholinergic properties (Table 183-1). These include H₁-histamine receptor antagonists, phenothiazines, tricyclic antidepressants, antiparkinsonian drugs, belladonna containing alkaloids (deadly nightshade, henbane, mandrake, jimsonweed), and certain mushrooms. Atropine and scopolamine are naturally occurring alkaloids that represent prototypical anticholinergic compounds.

Presentations of anticholinergic toxicity may take many guises. Most commonly, patients present after ingesting an overdose of medications that have anticholinergic properties. Antihistamine overdose (particularly diphenhydramine) is the most common presentation. In young children, unintentional ingestion of just a few pills with anticholinergic properties, such as orphenadrine, may cause significant toxicity.¹ The therapeutic use of hyoscyamine-containing agents to

TABLE 183-1 Anticholinergic Substances

Antihistamines	Belladonna alkaloids, synthetic congeners
Ethanalamines	Atropine (Hyoscyamine)
Dimenhydrinate (Dramamine)	Belladonna alkaloid mixtures
Diphenhydramine (Benadryl)	Glycopyrrolate (Robinul)
Ethylenediamines	Homatropine (Dia-Quel, Maltotran)
Tripeleminamine (Pyribenzamine)	Methscopolamine bromide (Pamine)
Alkylamines	Scopolamine hydrobromide (Hyosine)
Chlorpheniramine (Teldrin)	Cyclic antidepressants
Piperazines	Amitriptyline hydrochloride (Elavil, Amitril, Endep)
Astemizole (Hismanal)	Desipramine hydrochloride (Norpramin, Pertofrane)
Terfenadine (Seldane)	Doxepin hydrochloride (Sinequan, Adapin)
Loratadine (Claritin)	Imipramine hydrochloride (Tofranil, Pramine)
Cyclizine (Marezine)	Nortriptyline hydrochloride (Aventyl, Pamelor)
Meclizine (Antivert)	Protriptyline hydrochloride (Vivactil)
Phenothiazines	Trimipramine (Surmontil)
Prochlorperazine (Compazine)	Maprotiline hydrochloride (Ludiomil)
Promethazine (Phenergan)	Zimelidine hydrochloride
Antiparkinsonian drugs	Fluoxetine (Prozac)
Benzotropine mesylate (Cogentin)	Amoxapine (Asenden)
Biperiden (Akineton)	Ophthalmic products
Ethopropazine (Parsidol)	Atropine and scopolamine solutions
Trihexyphenidyl (Artane)	Cyclopentolate hydrochloride (Cyclogyl)
Procyclidine (Kemadrin)	Tropicamide (Mydracil)
Antipsychotics	OTC medications (including antihistamines and belladonna alkaloids)
Phenothiazines	Analgesics: Excedrin PM, Percogesic
Chlorpromazine (Thorazine)	Cold remedies: Actifed, Allerest, Coricidin, Dristan, Flavhist, Romex, Sine-Off
Thioridazine (Mellaril)	Hypnotics: Compoz, Sleep-Eze, Sominex
Perphenazine (Trilafon)	Menstrual products: Pamprin, Premesyn PMS
Nonphenothiazines	Skeletal muscle relaxants
Clozaril (Clozapine)	Orphenadrine citrate (Norflex)
Molindone (Moban)	Cyclobenzaprine hydrochloride (Flexeril)
Loxapine (Loxitane)	Mushrooms
Antispasmodics	<i>Amanita muscaria</i>
Clidinium bromide (Quarzan, Librax)	<i>Amanita pantherina</i>
Dicyclomine (Bentyl)	Other
Methantheline bromide (Banthine)	Diphenidol (Cephadol, Vontrol)
Propantheline bromide (Pro-Banthine)	
Tridihexethyl chloride (Pathilon)

treat infant colic and the topical use of diphenhydramine-containing salves has also resulted in anticholinergic toxicity.^{2,3} In the elderly, therapeutic doses of certain Pharmaceuticals may produce particularly bothersome anticholinergic side effects.⁴ The use of multiple medications with anticholinergic properties increases the likelihood of toxicity and may manifest itself as new-onset delirium.⁵

Another setting of anticholinergic toxicity is the intentional ingestion (or smoking) of belladonna alkaloid-containing plants. Group ingestion by adolescents is not uncommon and may result in multiple delirious patients presenting simultaneously to the ED.⁶ Alkaloid plants are abused for their hallucinogenic effects.⁷ Inadvertent poisoning from the ingestion of belladonna-contaminated herbal teas and Chinese traditional medicines has also been reported.^{8,9} In recent years, adulteration of commonly abused drugs such as heroin or cocaine with scopolamine or atropine has been increasingly observed.^{10,11} Such intoxications are suggested in drug-abusing patients who present with signs of anticholinergic toxicity. Such mixed presentations can be particularly challenging to diagnose and treat. Finally, systemic anticholinergic toxicity may sometimes result from the ophthalmologic instillation of anticholinergic mydriatic agents, especially in the elderly.¹²

PHARMACOLOGIC PROPERTIES

There are two major subtypes of cholinergic receptors: muscarinic receptors and nicotinic receptors. Muscarinic receptors are found pre-

dominantly on autonomic effector cells that are innervated by post-ganglionic parasympathetic nerves, some ganglia, and the brain (particularly the hippocampus, cortex, and thalamus). Nicotinic receptors are found at peripheral autonomic ganglia, neuromuscular junctions, and also the brain. Acetylcholine is the neurotransmitter that modulates both receptor types.

The term *anticholinergic* generally refers to drugs and plant toxins that act as muscarinic receptor antagonists. Muscarinic receptor antagonists block the binding of acetylcholine to muscarinic receptors and cause little blockade at nicotine receptor sites. The expected clinical effects from these drugs are modulated through disturbances in the parasympathetic nervous system (the peripheral effects) and the brain (the central effects).

Drug absorption can occur after ingestion, smoking, or ocular use. The rate of absorption varies depending on the drug and the route of exposure. Because cholinergic blockade slows gastric emptying and decreases intestinal motility, absorption and peak clinical effects are often delayed.

The signs and symptoms of anticholinergic toxicity are a result of both central and peripheral cholinergic blockade. The central anticholinergic syndrome refers to clinical presentation where the central effects of muscarinic receptor antagonism predominate.

Clinical manifestations associated with anticholinergic overdose may only be partly explained by muscarinic receptor blockade. Pharmacologically, many of these agents are impure, and toxicity after

overdose is secondary to multiple pharmacologic mechanisms. For example, the clinical findings associated with tricyclic antidepressant (TCA) overdose are only partly characterized by anticholinergic effects (and vary considerably among different tricyclic agents). The most life-threatening complications of TCA overdose are a result of the sodium channel-blocking effects on the heart producing wide-complex tachydysrhythmias, not the anticholinergic effects.

CLINICAL PRESENTATION

Anticholinergic toxicity is characterized by both peripheral and central clinical features. The characteristic features of patients with anticholinergic toxicity can be remembered as

Dry as a bone
Red as a beet
Hot as Hades
Blind as a bat
Mad as a hatter
Stuffed as a pipe

Dry skin (especially dry axillae) and dry mucous membranes (e.g., dry mouth) are the typical peripheral clinical manifestations and are a result of decreased sweat gland and salivary gland secretions. The skin may be warm and flushed (red) from vasodilatation. Other typical peripheral features of muscarinic blockade include hypoactive or absent bowel sounds secondary to decreased peristalsis and gastrointestinal (GI) motility. A palpable bladder secondary to urinary retention may sometimes be appreciated.

Sinus tachycardia is usually present with a pulse rate typically ranging from 120 to 160 beats/min. More malignant dysrhythmias are less common. Ingestions of large amounts of diphenhydramine have been associated with wide-complex tachydysrhythmias, but this complication is believed to be caused by a sodium channel effect and not an anticholinergic effect.^{1*}

Dilated pupils are another typical feature, although this clinical finding is not invariably observed despite the presence of other anticholinergic signs. Delay in onset of mydriasis for 12 to 24 h may occur.

The central anticholinergic syndrome is characterized by a dramatic delirium. While this delirium is usually accompanied by the peripheral manifestations discussed above, clinical presentations vary, and tachycardia without delirium or delirium without tachycardia may occur.

Delirium is common and may be confused with other conditions. Anticholinergic delirium is characterized by restlessness, irritability, disorientation, confusion, agitation, auditory and visual hallucinations, and incoherent speech. A particular characteristic feature of anticholinergic delirium is a dysarthria manifested by a staccato speech pattern and difficult-to-comprehend speech. This may be exacerbated by severe dysphasia from decreased mucus secretion. High-pitched cries may sometimes be heard.

The anticholinergic toxic patient has great difficulty attending and interacting appropriately with environmental stimuli. Lilliputian (little people) hallucinations have been described in this setting. Repetitive picking at the bed clothes or imaginary objects is also characteristic. Patients may also exhibit jerking movements of the extremities, and seizure activity may occur.

Agitation-induced hyperthermia is a worrisome complication of anticholinergic toxicity, and its development may be significantly potentiated by decreased sweating and the inability to dissipate heat. A markedly elevated body temperature may lead to multisystem organ dysfunction, resulting in liver, kidney, and brain injury, and coagulopathy. In some cases, these changes may be irreversible.

Central excitation and depression may both occur, and the term "agitated depression" is often the best way to describe this presentation. Depression is usually associated with higher doses. Depressive features include lethargy, somnolence, and coma.

Fatalities associated with anticholinergic overdose are characterized by severe agitation, status epilepticus, hyperthermia, wide-complex tachydysrhythmias (usually from sodium channel-blocker effect), and cardiovascular collapse.

LABORATORY EVALUATION

Routine laboratory evaluation, including measurement of electrolytes, glucose, and pulse oximetry, should be checked in the presence of abnormal mental status. In most cases of isolated anticholinergic toxicity, these tests should be normal. Limited urine drugs-of-abuse screening generally does not detect anticholinergic agents, although some rapid screens may pick up tricyclic antidepressants. Comprehensive urine drug screens (usually performed by thin-layer chromatography) may detect certain antihistamines and phenothiazines, although such testing does not usually detect plant alkaloids, scopolamine, and atropine. A positive drug screen for an anticholinergic agent does not necessarily imply an overdose or supertherapeutic ingestion, as an ingestion of a therapeutic dose of an anticholinergic agents may result in a positive screen.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of anticholinergic toxicity includes life-threatening presentations such as viral encephalitis, Reye syndrome, head trauma, alcohol and sedative-hypnotic withdrawal, postictal state, other intoxications, neuroleptic malignant syndrome, and an acute psychiatric disorder. The difference between anticholinergic toxicity and sympathomimetic toxicity (e.g., cocaine toxicity or delirium tremens) can be subtle as patients with anticholinergic or sympathomimetic toxicity may develop tachycardia, mydriasis, and delirium. The presence of dry skin and the absence of bowel sounds suggest anticholinergic poisoning. At times, patients presenting with acute psychiatric disorders may have an abnormal mental status suggesting anticholinergic toxicity, but true delirium and attention deficits are much more characteristic of the latter condition. On occasion, other central nervous system processes, such as viral encephalitis, may also affect cholinergic outflow and produce similar anticholinergic clinical signs not related to a toxic exposure.¹⁴

TREATMENT

Treatment of anticholinergic toxicity includes observation, monitoring, and good supportive care. Temperature monitoring is essential. Gastrointestinal decontamination with activated charcoal may be warranted to decrease absorption. Although the American Academy of Clinical Toxicology position statement on the administration of activated charcoal is equivocal regarding the potential benefits of charcoal administration after 1 h from ingestion, the decreased gut motility associated with anticholinergic ingestions may warrant charcoal administration beyond this 1-h window. Studies assessing charcoal efficacy in this setting have not been performed.

Intravenous sodium bicarbonate should be used to treat wide-complex tachydysrhythmias. Class Ia agents should be avoided because of their own sodium channel blockade effect.

The major therapeutic challenge in the treatment of moderate to severe anticholinergic poisoning involves obtaining adequate control of the agitated individual. Inadequate sedation may lead to worsening hyperthermia, rhabdomyolysis, and traumatic injuries. Physical restraints may be required to gain initial control. **Sedation is strongly recommended.** Prolonged use of physical restraints in the struggling and agitated patient may lead to further complications.

The intravenous administration of a benzodiazepine such as lorazepam (2.5 mg IV) is an appropriate first-line therapy to sedate the agitated patient. Pharmacologically, this approach is not specific to reverse anticholinergic delirium. Some patients may be refractory to relatively large doses of benzodiazepines. Phenothiazines should be avoided because of their anticholinergic effects.

The routine use of physostigmine to reverse anticholinergic toxicity remains controversial, and its use has resulted in significant complications. Physostigmine is a tertiary ammonium compound that is a reversible acetylcholinesterase inhibitor (mechanistically related to the carbamate insecticides) that crosses the blood-brain barrier. Acetylcholinesterase inhibition results in acetylcholine accumulation that reverses both central and peripheral anticholinergic effects. While once part of the coma cocktail, physostigmine may aggravate dysrhythmias and seizures and must be used with caution. In particular, the use of physostigmine to treat overdose of drugs with concomitant sodium channel effects such as tricyclic antidepressants may lead to bradycardia and asystole. **Patients without clear evidence of anticholinergic poisoning should not receive physostigmine**, as administration of the antidote to patients without muscarinic receptor blockade may produce cholinergic toxicity and sludge symptoms.

A recent retrospective study comparing benzodiazepines and physostigmine for the treatment of anticholinergic poisoning showed that physostigmine controlled agitation in 96 percent of patients and reversed delirium in 87 percent of patients, while benzodiazepines only controlled agitation in 24 percent of patients and was unable to reverse delirium.¹⁵ This study also showed that the patients treated with physostigmine had fewer complications and a shorter recovery time than did patients treated with benzodiazepines. There were no differences in the incidence of side effects between the two groups.

Physostigmine can be considered in cases of severe agitation and delirium, especially in cases necessitating physical restraints for control and not responsive to benzodiazepines. The dose of physostigmine is 0.5 to 2.0 mg IV, slowly administered over 5 min. When effective, a significant decrease in agitation may be apparent within 15 to 20 min. Because of rapid elimination, repeat doses may be necessary every 30 to 60 min. Patients receiving physostigmine should always be placed on a cardiac monitor and observed for signs of cholinergic excess (salivation, lacrimation, urination, and defecation). Although physostigmine has been used diagnostically, in cases of uncertain anticholinergic poisoning, such diagnostic challenge is not recommended.

Contraindications to physostigmine include asthma, nonpharmacologically mediated intestinal or bladder obstruction, cardiac conduction disturbances, and suspected concomitant sodium channel poisoning.

DISPOSITION

Patients with mild symptoms of anticholinergic toxicity can be discharged after 6 h of observation if their symptoms have resolved. More symptomatic patients usually require admission for at least 24 h. Because the half-life of physostigmine is generally shorter than the half-life of many anticholinergic agents and the reversal effect may dissipate and result in recurrent toxicity, **admission for continued observation is warranted in patients who have received this antidote.**

METALS AND METALLOIDS

Heather Long Lewis S. Nelson

Acute metal and metalloid toxicity is an uncommon clinical entity that can be a cause of significant morbidity and mortality if unrecognized and inappropriately treated. Because of their effects on numerous enzymatic systems in the body, the metals and metalloids often present with protean manifestations primarily affecting four systems: neurologic, gastrointestinal, hematologic, and renal. Effects on the endocrine and reproductive systems are less clinically apparent. It is important to recognize an initial "index case" to prevent others from being poisoned when the metal source is environmental or industrial (Table 184-1).

Epidemiology

Lead is the most common cause of chronic metal poisoning and remains a major environmental contaminant. Elevated blood levels in children ages 1 to 5 years have been linked with these community characteristics: urban dwellings, dwellings built before 1974 (especially those built before 1946), poverty, non-Hispanic black race or ethnicity, and higher population density.^{1,2} Data from phase 2 of the National Health and Nutritional Survey III for children ages 1 to 5 years indicate that an estimated 890,000 children have blood lead levels of 10 μ g/dL or higher; this estimate represents a substantial decline in the prevalence of elevated blood lead levels since 1976.³ This decline is attributed to bans on lead in household paints, gasoline, plumbing systems, food and drink cans, lead abatement programs, and the promulgation of standards for industrial use of lead.¹

Elevated lead levels may have detrimental effects on intellectual development,⁴ so lead toxicity remains a significant public health problem. Inorganic and organic forms of lead produce clinical toxicity. Inorganic lead affects the central and peripheral nervous systems, hematopoietic system, kidney, gastrointestinal tract, liver, myocardium, and reproductive capacity. With organic lead intoxication, central nervous system (CNS) effects predominate.

Inorganic Lead

PHARMACOLOGY Absorption is by the respiratory and gastrointestinal tracts, whereas skin absorption is negligible. Dietary deficiency

TABLE 184-1 Sources of Heavy Metals

Heavy Metal	Source
Lead	
Inorganic	Soldering; battery burning/reclamation, bronzing; brassmaking; glassmaking; ingesting ceramic lead glaze; stripping old paint, "deleading" homes; "moonshine" whiskey; liquids in improperly glazed pottery; contaminated herbal medications; indoor shooting ranges; ingestion of paint chips, lead-laden floor dust, lead foreign bodies; lead bullets in abdomen or joint spaces Workers at risk: jewelers, painters, lead burners and smelters, pipe cutters, pigment makers, printers, welders, pottery makers, radiator repair personnel, battery reclamation workers, construction workers
Organic	Leaded gasoline
Arsenic	
Inorganic [arsenite (As^{3+}), arsenate (As^{5+}) elemental]	Insecticides, rodenticides, herbicides, mining, smelting/refining, homeopathic medicines, kelp
Organic Gas (arsine)	Parasitical medicines (veterinary) Mining smelting/refining, semiconductor industry; made by mixing acids with arsenic-containing insecticides
Mercury	
Elemental	Battery and thermometer manufacture; sphygmomanometer repair; dentistry; jewelry and lamp manufacture; photography; mercury mining; manufacture of scientific instruments
Salts	Taxidermy; fur processing; tannery work; chemical laboratories; manufacture of explosives, fireworks, disinfectants, button batteries, inks, and vinyl chloride
Organic (methylmercury, ethylmercury, phenylmercury)	Contaminated seafood; embalming; manufacture of drugs, fungicides, bactericides, handling of insecticides; pesticides, coated seeds; manufacture of chloralkali; working with wood preservatives

cies in calcium, iron, copper, and zinc may contribute to increased gastrointestinal absorption in children. Absorption also occurs when retained lead bullets or shot are in contact with body fluids, such as synovial fluid. In the body, lead distributes into the blood, soft tissues, and bone. Greater than 90 percent of the total body lead is stored in bone, where it easily exchanges with the blood. Lead can be transferred across the placenta, a process exacerbated by increased bone turnover during pregnancy. Excretion of lead occurs slowly; the biologic half-life of lead in bone has been estimated to be 30 years.

PATHOPHYSIOLOGY In the CNS, 1) lead injures astrocytes, with secondary damage to the microvasculature and resulting disruption of the blood-brain barrier, cerebral edema, and seizures; 2) decreases cyclic adenosine monophosphate and protein phosphorylation, which contribute to memory and learning deficits; and 3) alters calcium homeostasis, which leads to spontaneous neurotransmitter release. In the peripheral nervous system, nerves undergo primary segmental demyelination, followed by secondary axonal degeneration, primarily of the motor nerves. In the hematopoietic system, lead interferes with porphyrin metabolism, which may contribute to lead-induced anemia. Coexisting iron deficiency may act synergistically with lead toxicity to produce a more profound anemia and, in children, may be more important than lead as the cause of a microcytic anemia. Hemolytic anemia also occurs as a result of inhibition of red blood cell (RBC) pyrimidine 5'-nucleotidase, an enzyme responsible for clearing cellular RNA degradation products. On a blood peripheral smear, these products produce the RBC basophilic stippling sometimes seen in lead-poisoned patients.

In the kidney, acute lead toxicity affects the proximal tubule, producing Fanconi syndrome with aminoaciduria, glycosuria, phosphaturia, and renal tubular acidosis. Chronic effects include persistence of partial Fanconi's syndrome for 13 years or longer,⁵ interstitial nephritis, and increased uric acid levels due to increased tubular reabsorption of urate. Chronic lead toxicity has been linked to gout, hypertension, and chronic renal failure.

Toxic hepatitis with mildly elevated transaminases, normal bilirubin, and normal alkaline phosphatase can occur. Lead-induced adverse effects on the reproductive system include increased fetal wastage, premature membrane rupture, depressed sperm counts, abnormal or nonmotile sperm, and sterility. Chronic lead toxicity can depress free thyroxine levels without producing clinical hypothyroidism.

CLINICAL FEATURES The common signs and symptoms of acute, chronic, and delayed toxicity are listed in Table 184-2. Young children are more susceptible than adults to the effects of lead. Encephalopathy, a major cause of morbidity and mortality, may begin dramatically with seizures and coma or develop indolently over weeks to months with decreased alertness and memory progressing to mania, delirium, and cerebral edema.⁶ It has developed in infants with blood lead levels (PbB) of 70 fJLg/dL or lower. Gastrointestinal and hematologic manifestations occur more frequently with acute than with chronic poisoning, and the colicky abdominal pains may be associated with concurrent hemolysis. Patients may complain of a metallic taste and, with long-term exposure, have bluish-gray gingival lead lines. Lead toxicity also causes constitutional symptoms, including arthralgias, generalized

TABLE 184-2 Common Signs and Symptoms of Lead Poisoning

System	Clinical Manifestations
Central nervous system	Acute: encephalopathy, seizures, altered mental status, papilledema, optic neuritis, ataxia Chronic: headache, irritability, depression, fatigue, mood and behavioral changes, memory deficit, sleep disturbance
Peripheral nervous system	Paresthesias, motor weakness (classic wrist drop) depressed or absent DTRs, sensory function intact
Gastrointestinal	Abdominal pain (mostly with acute poisoning), constipation, diarrhea
Renal	Acute: Fanconi syndrome (aminoaciduria, glucosuria, phosphaturia) renal tubular acidosis Chronic: interstitial nephritis, renal insufficiency, hypertension, gout
Hematologic	Hypoproliferative and/or hemolytic anemia; basophilic stippling (rare and nonspecific)
Reproductive	Decreased libido, impotence, sterility, abortions, premature births, decreased or abnormal sperm production

Abbreviation: DTRs = deep tendon reflexes.

weakness, and weight loss. Delayed cognitive development can occur in infants and children whose cord and PbB levels are 10 (xg/dL or higher. Adult and pediatric patients may be asymptomatic in the face of significantly elevated PbB levels.

DIAGNOSIS History of an exposure, occupational, hobby, environmental, or related to retained lead bullets, is the most important clue to making the diagnosis. The physician should focus on symptoms, developmental and dietary histories (in children), pica, any house or day-care remodeling, previous serum iron and PbB levels, and possible lead toxicity in other family members. Occupational and hobby histories should be elicited for adults being evaluated and for children who may be exposed to lead secondarily from these adult activities.

The combination of abdominal or neurologic dysfunction with a hemolytic anemia should raise the suspicion of lead toxicity. Emergency physicians should consider the diagnosis in all children presenting with encephalopathy. Toxicity due to retained lead bullets has manifested in patients as long as several decades after being shot. Hyperthyroidism, pregnancy, fever, re-injury, or immobilization of the affected extremity can promote lead release after years of dormancy.

Laboratory studies in the ED should focus on evaluation for anemia and examination of bone radiographs in children for "lead bands" and abdominal radiographs for radiopaque material consistent with lead in the GI tract. The anemia can be normocytic or microcytic, possibly with evidence of hemolysis, such as an elevated reticulocyte count and increased serum-free hemoglobin.

Anemia and basophilic stippling occur variably, and their absence does not rule out lead toxicity. Basophilic stippling of RBCs is non-specific for lead toxicity, because it is also found in arsenic toxicity, sideroblastic anemia, and the thalassemias. In children, radiographs of long bones, especially of the knee, may reveal horizontal, metaphyseal lead bands, which represent failure of bone remodeling rather than deposition of lead.

The definitive diagnosis rests on finding an elevated PbB, with or without symptoms. The PbB level is the best single test for evaluating lead toxicity, and levels of 10 [^]xg/dL or higher are considered toxic. Screening levels may be performed on fingerstick capillary blood, but, because of the potential for environmental lead contamination, elevated levels always should be confirmed on a venous blood sample.⁷ A calcium disodium edetate (CaNa²⁺-EDTA) provocation test was

used previously to evaluate total body lead stores and the need for chelation therapy when PbB levels were between 25 and 55 |xg/dL, but it is no longer recommended. Also, with the lowering of the toxic PbB level to 10 |xg/dL or lower, the erythrocyte protoporphyrin test can no longer be used to screen for lead toxicity, because of its unacceptably low sensitivity at these lower PbB levels.

DIFFERENTIAL DIAGNOSIS The differential diagnosis of lead toxicity includes causes of encephalopathy, such as Wernicke encephalopathy, withdrawal from ethanol and other sedative-hypnotic drugs, meningitis, encephalitis, human immunodeficiency virus infection, intracerebral hemorrhage, hypoglycemia, severe fluid and electrolyte imbalances, hypoxia, arsenic, thallium, and mercury toxicity, and poisoning with cyclic antidepressants, anticholinergic drugs, ethylene glycol, or carbon monoxide. The abdominal pains can mimic sickle cell crisis or the hepatic porphyrias. Chronic lead toxicity can masquerade as depression, neurosis, hypothyroidism, polyneuritis, gout, iron deficiency anemia, and learning disability.

TREATMENT All patients with appropriate symptoms and an elevated PbB level are classified as lead toxic and should be treated.

Severe Toxicity Lead-induced encephalopathy rarely occurs now, but it remains a major cause of serious morbidity and mortality. In severely toxic patients, standard life-support measures should be instituted and seizures treated with benzodiazepines, phenobarbital, and general anesthesia, if necessary. If abdominal films demonstrate radiopaque flecks consistent with lead, whole-bowel irrigation with a polyethylene glycol electrolyte solution should be instituted. The solution should be administered PO at a rate of 500 to 2000 mL/h for adults and 100 to 500 mL/h for children until the abdominal radiograph is clear. It will not alter fluid or electrolyte balance in the patient. Larger lead bodies, such as fishing sinkers, may require surgical removal. IV fluid administration should be controlled carefully to avoid worsening cerebral edema. Lumbar puncture may precipitate cerebral herniation and should be performed carefully, if at all, with the removal of a small amount of cerebrospinal fluid only.

Chelation therapy (Table 184-3) should be instituted immediately (i.e., in the emergency department) before obtaining laboratory verification of the diagnosis, if lead encephalopathy is suspected.

TABLE 184-3 Chelation Therapy for Lead-Poisoned Patients: Indications, Dosing, and Side Effects*

Severity, PbB (μg/dL)	Dose	Side Effects
Encephalopathy	BAL 75 mg/m ² IM q4h × 5 d and CaNa ²⁺ -EDTA 1500 mg/m ² /d, for 5 d as continuous IV infusion, or as 2–4 divided IV doses per d start 4 h after BAL	BAL: hypertension, febrile reaction, painful injection, GI Sx, headache, lacrimation, rhinorrhea, hemolysis in G6PD-deficient patients CaNa ²⁺ -EDTA: renal toxicity (especially if dehydrated) dermatitis, headache, fever/chills, myalgias
Symptomatic PbB >100 (adults) PbB >70 (children)	BAL 50–75 mg/m ² IM q4h × 3–5 d and CaNa ²⁺ -EDTA 1500 mg/m ² /d, for 5 d as continuous IV infusion, or as 2–4 divided IV doses per d start 4 h after BAL	As above
Mild symptoms or PbB 70–100 (adults) Asymptomatic with PbB 45–69 (children)	DMSA 350 mg/m ² PO TID × 5 d, then BID × 14 d	DMSA: GI Sx, rash, pruritus, sore throat, rhinorrhea, drowsiness, paresthesias, transient elevations in AST and alkaline phosphatase, thrombocytosis, eosinophilia
Asymptomatic PbB <70 (adults) PbB <45 (children)	Routine chelation not indicated Remove from source	

*Although the same agents are indicated for poisoning by other metals, see the text or call regional poison centers for specifics and dosing.

Abbreviations: AST = aspartate aminotransferase; BAL = British anti-Lewisite; CaNa²⁺-EDTA = edetate calcium disodium; div = divided; DMSA = 2,3-dimercaptosuccinic acid, (succimer); G6PD = glucose-6-phosphate dehydrogenase; GI Sx = nausea, vomiting, diarrhea, abdominal pain; PbB = blood lead level.

For symptomatic patients without encephalopathy and for asymptomatic patients with elevated PbB levels requiring chelation, the use of British anti-Lewisite (BAL) or succimer (2,3-dimercaptosuccinic acid, DMSA) with or without CaNa^{2+} -EDTA and the dosing schedules are determined by the PbB levels, the presence or absence of symptoms, and changing practice as more experience with DMSA is obtained. A retrospective study of 45 children with lead levels of 45 n-g/dL or higher treated with BAL plus EDTA or DMSA plus EDTA found comparable reductions in lead levels, with fewer side effects in the DMSA group.⁸ The Centers for Disease Control and Prevention recommend immediate chelation therapy for children with blood lead levels of 70 (xg/dL or higher).⁷ In asymptomatic patients, the standards for determining lead toxicity and the need for treatment differ for children and adults (see Table 184-3).

In patients in whom the lead level is elevated on a capillary stick sample, it is best to await verification on blood, unless the clinical presentation strongly supports lead toxicity.

Like all chelating agents, the two oral chelating agents used to treat lead toxicity provide sulfhydryl groups to which the lead attaches. DMSA, an analogue of dimercaprol, effectively chelates lead in adults and children.^{9,10} Its advantages include oral administration without increasing lead absorption from the GI tract, no serious adverse effects, and minimal chelation of essential metals. High cost is its main disadvantage. Repeat treatment may be necessary after a 2-week drug-free period. D-Penicillamine is a less effective chelating agent but is inexpensive. It has been used for outpatient therapy in asymptomatic children and adults with mild PbB elevations.

DISPOSITION Removal of the source of lead is mandatory for all patients. Patients should not be discharged to their former environments until appropriate deleading and decontamination measures have been accomplished. Family members and coworkers should be evaluated for occult lead toxicity.

A guide for hospitalization includes:

1. All children with symptoms or with a PbB level ≥ 70 [i-g/dL]
2. All adults with CNS symptoms
3. All patients with suspected toxicity when returning to the environment is considered dangerous

PROGNOSIS Approximately 85 percent of patients who suffer encephalopathy develop permanent CNS damage, including seizures, mental retardation in children, and cognitive deficits in adults. Abdominal colic usually subsides within days after beginning chelation therapy, and other acute manifestations clear within 1 to 16 weeks with therapy. Lead-induced nephropathy may be partly reversible with chelation therapy.

Organic Lead

Exposure to tetraethyl lead, found in leaded gasoline, can occur with gasoline sniffing or in the occupational setting. Tetraethyl lead is metabolized to inorganic lead and triethyl lead. Triethyl lead is the primary toxic product that produces predominantly CNS toxicity. Symptoms range from behavioral changes with irritability, insomnia, restlessness, and nausea and vomiting to tremor, chorea, convulsions, and mania. Muscle, hepatic, and renal damage can occur. Anemia and elevated erythrocyte protoporphyrin levels usually are not found. Blood lead levels may be normal or elevated. Therapy consists of removal from the source, symptomatic treatment, and chelation only if the PbB level is elevated. Sequelae include dementia, mental status alterations, and persistent organic psychosis.

ARSENIC

Arsenic is a nearly tasteless, odorless metal; it is the most common cause of acute metal poisoning and the second leading source of

chronic metal toxicity. Arsenicals are found in a variety of compounds and industries (see Table 184-1) and continue to be used as tools for homicides and suicides.

Elemental, inorganic and organic salts, and gaseous forms exist. Elemental and organic forms have little to no toxicity and will not be discussed further. Inorganic compounds include arsenite (As^{3+}) and arsenate (As^{5+}). These compounds are the most toxic forms, and the following discussion focuses on inorganic arsenic toxicity. Arsine, a gaseous form, has toxicopathologic mechanisms and treatment that differ from those of other arsenical compounds. It is discussed under a separate heading.

Pharmacology

Arsenic is well absorbed by the gastrointestinal, respiratory, and parenteral routes and may be absorbed through damaged skin. Owing to its water solubility, pentavalent arsenic (arsenate) is more readily absorbed through mucous membranes, for example, the gastrointestinal tract, than is trivalent arsenic (arsenite). Arsenite penetrates the skin more readily due to its increased lipid solubility. After absorption, arsenic localizes in erythrocytes and leukocytes or binds to serum proteins. Within 24 h, redistribution into the liver, kidney, spleen, lung, gastrointestinal tract, muscle, and nervous tissues occurs with subsequent integration into hair, nails, and bone. Elimination from the blood is rapid, and excretion is predominantly renal.¹¹ Toxicity of the various forms is partly determined by excretory rates, with the more toxic arsenite being excreted at a slower rate than arsenate or the organic arsenical compounds. Arsenic crosses the placenta and has produced teratogenicity in animals and humans.

Pathophysiology

Arsenic reversibly binds with sulfhydryl groups found in many tissues and enzyme systems. Acute exposure produces dilation and increased permeability of small blood vessels, resulting in gastrointestinal mucosal and submucosal inflammation and necrosis, cerebral edema and hemorrhage, myocardial tissue destruction, and fatty degeneration of the liver and kidneys. Subacute or chronic exposure can cause a primary peripheral axonal neuropathy with secondary demyelination.

Clinical Features

The signs and symptoms of toxicity vary with the form, amount, and concentration ingested and the rates of absorption and excretion of the various arsenical compounds. Arsenite is more toxic than arsenate. Symptoms usually occur within 30 min to several hours of ingestion. Severe gastroenteritis with nausea, vomiting, and cholera-like diarrhea is the hallmark of acute poisoning and may last several days to weeks, frequently necessitating hospitalization. Patients may complain of a metallic taste. Hypotension and tachycardia secondary to volume depletion, capillary leak, and myocardial dysfunction occur in moderate to severe cases. The electrocardiogram may demonstrate nonspecific ST-segment and T-wave changes with a prolonged QT_c, although these findings are more common in chronic intoxication. Ventricular tachycardia with a torsades de pointes morphology has been reported.¹² Secondary myocardial ischemia may occur, leading to an erroneous diagnosis of primary myocardial infarction. Acute encephalopathy, pulmonary edema, acute renal failure, rhabdomyolysis, and death may ensue.

Patients with subacute or chronic toxicity typically present with complaints of peripheral neuropathy, skin rash, or nonspecific malaise and weakness, often with a history of gastroenteritis occurring 1 to 6 weeks earlier. Survivors of acute poisonings can develop the same problems. The peripheral neuropathy develops in a stocking-glove distribution and is initially sensory, with motor symptoms developing later. Patients with severe poisoning can develop an ascending paralysis

mimicking Guillain-Barre syndrome. The dermatologic manifestations vary. Hyperpigmentation, hyperkeratosis of the palms and soles, morbilliform rash, and epidermoid cancer have been reported. Mees lines (1- to 2-mm-wide transverse white lines in the nails) may be seen 4 to 6 weeks after an acute ingestion. Perforation of the nasal septum has been found in workers exposed occupationally to arsenic. Patients may complain of weakness, muscle aches, abdominal pain, memory loss, personality changes, periorbital and extremity edema, or decreased hearing secondary to sensorineural damage. Chronic encephalopathy with delirium, hallucinations, disorientation, agitation, and confabulation resembling Korsakoff syndrome has been reported. Chronic exposure to arsenic has been linked to the development of squamous cell and basal skin carcinomas, respiratory tract cancer, hepatic angiosarcoma, and possibly with leukemia.

Diagnosis

Without a history of known exposure to arsenic, the diagnosis must be based on the presenting signs and symptoms and a strong index of clinical suspicion. Physicians rarely encounter arsenic toxicity, and, unfortunately, criminal poisonings often go undetected. The diagnosis of **acute arsenic poisoning should be considered in any patient with hypotension of unknown etiology that was preceded by severe gastroenteritis**. The diagnosis of chronic arsenic toxicity should be considered in a patient with a peripheral neuropathy, typical skin manifestations, or recurrent bouts of unexplained gastroenteritis.

An abdominal radiograph may demonstrate intestinal radiopaque metallic flecks in cases of arsenic ingestions.¹ The complete blood cell count may reveal a normocytic, normochromic, or megaloblastic anemia and/or a thrombocytopenia. The white blood cell count may be elevated in acute toxicity and decreased in chronic toxicity. A relative eosinophilia, up to 21 percent, and basophilic stippling of the RBCs have been reported. Elevated reticulocyte counts are found in cases with a component of hemolytic anemia. The electrocardiogram often reveals a prolonged QT_C interval, especially in chronic poisoning.

Definitive diagnosis of acute poisoning depends on finding elevated arsenic levels in a 24-h urine collection. All urinary measurements of metals should be collected in metal-free containers after a 5-day seafood-free diet. Normal urinary arsenic level is below 0.05 mg/L, and total urinary arsenic excretion in an unexposed patient should not exceed 0.1 mg per d. If the baseline urinary level is within normal limits and arsenic intoxication is still suspected, hair and nail clippings should be harvested for laboratory analysis. Owing to the rapid distribution of arsenic in tissues, blood arsenic levels are unreliable. Toxicologic texts provide a detailed discussion of laboratory testing and interpretation of results in arsenic toxicity.

Arsenic toxicity should be included in the differential diagnosis for septic shock, encephalopathy, peripheral neuropathy (including Guillain-Barre syndrome), Addison disease, hypo- and hyperthyroidism, patients with the previously mentioned dermatologic manifestations, Korsakoff syndrome, persistent gastroenteritis and/or cholera-like diarrhea, porphyria, other metal toxicities such as thallium and mercury, and unexplained, prolonged malaise and weakness.

Treatment

Acute arsenical toxicity is a life-threatening illness requiring aggressive management. The first task is to ensure adequate respiratory and circulatory function. Hypotension and dysrhythmias are the chief causes of death. Hypotension, usually due to volume depletion, should be **managed** initially with crystalloid volume replacement. Invasive hemodynamic monitoring followed by further crystalloid and pressor therapy with dopamine or norepinephrine may be required. Overhydration should be avoided, because pulmonary and cerebral edema can occur. Cardiac monitoring should be instituted. Ventricular tachycardia and fibrillation may be treated with lidocaine, amiodarone, and

electrical defibrillation, as necessary. Tsoproterenol, magnesium, and overdrive pacing therapies should be considered for torsades de pointes. Drugs that prolong the QT₀, including classes IA (procainamide, quinidine, disopyramide), IC, and III antidysrhythmics, should be avoided. Potassium, calcium, and magnesium levels should be monitored and corrected as necessary to prevent further prolongation of the QT_C and torsades de pointes dysrhythmias.

Gastric lavage with a large-bore orogastric tube should be performed in all cases of acute ingestion, and activated charcoal (1 g/kg of body weight) and a cathartic should be instilled. Activated charcoal poorly adsorbs arsenic but may be effective if coingestants were taken. Whole-bowel irrigation should be considered if abdominal radiographs reveal intestinal radiopaque materials consistent with arsenic. Seizures can be treated with benzodiazepines, phenobarbital, and general anesthesia as necessary.

Initial management of chronic toxicity should be directed toward prevention of further arsenic absorption and gastrointestinal decontamination, if appropriate, in cases of suspected homicidal intent, patients should be advised to avoid food and drinks prepared by others, and visitor contact with hospitalized patients should be monitored carefully.

Chelation therapy with BAL should be instituted immediately in all cases of known or suspected acute arsenical poisoning. British anti-Lewisite is dosed 3 to 5 mg/kg IM every 4 h for 2 days, followed by 3 to 5 mg/kg every 6 to 12 h. In severe, life-threatening toxicity, BAL therapy should be continued until the clinical condition stabilizes and DMSA, the less toxic oral chelating agent, can be substituted. In cases of suspected chronic toxicity with stable symptoms, therapy may be withheld pending diagnosis. DMSA is the preferred chelating agent in these patients.¹⁴ It is given according to the dosing regimen for lead, but therapy may be required beyond the initial 19-day regimen. D-Penicillamine does not effectively chelate arsenic and should not be used.¹⁵ During chelation, intermittent 24-h urinary arsenic levels should be measured and therapy continued until the urine level falls below 0.05 mg/L per d. Hemodialysis can remove small amounts of arsenic (2 to 4.5 mg) in patients with acute renal failure but is not indicated otherwise.¹⁶

Hospitalization Guidelines

Hospitalization should be considered in:

1. All patients with acute or life-threatening known or suspected arsenic poisoning
2. All chronically poisoned patients requiring BAL therapy
3. All patients in whom suicidal or homicidal intent is suspected

Disposition

In acute toxicity, prognosis may be influenced favorably by the rapid institution of BAL therapy. Recovery from arsenical neuropathy appears to be related more to initial severity of symptoms than to institution of chelation therapy, although, in those patients who do recover, BAL appears to significantly shorten the duration of illness. Often, neurologic recovery occurs slowly over months to years. Normalization of hematologic values can occur in the absence of any specific therapy. British anti-Lewisite has a variable effect on the dermatologic manifestations; hyperpigmentation is unresponsive to this therapy.

ARSINE

Arsine is a colorless, nonirritating gas encountered in the semiconductor industry, ore smelting, and refining processes and is produced when arsenic-containing insecticides are mixed with acids. Arsine attaches to sulfhydryl groups of hemoglobin, producing an acute hemolytic anemia with resulting jaundice, abdominal pain, and hemoglobinuria-induced acute renal failure. Acute poisonings are managed

with blood transfusions, exchange transfusion to remove the non-dialyzable arsine, and hemodialysis for the acute renal failure. British anti-Lewisite therapy has no role in the management of arsine toxicity.

MERCURY

Mercury occurs in inorganic and organic forms. Inorganic compounds are divided further into elemental mercury and mercurous and mercuric salts. Organic mercurials exist as short- and long-chained alkyl and aryl compounds. The short-chained alkyls, such as methyl mercury and ethyl mercury, are more toxic to humans, with dimethylmercury being lethal in small amounts.¹⁷ All forms of mercury are toxic but differ in the routes of absorption, constellations of clinical findings, and responses to therapy. Sources are listed in Table 184-1.

Pharmacology

Elemental mercury is absorbed primarily by inhalation of its vapor but also may be absorbed dermally. Absorption by the GI tract is usually negligible. Intramuscular injections of mercury can induce abscess and granuloma formation; delayed systemic toxicity can occur.¹⁸ Intravenous injections have produced mercury pulmonary and systemic emboli. Elemental mercury crosses the blood-brain barrier, where it is ionized and trapped in the CNS.

Mercuric salts and organic mercury are absorbed primarily through the gastrointestinal tract, with the short-chained alkyl organic compounds being better absorbed than the aryl organic compounds. Mercuric salts are deposited in the ionized form primarily in the kidney and then in the liver and spleen. The salts do not enter the CNS in consequential amounts.

With organic mercury compounds, the highly lipid-soluble short-chained alkyls easily cross membranes, accumulating in RBCs, the CNS, liver, kidney, and the fetus. Longer-chained alkyl and the aryl compounds are biotransformed into inorganic mercuric ions in the body. Therefore, toxicity with these compounds more closely resembles inorganic mercury toxicity.

Inorganic and the aryl organic mercurials are eliminated in the urine and feces. The short-chained alkyl compounds are excreted primarily in the bile, where they undergo significant enterohepatic circulation.

Pathophysiology

Mercury binds with sulfhydryl groups, affecting a diverse number of enzyme and protein systems. Methyl mercury also inhibits choline acetyl transferase, which catalyzes the final step in the production of acetylcholine, and may produce an acetylcholine deficiency. Mercuric salts produce proximal renal tubular necrosis.

Clinical Features

The clinical effects of mercury poisoning depend on the form and, in some cases, the route of administration. In general, the neurologic, gastrointestinal, and renal systems are predominantly affected. The short-chained alkyl compounds, methyl, dimethyl, and ethyl mercury, have the most devastating effects on the CNS, followed by elemental mercury, whose primary toxicity is neurologic. Both forms of mercury produce erethism, a constellation of neuropsychiatric abnormalities, including anxiety, depression, irritability, mania, sleep disturbances, excessive shyness, and memory loss. Tremor, either intention or non-intention, is a common physical finding.¹⁹ The short-chained alkyls produce paresthesias (early sign), ataxia, muscular rigidity or spasticity, and visual and hearing impairment and induce CNS teratogenic effects. Gastrointestinal effects of elemental and short-chained alkyl compounds are mild. In cases of severe, chronic poisoning with elemental mercury, stomatitis, gingivitis, and excessive salivation are seen. Chronic toxicity of elemental and organic forms may cause renal

glomerular and tubular damage. Acute elemental mercury inhalation can produce pneumonitis, adult respiratory distress syndrome, and progressive pulmonary fibrosis with death.

In contrast, the mercury salts have little to no effect on the CNS but produce a severe corrosive gastroenteritis with abdominal pain that may be followed rapidly by cardiovascular collapse. Renal effects are typical, including acute tubular necrosis within 24 h. Children exposed to all forms of mercury, except the short-chained alkyls, can develop acrodynia, an immune-mediated condition characterized by a generalized rash, fever, irritability, splenomegaly, and generalized hypotonia with particular weakness of the pelvic and pectoral muscles.

Swallowing mercury contained in a glass thermometer (elemental mercury) usually does not produce adverse effects, because the mercury is not absorbed from the GI tract unless the tract is damaged or contains fistulas.

Diagnosis

A thorough history, including occupational exposures, and typical physical findings, especially tremor or a constellation of signs and symptoms suggesting erethism or acrodynia, may alert the emergency physician to mercury toxicity. Ingestion of mercuric chloride can produce a rapidly fatal course and should be considered in any patient presenting with a corrosive gastroenteritis. Often, however, the diagnosis of mercury toxicity is subtle, arrived at only after many other diagnoses have been investigated.

For all forms of mercury, except short-chained alkyls, a 24-h urinary measurement of mercury should be performed after a 5-day seafood-free diet. A seafood meal (contaminated with mercury) can temporarily elevate the blood level to the toxic range until the mercury is eliminated. Most unexposed individuals will have levels of 10 to 15 (xg/L or lower. A level higher than 20 xg/dL before or after therapy indicates meaningful exposure. In cases of chronic toxicity, this measurement may be falsely low. Whole-blood mercury levels are less reliable diagnostically.

Short-chained alkyl mercury compounds are excreted predominantly by the bile, rendering urinary measurements invalid. Laboratory diagnosis rests on finding elevated whole-blood mercury levels, because these compounds concentrate in erythrocytes. Whole-blood mercury levels are normally lower than 1.5 xg/dL.

Magnetic resonance imaging findings in methyl mercury toxicity from ingestion of contaminated seafood include marked atrophy of the visual cortex, cerebellar vermis and hemispheres, and the postcentral cortex.²⁰

The differential diagnosis of mercury toxicity depends on the form ingested. Hypothyroidism, apathetic hyperthyroidism, metabolic encephalopathy, senile dementia, adverse effects of therapeutic drugs (such as lithium, theophylline, phenytoin), Parkinson disease, delayed neuropsychiatric sequelae of carbon monoxide poisoning, lacunar infarction, cerebellar degenerative disease or tumor, and ethanol or sedative-hypnotic drug withdrawal may produce behavioral changes or tremor similar to those caused by elemental mercury. Causes of corrosive gastroenteritis, such as iron, arsenic, phosphorus, acids, or alkalis, should be considered in the differential diagnosis for mercury salts. Many of the differential diagnoses for elemental mercury also apply to the organic mercury compounds. Cerebral palsy, intrauterine hypoxia, and teratogenic effects of therapeutic and illicit drugs and environmental contaminants should be considered when evaluating an infant thought to be affected in utero by the short-chained alkyl mercury compounds.

Treatment

General therapeutic measures include removal from exposure and supportive therapy. Ingestion of mercury salts should be treated with aggressive gastrointestinal decontamination, including gastric lavage and

SECTION 14 - TOXICOLOGY AND PHARMACOLOGY

activated charcoal. Given the profuse diarrhea that may ensue, a cathartic may not be indicated. Neostigmine may improve motor function in methyl mercury-poisoned patients by improving acetylcholine levels.

British anti-Lewisite is the preferred chelator for mercury salts and is administered in a regimen of 5 mg/kg IM once, 2.5 mg/kg IM every 8 to 12 h for 1 day, and then 2.5 mg/kg IM every 12 to 24 h until clinical improvement occurs. Adjust the dosing regimen according to clinical response and development of adverse reactions. The BAL-mercury complex is dialyzable, and hemodialysis may be helpful in patients receiving BAL who have diminished renal function. Plasma exchange transfusion also was beneficial in a case of mercuric chloride ingestion.²¹ British anti-Lewisite is contraindicated in methyl mercury poisoning owing to exacerbation of CNS symptoms. DMSA has demonstrated efficacy in binding mercury, including organic forms, and may become the treatment of choice for the short-chained alkyl compounds.²² It is given as a second agent after gastrointestinal

decontamination in cases of severe poisoning and is the chelator of choice in cases of chronic or mild toxicity. The dose of DMSA is 10 mg/kg PO every 8 h for 5 days and then every 12 h for 14 days.

Hospitalization Guidelines

1. All patients known or suspected of ingesting mercury salts
2. All patients known to have or suspected to have inhaled elemental mercury vapor with pulmonary injury
3. All patients requiring BAL therapy

Disposition

Outcome depends on the form of mercury and the severity of toxicity. Mild cases of elemental and mercury salt poisoning and very mild cases of organic mercury toxicity may result in complete recovery. Death can occur in severe cases of mercuric chloride poisoning and

TABLE 184-4 Miscellaneous Metal Poisoning: Unique Manifestations and Treatments of Patients Poisoned by Less Common Metals

Metal	Poisoning Source	Acute Clinical Manifestations*	Chronic Clinical Manifestations	Specific Treatment†
Bismuth	Antidiarrheals (bismuth subsalicylate), impregnated surgical packing paste	Abdominal pain, acute renal failure	Myoclonic encephalopathy	BAL (limited evidence)
Cadmium	Contaminated soil in cadmium-rich areas; alloys used in welding, soldering, jewelry, and batteries	Ingestion: GI symptoms Inhalation: pneumonitis, acute lung injury	Proteinuria, osteomalacia, ?lung cancer	Ingestion: DMSA (limited evidence; not generally indicated) Pneumonitis: chelation NOT indicated
Cobalt	“Hard metal dust” (tungsten–cobalt mixture), flexible magnets, drying agents	Contact dermatitis, asthma	Hard-metal lung disease (spectrum ranging from alveolitis to fibrosis), cardiomyopathy, hypothyroidism	NAC (animal studies suggest efficacy as chelator)
Copper	Leaching from copper pipes and containers; fungicide (copper sulfate); welding (copper oxide)	Ingestion: resembles iron poisoning; blue vomitus (copper salts), hepatotoxicity, hemolysis, methemoglobinemia Inhalation: metal fume fever (fever, chills, cough, dyspnea)	Hepatotoxicity (Indian childhood cirrhosis)	Chelation with intramuscular BAL if hepatic or hematologic toxicity
Chromium	Corrosion inhibitors (e.g., heating systems), pigment production	Skin irritation and ulceration, contact dermatitis; GI irritation, renal and hepatic failure	Mucous membrane irritation, perforation of nasal septum (“chrome holes”) eczema, lung cancer	Topical 10% ascorbic acid for skin ulcers
Silver	Colloidal (metallic) silver used for medicinal purposes as oral solutions, aerosols, and douches; cauterizing and antiseptic agent (silver nitrate); jewelry, wire	Mucosal irritation (silver oxide and nitrate)	Argyria (skin discoloration due to silver deposition and melanocyte stimulation)	No effective chelator
Thallium	Rodenticides (use prohibited in U.S.); contaminated herbal products; medical radioisotope (miniscule dose); most poisonings related to homicide	Early: GI Sx, constipation Delayed (>24 h): painful ascending neuropathy, cardiac dysrhythmias, AMS Delayed (2 wk): alopecia	Sensorimotor neuropathy, psychosis, dermatitis, hepatotoxicity	MDAC Prussian blue: 125 mg/kg PO bid (not FDA approved)
Zinc	Smelting, electroplating, military smoke bombs, zinc lozenges, welding/galvanizing (zinc oxide)	Ingestion: resembles iron poisoning Inhalation: mucosal irritation, metal fume fever (zinc oxide)	Copper deficiency, sideroblastic anemia, neutropenia	Chelation with CaNa^{2+} -EDTA

*Metal salts typically cause early gastrointestinal irritation (nausea, vomiting, diarrhea, cramping, hemorrhage) with subsequent neurologic, renal, hematologic, and cutaneous abnormalities.

■(Treatment universally involves removal of the patient from the source, topical decontamination, administration of activated charcoal (if metal ingested), and supportive care, including aggressive fluid and electrolyte repletion and hemodialysis, if required. Indications for chelation and its efficacy in treating metal toxicity vary with the specific metal. Consult with medical toxicologist or regional poison center for specific indications and drug doses.

Abbreviations: AMS = altered mental status; BAL = British anti-Lewisite; CaNa^{2+} -EDTA = calcium disodium edetate; DMSA = 2,3-dimercaptosuccinic acid; FDA = U.S. Food and Drug Administration; GI Sx = gastrointestinal symptoms which include but are not limited to nausea, vomiting, diarrhea, cramping; MDAC = multiple doses of activated charcoal; NAC = JV-acetylcysteine.

with dimethylmercury exposure. Most patients with organic mercury poisoning are left with residual neurologic deficits.

OTHER METALS AND METAL SALTS

Table 184-4 lists some of the other more commonly encountered metals and metal salts, their associated toxicity, and treatment specifics. Treatment universally involves removal of the patient from the source, topical decontamination, administration of activated charcoal (if metal has been ingested), and supportive care, including aggressive fluid and electrolyte repletion and hemodialysis, if required. Indications for chelation and its efficacy in treating metal toxicity vary with the specific metal (see Table 184-4). Consult with a medical toxicologist or a regional poison center for specific indications and drug doses.

TOXICOLOGY OF HAZARDOUS CHEMICALS

Suzanne R. White

Col. Edward M. Eitzen, Jr.

Kelly R. Klein

INTRODUCTION

A *hazardous material* can be defined as any substance (chemical, nuclear, or biologic) that may pose a risk to health, safety, property, or the environment. There are currently over 627,000 potentially toxic chemicals and compounds listed in the most commonly used poisoning database, PoisIndex, and it is estimated that 600 new chemicals are introduced yearly into the workplace. Given the quantity (1.5 billion tons per year) and frequency of transport (500,000 shipments per day) of hazardous substances throughout the United States, it seems inevitable that the practicing emergency physician will be faced with the management of a chemically exposed or contaminated patient.¹

The Hazardous Substances Emergency Events Surveillance (HSEES) database registered 24,359 hazardous chemical accidents during 1993-1997.² The number of events increased annually and is underestimated because petroleum products, which account for approximately 50 percent of hazardous materials spills, were not included. Other registries, such as the National Response Center, logged over 34,000 hazardous oil and chemical incidents during 2001 alone.³ Eighty percent of events occur at fixed facilities, whereas 20 percent are transportation-related, and over 10 percent occur within hospitals and schools. Highest-risk industries include those involved in chemical manufacture (especially agricultural types), petroleum refining, electric light and power, and milling of pulp/paper.⁴ Seventy percent of hazardous materials accidents occur Monday through Friday 6 A.M. to 6 P.M. Incidents typically result in one or two victims, usually employees (56 percent) and less frequently the general public (35 percent) and first responders (9 percent).² Of the 10 to 30 percent of incidents that involve victims, traumatic injury is common.^{5,6} Nontraumatic injuries most commonly include respiratory and eye irritation, nausea, vomiting, headache, dizziness, or other neurologic effects. Sixty-five percent of fatalities following a hazardous materials incident result from trauma, 22 percent from burns, and 10 percent from respiratory compromise. Many deaths occur in agricultural workers. Most injuries and deaths are associated with exposures to chlorine, ammonia, nitrogen fertilizer, or hydrochloric acid. Other commonly involved chemicals include petroleum products, pesticides, corrosives, metals, and volatile organics. Unknown or unclassified chemicals constitute a full 25 percent of events.^{2,7} It is important to note regarding hazardous materials victims that over 40 percent of the general public and 20 percent of employees are decontaminated at hospital emergency departments.²

As indicated by recent events, terrorist use of readily available hazardous substances has become a reality (see Chap. 8). Chemical disasters, whether they occur at industrial fixed-facility sites or are transportation-related or terrorist-mediated, share many features. They may involve mass casualties with serious concomitant injuries, such as trauma, burns, or smoke inhalation, that outstrip medical resources. Victims will arrive at the hospital without prior decontamination. Communication breakdown is prevalent, as is chaos among medical personnel who are unfamiliar with the agents involved, unaware of available resources, or have become contaminated secondarily. The need for emergency community and medical preparedness to mitigate the adverse consequences of such hazardous materials accidents cannot be overly stressed.

Preparedness steps for chemical disasters, and general principles of decontamination, are discussed in Chap. 8.

Following decontamination and the primary survey, a secondary survey should be carried out with attention to the identification of

common hazardous materials toxidromes (Table 185-1). Table 185-2 lists some important dermally absorbed toxins that can result in systemic toxicity. Some agents result in delayed onset of symptoms and require 24 h of monitoring or more to identify complications. Some of these agents are listed in Tables 185-3 and 185-4. Patients with chemical contamination require special medical followup, depending on the nature of the contaminant. About 30 percent of those who are acutely symptomatic will have persistent symptoms at 2 weeks.⁸ Victims of a hazardous materials incident may also experience posttraumatic stress disorder and psychological interventions can help prevent these delayed sequelae.

Children are uniquely sensitive to chemical exposures. The child's thinner stratum corneum results in increased skin permeability. A relatively greater surface area (approximately 2.5 times larger than that of adults on a pound-per-pound basis), greater fluid intake per body weight, and increased minute volume provide greater dermal, oral, and

respiratory uptake of chemicals. Children are at greater risk than adults to develop methemoglobinemia when exposed to oxidant stresses based on low NADH methemoglobin reductase activity. Other factors rendering them more susceptible to toxins include lower oxygen-carrying capacity, owing to lower baseline hematocrits, and greater susceptibility to bronchospasm following exposure to inhaled toxins.⁹ When wet, infants develop rapid hypothermia; therefore, special consideration for decontamination will need to be made with the use of warm liquids and control of ambient temperature. Finally, ocular irrigation is difficult in children. One method involves the use of a "papoose" followed by flooding the bridge of the nose with normal saline rather than the eyes directly.

This chapter discusses the pharmacology and toxicology of specific chemical agents: nerve agents (organophosphate-like substances); vesicants (blistering agents); respiratory toxins; metabolic toxins (including cyanide); riot-control agents; and incapacitating agents.

TABLE 185-1 Some Common Hazardous Materials Toxidromes

	NERVE AGENTS	VESICANTS	RESPIRATORY AGENTS
Substances	Tabun, Sarin, Soman, GF, VX	Lewisite, phosgene, nitrogen, and sulfur mustards	Phosgene, chlorine, vinyl chloride, nitrogen oxides, ammonia
Symptoms	Pinpoint pupils Eye pain Dyspnea, bronchospasm Muscle fasciculations Weakness Seizures, coma Tachycardia or bradycardia Diaphoresis Salivation Lacrimation Vomiting and diarrhea Abdominal cramps	Low doses cause vesicant response Skin erythema Skin blistering Cough and hoarseness Corneal ulcers Bronchospasm Sloughing of bronchial epithelium Phosgene: urticaria	Respiratory distress Pulmonary edema
Antidotes	Oxygen Atropine Pralidoxime (2-PAM) (See Chap. 182)	Supportive care Water irrigation BAL for Lewisite (See Chap. 179)	Possibly nebulized NaHCO ₃ for chlorine
	METABOLIC TOXINS	RIOT CONTROL AGENTS	INCAPACITATING AGENTS
Substances	Cyanides Hydrogen sulfide Carbon monoxide Ricin	Mace* Capsaicin (pepper spray)	BZ (3-quinucidinyl benzilate) Stimulants Potent opioids Hallucinogens Nausea producing drugs
Symptoms	Coma Seizures Death	Lacrimation Eye irritation Rhinoirrhoea Coughing, sneezing Bronchospasm	Non-lethal effects that prevent performance of duties
Antidotes	Cyanide kit for cyanides and hydrogen sulfide (see Chap. 188) 100% oxygen or hyperbaric oxygenation for CO (see Chap. 203)	Water irrigation Treat bronchospasm	Symptomatic treatment
	HYDROCARBONS		
Substances	Halogenated hydrocarbons Freons Aromatic hydrocarbons		
Symptoms	Confusion, lethargy Coma Cardiac dysrhythmias Freons: respiratory distress		
Antidotes	Symptomatic treatment Avoid sympathomimetic agents		

*Mace = omega-chloroacetophenone.

TABLE 185-2 Dermally Absorbed Agents Through Intact Skin Resulting in Systemic Toxicity

Acrylamide
Acrylonitrile, acetonitrile, propionitrile
Aniline
Chlordane
Dinitrophenol
Hydrocarbons: benzene, gasoline, toluene, toluene diisocyanate, xylene (all slowly absorbed)
Hydrogen cyanide, cyanide salts
Hydrofluoric acid
Metals (organic mercury, thallium)
Methyl bromide
Methylene chloride (slow)
Nerve agents
Nitrates
Nitrobenzene
Pesticides
Phenol
T2 toxin (biological)
Others: may be absorbed through abraded skin

NERVE AGENTS

The *nerve agents* are currently the most toxic chemical threats known. These organophosphates were developed by the Germans around World War II, placed in munitions, yet never employed on the battlefield. Despite the cessation of chemical synthesis for military use, precursors are commonly found in industry. Five organophosphate compounds are recognized as nerve agents: tabun (GA), sarin (GB), soman (GD), GF (believed to be obsolete), and VX. Properties of these liquids vary in terms of vapor pressure, persistence in the environment, and potency. VX is the most potent and persistent with a potentially fatal exposure involving a skin area of only 2 to 3 mm in diameter. GB is the most volatile. The nerve agents are mildly irritating to the eyes, mucous membranes and respiratory tract with odors variably described as fruity (tabun), odorless (sarin, VX), or fruity/camphorous (soman) (Table 185-5).

The nerve agents are powerful inhibitors of acetylcholinesterase (AChE), found in nerve, skeletal muscle, glands, and other tissues in-

nervated by cholinergic neurons. Additionally, red blood cell (RBC) cholinesterase and plasma pseudocholinesterase are inhibited and serve as laboratory markers of toxicity. The ability of nerve agents to interfere with normal acetylcholine hydrolysis at cholinergic synapses causes accumulation of this neurotransmitter and greatly enhanced neurotransmission. Excess acetylcholine at brain synapses, for example, results in seizures, coma, respiratory depression, and apnea. Acetylcholine accumulation at the motor endplate causes initial fasciculations with progression to weakness and paralysis. Overstimulation of sympathetic and parasympathetic ganglia of the peripheral nervous system results in tachycardia, hypertension, diaphoresis, miosis, lacrimation, salivation, bronchorrhea, bronchospasm, bradycardia, vomiting, diarrhea, and urination.

The onset and type of symptoms are determined by both concentration and route of exposure to nerve agents. Following sarin vapor inhalation, death may occur within minutes. Similarly, VX dermal exposure may cause death within minutes if the exposure is massive, but symptoms may be delayed for up to 18 h following milder dermal exposures. Vital sign abnormalities may result from stimulation of both the sympathetic and parasympathetic ganglia. While bradycardia is expected from stimulation of the parasympathetic nervous system, 90 percent of patients exposed to nerve agents have normal heart rates or are tachycardia. Vapor exposure typically creates a triad of ocular, nasal, and respiratory symptoms. The eyes and nose are most sensitive, with miosis, conjunctival injection, pain, and rhinorrhea developing at low doses. At higher concentrations, respiratory effects such as chest tightness, dyspnea, and copious secretions ensue. Neurologic findings with severe exposures include giddiness, collapse, convulsions, fasciculations, and flaccid paralysis. The predominant cause of death is from centrally mediated respiratory depression and apnea. In contrast to vapor exposure, dermal exposure results in a unique pattern of symptom onset and progression. Miosis may not be evident initially, but localized sweating and fasciculations will be noted surrounding the exposed area. Nausea, vomiting, diarrhea, and fatigue develop with increasing dose. As with vapor exposures, the presence of respiratory and neurologic symptoms indicate severe toxicity.

Once a nerve agent release has been recognized, self-protection and patient decontamination take precedence over other medical treatment. There is an extremely high risk of secondary contamination to the medical personnel caring for exposed patients. Appropriate skin and respiratory protection should be donned by the hospital staff because these agents are readily absorbed by all routes (e.g., skin, mucous membranes, respiratory tract). Neither surgical nor high-efficiency particulate-arresting (HEPA) masks render protection from these agents. Even double latex gloves are ineffective in preventing dermal exposure, and butyl rubber gloves should be worn. Removal of patient clothing alone may provide significant decontamination in those who are ambulatory. While a 0.5 percent sodium hypochlorite solution (9:1 household bleach to water) effectively inactivates nerve agents, its use on patients is inadvisable. Copious amounts of tepid water with a mild soap should be adequate for skin decontamination in most situations. However, a considerable amount of VX may remain on the skin even after initial decontamination, necessitating several washings and awareness of the potential for secondary contamination.

Following decontamination, restoring oxygenation is the single most critical step, because most deaths are respiratory in nature. Succinylcholine, if used to facilitate intubation, may have prolonged effect because the plasma cholinesterase level is inhibited. Cardiac monitoring for dysrhythmias should be instituted. Described dysrhythmias include torsade de pointes. Specific antidote therapy with atropine and pralidoxime chloride (2-PAM) should be anticipated. Atropine blocks muscarinic receptors and reverses the parasympathetic findings of lacrimation, bronchorrhea, bronchoconstriction, salivation, and gastrointestinal spasm, along with some central nervous system (CNS) manifestations. It does not affect the motor endplate or symptoms of fasciculations or weakness. The dose is best determined by signs, symptoms, and route of exposure. In contrast to organophosphate pesticide

TABLE 185-3 Toxins with Delayed Onset of Symptoms or Requiring Prolonged Monitoring

Acrylonitrile, acetonitrile, propionitrile	Cyanide toxicity
Aniline	Methemoglobinemia
Arsine	Hemolysis
Benzene	Bone marrow suppression and leukemia
Cadmium	Pulmonary toxicity
Chlorine	Pulmonary edema
Ethylene oxide	Pulmonary edema and neurotoxicity
Halogenated solvents	Hepatorenal toxicity
Hydrofluoric acid	Pulmonary edema, dermal burns, electrolyte changes
Hydrogen sulfide	Pulmonary edema
Metals	Hepatorenal, neurotoxicity
Methanol	Neurologic, acid-base disturbance
Methyl bromide	Pulmonary edema
Methylene chloride	Carbon monoxide toxicity, dysrhythmias
Organophosphates (highly lipid soluble), or dermal exposure to nerve agents	Cholinergic toxicity
Nitrogen oxides	Pulmonary edema, methemoglobinemia
Ozone (rare)	Pulmonary edema
Paraquat	Pulmonary edema/fibrosis
Phosgene	Pulmonary edema
Phosphine	Pulmonary edema
Zinc phosphide	Pulmonary edema

TABLE 185-4 Differential Diagnosis of Agents Causing Dyspnea

Agent	Findings	Onset	Irritant?
Phosgene (CG)	Pulmonary edema	Delayed	Mild/none
Nerve agents	Increased secretions/bronchospasm	Immediate (vapor); delayed (dermal/liquid)	Mild
Vesicants:			
Mustards (H)	Coughing, hoarseness (central airways most commonly affected) Pulmonary hemorrhage/airway necrosis (rare)	Delayed	Yes
Lewisite (L)	Coughing, hoarseness (central airways most commonly affected) Pulmonary hemorrhage/airway necrosis (rare)	Immediate	Yes
Phosgene oxime (CX)	Eye, mucous membrane, upper airway irritation Pulmonary edema (with inhalation and skin application)	Immediate	Yes
Chlorine	Coughing, nausea and vomiting (low level) Pulmonary edema (high level)	Immediate Delayed	Yes
Ammonia	Coughing, hoarseness, bronchospasm	Immediate	Yes
Hydrogen sulfide	Burning eyes and mucous membranes Pulmonary edema	Immediate Delayed	Yes
Riot control agents (CS, CN, OC)	Coughing, eye and mucous membrane burning (more intense than other agents)	Immediate	Yes
Cyanide (AC, CK)	Normal lung exam	Immediate	No

poisoning, high-dose or continuous atropine therapy generally is not necessary beyond 2 to 3 h following nerve agent exposure. **The end point for dosing of atropine is drying of pulmonary secretions.** Miosis is not a useful therapeutic end point, and sinus tachycardia is **not** a contraindication for the use of atropine. Oximes, like 2-PAM, are effective nerve agent antidotes via their ability to reactivate AChE. They carry out a nucleophilic attack on the nerve agent phosphorylated to AChE. Subsequent liberation of the enzyme occurs along with detoxification of the nerve agent. Whereas atropine is not effective in treating neuromuscular findings such as weakness or fasciculations, oximes reverse the nicotinic, muscarinic, and CNS effects of the nerve agent. One caveat to the use of oximes is the need for administration prior to "aging" of AChE. Aging is the process whereby permanent inhibition of AChE activity occurs as a result of nerve agent alkyl group hydrolysis and covalent binding. This reaction, which occurs within

2 min of soman exposure and within 5 h of sarin exposure, provides a rationale for early 2-PAM therapy. Like atropine, 2-PAM dosing in adults is determined by route of exposure and signs and symptoms (see Table 8-2). In contrast to organophosphate pesticide exposures, long-term or continuous infusions of 2-PAM have not been required in the management of victims of nerve agent exposure.

Seizures generally are not persistent once ventilatory support, atropine, and 2-PAM therapy are instituted. If present, they should be treated aggressively with benzodiazepines, which may be neuroprotective. Military Mark I autoinjector kits contain 2 mg atropine and 600 mg 2-PAM for immediate intramuscular administration in the field. The emergency physician should be familiar with this form of these antidotes, because these kits may be stockpiled for civilian first-responder use. Symptomatic patients or those with dermal exposures should be kept under close observation for 24 h.

TABLE 185-5 Nerve Agent Symptoms, Severity, and Treatment Summary

Exposure Route	Category	Signs and Symptoms	Drug Therapy
Inhalational (vapor)	Minimal	Miosis, rhinorrhea	Observation
		Visual complaints	Consider homatropine eye drops for intractable eye pain
	Mild	Miosis, rhinorrhea, and mild dyspnea	Atropine 2 mg* 2-PAM 600 mg
	Moderate	Miosis, rhinorrhea, moderate to severe dyspnea, nausea, vomiting	Atropine 4 mg 2-PAM 1200 mg
Dermal (liquid)	Severe	Severe dyspnea, copious secretions, nausea, vomiting, diarrhea, coma, seizures, flaccid paralysis, apnea	Atropine 2 mg* 2-PAM 600 mg
	Mild	Localized sweating, fasciculations	Atropine 2 mg* 2-PAM 600 mg
		Above plus nausea, vomiting, diarrhea	Atropine 6 mg 2-PAM 1800 mg
	Moderate	Above plus respiratory or neuromuscular signs (same as "severe inhalational" above)	

*May be given IM or IV Pediatric dose = 0.02 mg/kg (minimum 0.1 mg). Initial doses may be repeated every 10–15 min or administered by continuous infusion at 0.02–0.08 mg/kg per h. Higher doses (5 mg in adults or 0.05 mg/kg in children) may be needed to treat severe exposures. 2-PAM is most effective if given intravenously, although the IM route is an acceptable alternative. Adult doses begin at 600 mg. The pediatric dose is 25–50 mg/kg and may be repeated in 1 h if symptoms are worsening.

VESICANTS

The terrorist use of vesicants, or agents that produce blisters, would overwhelm the ED with patients presenting with severe dermal conditions. The toxicology of these agents is summarized below.

The three primary vesicants are mustards, lewisite, and phosgene oxime. Mustards are the most viable threat among this group, as more than a dozen countries have mustard in their arsenals and because mustards are the easiest of the chemical agents to synthesize. During World War I, mustards caused more casualties than all other chemical agents combined. More recently, 45,000 casualties occurred following their use during the Iran-Iraq war of the 1980s. Sulfur mustards (H, HS, HD) are alkylating agents that are highly reactive and electrophilic. They induce toxicity through rapid adduct formation with peptides, proteins, ribonucleic acid (RNA), deoxyribonucleic acid (DNA), and cell membranes and disappear from extracellular fluids within a few minutes. They are oily liquids with an odor of garlic, horseradish, or mustard. The median lethal dose (LD₅₀) is approximately 1.5 teaspoons, which can result in a 25 percent body surface area (BSA) burn.

Clinical effects are somewhat dose dependent. At low doses, vesication occurs, whereas at higher doses, systemic cytotoxicity is seen. Characteristically, symptoms are delayed for 4 to 8 h. Eyes, skin, and airways are relatively equally affected. Skin findings include initial erythema that progresses to blister formation over 24 h. Warm, moist areas are affected most. Ocular findings are similarly delayed and include edema of the lid, conjunctival injection, and corneal ulceration, with the most severe exposures. Respiratory involvement manifests as a dry, barking cough and hoarseness beginning 4 to 6 h postexposure. Early tachypnea or dyspnea indicates exposure to a potentially lethal amount of mustard. In such cases, bronchospasm, bronchiolar obstruction by sloughed pseudomembranous bronchial epithelium, and hemorrhagic pulmonary edema may ensue over 1 to 2 days. Systemic absorption is seen with massive exposures and results in hematopoietic, gastrointestinal tract, and CNS involvement. Overall, the expected mortality is approximately 3 percent for those reaching medical facilities.

Lewisite

Lewisite (L) is an oily colorless liquid with the odor of geraniums. It has a potency similar to that of mustard. It was used by Japan during wartime, and known stockpiles of a Lewisite-mustard mixture are possessed by Russia. While its active ingredient, trivalent arsenic, inhibits various enzymes throughout the body and interferes with glycolysis, the mechanism for vesication is not clear. In contrast to mustard exposure, skin irritation and pain are characteristically present within 15 to 30 min of Lewisite exposure. Blister formation also occurs more quickly than that seen with mustard exposure (within 2 h). Resulting lesions have less surrounding erythema and result in more tissue destruction than those caused by mustards. Ocular pain and irritation also occur within minutes, and fortunately in most cases, reflex blepharospasm seems to prevent the severe ocular injury seen with mustard exposure. Pulmonary involvement is characterized by immediate upper airway irritation and central airway inflammation. Parenchymal involvement is rare and progression to pulmonary edema occurs only in the most severe cases. Hypotension and hemolytic anemia are seen rarely and result from systemic arsenic toxicity.

Phosgene

Phosgene oxime (CX), an agent that causes extensive tissue damage, is discussed here even though it is not a true vesicant. It is actually an urticaric with an unknown mechanism of action. Following exposure, instantaneous pain and irritation of the skin, eyes, and airways

occurs. The affected skin then blanches, turns grayish, and becomes urticarial, erythematous, and edematous. Vesicle formation does not occur. Necrosis of the area may penetrate to the muscle layers and results in eschar formation. Ocular findings are similar to those described for Lewisite. Pulmonary edema is common and bronchiolitis has been described.

The diagnosis of vesicant exposure is a clinical one. Urinary thiodiglycol metabolites will confirm exposure to sulfur mustards, but this test is not widely available. Treatment begins with immediate skin and eye decontamination, ideally within 1 to 2 min of exposure. This is the only effective way of preventing tissue damage. Late decontamination is recommended, however, to prevent spread to uninvolved areas of the skin and to medical or rescue personnel. Copious soap and water decontamination is appropriate for the skin. A dilute hypochlorite solution is recommended by some for skin decontamination of the relatively water-insoluble mustards and Lewisite, but this is controversial. Water alone is the preferred decontamination solution for phosgene oxime. BAL (British anti-Lewisite, or dimercaprol) is an arsenic chelator that will prevent or greatly decrease the severity of skin and eye lesions if applied topically within minutes of Lewisite exposure, but the topical form is not widely available. Given intramuscularly, BAL reduces the mortality from systemic effects of Lewisite. There are no antidotes for mustard poisoning, although mustard scavengers, antioxidants, nicotinamide-adenine dinucleotide (NAD) precursors, polymerase inhibitor, and corticosteroids are investigational. As with thermal burns, aggressive airway, fluid, electrolyte, and pain management coupled with prevention of secondary infection with topical antibiotics and sterile dressing changes is the mainstay of therapy. In contrast to thermal burns, however, mustard burns do not trigger the same magnitude of fluid loss. All burns resulting from caustic chemicals are classified as "major" by the American Burn Association and should be referred to a burn center.

RESPIRATORY AGENTS

Gases, mists, aerosols, fumes, or dusts may be inhaled. Determinants of airborne agent toxicity include many factors such as concentration of the inhaled toxin, duration of exposure, and whether the exposure occurred in an enclosed space. Other influential factors include vapor density, allergic or nonallergic bronchospastic response, exertional state or metabolic rate of the victim, and unique host susceptibility such as the underlying reactive airways disease, history of smoking, or extreme age. Aspiration of gastric contents may cause further pulmonary insult.

Other primary determinants of injury pattern include toxin particle size and solubility in water. Agents with particle diameters greater than 10 μ m or that are highly water-soluble are deposited primarily in the upper airways. Examples of water-soluble chemicals include ammonia, sulfur dioxide, and acid gases such as hydrochloric acid and sulfuric acid. Following exposure, signs of upper airway irritation develop rapidly and are accompanied by eye and mucous membrane irritation. Coughing, wheezing, or stridor may progress to upper airway obstruction in severe exposures. Those inhaled toxins of smaller particle size or lower water solubility such as phosgene, ozone, or nitrogen oxides will reach the lower respiratory tract and may result in delayed symptom onset. Gases with intermediate water solubility, such as chlorine, may cause early irritative symptoms following mild exposure or delayed pulmonary edema after massive exposure.

The presence of smoke complicates the ability to predict patterns of illness following toxin inhalation. Because it is particulate, smoke carries adherent products of combustion such as acrolein, ammonia, acids, and diisocyanates deeper into the lungs than normally would be expected. Thermal physical damage to the respiratory tract also may occur, particularly in the presence of steam. General management of the patient with toxic inhalation injury involves removal from the

source, application of 100 percent oxygen, humidification for irritative symptoms, and inhaled bronchodilators for bronchospasm. A detailed examination should include inspection of the upper airway for evidence of singed nasal hair, soot in the oropharynx, facial or oropharyngeal burns, erythema or parching of the mucous membranes, stridor, hoarseness, dysphagia, cough, carbonaceous sputum, tachypnea, retractions, accessory muscle use, wheezing, rales, diaphoresis, or cyanosis. Early intubation should be considered for patients with upper airway edema. Pertinent laboratory studies include arterial blood gas analysis with carboxyhemoglobin, methemoglobin, and lactate levels; RBC cyanide levels if persistent acidosis occurs; electrocardiographic (ECG) monitoring; and chest x-ray. The role for diagnostic or therapeutic bronchoscopy in inhaled toxin exposure is controversial. Administration of sodium thiosulfate to victims of smoke inhalation with persistent acidosis suspected to have cyanide toxicity is indicated. Management of noncardiogenic pulmonary edema may involve the use of positive end-expiratory pressure or bilevel positive airway pressure (BiPAP), but diuretics generally are not indicated. The use of prophylactic steroids with antibiotics is reserved for nitrogen oxide exposures. Systemic toxicity from products of combustion such as cyanide or carbon monoxide is common and is reviewed in Chaps. 188 and 203, respectively.

Many highly toxic gases produced in large quantities in the industrial sector are potential agents for malicious use. Those with a history of previous battlefield use or stockpiling, such as phosgene, chlorine, or ammonia, are of particular concern. Their toxicology is summarized below, and in Table 185-1.

Phosgene

Phosgene (CG, carbonyl chloride, D-Stoff, or green cross) is a gas with a density four times that of air. Beyond its military application, it is found in the plastics, pharmaceutical, and textile industries. Upon release, it forms a white cloud with a characteristic odor of newly mown hay. It is relatively water insoluble and therefore has poor warning properties. Only mild initial eye, nose, throat, and upper airway irritation are expected, and these may be entirely absent. The major toxicity involves an acid burn to lower airways as phosgene reaches the alveoli and hydrolyzes to carbon dioxide and hydrochloric acid. Acylation of alveolar capillary membranes results in diffuse capillary leak and noncardiogenic pulmonary edema, which is characteristically delayed for up to 24 h. This clinical latent period is followed by onset of dyspnea and chest tightness, heralding the onset of pulmonary edema. If the exposure is massive, immediate dyspnea and mucous membrane and eye irritation may occur. The onset of dyspnea or pulmonary edema within 4 h of exposure suggests a very poor prognosis. Those who become symptomatic greater than 6 h after exposure generally survive if intensive medical care is available. Recovery occurs in 3 to 4 days with respiratory supportive care and management of noncardiogenic pulmonary edema. Because exertion is known to increase pulmonary edema from phosgene, rest is mandatory for those exposed. Furthermore, a 24-h observation period with frequent reassessments is indicated for asymptomatic patients.

Chlorine is also widely available in the industrial sector, in the setting of laboratories, paper manufacture, swimming pool chemical distribution, and municipal water treatment. When dispersed, this dense green-yellow gas has an acrid, pungent odor and excellent warning properties. It is of intermediate water solubility, which is consistent with the observation that moderately exposed World War I soldiers exhibited both central airway damage and pulmonary edema. Early inflammatory injury results from the formation of acids and oxidants upon contact with moist membranes. Immediate ocular and upper airway irritation along with nausea and vomiting are common following

mild exposures. More significant exposure results in coughing, hoarseness, and pulmonary edema, usually within 12 to 24 h. Permanent reactive airways disease has been described following significant chlorine gas inhalation. Care is primarily supportive with the use of humidified oxygen and bronchodilators as needed. The role of nebulized sodium bicarbonate as a neutralizing therapy is controversial.¹⁰ Chlorine may cause dermal injury at high concentration and skin decontamination may be required.

Nitrogen Oxides

Nitrogen oxides are encountered in the form of silo gas ("silo filler disease"), as products of fire combustion, in industrial processes, or as components of military blast weapons, smokes and obscurants. These oxides have limited water solubility and generally result in mainly lower airway toxicity. Slow conversion of nitrogen oxide to nitric acid in the alveoli results in delayed alveolar injury and pulmonary edema. A triphasic illness typically is seen with initial dyspnea and flulike symptoms, transient improvement, and then worsening dyspnea, which heralds the onset of pulmonary edema 24 to 72 h after exposure. Methemoglobinemia also may occur. Bronchiolitis obliterans, a potential late complication, may be prevented by the use of steroids.

Ammonia

Ammonia, widely available as a fertilizer and industrial chemical, is a highly water-soluble, colorless, alkaline corrosive gas. It has good warning properties and rapidly reacts with wet surfaces to form ammonium hydroxide. The presence of ammonia is usually obvious based on its characteristic pungent odor and immediate induction of symptoms of mucous membrane, eye, and throat irritation. Lower airway involvement resulting in bronchospasm, pulmonary edema, and residual reactive airways disease have all been described following massive exposures, especially in those who are entrapped in enclosed spaces. Treatment is supportive with humidified oxygen and bronchodilators. Anhydrous ammonia is extremely hazardous to the eyes and can penetrate the anterior chamber within 1 min of exposure. Therefore, following ocular irrigation in symptomatic patients, evaluation for the presence of corneal burns should be considered and a careful ophthalmologic examination is warranted.

Many of the chemical warfare agents can cause dyspnea. Table 8-2 outlines the differentiating features.

Overall, treatment for respiratory agents is supportive and involves removal from the source of exposure, executing the ABCs (airway, breathing, and circulation), application of humidified oxygen, and enforced rest. Flushing of the eyes and skin should be carried out as appropriate. Copious airway secretions, hypoxia, bronchospasm and pulmonary edema should be anticipated. Antibiotics are reserved for those with positive sputum gram stains or cultures. No human studies have shown benefit from the use of steroids. Their use may be considered in those with underlying reactive airway disease or nitrogen oxide exposure (see above).

METABOLIC TOXINS

Cyanide

Cyanide (AC hydrocyanic acid, CK cyanogen chloride) is the least toxic of the lethal military agents. It was employed by the French during World War I, the Nazis in World War II, and by Iraq in the 1980s. It is a popular homicidal/suicidal agent, especially among chemists and laboratory workers. Nonmilitary incidents include a mass cult suicide of the People's Temple in Guyana, Tylenol product tampering, and the World Trade Center bombing. Cyanogen sources are natural (plants), medicinal (nitroprusside), industrial (300,000 tons produced

annually), fire-related (from the combustion of organonitrogen or plastics), and commercial (solvents acetonitrile, propionitrile). The military agent AC is a volatile, nonpersistent liquid or gas with the odor of bitter almonds detectable by 40 percent of the population, whereas CK is odorless and slightly irritating to mucous membranes. Cyanide is covered in detail in Chap. 188.

Hydrogen Sulfide

Hydrogen sulfide is a colorless, flammable gas that may be encountered in industry or as a natural product of organic decomposition, such as sewer or manure gas. The ability to detect its characteristic "rotten egg" odor is lost at high concentrations or with lengthy exposures to low concentrations. Its mechanism of toxicity is similar to that of cyanide, with disruption of oxidative phosphorylation through inhibition of cytochrome oxidase aa3. Cellular asphyxia and impaired adenosine triphosphate (ATP) production promote anaerobic metabolism with lactate accumulation and metabolic acidosis. It is one of the few chemical asphyxiants that also possesses irritative properties, such that respiratory and ocular irritation are common following exposure. In high concentrations, rapid loss of consciousness, seizures, and death may occur after only a few breaths. Delayed pulmonary edema and corneal destruction should be anticipated with massive exposures. Treatment involves decontamination of the skin and eyes as appropriate. Administration of the nitrite component of the cyanide antidote kit to promote low-level methemoglobin formation may result in conversion of sulfide to less toxic sulfmethemoglobin. Other treatments include 100 percent oxygen and possibly hyperbaric oxygen therapy. Phosphine and azide exposure may cause similar clinical symptoms and metabolic derangements as cyanide. Carbon monoxide is discussed in depth in Chap. 203.

Miscellaneous Industrial Toxins

Derivatives of aniline or nitrites are the industrial chemicals most frequently associated with RBC oxidant stress. Other workplace hematologic toxins include chlorates, benzene, acetanilid, nitrogen oxides, nitrophenols, para-toluidine, phenols, and sulfonamides.

Ricin is a plant cytotoxin that attacks rRNA and is a ribosome inhibiting protein. It is made from the mash by-product of castor bean processing. It is available as a powder, mist, or pellet, or can be dissolved in water or a weak acid. It is extremely stable and is unaffected by extreme heat or cold. When injected, as little as 500 (xg can cause death. When ricin is injected, multi-organ failure and coagulopathies result in death within 36 h. Ingestion results in multi-organ failure and profuse gastrointestinal bleeding. Inhalation results in acute respiratory distress, followed by pulmonary edema. There is no laboratory test to confirm the diagnosis. The only treatment available is supportive care. Suspected ricin poisoning should be reported to the Agency for Toxic Substances and Disease registry (ATSDR) at 1-888-422-8737. (<http://www.bt.cdc.gov/agent/ricin/faq/index.asp>).

HYDROCARBONS

Certain solvents such as halogenated hydrocarbons, Freons (chlorofluorocarbons), and aromatic hydrocarbons may sensitize the myocardium to the dysrhythmic effect of catecholamines. Myocardial irritability may persist for several hours following exposure. Avoidance of physical activity or sympathomimetic drugs, other than selective (β_2) agonists, for the treatment of bronchospasm is warranted. Furthermore, **direct-current countershock cannot be administered to patients soaked with flammable chemicals** until decontamination has been carried out due to fire and explosion risk. Hydrocarbon inhala-

tion also results in early stimulation, followed by confusion, lethargy, stupor, or coma. Freons cause intense respiratory symptoms, which can persist for years.¹¹

RIOT CONTROL AGENTS

Riot control agents such as mace, or capsaicin (pepper spray) belong to a group of compounds that cause transient but intensely noxious effects on exposure. Although generally considered to be only briefly incapacitating, fatalities from pulmonary edema have occurred following large exposures in confined spaces. Typically, symptoms include immediate irritation of the eyes and respiratory tract, blepharospasm, lacrimation, coughing, sneezing, and rhinorrhea, followed by a burning sensation of exposed skin and mucous membranes. Nausea, vomiting, headache, and photophobia may be seen. These symptoms usually disappear within a few hours after cessation of the exposure. Burns and sensitization of the skin have been described, especially if contact with the agent is prolonged. Management includes removal of the patient from the area, copious irrigation of the eyes with normal saline, and skin decontamination with soap and water. Contact with water can briefly exacerbate skin symptoms from CS. The use of bleach solutions to decontaminate the skin is not recommended as this may increase irritation or trigger blister formation from some agents. Patients with preexisting lung disease should be observed and treated for bronchospasm.

INCAPACITATING AGENTS

Military incapacitating agents produce physiologic or mental effects that render the exposed victim unable to perform assigned duties. These agents are generally not lethal, but recovery may take several hours to days. The anticholinergic deliriant, 3-quinuclidinyl benzilate (QNB, BZ) is of military interest. BZ's clinical profile most closely represents that of atropine, with a slower onset and longer duration of action. Recognition of an anticholinergic toxidrome is key to diagnosing a BZ exposure. Expected symptoms are delirium, hallucinations, mydriasis, tachycardia, ileus, dry mucous membranes, absent axillary sweat, urinary retention, and hyperthermia. Treatment involves supportive care and sedation with benzodiazepines to prevent hyperthermia and rhabdomyolysis. In the past, physostigmine was used to reverse the action of BZ, and was associated with untoward side effects. Its use should be reserved for patients with refractory seizures or tachycardia.

Incapacitation can be produced by a variety of other chemical agents including stimulants, potent opioids, hallucinogens, or nausea-producing drugs. Their battlefield use is problematic, but covert or terrorist use is possible.

ACKNOWLEDGMENT

VITAMINS AND HERBALS G.

Richard Braen

Vitamins and herbal preparations, particularly those sold in health food stores, are considered by many to be innocuous, but several have tremendous potential as toxins. This chapter covers most of the available vitamins and selected herbals. Agents compounded with vitamins, such as iron, are covered in other chapters. Helpful resources include: Natural Medicines Comprehensive Database (<http://www.naturaldatabase.com>); NIH Office of Dietary Supplements (<http://dietary-supplements.info.nih.gov>); and HerbMed (www.herbmed.org).

VITAMIN A

Vitamin A has two primary preformed types: retinol (vitamin A₁) and 3-dehydroretinol (vitamin A₂). The retinyl esters of dietary vitamin A are hydrolyzed into retinol in the gastrointestinal tract. Retinol is then absorbed into intestinal mucosal cells where it combines with a fatty acid to again become a retinyl ester. The retinyl ester then travels through the lymphatic system and bloodstream to storage sites in the liver. The liver contains approximately 95 percent of the vitamin A of the entire body.

Vitamin A forms part of the visual pigments of the retina (rhodopsin and iodopsin), is important for the formation of mucus-secreting cells of the columnar epithelium, maintains bone growth, and maintains cellular membrane stability. The daily adult recommended doses range from 4000 IU for women to 5000 IU for men.

Hypervitaminosis A generally occurs when children are given excessive amounts of a high-potency supplement. Retinol is bound to a liver protein (retinol-binding protein) and is stored in this bound form. As the liver binding and storing capacities are exceeded, blood levels of a retinyl ester loosely bound to low-density lipoproteins increase. This loosely bound vitamin is believed to be toxic to cell membranes. Members of Mawson's Antarctic expedition (1911-1913) are said to have died from hypervitaminosis A after eating the livers of their dogs to try to avoid starvation.

When the total dosage is similar, water-miscible preparations are more toxic than oily preparations because of better absorption. High doses of preformed vitamin A must be ingested for long periods before signs and symptoms of hypervitaminosis A develop. There is a high degree of variability among patients in the amounts necessary to develop hypervitaminosis. Dialysis patients can be at risk of developing a type of vitamin A toxicity in which resorption of bone causes hypercalcemia.

Symptoms of hypervitaminosis A include blurred vision, appetite loss, abnormal skin pigmentation, loss of hair, dry skin, pruritus, long-

bone pain, and an increased incidence of bone fractures. Massive doses can additionally cause pseudotumor cerebri.

The treatment of hypervitaminosis A depends on the condition of the patient. Generally, when vitamin A is discontinued, the symptoms resolve over a period of time and no additional treatment is needed.¹ Chap. 27 outlines treatment of hypercalcemia. pJ-Carotene intoxication is very rare and does not generally cause hypervitaminosis A. In diabetics and patients with hypothyroidism, however, large doses of p-carotene can cause a yellowish discoloration of the skin, which fades once β -carotene is stopped.

VITAMIN D

Vitamin D function comes from two major compounds: calciferol (vitamin D₃) and ergocalciferol (vitamin D₂). The naturally occurring provitamin forms of each of these two compounds (7-dehydrocholesterol for D₃ and ergosterol for D₂) convert to the active forms following irradiation by ultraviolet light. Most studies in humans have been made on vitamin D₃ (cholecalciferol), which is converted in the body to 1,25-dihydroxycholecalciferol, the physiologically active form of vitamin D.

Absorption of vitamin D is aided by bile and takes place in the jejunum. From there it is transported via lymph chylomicrons to the bloodstream.¹ When it reaches the liver, it is hydroxylated to 25-hydroxycholecalciferol. From the liver, it travels to the kidney, where it is again hydroxylated to 1,25-dihydroxycholecalciferol. The major function of 1,25-dihydroxycholecalciferol is to elevate the plasma calcium and phosphorus levels to enable normal bone mineralization.

The average daily adult requirement of vitamin D is approximately 400 IU, and therapeutic doses sometimes exceed 5000 IU. Infants may develop hypercalcemia from doses as low as 2000 IU, but adults require much higher doses before toxicity develops. The toxicity results from the hypercalcemia and includes anorexia, nausea, abdominal pain, lethargy, weight loss, polyuria, constipation, confusion, and coma.¹ Symptoms from massive doses (1000 to 3000 IU/kg) develop in 2 to 8 days. Persistently elevated levels of calcium can cause soft tissue calcification and renal failure.

Treatment of hypervitaminosis D includes discontinuation of vitamin D, reduction of the calcium intake, and reduction of serum calcium levels.

VITAMIN E

Vitamin E activity is not limited to one compound alone. Eight different fat-soluble, naturally occurring alcohols (called tocopherols and tocotrienols) have vitamin E activity, but α -tocopherol is the most active form. Because of its ability to be rapidly oxidized, α -tocopherol protects other foods from being oxidized, and thus is termed an *antioxidant*.² Foods high in vitamin E include wheat germ, corn, soybean, sunflower seed, cod liver, and others.

Vitamin E is absorbed and distributed through the body just as any fat-soluble vitamin, through the intestines, and then through lymphatic chylomicrons. Between 30 and 90 percent of available vitamin E in the diet is absorbed. Normal tocopherol levels in adults range from 0.5 mg to 2.0 mg/dL. The minimum daily requirement for women is about 8 mg α -tocopherol; for men, it is 10 mg α -tocopherol. An IU is the activity of 1 mg of α -tocopherol. Vitamin E needs for children increase with increasing body weight and increase for pregnant or lactating women.

Vitamin E is felt to be nontoxic at daily doses of up to 600 IU. At doses higher than 600 IU per d, taken on a long-term basis, a metabolite of vitamin E acts as a competitive inhibitor of vitamin K-dependent γ -carboxylation, increasing the daily vitamin K requirements. Additionally, through the production of thromboxane, high levels of vitamin E inhibit platelet aggregation. People ingesting large amounts of vitamin E who are taking anticoagulants should be observed closely for bleed-

ing tendencies, but those not taking anticoagulants rarely have coagulation difficulties, except for neonates, who are more sensitive to the effects of vitamin E. Other effects in adults who take large doses for a long period of time include nausea, fatigue, headache, weakness, and blurred vision. These symptoms resolve weeks after discontinuation of the vitamin.

VITAMIN K

Vitamin K is represented by several compounds that have antihemorrhagic activity: the parent compound called menadione; vitamin K₁, which is a naturally occurring phyloquinone from plant sources; and vitamin K₂, which is a naturally occurring menaquinone from microbial sources. High levels of dietary vitamin A inhibit the absorption of vitamin K. Vitamin E at high levels acts as a vitamin K-antagonist in its liver production of clotting factors.

Phylloquinones are absorbed from the proximal intestine through an energy-requiring process. Menadione and menaquinones are absorbed from the lower intestine and colon through a passive mechanism. Both mechanisms require the presence of bile and pancreatic juice. Between 10 and 80 percent is absorbed. Once absorbed, it is carried by the lymph chylomicrons and then transferred in the blood to (3-lipoproteins. Approximately 50 percent of the vitamin comes from the diet and 50 percent from bacterial synthesis in the intestines. The total dietary requirement of vitamin K is about 2 (xg/kg body weight. Because most adults ingest a diet that contains 300 to 500 μ g vitamin K, deficiency states are uncommon. In contrast to the other fat-soluble vitamins, vitamin K is not stored in the body to any significant extent. Approximately 70 percent of menadione is excreted in the urine. Phylloquinone is excreted mainly in bile.

Vitamin K is required for the maintenance of normal prothrombin times through its effect on factor II (prothrombin), factor VII (proconvertin), factor IX (Christmas factor), and factor X (Stuart-Prower factor). These factors are part of the extrinsic, intrinsic, and common pathways for blood clotting. Coumarin compounds work on the clotting-factor synthesis sites in the liver to stop prothrombin synthesis and to reduce the levels of all vitamin K-dependent clotting factors.

Megadoses of menadione can be toxic. Toxic effects include hemolytic anemia, kernicterus, and hemoglobinuria in premature infants and renal tubular degeneration, liver damage, hypoprothrombinemia, and petechial hemorrhages in adults. Large doses can also paradoxically inhibit the effects of oral anticoagulants. Treatment includes stopping vitamin K, monitoring prothrombin times, and monitoring liver function studies. Additionally, doses exceeding 500 μ g daily are associated with skin rashes. Fatalities from overingestion of vitamin K are rare.

VITAMIN B₁ (THIAMINE)

Vitamin B₁ is converted to thiamine pyrophosphate which acts as a cofactor for several metabolic reactions, including transketolations. Measurement of erythrocyte transketolase activity is used to reflect the availability of thiamine pyrophosphate in the tissues. Food sources of thiamine include fruits, grain, meats, fish, and milk, among others. The highest levels are found in pork products (0.63 mg/serving). The average daily adult requirement is 1.5 mg.¹

Intestinal absorption of thiamine seems to be greatest in the jejunum. An active carrier-mediated absorption process occurs at normal levels of dietary thiamine, but passive diffusion is the major means of thiamine absorption at higher levels.

Thiamine is not stored in the body to any significant extent. At low dietary levels, renal excretion decreases, whereas, at high levels of ingestion, renal excretion increases proportionately. Because of the renal excretion of thiamine, there is no toxicity to the ingestion of large doses of vitamin B₁ over prolonged periods.

VITAMIN B₂ (RIBOFLAVIN)

Vitamin B₂ (riboflavin) works as an antioxidant through its activity in the formation of glutathione reductase and glutathione. As a part of the group of enzymes called flavoproteins, it is involved in the metabolism of fats, proteins, and carbohydrates. It is not stored in appreciable quantities in the body and must be replenished daily. Vigorous exercise increases the daily requirement of riboflavin, and a deficiency results in cracked lips, reddened tongue, and eczema of the face and genitals. The average daily adult requirement is 1.7 mg.¹

Riboflavin is excreted through the urine, and toxicity is rare regardless of the amount ingested. No adverse effects result from overdosage.

VITAMIN B₃ (NIACIN)

There are two active forms of niacin—nicotinic acid and nicotinamide—which, in conjunction with thiamine and riboflavin, have antipellagra activity. Niacin, thiamine, and riboflavin all function as a coenzyme in energy metabolism. Niacin becomes part of the coenzymes nicotinamide-adenine dinucleotide (NAD) and nicotinamide-adenine dinucleotide phosphate (NADP). NAD is required in all major metabolic pathways in which there is oxidative breakdown of amino acids, fatty acids, and other compounds. It also acts in the oxidation of ethanol.

Niacin is found in poultry, meat, and fish, with less found in plants. Niacin deficiency causes changes first in cells of the skin, nervous system, and gastrointestinal tract. Deficiency states create symptoms such as anorexia, anxiety, depression, irritability, and weakness.

Whereas doses of nicotinic acid in the range of 100 to 200 times the recommended allowance of 20 mg daily lowers serum cholesterol and (3-lipoprotein, nicotinamide does not. Large doses can also deplete cardiac muscle glycogen and can cause liver toxicity. Some patients experience a frightening "niacin flush" when taking a dose of more than 100 mg. The niacin flush, caused by histamine release and vasodilation, is characterized by face, neck, and chest burning, itching, and reddening.¹ It generally resolves within an hour. Antihistamines can provide symptomatic relief. Higher doses may additionally cause nausea, abdominal cramping, diarrhea, and headache. Even higher doses (2000 mg and above) over a prolonged period can produce abnormalities of liver function, impaired glucose tolerance, hyperuricemia, and skin changes such as dryness and discoloration. Subacute and chronic symptoms resolve within days to weeks.

VITAMIN B₆ (PYRIDOXINE)

Vitamin B₆ is a complex of three physiologically active compounds, the most active being pyridoxine. Pyridoxine is converted to pyridoxal-5-phosphate, which is a coenzyme in the transamination of amino acids that is required for the utilization of most amino acids for energy and for the synthesis of nonessential amino acids. A deficiency in vitamin B₆ in infants results in convulsive seizures (as a consequence of a reduced synthesis of 7-aminobutyric acid), anemia (caused by impaired synthesis of heme), xanthurenic aciduria (because of reduced formation of hydroxyanthranilic acid), cystathionuria (because of decreased cleavage of cystathionine to cysteine and homoserine), and homocystinuria (because of impaired formation of cystathionine). Deficiency states can be induced through ingestion of antagonists to vitamin B₆, such as isoniazid, cycloserine, and penicillamine.

Vitamin B₆ deficiency in infants may lead to growth retardation, weight loss, hyperirritability, convulsions, and anemia. Vitamin B₆ deficiency in adults may result in depression, convulsions, seborrheic dermatitis, and cheilosis. The daily requirement is 2.2 mg/d for men and 2.0 mg/d for women, with increased requirements during pregnancy and lactation. Many animal and vegetable sources contain vitamin B₆ (especially pork and glandular meats, legumes, potatoes,

oatmeal, wheat germ, and bananas), but there is considerable loss of the vitamin during cooking.

In high doses, particularly over a long period of time, vitamin B₆ excess will cause nerve damage. Most people can tolerate 20 mg/d without difficulty, but 5 g/d or more over several weeks will produce an unstable gait and numbness of the feet. This is followed by similar symptoms in the hands and arms. There may be a marked loss of position and vibration senses. After withdrawal of the vitamin, recovery occurs within several months. Some patients, however, have residual neurologic losses.

Vitamin B₆ also can cause intestinal inactivation of levodopa in patients receiving that medication for Parkinson disease. Patients should be instructed not to take the vitamin at the same time as the medication.

VITAMIN B₁₂

Vitamin B₁₂ deficiency causes pernicious anemia identified by macrocytosis (high mean corpuscular volume) and intramedullary hemolysis (very high lactate dehydrogenase level). Associated neurologic problems include symmetric paresthesias of the hands and feet, and decreased position and vibratory senses. Vitamin B₁₂ is a very potent vitamin (relatively small amounts are needed to treat patients with pernicious anemia) that takes several forms: cyanocobalamin (vitamin B₁₂), hydroxocobalamin (vitamin B_{12a}), aquocobalamin (vitamin B_{12b}), nitritocobalamin (vitamin B_{12c}), 5'-deoxyadenosylcobalamin (coenzyme B₁₂), and methylcobalamin (methyl B₁₂). All are complex nitrogenous compounds associated with cobalamin that participate in metabolic reactions necessary for the formation of amino acids, protein, and DNA.

Partially because of the size and complexity of the vitamin B₁₂ molecules, deficiencies of this water-soluble vitamin result more from absorption problems than from dietary insufficiencies.² Absorption depends on the production of intrinsic factor (IF) by the parietal cells of the stomach. Vitamin B₁₂-IF complexes are formed in the stomach. The complexes pass to the ileum, where IF attaches to the intestinal epithelium, facilitating the absorption of the vitamin B₁₂. Once absorbed, the cobalamin portion of the molecule attaches to the protein transcobalamin II, which carries the B₁₂ through the bloodstream to various tissues. Vitamin B₁₂ is stored in the liver in such quantities that it takes several years for pernicious anemia to develop in an individual who is a strict vegetarian and ingests little B₁₂ or in someone unable to produce IF. Meat, eggs, dairy products, and seafood contain vitamin B₁₂.

Health food enthusiasts believe that supplemental vitamin B₁₂ will energize the body, prevent mental deterioration, and protect against cancer, toxins, and infections. Because of the rate limited fashion in which vitamin B₁₂ is absorbed, there is no toxicity to the ingestion of large amounts of vitamin B₁₂. Overdosage from injection is rare and results primarily in a variety of skin changes that clear over 1 to 2 weeks.

BIOTIN

Biotin is produced in the intestines by bacterial action and is a cofactor in fatty acid synthesis. Deficiencies of biotin result in baldness and dry skin, lassitude, anorexia, depression, and hypercholesterolemia. Those taking chronic antibiotics and those on extremely low-calorie diets are at risk of developing a biotin deficiency. For such individuals, 100 to 300 [xg of biotin per day are recommended. There is no known toxicity to biotin overdosage.

FOLIC ACID

Folic acid is essential for the production of DNA, RNA, and proteins. Although folic acid may reverse the megaloblastic red blood cell aspects of pernicious anemia, it will not reverse the neurologic changes associated with pernicious anemia. It is found in fresh leafy green vegetables, yeasts, and liver. Folic acid is absorbed in the small and large

intestines in the form of polyglutamates. At the brush border of the intestinal cells, excess glutamates are removed from the folate molecule, making a functioning intestinal mucosa necessary for absorption.

The adult daily recommended dosage of folic acid is 400 fxg/d.² Dietary supplementation of 100 (xg/d will reverse the red cell changes of pernicious anemia but will not reverse the neurologic effects; therefore, preparations with more than 100 [xg are available only through prescription. Except for the problem with masking of the hematologic changes of pernicious anemia, there are no known adverse effects to the ingestion of large doses of folic acid.

VITAMIN C

The major form of vitamin C, l-ascorbic acid, is a strong reducing agent that participates in hydroxylation reactions such as that necessary for the formation of collagen. Scurvy results from vitamin C deficiency and results in collagen, protein, and lipid metabolism abnormalities. Additionally, the presence of vitamin C in the intestines increases the absorption rate of iron. Those with a vitamin C deficiency will also be iron depleted.

Vitamin C, which is found primarily in fruits and vegetables,² is absorbed through the jejunum and ileum. The absorption rates decrease with increasing intraluminal quantities of vitamin C. For example, 90 percent of a 100-mg dose might be absorbed, whereas only 20 percent of a 10-g dose might be absorbed. The daily recommended dose for adults is 60 mg. Vitamin C levels, although high in fruits and vegetables, are reduced by heat, drying, and storage.

Large doses of vitamin C can produce attacks of gout and nephrolithiasis in individuals with these conditions. Others may develop diarrhea and abdominal cramps, which subside with discontinuation. Megadoses of vitamin C may result in false negative guaiac testing of feces, and may give falsely elevated glucose levels on dipstick testing.

TABLE 186-1 Some Generally Safe Herbal Agents

Agent	General Use	Rare Adverse Effect
Chamomile	Antispasmodic	Anaphylaxis if patient allergic to ragweed
Echinacea	To cure URIs and UTIs	Anaphylaxis if patient allergic to daisies May deplete vitamin stores
Feverfew ⁵	To cure migraines	Suddenly discontinuing may precipitate migraine If chewed, can cause mouth ulcers and dermatitis
Garlic	For hypertension, colic, hyperlipidemia	Hypotension, rash, nausea, vomiting, diarrhea; death has been reported in massive doses in children
Ginkgo	For dementia, vertigo, Raynaud disease	May inhibit platelet aggregation and interact with warfarin May cause gastrointestinal upset
Ginseng ⁶	For impotence, fatigue, ulcers, stress	May interact with warfarin Lowers blood glucose May cause insomnia, nervousness
St. John's wort	As antidepressant	Phototoxicity May interact with serotonin reuptake inhibitors; avoid tyramine-containing foods
Valerian	For sedation	Interacts with other sedating drugs May have paradoxical stimulant effect

Abbreviations URIs = upper respiratory infections; UTIs = urinary tract infections.

HERBAL AGENTS

In 1994, the Dietary Supplement Health and Education Act (DSHEA) classified herbal medicines as "dietary supplements." Under DSHEA, herbals may not be marketed with claims of definitive therapeutic effects. Instead, manufacturers are allowed to market an herbal agent by describing its *intended effect* on the human body. For example, European controlled studies show that saw palmetto is effective for alleviating symptoms of benign prostatic hypertrophy, but in the United States, claims that saw palmetto is a treatment for benign prostatic hypertrophy cannot be made, and saw palmetto is advertised as an herbal agent that can "support healthy prostate function."³

Herbals themselves are not controlled by the Federal Drug Administration (FDA). Instead, the FDA controls the wording of the product label, even though manufacturers and distributors are not required to notify the FDA of label claims until 30 days after the product is first marketed.

In 1997, sales of over-the-counter herbal preparations exceeded \$1.5 billion in the United States. Home grown and imported herbal preparations add to the total amount of herbal agents ingested, inhaled, and rubbed on. The list is staggering. Herbal agents can be classified as generally safe, potentially toxic, and toxic. Some generally safe herbal agents are listed in Table 186-1.

Some of the moderately unsafe herbal preparations include absinthe (wormwood), black cohosh, comfrey, juniper, and lobelia. *Absinthe* (wormwood)—which is popular in Europe and is being produced there in clandestine laboratories—is a toxic liquor that contains volatile oils that produce psychosis, intellectual deterioration, ataxia, headache, vomiting, and diarrhea. Absinthe is used as a flavoring in alcoholic drinks.

Black (or blue) cohosh contains an estrogen-like compound and has been used to delay or treat menopause. It may cause nausea, vomiting, dizziness, and weakness.

Comfrey is used as a digestive stimulant in teas. It has, however, been linked to liver toxicity and hepatic carcinoma. The toxic action comes from the formation of pyrroles that act on DNA.⁴

Juniper is used as a diuretic but may also be hallucinogenic. Toxicity also includes renal toxicity, nausea, and vomiting.

Lobelia is used for asthma and as an expectorant. Other uses include smoking it as a marijuana substitute for its mild euphoric effect. The active ingredients include lobeline, atropine, and scopolamine, which can produce anticholinergic symptoms.

Some herbs that are unsafe but are commonly found on store shelves include chaparral, ephedra, nutmeg, and yohimbine.

Chaparral is derived from the leaves of the creosote bush and is used for its antioxidant effects as a potential cancer preventative. It is also thought to be effective in pain control but is also thought to be hepatotoxic.

Ephedra is used in weight loss and has been implicated in multiple toxic deaths. This herbal agent is contraindicated for patients with hypertension, diabetes, or glaucoma.

Nutmeg is used for dyspepsia, muscle aches, and arthritis. It contains terpenes, ethers, and myristicin. Myristicin can produce hallucinations (at about 2 to 4 teaspoonfuls of ground nutmeg). At various dosages, it can also produce gastrointestinal upset, agitation, coma, miosis, and hypertension.

Yohimbine is thought to be an aphrodisiac. Toxic effects include hallucinations, weakness, hypertension, and paralysis. Yohimbine, if combined with pheopropanolamine, can lead to a stroke through marked elevation of the blood pressure.

In addition to any potential toxicity to overingestion or overuse of herbals themselves, herbals may also interact with prescription medications. Herbals may have either pharmacokinetic interactions (changing a drug's absorption, distribution, metabolism or elimination) or pharmacodynamic interactions (altering a drug's effects). Much of the available literature on herb-drug interactions are anecdotal and nonreproducible. There are some herb-drug interactions that, because of larger numbers of clinical reports, animal studies and/or controlled clinical studies, can be deemed to be "likely" and should be considered by the emergency physician (Table 186-2).^{7,8}

TABLE 186-2 Some Likely Herb-Drug Interactions*

Herb	Herb Used for	Drug	Effect of Interaction
Cayenne (Capsicum)	Arthritis, neuralgia, analgesic	ACE Inhibitors Theophylline SR	Increase of cough Increased absorption
Dan shen (salvia)	Reduction of lactation	Warfarin	Decreased warfarin metabolism
Ephedra	Energizer, weight loss, asthma, sinus congestion	MAOIs	MAOI intoxication
Grapefruit juice	For vitamin C effects	Amiodarone Benzodiazepines Calcium channel blockers Carbamazepine Clomipramine Ethinyl estradiol Statins Sertraline	Increased drug availability of any one of these drugs because of inhibition of intestinal cytochrome P450
Licorice in chronic, high doses	Respiratory disorders, hepatitis, inflammatory diseases, infections	Antihypertensives Diuretics Prednisolone	Decreased effect (can cause pseudohyperaldosteronism by inhibiting 11-beta-dehydrogenase) Increased K ⁺ loss, myopathy Increased drug levels
St. John's wort	Depression	Cyclosporin Digoxin Indinavir	Decreased serum levels; transplant rejection Decreased serum level Decreased serum level
Yohimbine	Erectile dysfunction, sexual potency	Clonidine Tricyclic antidepressants	Decreased effect Enhanced autonomic and central effects of yohimbine

*Based on case reports, clinical studies, and animal studies.

Abbreviations: ACE = angiotensin-converting enzyme; MAOI = monoamine oxidase inhibitor; SR = sustained release.

ANTIMICROBIALS G.

Richard Bruno Wallace
A. Carter

Antimicrobial agents are estimated to account for 15 to 30 percent of the world medical drug expenditure.¹ Most adverse reactions to antibiotics occur at therapeutic doses. The most common adverse effects of antimicrobial use include hypersensitivity reactions, alterations in body microbial flora, interactions with other drugs, and cutaneous drug reactions. A thorough review of adverse effects of antimicrobials at therapeutic doses is beyond the scope of this chapter. Rather, this review focuses on the medical considerations of acute antimicrobial overdose. Data from the American Association of Poison Control Centers (AAPCC) suggest that antimicrobial exposures are a frequent source of inquiry to poison control centers but rarely result in life-threatening outcomes. In 2001, the AAPCC reported 61,215 exposures, which resulted in significant morbidity in 365 cases (0.6 percent) and 13 fatalities (less than 0.02 percent).² Most patients who present after antimicrobial overdose are asymptomatic. Observation and screening for coingestants are adequate before medical clearance in most cases. The poison control center should be contacted to assist in patient management and to aid in accurate statistical tracking of toxin exposures.

EVALUATION AND TREATMENT OF ANTIMICROBIAL OVERDOSE

Most antimicrobial overdoses will be asymptomatic; however, significant ingestions of agents such as isoniazid (INH), chloroquine, and quinine can result in severe toxicities. The history should include the amount and type of antimicrobial ingested. Patients should also be asked about possible coingestants. Suicide potential should be assessed.

Asymptomatic antimicrobial ingestions require minimal laboratory evaluation. As is common in all cases of possible overdose, determining acetaminophen levels and taking a 12-lead electrocardiogram should be considered as a means to screen for coingestants. Emergency medicine and critical care principles should guide laboratory evaluation in symptomatic overdoses. The electrolyte level should be determined to evaluate potential anion-gap acidosis in cases of suspected INH overdose. Methemoglobin levels should be determined in dapsone, chloroquine, and primaquine overdoses.³ Drug levels are not helpful in the management in the acute antimicrobial overdose but may be confirmatory and are available for several antibiotics (INH, quinine, and chloroquine).

Patients who present with symptomatic ingestions (altered mental status, seizure, electrolyte disturbances, anion-gap acidosis, or renal failure) should be treated with supportive care using emergency medicine principles. Gastric decontamination should be initiated in all patients with suspected antimicrobial overdoses. Activated charcoal with the cathartic sorbitol should be given orally or through a nasogastric tube. Repeat-dose activated charcoal without sorbitol is indicated in symptomatic patients. Dialysis and charcoal hemoperfusion are effective at eliminating aminoglycosides and possibly pentamidine but are not highly effective at removing other antimicrobial agents.

SPECIFIC AGENTS IN OVERDOSE

Isoniazid

Infection with *Mycobacterium tuberculosis* (tuberculosis or TB) is common in developing countries, and has over the past decade increased in incidence in the United States. Patients being treated for active TB as well as patients taking chemoprophylaxis for positive purified protein derivative (PPD) skin tests are now commonplace in many urban emergency departments. Isoniazid (isonicotinylhydrazide or INH) is a first line drug utilized in both chemoprophylaxis and treatment of active TB. INH is also associated with high morbidity and mortality in overdose. According to AAPCC data from 2001, INH is the antimicrobial agent that accounted for the most cases of significant morbidity, almost one fourth of all major morbidity from antibiotic exposures.

INH is a hydrazide of isonicotinic acid that is bacteriostatic and whose mechanism of action is not well understood. At therapeutic doses (5 mg/kg) there are numerous side effects that may cause significant morbidity including neuropathy and hepatic injury. These side effects are separate and distinct from the clinical signs and symptoms of acute overdose.

The clinical symptoms of acute INH overdose typically present initially with nausea, mental status changes, and ataxia. These symptoms may progress to the clinical triad of seizure, coma, and metabolic acidosis. Seizures are typically seen in acute INH ingestion of more than 20 to 30 mg/kg. These seizures are generalized tonic-clonic in nature, and are often refractory to standard anticonvulsive therapy (benzodiazepines, barbiturates, etc.). The postulated mechanism for INH-induced seizures is INH depletion of vitamin B₆, which decreases activity of coenzyme pyridoxal 5-phosphate, which, in turn, impairs the synthesis of the inhibitory neurotransmitter γ -aminobutyric acid (GABA).

INH ingestion should be entertained in any patient presenting with refractory seizures.⁴ Seizures are treated with pyridoxine (vitamin B₆). The dose is gram-for-gram equivalent to the amount of INH ingested. For patients who ingest an unknown quantity of INH, the recommended dose of pyridoxine is 5 g IV. The pyridoxine may be administered at a rate of approximately 1 g every 2 to 3 min.⁵ Single-dose therapy of pyridoxine should be effective to stop seizures, but patients who do not receive adequate pyridoxine dosing may have repeat seizures. There are case reports of pyridoxine also helping to reverse INH-induced comas.⁶ It has been documented in the literature that the large doses of pyridoxine required for therapy are often not found in hospitals.⁷ For those involved in emergency medicine administration and operations it is prudent to ensure adequately stocked levels of pyridoxine in the ED and pharmacy.

The acidosis associated with large INH ingestions is believed to be a lactic acidosis secondary to seizure activity. **There is little role for sodium bicarbonate in acute INH overdose.**

Most INH-induced toxicity (i.e., seizures, obtundation, and acidosis) occur within 2 h of overdose. Patients who remain asymptomatic for 6 h after presentation are unlikely to manifest delayed INH related symptoms and are safe for medical clearance.

Antimalarial Drugs

Antimalarials are not used in the United States as frequently as other antimicrobials; however, they are among the agents with the greatest potential for toxic effects. Common agents include quinine, chloroquine, mefloquine, and primaquine.

Quinine and chloroquine may both result in severe central nervous system (CNS) and cardiac abnormalities in acute overdose. CNS manifestation of toxicity includes obtundation, headache, and seizures. Quinine also has significant ocular toxicity in acute overdose, and blindness may result with serum levels of greater than 10 to 15 jig/mL. Possible electrolyte abnormalities include hypoglycemia with quinine and hypokalemia with chloroquine. Both drugs have cardiac effects and may lead to PR, QT, or QRS prolongation. Patients may be hypotensive, with early cardiovascular collapse. Aggressive supportive care is used for overdose.⁸ A decreased mortality rate has been demonstrated in chloroquine overdose treated with early intubation, gastric lavage, deep sedation with benzodiazepines, and vasoactive pressor support with epinephrine to maintain a systolic blood pressure of 100 mm Hg.⁹ Sodium bicarbonate (to adjust serum pH of 7.45 to 7.50) may be helpful in treating dysrhythmias related to the sodium-channel blockade from quinine and chloroquine, although solid data do not exist to support its use.

Penicillins and the 3-Lactam Agents

Penicillins and the P-lactam agents are relatively benign in acute overdose. Confusion, agitation, myoclonic jerking, and seizures have been reported with high-dose penicillin G (more than 20 to 30 million units/d), cephalosporins, and imipenem. Encephalopathy, agitation, and absence seizures have been reported with ceftazidime. CNS effects of penicillins and p-lactam agents are believed to result from antagonism of the GABA receptor. Patients most at risk for adverse CNS effects during p-lactam therapy are those with renal failure, with underlying CNS abnormalities, or who are receiving high-dose therapy. Therapy for β -lactam agent-related seizures are based on general emergency management principles for seizure management with first-line agents being benzodiazepines.

Aminoglycosides

Aminoglycosides are not available in oral forms, so intentional ingestions have not been reported; rather most aminoglycoside acute overdoses are iatrogenic in nature. It is presumed most of these errors occur in the order process (miscalculation of dose or wrong dose dispensed). Catastrophic aminoglycoside overdoses are rare but have been reported in neonates and hospitalized patients. Aminoglycosides have a low therapeutic to toxic ratio, with ototoxicity and nephrotoxicity common in both therapeutic use and acute overdose. All aminoglycosides have the potential to damage vestibular and cochlear sensory cells, but neomycin is by far the most ototoxic. The incidence of hearing loss related to aminoglycoside has been reported to be between 2 and 25 percent. Hearing loss correlates closely with high-dose or prolonged therapy. Nephrotoxicity results from damage to the proximal renal tubules and correlates with drug dose, therapy duration, volume status, and extremes of age.

Therapy for acute aminoglycoside overdose is typically hydration and monitoring of hearing and renal function. Hemodialysis has been used to enhance elimination of aminoglycosides but it is unclear what role it should play in acute overdose because most patients recover with only supportive care.

Cyanide is a potent cellular toxin with an infamous history. It was the agent of mass suicide at Jonestown, Guyana; of murder in the Tylenol-tampering incidents; and of genocide in the gas chambers of Nazi Germany.^{1,2} Cyanide is widely available. Table 188-1 lists common sources of cyanide.

SOURCES OF EXPOSURE

Acute cyanide poisoning occurs in 1) occupational settings; 2) inadvertent, suicidal, or homicidal ingestions of cyanide or chemicals metabolized to cyanide³; 3) patients on infusions of sodium nitroprusside⁴; 4) persons who ingest plant products that contain cyanogenic glycosides⁵; and 5) inhalation of smoke from burning plastics in closed-space fires.^{6,8}

Industrial Exposures

Cyanide compounds are both precursors and incidental by-products in the production of many industrial materials. Occupational exposures are caused by inhalation of hydrogen cyanide (HCN) gas and dermatologic exposure to solutions of cyanide salts. Inadvertent ingestion of cyanide salts can occur from eating in a contaminated workplace.

Smoke Inhalation

Smoke inhalation is a common, though often unrecognized, cause of acute cyanide toxicity. Large amounts of HCN are released when

natural and synthetic nitrogen-containing polymers, such as wool and vinyl, are burned. Elevated cyanide levels, often associated with elevated carbon monoxide levels, are implicated in fire-related fatalities.^{6,10}

Other Exposures

Suicides and homicides account for some cases of cyanide poisoning. Persons with occupational access to cyanide salts, such as chemists and jewelers, are more at risk. Naturally occurring plant glycosides have been a cause of poisoning. Amygdalin, a cyanogenic glycoside found in high concentrations in apricot pits and bitter almonds, was the principal ingredient in Laetrile. During the 1970s, the use of Laetrile as a nontraditional cancer therapy led to numerous deaths.⁵ Ingestion of acetonitrile-containing cosmetic products caused severe poisoning in several children.³

Chronic Exposure

Adverse physiologic effects due to chronic subacute cyanide exposure have been proposed but are poorly defined. Studies of workers chronically exposed to cyanide demonstrated a higher incidence of thyroid disease and vitamin B₁₂ deficiency. Cassava, a tropical root that contains the cyanogenic glycoside *linamarin*, is a food staple in many countries. Tropical ataxic neuropathy is endemic in countries where cassava consumption is high. The combination of chronic tobacco use and a diet poor in cyanide-scavenging carotenes is epidemiologically associated with the development of optic neuropathy.¹⁰

BIOCHEMICAL TOXICOLOGY

The avidity with which cyanide binds to metal-containing enzymes accounts for its serious cellular toxicity. Its key physiologic effect is produced by inhibition of the iron-dependent reduction of molecular oxygen to water by cytochrome aa₃, the final step in oxidative phosphorylation.^{11,12} Anaerobic reduction of pyruvate to lactate and impaired conversion of adenosine diphosphate (ADP) to adenosine triphosphate (ATP) result in severe metabolic acidosis. The biochemical bases of observed effects such as altered calcium homeostasis, the release of excitatory neurotransmitters in the central nervous system (CNS), and pulmonary and coronary arteriolar vasoconstriction remain poorly defined.²

CLINICAL TIME COURSE OF POISONING: ROUTES OF EXPOSURE

The time course and severity of the clinical effects of cyanide are a function of the nature of the cyanide-containing compound, the route of exposure, and the concentration of cyanide to which the patient is exposed. The onset of symptoms following inhalational exposure to HCN gas is virtually immediate. Concentrations of <50 parts per million (ppm) cause restlessness, anxiety, palpitations, dyspnea, and headache.¹³ Higher levels of HCN gas cause severe dyspnea, loss of consciousness, seizures, and cardiac dysrhythmias. Coma, cardiovascular collapse, and death may occur immediately on exposure to very high levels. The median lethal dose (LD₅₀) for humans is estimated to be 200 ppm for a 30-min exposure and 600 to 700 ppm for a 5-min exposure.¹³

The onset of symptoms following ingestion of a cyanide salt occurs within minutes. Death has resulted from the ingestion of as little as 50 mg of cyanide salt in an adult, while survival has been reported in much larger ingestions when antidotes are used. The LD₅₀ of the potassium or sodium salt of cyanide in an untreated adult is estimated at 140 to 250 mg.¹³ Symptoms of poisoning are delayed following the ingestion of compounds that require metabolic activation to release free cyanide. Acetonitrile, a solvent sold commercially as a cosmetic nail remover, undergoes hepatic oxidative metabolism that results in

the release of HCN. The onset of symptoms of cyanide poisoning following ingestion of acetonitrile occurred at 24 h in one case.³ Cyanide is released from amygdalin by hydrolysis in the small intestine, resulting in delayed progression of symptoms. The slow release of cyanide by the spontaneous degradation of sodium nitroprusside also results in delayed toxicity, particularly during prolonged or high-dose infusions. The rate of degradation of sodium nitroprusside is increased by exposure to sunlight.⁴

CLINICAL FEATURES

History

An occupational history may provide a clue to the possibility of cyanide poisoning, particularly in the suicidal patient. Careful identification of ingestants in asymptomatic patients will prevent the discharge of a patient who has potential for delayed toxicity from a cyanogenic compound.

Symptoms of Poisoning

Antidotal treatment may be lifesaving. It is important to recognize that rapid onset of symptoms is an important clue. Patients who are alert may hyperventilate and complain of breathlessness. These symptoms can be indistinguishable from anxiety produced by knowledge of a possible exposure. CNS and cardiovascular toxicity are prominent. The severity of effects is correlated with the degree of exposure. CNS effects range from anxiety and confusion to seizures and coma. The inability to use oxygen results in functional hypoxemia except that the patient is not cyanotic, as cyanide does not significantly alter the oxygen-carrying capacity of hemoglobin. Cyanosis does follow respiratory arrest. The cardiac effects of cyanide poisoning are similar to those of hypoxemia. Sinus tachycardia, atrial dysrhythmias, and premature ventricular contractions progress to bradycardia and asystole. Ventricular tachycardia and fibrillation are uncommon. Table 188-2 summarizes common signs and symptoms of toxicity. The typical seriously poisoned patient is comatose, hyperventilating, hypotensive, and bradycardic without cyanosis. Severe metabolic acidosis is a consistent clinical clue; indeed, the absence of metabolic acidosis precludes the diagnosis of cyanide toxicity.¹ In victims of smoke inhalation, toxic cyanide levels correlate with plasma lactate levels greater than 10 mmol/L, independent of the carbon monoxide level.⁸ Decreased cellular extraction of oxygen results in increased oxygenation of venous blood and a decrease in the normal arteriovenous oxygen [(a-v)CO₂] difference. Although this concept facilitates understanding of the cellular effects of cyanide, it is difficult (and impractical) to detect this underuse of oxygen in an emergency setting, as normal val-

ues for peripheral venous oxygen saturation and the effects of oxygen therapy on these values have not been well studied. A reliable estimation of the (a-v)CO₂ requires that the venous sample be taken from the pulmonary artery or vena cava. A possibly useful finding related to this phenomenon is the reported "arterialization" of veins on funduscopic examination by increased venous partial pressure of oxygen.¹⁴ A smell of bitter almonds supports the diagnosis of cyanide poisoning, but it is estimated that only 60 to 80 percent of the population can detect the characteristic almond odor of cyanide. Table 188-3 lists other anticipated laboratory abnormalities.

DIFFERENTIAL DIAGNOSIS

Cyanide poisoning should always be considered in the poisoned patient with a normal partial pressure of arterial oxygen (Pao₂) and a high anion gap metabolic acidosis because of lactate. Chap. 25 discusses the differential diagnosis of lactic acidosis and includes poisonings that accumulate lactate (iron, methemoglobin inducers, methanol, biguanides, strychnine), other cellular toxins/asphyxiants (salicylates, carbon monoxide, hydrogen sulfide, azides, arsine, phosphine, nerve agents, or other organophosphates) and seizure-causing agents (cocaine and other stimulants, theophylline, camphor, cicutoxin).

TREATMENT

The standard accepted therapy for cyanide poisoning in the United States has been well established for half a century, and is based on experimental and chemical principles developed by Chen and colleagues in 1933.¹⁵⁻¹⁶ The antidotes are contained in a kit (approximately \$200 per kit) now provided by Taylor Pharmaceuticals, which includes an ampule of amyl nitrite for inhalation, 10 mL of 3 percent sodium nitrite (300 mg), and 50 mL of 25 percent sodium thiosulfate (12.5 g). Table 188-4 gives the adult and pediatric doses of the three components of the kit.

Nitrites

Nitrites have significant side effects that include hypotension and the development of excessive methemoglobinemia.^{11,17} **The reported death of a child from methemoglobinemia that followed aggressive treatment of a nonlethal ingestion of cyanide has led to the practice of adjusting the pediatric dose of sodium nitrite according to**

TABLE 188-3 Anticipated Laboratory Findings in Cyanide Poisoning

Test	Result	Cause
Serum electrolytes	Elevated anion gap	Lactic acidosis from anaerobic metabolism
Arterial blood gases	Metabolic acidosis Normal Po ₂	As above
Measured % oxygen saturation (by co-oximetry)	Normal	Hemoglobin has normal oxygen-carrying capacity
(a-v)O ₂	Decreased	Decreased tissue oxygen use
Whole-blood cyanide level:		Note: plasma cyanide levels are roughly 1/10 of the whole-blood cyanide levels
Toxic	>0.5 jxg/mL	
Fatal	>2.5 (JLg/mL)	
Fire victims		
COHb	Elevated	Mixed toxicity, synergistic
Lactate	>10mmol/L	Correlates with toxic cyanide level

t Avoid nitrites in the presence of severe hypotension if diagnosis is unclear.

the patient's hemoglobin level, as illustrated in Table 188-4.¹³¹⁷

The amyl nitrite offers a temporizing measure when an intravenous line is not available. It does not need to be administered when sodium nitrite can be given IV.

The rationale for using nitrites was based on their capacity to form methemoglobin, which has an avid affinity for cyanide. Although the antidotal efficacy of nitrites is not disputed, their actual mechanism of action has been questioned.¹² Studies have shown that inhibition of methemoglobin synthesis by methylene blue does not affect the efficacy of the nitrites. In addition, rapid methemoglobin inducers such as 4-dimethylaminophenol (DMAP) are not more efficacious than nitrites.² It has also been demonstrated that the rapid clinical reversal of cyanide toxicity occurs despite the demonstration of only very small amounts of methemoglobin.¹⁸

Sodium Thiosulfate

Following the administration of sodium nitrite, sodium thiosulfate is infused. Sodium thiosulfate enhances the activity of the enzyme rhodanese, a mammalian enzyme that likely evolved in response to the ubiquitous presence of cyanide in nature. Rhodanese catalyzes the transfer of sulfate from sodium thiosulfate to cyanide to form thiocyanate, a less-toxic form that is excreted by the kidneys.^{11,15} Studies of the cyanide LD₅₀ in animals demonstrate that the therapeutic effects of sodium nitrite and sodium thiosulfate are synergistic.^{11,15}

Sodium thiosulfate has very limited toxicity in comparison with nitrites and is a safer empirical therapy when the diagnosis is not clear. It may also be useful as a sole therapy for victims of inhalation injury where there is concern that the induction of methemoglobinemia in the setting of carbon monoxide exposure may further reduce oxygen carrying capacity.⁷

Oxygen

Surprisingly, the administration of 100 percent oxygen enhances the therapeutic efficacy of antidotal therapy.¹¹ It has been proposed that oxygen may affect the binding of cyanide to cytochrome oxidase or the ability to form methemoglobin. Animal studies of cyanide poisoning show no benefit of hyperbaric oxygen over 100 percent oxygen.¹¹

Hyperbaric oxygen is useful in the management of patients with suspected cyanide poisoning who have concomitant carbon monoxide poisoning.

Other Therapies

Because of the side effects of nitrites, an effort has been made to develop equally efficacious but less toxic therapies. Dicobalt edetate (Kelocyanor), a cobalt compound with a high affinity for cyanide, is the first-line agent for the treatment of cyanide poisoning in the United Kingdom. Although highly effective as a cyanide antidote, the toxicity of dicobalt edetate is greater when cyanide is not present, limiting its use to cases where the presence of cyanide is unequivocal.^{1,2,11}

Hydroxocobalamin (vitamin B_{12a}, 5 g IV; 70 mg/kg over 30 min), in combination with sodium thiosulfate, has been the antidote of choice in France since the 1970s. Because of its low toxicity and its efficacy, it is ideal in cases where the diagnosis is uncertain or in cases where the induction of methemoglobinemia may be detrimental.⁸ Unfortunately, solutions of this antidote in concentrations adequate to treat cyanide poisoning are not readily available in the United States. Side effects associated with hydroxocobalamin include transient hypertension, a reddish discoloration of the skin and mucous membranes, and rare anaphylactoid reactions.⁷ In practice, hydroxocobalamin is used in combination with sodium thiosulfate.

DMAP is a rapid methemoglobin-inducer developed in Germany for the treatment of cyanide poisoning. It has not been demonstrated to be more clinically efficacious than sodium nitrite. DMAP (5 mL of 5 percent solution [250 mg] IV over 1 min) is used in combination with sodium thiosulfate.

Supportive Care

Severely poisoned patients have survived with supportive care, although survival in cases of massive exposure undoubtedly has been facilitated by antidotal therapy. All patients with known or suspected cyanide poisoning should receive 100 percent oxygen by mask, be put on a cardiac monitor, and have an intravenous line in place. Hypotension should be treated with fluids and standard vasopressors (see Chap. 30). Seizures can be treated with benzodiazepines (see Chap. 232).

Decontamination

Gastric decontamination should never take priority over resuscitation of the symptomatic patient. Following resuscitation, patients with a history of ingestion may benefit from gastric decontamination with lavage and/or activated charcoal. Superactivated charcoal binds small amounts of cyanide and may be useful in decreasing the significance of an ingestion.¹⁷ Topical exposures require copious irrigation with water.

CYANIDE AND CARBOXYHEMOGLOBIN

Patients with inhalational exposures often recover following their removal from the toxic exposure. They do not require antidotal treatment if significant recovery has occurred prior to reaching medical attention.

The decision to administer the sodium nitrite-thiosulfate antidote is straightforward when faced with a comatose, bradycardic patient with a clear history of cyanide exposure. **Hypotension is not a contraindication to sodium nitrite therapy in this setting.** A patient with mild to moderate symptoms may be observed closely for more serious signs prior to the initiation of treatment.

More difficult management decisions arise in patients with smoke inhalation who have or may have carbon monoxide exposure as well as suspected cyanide exposure, and patients who are critically ill and acidotic without any known history of cyanide exposure. It is prudent to avoid the vasodilating effects of nitrites in patients whose diagnosis is

uncertain. There is a correlation between carboxyhemoglobin and cyanide levels after smoke inhalation. **The empirical administration of nitrites to patients who have elevated carboxyhemoglobin levels is relatively contraindicated because of the potential for methemoglobinemia to further decrease oxygen-carrying capacity,**⁷ although a limited study failed to show clinically significant methemoglobinemia in victims of smoke inhalation who also had carbon monoxide poisoning.⁶ For the victim of smoke inhalation who arrives to the ED alive and has significant unexplained lactic acidosis, the safest immediate empirical therapy that avoids the hypotensive effects of nitrites and the concerns about methemoglobin formation is the administration of sodium thiosulfate in addition to 100 percent oxygen. Hydroxocobalamin, which has orphan drug status in the United States, will be an ideal agent for both of these settings if it becomes available.⁷ In critically ill, acidotic patients where the possibility of cyanide poisoning is considered, anecdotal reports support the utility of the empirical administration of sodium thiosulfate alone.

LABORATORY EVALUATION

The decision to institute antidotal treatment of cyanide poisoning must be made long before confirmatory laboratory studies can be obtained. Although cyanide levels are not closely correlated with toxicity, they can be used to confirm a clinical diagnosis in retrospect, or for forensic purposes. Whole-blood cyanide levels are the most commonly reported values.¹³ Whole blood cyanide levels are normally less than 0.02 (xg/nL, while potentially fatal levels are greater than 2.5 (jig/mL. Because cyanide is sequestered in erythrocytes, plasma cyanide levels approximate one-tenth of the whole-blood cyanide levels.

The arterial blood gas is a rapid and useful test when cyanide poisoning is suspected. The absence of a metabolic acidosis is inconsistent with the diagnosis of acute cyanide poisoning.

As previously noted, the demonstration of a serum lactate level greater than 10 mmol/L was significantly correlated with toxic cyanide levels in victims of smoke inhalation.⁸ Table 188-3 summarizes laboratory findings anticipated in cyanide poisoning.

DISPOSITION

All patients who receive antidotal therapy should be admitted. Patients who have ingested a substance that may result in delayed toxicity should also be admitted. Full recovery is anticipated in many cases of severe poisoning where treatment is initiated rapidly and cardiac arrest has not yet occurred. Recovery despite cardiac arrest also has been reported, but anoxic encephalopathy may ensue.

interacts with compounds seeking electrons, such as oxygen, and in the process is oxidized to the ferric (Fe^{3+}) state. On exposure to a nonoxygen oxidizing agent, iron donates an electron and transforms oxidation states from Fe^{2+} to Fe^{3+} . The Fe^{3+} that remains is unreactive, and the hemoglobin that contains the Fe^{3+} is termed *methemoglobin*. Methemoglobin, therefore, is unable to bind oxygen. Under normal circumstances, a small amount of methemoglobin exists in the blood (<1 percent). A level higher than 1 percent defines methemoglobinemia. This is somewhat of a misnomer as the hemoglobin is contained within the erythrocyte and not free within the blood. The accumulation of methemoglobin is normally limited enzymatically by the rapid reduction of the ferric iron back to the ferrous form as it forms. The enzyme NADH-methemoglobin reductase (also referred to as NADH cytochrome- b_5 reductase) is primarily responsible for this reduction, in which NADH (reduced nicotinamide adenine dinucleotide) donates its electrons to cytochrome- b_5 , which subsequently reduces methemoglobin to hemoglobin.² In this process, NAD^+ (oxidized nicotinamide adenine dinucleotide) is regenerated (Figure 189-1). This pathway is responsible for reducing nearly 95 percent of the methemoglobin. A second enzymatic pathway uses NADPH and NADPH-methemoglobin reductase to effect methemoglobin reduction analogous to the NADH-linked enzyme system. This enzyme is of limited importance normally (<5 percent total reduction) because of the lack of a suitable molecule to shuttle electrons in a manner similar to cytochrome- b_5 . However, this enzyme is crucial for the antidotal effect of methylene blue, which performs this function when administered exogenously (see Figure 189-1). To a very limited extent, nonenzymatic reduction systems, such as vitamin C and glutathione, may participate in the reduction of methemoglobin to hemoglobin. This limited effect of glutathione partially explains why patients with glucose-6-phosphate dehydrogenase deficiency (G6PD), who are deficient in reduced glutathione, are not at increased risk of developing methemoglobinemia.

The primary clinical effect of methemoglobin is to reduce the oxygen content of the blood. Because the hemoglobin-bound oxygen accounts for the vast majority of an individual's oxygen-carrying capacity, as the methemoglobin level rises oxygen delivery to the tissues falls. However, patients with methemoglobinemia are often more symptomatic than patients who suffer from a simple anemia that produces an equivalent reduction in oxygen-carrying capacity. This is caused by a leftward shift in the oxyhemoglobin dissociation curve, the consequence of which is a reduced release of oxygen from the erythrocyte to the tissue at a given partial pressure of oxygen (Figure 189-2).

DYSEMOGLOBINEMIAS Sean

M. Rees Lewis S. Nelson

The dyshemoglobinemias are a constellation of disorders in which the hemoglobin molecule is functionally altered and prevented from carrying oxygen. The most clinically relevant dyshemoglobinemias are carboxyhemoglobin, methemoglobin, and sulfhemoglobin. Carboxy-hemoglobin develops following carbon monoxide exposure and, because of its unique importance and prevalence, is discussed in Chap. 203. This chapter reviews methemoglobinemia and sulfhemoglobinemia. Although the exact prevalence of these disorders remains undefined, the American Association of Poison Control Centers database reports thousands of exposures to drugs and chemicals capable of producing methemoglobinemia, but, unfortunately, cases in which methemoglobinemia actually occurred are not tallied.¹

METHEMOGLOBINEMIA

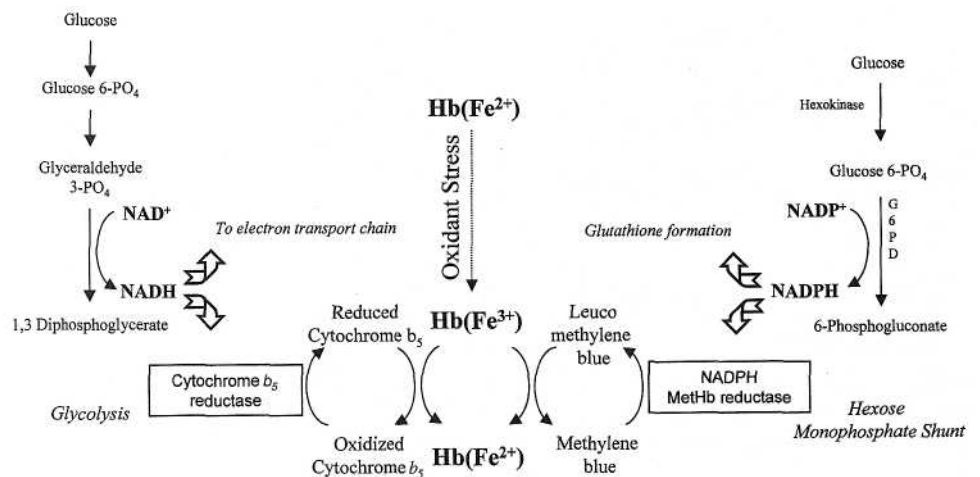

Pathophysiology

Under normal circumstances, the iron moiety within deoxyhemoglobin exists in the ferrous (Fe^{2+}) form. Iron in this oxidation state avidly

Acquired Methemoglobinemia

Methemoglobinemia is acquired when the normal mechanisms responsible for the elimination of methemoglobin are overwhelmed by an exogenous oxidant stress, such as a drug or chemical agent (Table

FIG. 189-1. Pathophysiology of methemoglobin formation and mechanism of action of methylene blue.

FIG. 189-2. The oxyhemoglobin dissociation curve describes the change in oxygen binding to hemoglobin as the dissolved oxygen (P_{O_2}) varies. The oxyhemoglobin dissociation curve of blood with a 50 percent reduction in erythrocytes (anemia) follows a curve similar to that of nonanemic blood, although the oxygen content is lower to start; i.e., unbinding of half of the oxygen occurs at the same P_{O_2} . The oxygen dissociation curve of blood with 50 percent methemoglobin is shifted to the left so that it is less willing to give up its oxygen despite a similar reduction in oxygen binding sites as the anemic blood.

189-1). Drugs in conventional doses rarely produce clinically significant methemoglobinemia, although subclinical methemoglobinemia may go unrecognized. Currently, most cases of drug-induced methemoglobinemia are caused by phenazopyridine (a commonly used agent for the symptomatic treatment of urinary tract infections), benzocaine (a topical anesthetic), and dapsone (an antibiotic often used in HIV-related therapy). Nitrate and nitrite salts (such as sodium nitrate) are the chemicals most often responsible for epidemic methemoglobinemia.³ Methemoglobin induction with sodium nitrite is a therapeutic goal in the management of patients suffering from cyanide poisoning. Many of the aforementioned compounds, particularly dapsone, require metabolism to the "active" oxidant, and there may be substantial delay until toxicity is evident.

Methemoglobinemia can affect any age group and, because of undeveloped methemoglobin reduction mechanisms, the perinatal and infant age groups are more susceptible than older age groups. This explains the relatively common development of methemoglobinemia in infants given certain nitrogenous vegetables (e.g., spinach) or well-water that contains high nitrate levels. Bacteria within the gastrointestinal flora convert nitrate to the nitrite form, which is a more potent oxidant. Another common cause of acquired infantile methemoglobinemia is gastroenteritis, which is presumably caused by an increased oxidant burden originating in the gastrointestinal tract.⁴

Hereditary Methemoglobinemia

Hereditary methemoglobinemia results from either an enzymatic deficiency (i.e., NADH cytochrome-6₅ reductase) or from the presence of

an amino acid substitution within the hemoglobin molecule itself [i.e., hemoglobin M (HbM)]. Patients with NADH cytochrome-Z₅ reductase deficiency develop methemoglobin levels of 20 to 40 percent, but these are easily reduced by the administration of daily oral doses of methylene blue or vitamin C. Cyanosis in these individuals begins at birth, but they remain asymptomatic and develop normally.

HbM is an abnormal form of hemoglobin in which its tertiary structure is altered and the heme iron exists in an environment favoring the ferric form. This disease only occurs in the heterozygous form, as the homozygous form is incompatible with life. Currently there is no treatment for this form of methemoglobin. As with NADH cytochrome-65 reductase deficiency, patients develop profound cyanosis, but tolerate the elevated methemoglobin concentrations extremely well.

Clinical Features

Patients who have normal hemoglobin concentrations do not usually develop clinically significant effects until the methemoglobin concentration rises above 20 percent of the total hemoglobin. However, patients may seek evaluation for the profound cyanosis that occurs when the methemoglobin concentration reaches about 1.5 g/dL, which is approximately 10 percent of the total hemoglobin in normal individuals. At methemoglobin concentrations between 20 and 30 percent, symptoms, including anxiety, headache, weakness, and lightheadedness develop, and patients may exhibit tachypnea and sinus tachycardia. Methemoglobin concentrations of 50 to 60 percent impair oxygen delivery to vital tissues, resulting in myocardial ischemia, dysrhythmias, depressed mental status (including coma), seizures, and lactate-associated metabolic acidosis. Levels above 70 percent are largely incompatible with life. Anemic patients may not exhibit cyanosis until the methemoglobin concentration rises dramatically above 10 percent, because it is the absolute concentration (i.e., 1.5 g/dL), not the percentage of methemoglobin, that determines cyanosis. Anemic patients may likewise suffer significant symptoms at lower methemoglobin concentrations because the relative percentage of hemoglobin in the oxidized form is greater. Patients with preexisting diseases that impair oxygen delivery to the red blood cells (e.g., chronic obstructive pulmonary disease, congestive heart failure) will also manifest symptoms

TABLE 189-1 Agents Commonly Implicated in Patients with Methemoglobinemia

with less significant elevations in their methemoglobin levels. On the other hand, conditions that shift the oxyhemoglobin dissociation curve to the right, such as acidosis or elevated 2,3-diphosphoglycerate, may result in somewhat better toleration of methemoglobin.

Diagnosis

The diagnosis of methemoglobinemia should be considered in all patients who present with cyanosis, and is particularly suspect in those whose cyanosis does not improve with supplemental oxygen. The blood has a characteristic "chocolate brown" color, analogous to that seen in the chocolate agar (which contains methemoglobin) used to plate gonococcus. The ability to detect this discoloration is improved when compared directly to normal blood.⁵

Pulse oximetry should be used cautiously in patients with methemoglobinemia. Because the pulse oximeter typically trends toward 80 to 85 percent in patients with methemoglobinemia, in patients with significant elevations in their methemoglobin concentrations (e.g., >20 percent), **the pulse oximeter will suggest a falsely high oxygen saturation.⁶ Arterial blood gas measurement may also be initially deceptive because the partial pressure of oxygen, a measure of dissolved—not bound—oxygen, is normal.** Thus, its extrapolation to the expected oxygen saturation, as performed by the analyzer, will provide a falsely elevated result. **Definitive identification of this abnormal hemoglobin species relies on co-oximetry,** which is an in vitro spectrophotometric method that is capable of differentiating among oxy-, deoxy-, met-, and carboxyhemoglobin species. This widely available test requires only a venous specimen, although arterial blood may be used if arterial puncture is indicated for another reason. The oxygen saturation obtained from a conventional arterial blood gas analyzer will also be falsely normal, because it is calculated from the dissolved oxygen tension, which is appropriately normal.

Treatment

Patients with methemoglobinemia require optimal supportive measures to ensure oxygen delivery and the administration of appropriate antidotal therapy if indicated. In general, gastric decontamination is limited, because there often is a substantial time interval between exposure to the toxic agent and the development of methemoglobin. If a source of continuing exposure exists, decontamination is indicated, and in most stable patients, a single dose of activated charcoal is likely sufficient. Antidotal therapy with methylene blue is reserved for patients with documented methemoglobinemia or a high clinical likelihood of the disease. Highly unstable patients should receive methylene blue, and may rarely benefit from transfusion or exchange transfusion to produce an immediate enhancement of oxygen delivery.

Methylene blue serves to indirectly accelerate the enzymatic reduction of methemoglobin by NADPH-methemoglobin reductase, a normally minor enzymatic pathway. In this capacity, methylene blue is reduced to leucomethylene blue, which itself is capable of directly reducing the oxidized iron back to its oxygen carrying form (see Figure 189-1). The initial dose of methylene blue is 1 to 2 mg/kg IV (0.1 mL/kg of the 1% solution, approximately 7 mL in an adult) and its effect should be seen within 20 min. As the methemoglobin concentration falls, the most severe signs and symptoms will resolve first. Resolution of the cyanosis is a late finding, occurring only after the concentration of methemoglobin falls below 1.5 g/dL. Repeat dosing of methylene blue may be acceptable if needed, but high doses of methylene blue (>7 mg/kg) may actually induce methemoglobin formation.

Treatment failures may result if the patient is deficient in G6PD, because this enzyme is critical for the production of NADPH by the hexose monophosphate shunt (see Figure 189-1).⁷ Because this group of patients does not lack NADH cytochrome-*b₅* reductase, they are not at increased risk of developing methemoglobinemia, and they only lack the ability to respond to methylene blue. However, G6PD-

deficient patients are at greater risk of developing hemolysis following exposure to an oxidant stress. Some oxidants, such as chlorate salts, routinely produce hemolysis even in non-G6PD-deficient patients. Importantly, hemolysis may impede a response to methylene blue, which requires an intact erythrocyte to be effective. Oxidant drugs with long serum half-lives, such as dapsone (T_{1/2} ~50 h), produce prolonged oxidant stress to the red blood cell. Dapsone-exposed patients may require repetitive dosing of methylene blue. Because dapsone's hydroxylamine metabolite is responsible for its toxicity, inhibition of its formation by cytochrome P450 with cimetidine (in conventional doses) is generally recommended. In rare instances, patients may be deficient in NADPH-methemoglobin reductase, the required enzyme for methylene blue activation. Lastly, treatment failure may occur in patients with sulfhemoglobinemia, which is clinically indistinguishable from methemoglobinemia, but which is not responsive to methylene blue (see below). Patients that do not respond to methylene blue should be treated supportively. If clinically unstable, the use of blood transfusions or exchange transfusions is indicated. In the event that the newly administered red blood cell hemoglobin undergoes oxidation, it will likely respond appropriately to methylene blue. Although some additional modalities for the treatment of methemoglobinemia are being investigated, such as the use of the reducing agent TV-acetylcysteine,⁸ none of them are currently used clinically.

SULFHEMOGLOBINEMIA

Sulfhemoglobinemia is less common than methemoglobinemia. Although patients with sulfhemoglobinemia have a clinical presentation similar to those with methemoglobinemia, the disease process itself is substantially less concerning. Although the reduction in the patient's oxygen-carrying capacity is quantitatively similar, the patient's oxygen dissociation curve is shifted rightward, not leftward as in methemoglobinemia, favoring the release of hemoglobin-bound oxygen to the tissue. Because the pigmentation of the blood by sulfhemoglobin is substantially more intense than other colored hemoglobin species, only 0.5 g/dL of sulfhemoglobin is needed to produce a cyanosis equivalent to that produced by 1.5 g/dL of methemoglobin. At the level of the hemoglobin molecule, sulfhemoglobin occurs by oxidation of the porphyrin ring rather than the iron moiety. Many of the responsible agents are identical to those that induce methemoglobin, and the agents do not need to contain sulfur. The diagnosis is difficult to confirm. Standard co-oximetry does not differentiate sulfhemoglobin from methemoglobin because of similar spectral absorbances. The addition of cyanide to the laboratory sample differentiates the two hemoglobin species, because cyanide binds to methemoglobin and changes its spectrophotometric pattern. Thus, if the addition of cyanide to this sample fails to eliminate the methemoglobin peak, the diagnosis of sulfhemoglobinemia is confirmed. Sulfhemoglobin is not reduced by treatment with methylene blue, and generally patients require only supportive care, although transfusions may be necessary for severe toxicity.

HYPOGLYCEMIC AGENTS

Joseph G. Rella Lewis S. Nelson

Diabetes mellitus is the most common endocrine disorder in the United States, and the mainstay of pharmacotherapy includes hypo-glycemic agents. Poisoning by hypoglycemic agents may be the result of unintentional therapeutic misadventures, intentional self-poisoning, or homicidal intent. Many factors contribute to unintentional poisoning including prescription errors, dosing errors, and the onset of complicating metabolic factors.

It is difficult to ascertain an accurate incidence of toxicity caused by hypoglycemic agents for several reasons. Passive reporting to poison centers of overdoses is widely thought to underestimate the true number of exposures. Additionally, laboratory confirmation of actual ingestion is frequently missing from most reports, possibly contributing to a false sense of security. The 2001 *Annual Report of the American Association of Poison Control Centers* recorded 7945 exposures to oral hypoglycemics, 2652 of them in children younger than 6 years of age. There were 21 reported deaths.¹

Hypoglycemia (defined as occurrence of suggestive symptoms with serum glucose less than 50 to 60 mg/dL that responds to glucose administration) is perhaps the most common endocrine emergency. Initially, hypoglycemia precipitates a physiologic attempt to correct the deficiency in blood glucose. This response includes an autonomic nervous system-mediated release of catecholamines and glucagon, which produce the most common symptoms in hypoglycemic patients, including diaphoresis, anxiety, nausea, tremor, and palpitations.² However, because the brain is the only organ that uses glucose as its primary energy source, the consequential clinical findings of hypoglycemia are a result of neuroglycopenia, or insufficient glucose supply to the brain. The manifestations of neuroglycopenia are quite variable and include dizziness, decreased concentration ability, headache, diplopia, confusion, dysarthria, lethargy, coma, focal neurologic findings, and generalized seizures, including status epilepticus.³

In healthy persons, there are complex regulatory systems that maintain the blood glucose at a constant level. Unfortunately, certain medical conditions may impair the ability of the body to perform this task, resulting in hypoglycemia. Chronic ethanol users are at increased risk for hypoglycemia because of their diminished glycogen supply and impaired gluconeogenesis. Persons at extremes of age are also potentially at increased risk for hypoglycemia. Young children have a disproportionately higher brain requirement of glucose as well as smaller glycogen reserves. The elderly are more likely to have health problems or be using medications (e.g., (J)-adrenergic antagonists) that either contribute to or alter the normal counterregulatory responses to hypoglycemia.

INSULIN

Insulin is the agent most commonly associated with severe hypoglycemia in patients evaluated in the ED. The Diabetic Control and Complications Trial research group demonstrated that, although tighter glycemic control delayed the onset and progression of microvascular and neurologic complications in patients with type I diabetes, there were at least 61.2 episodes of treatment-requiring hypoglycemia per 100 patient years.⁴⁻⁵ Therefore, intensive therapy directed at maintaining euglycemia increases the risk of hypoglycemia.

The pharmacokinetics of the different forms of insulin weighs heavily in management decisions. Regular insulin acts rapidly but is short-lived and produces relatively predictable hypoglycemia, whereas the long-acting insulins, such as NPH (neutral protamine Hagedorn insulin), have less-predictable kinetic characteristics. Following large subcutaneous overdose, regular insulin manifests the unpredictable kinetics characteristic of the long-acting forms of insulin (Table 190-1).

SULFONYLUREAS

Sulfonylureas represent approximately 1 percent of all prescriptions in the United States and approximately 66 percent of all oral agents prescribed for diabetes, making them a prevalent cause of hypoglycemia.⁶⁻⁷ Sulfonylureas bind to adenosine triphosphate-sensitive potassium channels on pancreatic β -islet cells and induce the release of insulin by changing the cell's membrane potential.⁸ First-generation sulfonylureas, such as chlorpropamide, are infrequently used because of their near-complete reliance on renal elimination and long elimination half-lives. Second-generation sulfonylureas are cleared by several routes, although they typically have half-lives that approach 24 h with therapeutic use and are expectedly longer following overdose. The second-generation agents are associated with frequent episodes of hypoglycemia, the onset of which may be both delayed (e.g., 12 to 16 h following overdose) and precipitous. Certain sulfonylureas are currently available in sustained-release formulation that results in even more unpredictable overdose kinetics and clinical effects.

BIGUANIDES

The biguanides include phenformin and metformin, both of which are derivatives of guanidine, the active component of the French lilac (*Galega officinalis*). Phenformin, withdrawn from the U.S. market in 1977 because of the high incidence of fatal lactic acidosis, was replaced by metformin in the mid-1990s for the treatment of type II diabetes. Metformin suppresses hepatic glucose output by inhibiting gluconeogenesis and stimulates insulin-mediated glucose uptake by muscle and other tissues. Unlike the sulfonylureas, it does not stimulate insulin secretion.⁹ Metformin does not directly reduce blood glucose and is more appropriately termed an antihyperglycemic agent.

TABLE 190-1 Characteristics of Hypoglycemic Agents

Class/Name	Duration of Action (h)	Peak Action (h)
<i>Insulin</i>		
Ultraslow-acting		
Lispro (Humalog)	<6	0.5-2.5
Short-acting		
Regular (Humulin)	6-10	1-5
Semilente	12-16	Hepatic
Intermediate-acting		
Lente	16-24	6-14
NPH	16-24	6-14
Mixture*	24	bimodal
Long-acting		
PZI	24-36	8-20
Ultralente	24-28	8-20
Glargine	24+	2-20
<i>Sulfonylureas</i>		
First-generation		
Acetohexamide	12-24	1-2
Chlorpropamide	24-72	2-4
Tolazamide	12-24	1
Tolbutamide	6-12	1
Second/third generation		
Glipizide	10-16	.5-2
Glyburide	24	1-2
Glimepiride	16-24	2-3

*Isophane and regular insulin as 70/30 or 50/50 combinations. *Abbreviations:* NPH = neutral protamine Hagedorn or isophane insulin; PZI protamine zinc insulin, no longer available in US.

Metformin is also associated with lactic acidosis that is fatal in nearly 50 percent of the cases. Lactic acidosis occurs in approximately 3 cases per 100,000 patient years of therapy, or about 10 to 20 times less frequently than with phenformin.¹⁰ Although not completely clear, the mechanism appears to be an enhanced production and inhibited metabolism of lactic acid, with a resultant fall in serum pH and cardiovascular collapse. The risk of lactic acidosis from metformin rises with coexisting medical conditions, particularly renal insufficiency as it is cleared by the kidneys; it rarely occurs following large overdose of the drug. The association of metformin-associated lactic acidosis with the use of intravascular iodinated contrast media relates to the increased likelihood of developing renal insufficiency following the administration of radiographic contrast. In most situations, intravenous contrast medium may be administered as needed, but the patient's metformin should not be readministered until the renal function proves to be normal.¹¹

a-GLUCOSIDASE INHIBITORS

There are three α -glucosidase inhibitor agents. Acarbose was the first to be marketed, followed by miglitol and voglibose. These agents, frequently used in combination with sulfonylureas, act to decrease postprandial glucose concentrations by decreasing gastrointestinal absorption of carbohydrates. Specifically, they inhibit the brush-border enzyme α -glucosidase, thereby preventing the metabolism of polysaccharides into smaller units for absorption. By themselves, α -glucosidase inhibitors do not cause hypoglycemia. Experience with α -glucosidase inhibitor overdose remains limited. However, flatulence, bloating, and malabsorption can complicate the therapeutic use of this medication and should be expected in overdose. Additionally, hepatic toxicity is reported in patients taking acarbose.¹²

THIAZOLIDINEDIONES

Although troglitazone was withdrawn from the market in 2000 secondary to reports of liver failure and death, two drugs in this class remain on the market: rosiglitazone and pioglitazone. Structurally similar to troglitazone, these agents offer the theoretical advantage over sulfonylureas of ameliorating hyperglycemia without increasing insulin secretion. These agents reduce hepatic output of glucose and increase peripheral uptake, thus enhancing the effect of endogenous insulin. Both are rapidly absorbed, undergo extensive hepatic metabolism, and are generally well tolerated. However, because of the structural similarity with troglitazone there is some concern for hepatic toxicity, although few cases of reversible hepatocellular injury are reported. Additionally, because of their ability to alter cell differentiation, the long-term consequences of the use of these agents remain undefined.¹³

BENZOIC ACID DERIVATIVES (MEGLITINIDES)

Repaglinide (Prandin, GlucoNorm) is a relatively new nonsulfonylurea insulin-releasing drug derived from benzoic acid. Its mechanism of action is thought to involve the regulation of adenosine triphosphate-sensitive potassium channels in pancreatic (3-islet cells at a different site than used by sulfonylureas. Extrapankretic activity is also likely as human trials have demonstrated reductions in overall insulin concentrations, as compared with sulfonylurea use. Repaglinide is metabolized in the liver to inactive metabolites and eliminated primarily in bile. Overdose experience with this agent is lacking.¹⁴

MISCELLANEOUS SOURCES OF HYPOGLYCEMIA

The ackee tree, found in Jamaica, produces a fruit that may cause hypoglycemia when eaten prior to ripening. The unripened fruit contains hypoglycins, a group of toxins that inhibit hepatic gluconeogenesis and may contribute to hypoglycemia. Epidemic ackee-associated hy-

poglycemia occurs during times of famine when poor nutrition and the increased eating of unripened fruit is presumably more common. Hypoglycins also produce vomiting (i.e., Jamaican vomiting sickness), central nervous system sedation, and seizures. Ackee is available in the United States in canned form, but only the unripe, fresh fruit is associated with hypoglycemia. Several medications can potentiate or have been associated with hypoglycemia (Table 190-2).

The sympathetic nervous system mediates glucose autoregulation partly through the release of epinephrine, which prevents the release of insulin and elevates blood glucose levels. This mechanism explains the role of epinephrine in the counterregulatory response to hypoglycemia. (3-Adrenergic antagonists interfere with both of these effects, potentially resulting in hypoglycemia through excessive insulin release while preventing the development of the typical autonomic response to hypoglycemia.^{15,16} In addition, caffeine may enhance patients' awareness of a hypoglycemic event, perhaps because of its ability to induce neuroglycopenia.¹⁷ Low carbohydrate diets in normal individuals should not cause hypoglycemia as gluconeogenesis supplies adequate glucose.

TREATMENT

Hypoglycemia should be considered as part of the differential diagnosis for all patients with either gross or subtle alterations in their mental status. Initial management includes rapid blood glucose determination with a reagent strip or glucometer, followed by administration of 1 g/kg body weight dextrose using D50W in adults. Because approximately 3 percent of hypoglycemic patients present with a new focal neurologic deficit,³ rapid glucose assessment prior to further care, such as computed tomography scan or thrombolytic therapy, is critical in patients with presumed cerebrovascular accidents. For children, D10W or D25W is used because the hypertonicity of the dextrose preparation may irritate or damage their smaller blood vessels.

The duration of euglycemia or hyperglycemia following intravenous dextrose administration is only about 30 min. In fact, intravenous glucose frequently induces a rebound hypoglycemia 1 to 2 h following the bolus, presumably because of pancreatic insulin release (in some type II diabetics and nondiabetics). Thus, it is critical that after the initial serum glucose correction has been made, assessment and therapy continue to prevent recurrent hypoglycemia.

Once the patient has improved following bolus therapy, D10W should be infused (1 to 2 mL/kg per h) in an attempt to maintain euglycemia. This, along with food, is generally definitive therapy for patients with insulin overdose. Failure to maintain euglycemia with even high infusion rates should prompt repeat boluses of the more concentrated dextrose solutions. Fluid overload, hypokalemia and dilutional hyponatremia and their sequelae are potential complications of large dextrose in water infusions. Feeding patients with at least 300 g of carbohydrates should allow the partial repletion of hepatic glycogen stores and help maintain euglycemia. Simple sugars in soda, chocolate, orange juice, or apple juice are probably not as useful in this effort as are carbohydrates from sandwiches or other foods.

TABLE 190-2 Drugs or Toxins Commonly Associated with Hypoglycemia

Angiotensin-converting enzyme inhibitors	Pentamidine
Acetaminophen	Phenylbutazone
Ackee	Propoxyphene
P-Adrenergic antagonists	Quinine
Chloramphenicol	Salicylates
Disopyramide	Sulfonamide
Ethanol	Streptozocin
Haloperidol	Trimethoprim-sulfamethoxazole
Monoamine oxidase inhibitors	Pyriminil
Para-aminobenzoic acid	

Glucagon should not be used as empiric therapy for hypoglycemia except in specific situations. Because the action of glucagon is to mobilize glycogen stores, those patients who are glycogen depleted (e.g., alcoholics, children, the malnourished, and the elderly) may not improve with glucagon. This may mislead the health care provider, preventing the provider from establishing the etiology of the hypoglycemia. In addition, glucagon stimulates insulin release (mechanism unclear), rendering it unsuitable as an antidote for sulfonylurea toxicity. For this reason, glucagon is better used in those patients known to have type I diabetes or in those for whom intravenous access is not easily obtained. In these patients, glucagon 1 mg IM or IV may be administered in adults and children who weigh more than 10 kg. In children who weigh less than 10 kg, 0.1 mg/kg up to a maximum dose of 1 mg may be given. Glucagon requires several minutes for effect, and intravenous administration of hypertonic dextrose should never be delayed while awaiting glucagon's effect. Because emesis is common following glucagon administration, precautions should be taken to assure airway protection. Intubation per se is not a prerequisite without other standard indications.

Diazoxide directly inhibits insulin secretion by opening potassium channels in β -islet cells. Because diazoxide may cause hypotension and sodium retention, it is rarely used today. Diazoxide may improve hypoglycemia secondary to severe oral hypoglycemic poisoning, but not that caused by insulin poisoning.¹⁸ Diazoxide 300 mg is administered IV over 30 min and dosing may be repeated every 4 h.

Octreotide, a somatostatin analogue, inhibits insulin release by the pancreatic β -islet cells. Octreotide reverses hypoglycemia from oral hypoglycemic agents in both healthy volunteers¹⁹ and in patients with sulfonylurea overdoses.²⁰ It currently has no role in the management of insulin overdose, although it is used in patients with insulinoma. The early use of octreotide should limit recurrent hypoglycemia and prevent the complications of excessive dextrose administration. Octreotide is given in a dose of 50 μ g SC every 6 h.

The cornerstone of management of most poisoned patients is gastrointestinal decontamination to prevent drug absorption into the body. Several oral hypoglycemic agents have been demonstrated to effectively adsorb to activated charcoal in vitro, and there is no reason to suspect that the remainder are not similarly well adsorbed. A single dose, and perhaps several doses, of activated charcoal may be beneficial for these patients.

The use of other decontamination techniques such as emesis, gastric lavage, and whole-bowel irrigation should be considered. Emesis has not been demonstrated to produce consistent evacuation of the stomach contents and may be complicated should altered consciousness or seizure activity develop abruptly from the hypoglycemia. Gastric lavage with a large-bore tube may evacuate some (but not necessarily all) pill fragments and allow administration of activated charcoal, but is associated with aspiration, esophageal injury, and vagal complications. Whole-bowel irrigation with a polyethylene glycol-based electrolyte solution may specifically benefit patients who have ingested sustained-release preparations.

Following large subcutaneous deposition of insulin, toxicity may be reduced by removal of the reservoir. Percutaneous aspiration or excision may reduce the extent and duration of hypoglycemia, although this therapy is not commonly recommended.

The half-life of chlorpropamide may be reduced from 49 to 13 h by ion trapping through alkalization of the urine, in a fashion analogous to treatment of salicylate toxicity.²¹ However, this effect appears limited to this agent.

Metformin overdose patients generally require only gastrointestinal decontamination and expectant management. The likelihood of concomitant sulfonylurea overdose should be assessed. Metformin-associated lactic acidosis must be aggressively treated to reduce its potential mortality rate. Hemodialysis appears to be the most beneficial therapy and should be instituted early.

DISPOSITION

Patients with hypoglycemia resulting from unintentional overdose of a short- or intermediate-acting insulin may not require admission if their condition is corrected and a normal blood glucose level is maintained for 4 to 6 h prior to discharge. Those with hypoglycemia resulting from long-acting insulin or sulfonylureas should be admitted, as should those with underlying diseases such as liver or renal insufficiency or starvation. Patients with serious complications of hypoglycemia such as seizures, or those who have refractory hypoglycemia, should be closely monitored. Obviously, patients who are hypoglycemic because of an attempted suicide, attempted homicide, or abuse should be admitted as needed.

Hypoglycemia may occur in a delayed fashion after the ingestion of an oral hypoglycemic agent, particularly in children. Therefore, adults who have deliberately overdosed with oral hypoglycemics and **children who have ingested even a single pill should be admitted** for 24 h of observation, even though they may demonstrate euglycemia for many hours. Investigations of child abuse may arise from the unindicated administration of insulin to children.

Section Fifteen

ENVIRONMENTAL INJURIES

FROSTBITE AND OTHER LOCALIZED COLD-RELATED INJURIES

Mark B. Rabold

Throughout history, the most celebrated and extreme reports of cold-related injuries have been in the field of military endeavor. From Hannibal's losing half his 46,000-man army crossing the Pyrenean Alps to frostbite and hypothermia to the tens of thousands of cases of trench foot during World War I, we have learned much. Perhaps the most famous cold-injury mass-casualty incident was Napoleon's retreat from Moscow during the dreadful winter of 1812-1813. Napoleon's surgeon-in-chief, Baron de Larrey, described how each evening thousands of French soldiers thawed and often inadvertently burned their frozen extremities over campfires, only to refreeze them again on the next day's march. Combined heat and cold injury coupled with refreezing and forced ambulation resulted in abysmal outcomes. In addition, thousands died from the tetanus sustained from their frostbite wounds. It was from this experience that Larrey recommended rubbing frostbitten extremities with snow. This destructive therapy was the standard of care until the 1950s and is still used occasionally by the lay public. It was not until 1956 that rapid rewarming of frozen extremities was studied by a Public Health Service medical officer in Tanana, Alaska, which laid the foundation of modern therapy.

EPIDEMIOLOGY

It is the inability to physiologically compensate for cold that produces injury.¹ However, cold itself is not the only factor in determining whether injury will occur. Duration of exposure, humidity, wind, altitude, clothing, medical conditions, behavior, and individual variability all contribute to the picture.^{2,3}

Cold-induced injury may be instantaneous, as with contact frostbite after touching a cold metal bottle of fuel, or more chronic, as in chilblains. Humidity is also important because it contributes to evaporative heat loss. Wet skin is more conducive to both subcutaneous ice crystal formation and trench foot. Wind velocity and cold, the wind-chill factor, have a synergistic effect on heat loss. For example, an ambient temperature of -7°C (19.4°F), when combined with a wind of 72.5 km/h (45 mi/h), will feel equivalent to -40°C (-40°F) on a windless day. The rigors of travel at high altitude also may predispose to cold injury. Although the lower barometric pressure has not been shown to directly influence susceptibility to cold injury, a number of factors associated with high altitude travel have. The fatigue, dehydration, and hypoxia often seen in climbers or trekkers, coupled with the extreme weather conditions and remote locations, all contribute to the incidence and severity of cold-related injuries at high altitude.

Inadequate clothing is probably the most preventable cause of cold-related injuries. Constrictive clothing and boots can reduce circulation to extremities and predispose to frostbite. An exposed head and neck can account for 80 percent of body heat loss. Natural-fiber clothing, such as wool and cotton, when compared with modern synthetics, such as polypropylene, have poorer wicking ability and greater thermal conductance and moisture retention. Simply changing out of cold, wet clothes into dry ones also can be preventive. During World War I, the British decreased the number of trench foot cases from over 29,000 in 1915 to a total of less than 500 in 1916-1918 by frequent foot drying and sock changing.

Individual behavior is extremely important as well. In fact, alcohol- or drug-intoxicated persons, combined with psychiatric patients, account for the majority of frostbite cases in the United States. Impaired judgment and lack of self-preservation instincts prevent these populations from dressing adequately and making rational decisions about exposure to the cold. Alcohol consumption also increases peripheral vasodilation and heat loss, which increases the risk for hypothermia, in addition, many of these patients smoke, which results in peripheral vasoconstriction and increases the risk of frostbite. Other examples of the precipitation of cold injury by individual behavior can be seen in case reports of significant facial frostbite by inhalation abuse of fluorinated hydrocarbons (e.g., Freon) and nitrous oxide.^{4,5} There also have been case reports of full-thickness frostbite resulting from inappropriate use of dry ice as a first-aid cold pack.⁶

Certain disease states, such as atherosclerosis, arteritis, hypovolemia, diabetes, vascular injury secondary to trauma or infection, and previous cold-related injuries, may predispose to cold-related injury.^{2,3,7} Military studies suggest that dark-skinned soldiers and those from warmer climatic regions are more susceptible to frostbite. Conversely, peoples indigenous to frigid climates, such as Eskimos, Tibetans, and Laplanders, are often "acclimated" to the cold and are less prone to injury.

Local cold-related injuries are classified into nonfreezing and freezing injuries.

NONFREEZING COLD INJURIES: CHILBLAINS AND TRENCH FOOT

Clinical Features

Chilblains, or pernio, is characterized by usually mild but uncomfortable inflammatory lesions of the skin of bared body areas caused by chronic intermittent exposure to damp, nonfreezing ambient temperatures with symptoms precipitated by acute exposure to cold.⁸ The hands, ears, lower legs, and feet are involved most commonly. The cutaneous manifestations, which appear up to 12 h after acute exposure, include localized edema, erythema, cyanosis, plaques, nodules, and in rare cases, ulcerations, vesicles, and bullae. Patients may complain of pruritus and burning paresthesias. Rewarming may result in the formation of tender blue nodules, which may persist for several days. This is primarily a disease of women and children, and although rare in the United States, chilblains is common in the United Kingdom and other countries with a cold or temperate, damp climate. In addition, it appears that young females with Raynaud phenomenon are at greatest risk, as well as those in households with inadequate heating and lack of warm clothing.

Trench foot was given its current name after it was found frequently among World War I troops who had been confined for long periods in trenches filled with standing cold water.⁹ Significant numbers of cases also were seen in the Falkland and Vietnam wars. Immersion foot describes a more severe variant of trench foot seen in downed pilots and shipwrecked sailors exposed for extended periods in life rafts in the North Atlantic Ocean. Although they are a significant problem in military operations, trench foot and immersion foot are seen rarely in the civilian population.

The pathophysiology of trench foot is multifactorial but involves direct injury to soft tissue sustained from prolonged cooling, and it is accelerated by wet conditions. The peripheral nerves seem to be the most sensitive to this form of injury. Trench foot develops slowly over

hours to days and is reversible initially but will become irreversible if allowed to progress. Early symptoms progress from tingling to numbness of the affected tissues. On initial examination, the foot is pale, mottled, anesthetic, pulseless, and immobile, which initially does not change after rewarming. A hyperemic phase begins within hours after rewarming and is associated with severe burning pain and reappearance of proximal sensation. As perfusion returns to the foot over 2 to 3 days, edema and bullae form, and the hyperemia may worsen. Anesthesia frequently persists for weeks but may be permanent. In more severe cases, tissue sloughing and gangrene may develop. Hyperhidrosis and cold sensitivity are common late features and may persist for months to years. Severe cases may be associated with prolonged convalescence and permanent disability.

Treatment

Management of chilblains is supportive. The affected skin should be rewarmed, gently bandaged, and elevated. Some European studies support the use of oral nifedipine 20 mg three times daily, oral pentoxifylline 400 mg three times daily, or an oral analogue of prostaglandin E₁, limaprost, 20 [xg three times daily as both a prophylactic and therapeutic treatment for local cold injury.^{9,10} Topical corticosteroids (0.025% fluocinolone cream) and even a brief burst of oral corticosteroids, such as prednisone, have been shown to be useful. Affected areas are more prone to reinjury.

Effective prophylaxis for trench foot includes keeping warm, ensuring good boot fit, changing out of wet socks several times a day, never sleeping in wet socks and boots, and once early symptoms are identified, maximizing efforts to warm, dry, and elevate the feet. Once injury has occurred, treatment is supportive. Oral pentoxifylline 400 mg three times daily or an oral analogue of prostaglandin E₁, limaprost, 20 [xg three times daily can be used.^{9,10} Feet should be kept clean, warm, dry, bandaged, elevated, and closely monitored for early signs of infection.⁹

FREEZING COLD INJURIES: FROSTNIP AND FROSTBITE

Pathophysiology

Cutaneous vascular tone can be altered by direct heating (e.g., warming hands over a fire) and indirect heating (e.g., putting on a hat to increase core temperature) and is modulated by sympathetic adrenergic vasoconstrictive fibers. In a euthermic 70-kg male, the total basal cutaneous blood flow is 200 to 500 mL/min. However, as the skin temperature drops to 14°C (57.2°F), the flow falls to 20 to 50 mL/min. As cooling continues to 10°C (50°F), cutaneous blood flow becomes negligible, with occurrence of 5- to 10-min cycles of vasodilatation and vasoconstriction, known as the *hunter's response* (Table 191-1). For individuals who are well acclimated to the cold, such as Eskimos, the intervals between cycles are often much shorter. As the vasodilatory phases carry cooled blood back from the extremities, the core temperature begins to fall. These cycles continue until the core temperature is threatened. The body attempts to maintain thermal integrity by completely shutting down flow to the coldest extremities. This begins phase I of frostbite, and irreversible tissue damage commences.¹ As skin temperatures fall well below 0°C (32°F), ice crystals form in the extracellular space. Crystals exert an osmotic force and pull fluid from the intracellular space, resulting in cellular dehydration and hyperosmolarity. The intracellular sodium concentration may raise tenfold. As the damage continues, proteins are denatured, enzymes are destroyed, and the cellular membranes are altered. Theoretically, intracellular ice crystals then form, especially in rapid freeze and refreeze injuries, producing structural damage to the cell.

Phase II is characterized by reperfusion injury as the involved extremity is rewarmed and some initial blood flow returns. Over a period

TABLE 191-1 Frostbite Pathophysiology Summary

Leakage of destructive prostaglandins and oxygen free radicals
Vasoconstriction and arteriovenous shunting
Necrosis demarcation and gangrene

of several hours to days, the damaged endothelium-lined capillaries allow leakage of fluid into the interstitium, intracellular swelling occurs, and oxygen free radicals are generated, which furthers endothelial damage. An arachidonic acid cascade forms, which liberates prostaglandin and thromboxane. This cascade promotes vasoconstriction, platelet aggregation, and leukocyte sludging, which results in venule and arterial thrombosis and subsequent ischemia, necrosis, and dry gangrene. Profound vasoconstriction and arteriovenous shunting occur at the margin between injured and noninjured tissue. Phase II is remarkably similar to the dynamics of a burn injury.

Frostbite injury can be divided into three zones. The zone of coagulation is the most severe, usually distal, and is irreversible. The zone of hyperemia is the more superficial, typically proximal, with the least cellular damage, and generally recovers without treatment in less than 10 days. The zone of stasis is the middle ground and is characterized by severe, but possibly reversible, cell damage. It is this middle zone where treatment may have benefit.

Clinical Features

Frostbite can occur on any skin surface but generally is limited to the nose, ears, face, hands, and feet.¹³ Frostbite has been reported in the penis and scrotum of joggers and in burn patients after prolonged treatment with ice. Also, a freezing keratitis of the cornea has been reported in snowmobilers and skiers who did not wear protective goggles.

Frostnip is on a continuum with frostbite and is a superficial freeze injury characterized by lack of extracellular ice crystal formation and absence of progressive tissue loss. The involved area appears pale from intense vasoconstriction and is associated with some discomfort. Symptoms resolve on rewarming, and tissue loss does not occur.

There has been much debate over the proper classification of the severity of frostbite.¹¹ One may classify frostbite into degrees of injury or into superficial and deep groups based on appearance at the time of presentation (Table 191-2). First- and second-degree injuries are classified as superficial, whereas third- and fourth-degree injuries are classified as deep. The initial clinical appearance is often deceiving, especially if some warming has not occurred. Most patients present after some warming has occurred and are in phase II of the injury.

First-degree injury is characterized by partial skin freezing, erythema, mild edema, lack of blisters, and occasional skin desquamation several days later. The patient may complain of transient stinging and burning, followed by throbbing. Prognosis is excellent.

Second-degree injury is characterized by full-thickness skin freezing, formation of substantial edema over 3 to 4 h, erythema, and formation of clear blisters rich in thromboxane and prostaglandins. The blisters form within 6 to 24 h, extend to the end of the digit, and usu-

hours to days and is reversible initially but will become irreversible if allowed to progress. Early symptoms progress from tingling to numbness of the affected tissues. On initial examination, the foot is pale, mottled, anesthetic, pulseless, and immobile, which initially does not change after rewarming. A hyperemic phase begins within hours after rewarming and is associated with severe burning pain and reappearance of proximal sensation. As perfusion returns to the foot over 2 to 3 days, edema and bullae form, and the hyperemia may worsen. Anesthesia frequently persists for weeks but may be permanent. In more severe cases, tissue sloughing and gangrene may develop. Hyperhidrosis and cold sensitivity are common late features and may persist for months to years. Severe cases may be associated with prolonged convalescence and permanent disability.

Treatment

Management of chilblains is supportive. The affected skin should be rewarmed, gently bandaged, and elevated. Some European studies support the use of oral nifedipine 20 mg three times daily, oral pentoxifylline 400 mg three times daily, or an oral analogue of prostaglandin E_j, limaprost, 20 [xg three times daily as both a prophylactic and therapeutic treatment for local cold injury.^{9,10} Topical corticosteroids (0.025% fluocinolone cream) and even a brief burst of oral corticosteroids, such as prednisone, have been shown to be useful. Affected areas are more prone to reinjury.

Effective prophylaxis for trench foot includes keeping warm, ensuring good boot fit, changing out of wet socks several times a day, never sleeping in wet socks and boots, and once early symptoms are identified, maximizing efforts to warm, dry, and elevate the feet. Once injury has occurred, treatment is supportive. Oral pentoxifylline 400 mg three times daily or an oral analogue of prostaglandin E_j, limaprost, 20 [jug three times daily can be used.^{9,10} Feet should be kept clean, warm, dryly bandaged, elevated, and closely monitored for early signs of infection.⁹

FREEZING COLD INJURIES: FROSTNIP AND FROSTBITE

Pathophysiology

Cutaneous vascular tone can be altered by direct heating (e.g., warming hands over a fire) and indirect heating (e.g., putting on a hat to increase core temperature) and is modulated by sympathetic adrenergic vasoconstrictive fibers. In a euthermic 70-kg male, the total basal cutaneous blood flow is 200 to 500 mL/min. However, as the skin temperature drops to 14°C (57.2°F), the flow falls to 20 to 50 mL/min. As cooling continues to 10°C (50°F), cutaneous blood flow becomes negligible, with occurrence of 5- to 10-min cycles of vasodilatation and vasoconstriction, known as the *hunter's response* (Table 191-1). For individuals who are well acclimated to the cold, such as Eskimos, the intervals between cycles are often much shorter. As the vasodilatory phases carry cooled blood back from the extremities, the core temperature begins to fall. These cycles continue until the core temperature is threatened. The body attempts to maintain thermal integrity by completely shutting down flow to the coldest extremities. This begins phase I of frostbite, and irreversible tissue damage commences.¹ As skin temperatures fall well below 0°C (32°F), ice crystals form in the extracellular space. Crystals exert an osmotic force and pull fluid from the intracellular space, resulting in cellular dehydration and hyperosmolarity. The intracellular sodium concentration may raise tenfold. As the damage continues, proteins are denatured, enzymes are destroyed, and the cellular membranes are altered. Theoretically, intracellular ice crystals then form, especially in rapid freeze and refreeze injuries, producing structural damage to the cell.

Phase II is characterized by reperfusion injury as the involved extremity is rewarmed and some initial blood flow returns. Over a period

of several hours to days, the damaged endothelium-lined capillaries allow leakage of fluid into the interstitium, intracellular swelling occurs, and oxygen free radicals are generated, which furthers endothelial damage. An arachidonic acid cascade forms, which liberates prostaglandin and thromboxane. This cascade promotes vasoconstriction, platelet aggregation, and leukocyte sludging, which results in venule and arterial thrombosis and subsequent ischemia, necrosis, and dry gangrene. Profound vasoconstriction and arteriovenous shunting occur at the margin between injured and noninjured tissue. Phase II is remarkably similar to the dynamics of a burn injury.

Frostbite injury can be divided into three zones. The zone of coagulation is the most severe, usually distal, and is irreversible. The zone of hyperemia is the more superficial, typically proximal, with the least cellular damage, and generally recovers without treatment in less than 10 days. The zone of stasis is the middle ground and is characterized by severe, but possibly reversible, cell damage. It is this middle zone where treatment may have benefit.

Clinical Features

Frostbite can occur on any skin surface but generally is limited to the nose, ears, face, hands, and feet.^{1,3} Frostbite has been reported in the penis and scrotum of joggers and in burn patients after prolonged treatment with ice. Also, a freezing keratitis of the cornea has been reported in snowmobilers and skiers who did not wear protective goggles.

Frostnip is on a continuum with frostbite and is a superficial freeze injury characterized by lack of extracellular ice crystal formation and absence of progressive tissue loss. The involved area appears pale from intense vasoconstriction and is associated with some discomfort. Symptoms resolve on rewarming, and tissue loss does not occur.

There has been much debate over the proper classification of the severity of frostbite.¹¹ One may classify frostbite into degrees of injury or into superficial and deep groups based on appearance at the time of presentation (Table 191-2). First- and second-degree injuries are classified as superficial, whereas third- and fourth-degree injuries are classified as deep. The initial clinical appearance is often deceiving, especially if some warming has not occurred. Most patients present after some warming has occurred and are in phase II of the injury.

First-degree injury is characterized by partial skin freezing, erythema, mild edema, lack of blisters, and occasional skin desquamation several days later. The patient may complain of transient stinging and burning, followed by throbbing. Prognosis is excellent.

Second-degree injury is characterized by full-thickness skin freezing, formation of substantial edema over 3 to 4 h, erythema, and formation of clear blisters rich in thromboxane and prostaglandins. The blisters form within 6 to 24 h, extend to the end of the digit, and usu-

long was the extremity frozen, and if it was thawed, did any refreezing occur? Was there any self-treatment, such as rubbing with snow or use of aloe vera cream or ibuprofen? Were recreational drugs, alcohol, or tobacco involved? Are there any predisposing medical conditions?

Frostbite is often associated with systemic hypothermia and dehydration, both of which can have a negative impact on the prognosis for tissue salvage. Rehydration and general warming are important adjuncts to therapy when indicated.

Frostbitten patients often present to the ED subacutely (>24 h after injury) and with the involved extremity in a partially thawed state. This more prolonged injury and slow, partial thawing usually translate into significantly longer hospital stays and greater tissue loss. However, this should not mean that the patient is treated any less aggressively than the acute patient. The target of treatment remains minimizing tissue loss by focusing on the zone of stasis, where damaged but potentially salvageable tissue exists.

Rapid rewarming is the core of frostbite therapy and should be initiated as soon as possible. **The injured extremity should be placed in gently circulating water at a temperature of 40° to 42°C (104°–107.6°F) for approximately 10 to 30 min, until the distal extremity is pliable and erythematous.** Frostbitten faces can be thawed using moistened compresses soaked in warm water. Some patients may tolerate immersion of their ears in a bowl or pool of warmed water. Anticipate severe pain during rewarming, and treat with parenteral opiates. The patient probably will require daily hydrotherapy and physical therapy during the inpatient phase.

Blister management and the use of prophylactic antibiotics are somewhat controversial. The current consensus is that clear blisters should be debrided or at least aspirated. The blister fluid is rich in destructive thromboxane and prostaglandins. Removal limits damage from these chemicals and enables access to the underlying tissue for topical therapy. Hemorrhagic blisters should not be debrided because this often results in tissue desiccation and worse outcome. However, there is some controversy as to whether aspiration is helpful. **Both blister types should be treated with topical aloe vera cream every 6 h, which helps to combat the arachidonic acid cascade.** Affected digits should be separated with cotton and wrapped with sterile, dry gauze. Elevation of the involved extremities helps decrease edema and pain.

The role of prophylactic antibiotics is unclear. The edema associated with the first several days after injury does appear to predispose to infection. *Staphylococcus aureus*, *Staphylococcus epidermidis*, and (J-hemolytic streptococci account for nearly half of infections, but anaerobes, *Pseudomonas*, and *Enterococcus* are important pathogens as well. Therapy with penicillin G 500,000 U IV every 6 h for 48 to 72 h is recommended in several successful protocols and seems to be beneficial. However, infection prophylaxis using topical bacitracin may be as good or better than intravenous penicillin. Silver sulfadiazine cream also has been advocated by some, but it has not been shown to be consistently beneficial. One disadvantage of using topical antibiotics is that they complicate the concurrent use of aloe vera cream. Tetanus immunization status should be assessed and appropriate vaccination administered if needed because frostbite is considered a tetanus-prone wound (see Chap. 48).

Several agents besides aloe vera cream have been advocated to battle the arachidonic acid cascade and thereby limit tissue damage. The most commonly advocated oral medication is ibuprofen 12 mg/kg per d PO in divided doses. Animal studies suggest possible future roles for oral methimazole (a thromboxane synthetase inhibitor) and topical 1% methylprednisolone acetate (a phospholipase A₂ inhibitor) in preventing the formation of arachidonic acid.

Another controversial area is the use of sympathetic blockade with either intraarterial reserpine or surgical sympathectomy to relieve vasospasm and edema. There is no role for early sympathectomy, and the controversy is beyond the scope of ED management.

Heparin and hyperbaric oxygen therapy have been studied and appear to be of little value. To date, frostbite treatment with intravenous

low-molecular-weight dextran has not been studied clinically in humans, but anecdotal reports have been encouraging. Some preliminary data from a study using intraarterial recombinant tissue plasminogen activator in patients with third-degree frostbite suggest that it may hold some promise in decreasing the rate of amputation.¹⁴ A recent limited study suggests that the oral prostaglandin E₁ analogue iloprost 20 [µg three times daily may be an effective prophylactic and therapeutic vasodilator for local cold injuries at high altitudes.¹⁰

Early surgical intervention is not indicated in the management of frostbite. Premature surgery has been an important contributor to unnecessary tissue loss and poor results in the past. This is due primarily to the inability to assess the depth of frostbite at early stages and the fact that the blackened, mummified carapace is protective of the underlying regenerating tissue. Limited early escharotomy may be indicated if the eschar is preventing adequate range of motion or circulation. Fasciotomy is rarely, if ever, indicated. Amputation may be unavoidable, however, if wet gangrene or infection complicates recovery. It usually takes at least 3 to 4 weeks for full demarcation to occur. Most amputations and grafts occur during the third week. The mean length of hospital stay for all degrees of frostbite is reported to be from 8.5 to 33.2 days. To minimize extended hospital stays, some have advocated the early use of radionuclide angiography with bone scan at 7 to 14 days to assess tissue viability and possible early surgical debridement.¹⁵ However, a recent case report suggests that the use of magnetic resonance imaging with magnetic resonance angiography may prove to be more helpful in the early determination of the degree of tissue damage and the eventual prognosis.¹⁶

Disposition

Since it is difficult to determine the extent of frostbite on initial examination, it is best to be conservative when contemplating admission.¹³ It has been the standard of care in the past to admit all but the most isolated and superficial frostbite cases. It is important to consider the associated social factors as well. The homeless or elderly, especially when unable to care for themselves adequately, should never be discharged into subfreezing temperatures. If the frostbite is extensive and the hospital and staff are not equipped to treat the degree of severity, transfer of the patient to a tertiary hospital should be considered after initial rewarming and treatment. Patients who are discharged from the ED should be treated with topical aloe vera cream and oral ibuprofen and encouraged not to smoke. Close surgical follow-up should be arranged.

Sequelae

The sequelae of frostbite can be significant and prolonged.³ Permanent cold sensitivity, pain, tingling, and hyperhidrosis are common. Skin color changes may occur. When deep frostbite involves bones or joints, arthritis may result. In pediatric patients, growth plate damage may result in digit shortening and radial deviation. As noted earlier, infection is a possible complication, and deep frostbite often results in amputation.

HYPOTHERMIA

Howard A. Bessen

EPIDEMIOLOGY

Hypothermia is defined as a core temperature of less than 35°C (95°F). While most commonly seen in cold climates, it may develop without exposure to extreme environmental conditions. Hypothermia is not uncommon in temperate regions and may even develop indoors during the summer. In the United States, an average of 700 people die from hypothermia each year. Half of those who die from hypothermia are older than 65 years of age.¹

Individuals at the extremes of age and those with an altered sensorium for any reason are particularly susceptible to developing hypothermia. The elderly may lose their ability to sense cold, and neonates easily become hypothermic because of their large surface-area-to-volume ratio. Both groups have a limited ability to increase heat production and to conserve body heat. Individuals with an altered sensorium, if unable to carry out the appropriate behavioral responses to cold stress, may develop hypothermia despite otherwise intact thermoregulatory mechanisms.

PHYSIOLOGY OF TEMPERATURE HOMEOSTASIS

Body temperature may fall as a result of heat loss by conduction, convection, radiation, or evaporation. *Conduction* is the transfer of heat by direct contact down a temperature gradient, e.g., from a warm body to the cold environment. Since the thermal conductivity of water is approximately 30 times that of air, the body loses heat rapidly when immersed in water, producing a rapid decline in body temperature. *Convection* is the transfer of heat by the actual movement of heated material, e.g., wind disrupting the layer of warm air surrounding the body. Convective heat loss increases markedly in windy conditions. Heat also may be lost by *radiation* to the environment (primarily from noninsulated body areas) and by *evaporation of water*. Evaporation of the water contained in exhaled, water-saturated air occurs over a wide range of ambient temperatures and may be prevented by inhalation of warmed, humidified air.

Opposing the loss of body heat are the mechanisms of heat conservation and gain. In general, these are controlled by the hypothalamus; thus hypothalamic dysfunction may cause impairment in temperature homeostasis. Heat is conserved by peripheral vasoconstriction and, importantly, by behavioral responses. If behavioral

responses such as putting on clothing or coming indoors from a cold environment are impaired for any reason (e.g., drug intoxication or trauma), the risk of hypothermia is increased.

Heat gain is effected by shivering and by nonshivering thermogenesis. The nonshivering component of heat production consists of an increase in metabolic rate brought about by increased output from the thyroid and adrenal glands.

ETIOLOGY

The most important causes of hypothermia are listed in Table 192-1. "Accidental" hypothermia may be divided into immersion and nonimmersion cold exposure. Exposure to cold environmental conditions may lead to hypothermia even in healthy subjects, especially in wind and rain. Inadequate clothing and physical exhaustion contribute to the loss of body heat. The high thermal conductivity of water leads to the rapid development of hypothermia during immersion. The rate of heat loss is determined by water temperature, and immersion in any water colder than 16° to 21°C (60.8° to 69.8°F) can lead to severe hypothermia.

Metabolic causes of hypothermia include various hypoendocrine states (hypothyroidism, hypoadrenalism, hypopituitarism) that lead to a decrease in metabolic rate. Hypoglycemia also may lead to hypothermia; the probable mechanism is hypothalamic dysfunction secondary to glucopenia. Other causes of hypothalamic and central nervous system (CNS) dysfunction (e.g., head trauma, tumor, stroke) may interfere with mechanisms of temperature regulation. Wernicke disease may involve the hypothalamus; this is a rare but important cause of hypothermia because it is potentially reversible with parenteral thiamine administration.

In the United States, most hypothermic patients are intoxicated with ethanol or other drugs. Ethanol is a vasodilator, and because of its anesthetic and CNS depressant effects, intoxicated subjects neither feel the cold nor respond to it appropriately. Other sedative-hypnotic and vasodilating drugs also may be implicated in the development of hypothermia, as may insulin and other hypoglycemic agents.

Sepsis may alter the hypothalamic temperature set point and is a well-known cause of hypothermia. Subnormal body temperature is a poor prognostic factor in patients with bacteremia. Severe dermal disease may impair the skin's thermoregulatory functions. Significant burns or severe exfoliative dermatitis may prevent cutaneous vasoconstriction and increase transcutaneous water loss, predisposing to the development of hypothermia. Hypothermia may develop in anyone with an acute incapacitating illness. Thus patients with severe infections, diabetic ketoacidosis, immobilizing injuries, and various other conditions may have impaired thermoregulatory function, including altered behavioral responses. Hypothermia also may be induced by resuscitation with room-temperature fluid or cold blood. This is a particular risk in patients undergoing massive volume replacement, such as trauma patients.

PATHOPHYSIOLOGY AND CLINICAL FEATURES

The response of various organ systems to lowered temperature varies widely among individuals.^{2,3,4} In general, body temperatures from 32°

SECTION 15 • ENVIRONMENTAL INJURIES

to 35°C (89.6°-95°F) constitute "mild" hypothermia. In this temperature range, the patient is in an excitation (responsive) stage, in which physiologic adjustments attempt to retain and generate heat.

When temperature drops below 32°C (89.6°F), general excitation gives way to the slowing (adynamic) stage, in which there is a progressive slowdown of bodily functions and metabolism, causing a decrease in both oxygen utilization and CO₂ production. Shivering ceases when body temperature falls below 30° to 32°C (86°-89.6°F), removing a major source of heat production.

In the initial excitation phase, heart rate, cardiac output, and blood pressure all rise. With decreasing temperature, these all decline. Cardiac output and blood pressure may be markedly depressed by the negative inotropic and chronotropic effects of hypothermia and further depressed by concomitant hypovolemia. Hypothermia causes characteristic electrocardiographic (ECG) changes and may induce life-threatening dysrhythmias⁵ (Table 192-2). The Osborn (J) wave, a slow, positive deflection at the end of the QRS complex, is characteristic, though not pathognomonic, of hypothermia (Figure 192-1).

Patients are at risk for dysrhythmias at body temperatures below 30°C (86°F); the risk rises as body temperature decreases. Although various dysrhythmias may occur at any time, the typical sequence is a progression from sinus bradycardia to atrial fibrillation with a slow ventricular response, to ventricular fibrillation, and ultimately, to asystole. The hypothermic myocardium is extremely irritable, and ventricular fibrillation may be induced by a variety of manipulations and interventions that stimulate the heart, including rough handling of the patient.^{3,6}

Pulmonary effects include initial tachypnea, followed by a progressive decrease in respiratory rate and tidal volume. Cold-induced bronchorrhea, along with a depression of cough and gag reflexes, makes aspiration pneumonia a common complication.

Much attention has been paid to the temperature correction of arterial blood gases in the hypothermic patient. Since the blood gas analyzer warms the blood to 37°C (98.6°F), thus increasing the partial pressure of dissolved gas, the machine will report a higher Po₂ and Pco₂ and lower pH than the actual values at the patient's body temperature. Correction factors and nomograms are available to determine the actual values in the patient's body; however, the optimal or normal values in hypothermia are not known. The simplest solution is to use the uncorrected values as if the patient were normothermic; studies suggest that this approach is the most physiologically sound. Pco₂ is often quite low secondary to depressed metabolism and decreased CO₂ production, and iatrogenic hyperventilation may lead to marked respiratory alkalosis.

Hypothermia causes a leftward shift of the oxyhemoglobin dissociation curve, potentially impairing oxygen release to tissues. Patients may have minimal oxygen reserves despite diminished oxygen requirements, warranting the administration of supplemental oxygen.

The CNS is affected by hypothermia, with a progressive depression of consciousness with decreasing temperature. Mild incoordination is followed by confusion, lethargy, and coma; pupils may be dilated and unreactive. These changes are associated with a decrease in cerebral blood flow. An even greater decrease in cerebral oxygen requirements may protect the brain against anoxic or ischemic damage.

Hypothermia impairs renal concentrating abilities and induces a cold diuresis, leading to significant volume losses. Because of this concentrating defect, urine flow and specific gravity are unreliable indicators of intravascular volume and circulatory status. The immobile hypothermic patient is prone to rhabdomyolysis, and acute renal failure may occur because of myoglobinuria and renal hypoperfusion. Intravascular volume is also lost due to a plasma shift to the extravascular space.

The combination of hemoconcentration, cold-induced increase in blood viscosity, and poor circulation may lead to intravascular thrombosis and subsequent embolic complications. Disseminated intravascular coagulation may occur because of release of tissue thromboplastins into the bloodstream, especially when circulation is restored during rewarming. Because cold inhibits both platelet function and the enzymatic reactions of the coagulation cascade, hypothermic patients are prone to bleeding. The coagulopathy may be evident clinically but not detected with routine coagulation tests, which are performed at 37°C (98.6°F).

Endocrine function is fairly well preserved at low body temperatures. Plasma cortisol and thyroid hormone levels are usually normal or elevated unless the patient has a preexisting deficiency. Glucose levels may be normal, low, or elevated. Although hyperglycemia is common due to decreased insulin release as well as decreased glucose utilization, hypoglycemia may occur in a significant percentage of patients.

Acid-base disturbances are common in hypothermia but follow no uniform pattern. Acidosis may occur due to severe respiratory depression and CO₂ retention, as well as due to lactic acid production from shivering and poor tissue perfusion. Alkalosis may result from diminished CO₂ production with low metabolic rates, from iatrogenic hyperventilation, or sodium bicarbonate administration.

Pancreatitis (not only hyperamylasemia but true pancreatic necrosis) may occur in hypothermia. Hepatic function is depressed by cold, and drugs normally metabolized, conjugated, or detoxified by the liver may accumulate rapidly to toxic levels. Finally, local cold injury and frostbite may occur in the hypothermic patient.

DIAGNOSIS

The diagnosis of hypothermia is often not obvious, especially in patients without exposure to profoundly cold environments. Since some standard clinical thermometers record only to 34.4°C (94°F), low-reading thermometers are required to accurately measure the temperature of hypothermic patients. Electronic thermometers with flexible probes can be used to continuously monitor rectal, bladder, or esophageal temperatures.

TREATMENT

Treatment includes both general supportive measures and specific rewarming techniques. Therapy begins with careful, gentle handling be-

cause manipulation can precipitate ventricular fibrillation in the irritable hypothermic myocardium. Pulses may be difficult to detect in the profoundly hypothermic patient, and chest compressions may cause ventricular fibrillation. To avoid inappropriate chest compressions, the patient who is unmonitored or in a "nonarrested rhythm" (a rhythm other than ventricular fibrillation or asystole, such as sinus bradycardia or atrial fibrillation) should be examined carefully for respiratory activity and pulses. If no respiration is seen, ventilation should be initiated. Then 30 to 60 s should be spent attempting to palpate a pulse. If no pulses are detected, CPR should be initiated.^{7,8}

Oxygen and intravenous fluids should be warmed, and patients should have constant monitoring of their core temperature, cardiac rhythm, and oxygen saturation. Pulse oximetry is usually accurate in hypothermic patients, although unreliable data may be obtained with profound vasoconstriction or a very low cardiac output. If central venous lines are placed, care should be taken to avoid entering and irritating the heart. In general, indications for endotracheal intubation are the same as in the normothermic patient. Concern has been raised regarding induction of dysrhythmias during intubation; however, there is a very low complication rate with careful intubation after oxygenation.⁹

Although dysrhythmias in the hypothermic patient may represent an immediate threat to life, most rhythm disturbances (e.g., sinus bradycardia, atrial fibrillation or flutter) require no therapy and revert spontaneously with rewarming. In addition, the activity of antiarrhythmic and cardioactive drugs is unpredictable in hypothermia, and the hypothermic heart is relatively resistant to atropine, pacing, and countershock. Ventricular fibrillation may be refractory to therapy until the patient is rewarmed. The American Heart Association's 2000 guidelines suggest initial defibrillation attempts with up to three shocks. If this is unsuccessful, CPR should be instituted and rapid rewarming begun. Defibrillation should be reattempted when the core temperature reaches 30°C (86°F).⁷

Drug Therapy

Because many hypothermic patients are thiamine-depleted alcoholics (and because Wernicke disease may cause hypothermia), patients should be given intravenous thiamine 50 mg. Between 50 and 100 mL of 50% glucose should be administered if a test-strip serum glucose measurement is low or if a rapid test is unavailable.

Administration of antibiotics, steroids, and thyroid hormone must be individualized. Serious, often occult infections may either precipitate or complicate hypothermia, and a thorough search for infection is indicated. Empirical antibiotic therapy is appropriate when a noninfectious cause of hypothermia cannot be identified.¹⁰ Routine steroid therapy generally is not indicated, but hydrocortisone (100 mg) should be given to the patient with a history of adrenal suppression or insufficiency preceding the hypothermic episode, as well as to the patient with myxedema coma.

Hypothermia and hypothyroidism share many clinical features. While most patients with myxedema coma are hypothermic, only a small minority of hypothermic patients are hypothyroid; thyroid hormone levels are most often normal or elevated.¹⁰ Thyroxine in large doses is necessary for the patient in myxedema coma but potentially could cause dysrhythmias or cardiac ischemia in other hypothermic patients. Therefore, thyroid hormone replacement is indicated only in patients with a known history of hypothyroidism, a thyroidectomy scar, or other strong clinical evidence of myxedema coma.

Rewarming Techniques

Many modalities are available for rewarming; the choice of method is a matter of controversy (Table 192-3). There are no prospective, controlled studies comparing rewarming methods in humans, and each method has advantages and disadvantages.

TABLE 192-3 Rewarming Techniques

Passive rewarming:		
Removal from cold environment		
Insulation	Active	
external rewarming:		
Warm water immersion		
Heating blankets set at 40°C		
Radiant heat		
Forced air	Active	core
rewarming at 40°C:		
Inhalation rewarming		
Heated IV fluids		
GI tract lavage		
Bladder lavage		
Peritoneal lavage		
Pleurallavage		
Extracorporeal rewarming		
Mediastinal lavage via thoracotomy		

Passive rewarming allows patients to rewarm on their own, using endogenous heat produced by metabolism. Since patients often become hypothermic over a period of hours to days, slow, passive rewarming is physiologically sound, avoiding rapid changes in cardiovascular status and the complications associated with active rewarming methods.¹¹ Patients must have intact thermoregulatory mechanisms and be capable of metabolic heat production for successful passive rewarming. With severe hypothermia or hypothermia secondary to an underlying illness, patients may fail to rewarm passively; active rewarming is then indicated. In addition, since temperature rises slowly with passive rewarming, it is inappropriate for patients with cardiovascular compromise.

Active external rewarming (application of exogenous heat to the body surface) is often very effective in raising body temperature. Warm water immersion affords rapid rewarming but makes resuscitation and monitoring difficult and is impractical for use in the ED. Rewarming with heated air forced through slits in commercially available plastic or paper blankets (e.g., Bair-Hugger, Augustine Medical, Eden Prairie, MN) appears very promising; this method has been used successfully in moderately to severely hypothermic patients.^{12,13}

External rewarming does have disadvantages. It may be ineffective with poor perfusion of the periphery, especially in patients in cardiac arrest. Application of external heat may cause peripheral vasodilation and venous pooling, leading to relative hypovolemia and hypotension (rewarming shock). Washout of lactic acid from the peripheral tissues may lead to rewarming acidosis, and an increase in metabolic demands of the periphery before the hypothermic heart can provide adequate tissue perfusion may lead to further tissue hypoxia and acidosis.

The core temperature may continue to decline after rewarming has begun. This *core temperature afterdrop* has been ascribed to the return of cold blood to the core induced by external warming and peripheral vasodilation. This may occur, but afterdrop also can be explained by the continued conduction of heat from the relatively warmer core to the colder peripheral tissues. The incidence and magnitude of afterdrop are unclear, as is its clinical significance.^{3,6}

Active core rewarming has several theoretical advantages. Internal organs including the heart are preferentially rewarmed, decreasing myocardial irritability and returning cardiac function. Peripheral vasodilation is avoided, decreasing the incidence and magnitude of rewarming shock and acidosis. However, some internal rewarming techniques are invasive and may be unavailable or difficult to institute.

Inhalation rewarming is the administration of warmed, humidified air or oxygen by face mask or endotracheal tube. By itself, it provides a small heat gain but also minimizes heat loss from the lungs, which can account for up to 30 percent of the body's total metabolic heat production. A heater is interposed in the ventilator or face mask tubing,

and the tubing must be covered with insulating material to prevent heat loss during delivery. The temperature of the gas delivered to the face mask or endotracheal tube should measure 40°C (104°F).

Intravenous fluids and blood should also be warmed to 40°C (104°F) before administration, especially in patients receiving massive volume resuscitation. Commercial fluid warmers allow the temperature of infused fluids to be controlled precisely.

Both inhalation rewarming and administration of heated fluids should be used in all patients because these are simple techniques without complications, as long as the temperature is controlled. Temperatures >50°C (122°F) can cause airway burns and intravascular hemolysis.

Gastrointestinal tract (gastric or colonic) lavage with warmed saline is technically simple, and patients can be lavaged with large volumes of warm fluid in a short time period. However, the obtunded hypothermic patient may develop pulmonary aspiration if lavaged with an unprotected airway. In a manner similar to gastrointestinal tract lavage, the bladder can be lavaged with warm saline solution using a urinary drainage catheter.

Peritoneal lavage affords relatively rapid rewarming.¹⁴ It is widely available, may be instituted rapidly and with little technical difficulty, and has been shown to be effective in both animal studies and human applications. Potassium-free dialysis solution is warmed to 40° to 45°C (104°-113°F), instilled, and then removed; the use of two catheters (one for fluid instillation and one for removal) may increase the rewarming rate.

Pleural lavage using thoracostomy tubes has provided effective rewarming in animal studies and a few human cases.¹⁵ Lavaging the left thoracic cavity delivers heated fluid in close proximity to the heart, potentially allowing rapid cardiac warming. Two thoracostomy tubes (for fluid inflow and outflow) generally have been employed. If this technique is chosen, care must be taken to monitor the net fluid infusion because increased intrathoracic pressure and tension hydrothorax may complicate the procedure. The risk of precipitating dysrhythmias during chest tube insertion is unknown.

Rapid internal rewarming also can be accomplished through an extracorporeal circuit.^{16,17} This consists of an arteriovenous or venovenous shunt in which blood is routed to a warming device and then returned to the patient. Pump-assisted cardiopulmonary bypass using the femoral vessels for access is the most commonly used extracorporeal technique; right atrial-aortic bypass using a median sternotomy and heated hemodialysis also has been employed. Continuous arteriovenous rewarming using a countercurrent heat exchanger (a modified commercial fluid warmer) interposed between catheters placed in the femoral vessels, with flow driven by the patient's blood pressure, also has been reported.¹⁸ This technique obviates the need for pump support and systemic heparinization but relies on the patient's circulation and is ineffective in patients with significant hypotension. Venovenous bypass is a similar technique that employs a roller pump to assist blood flow.¹⁹

Profoundly hypothermic patients may be rewarmed in a very short time period with these methods.^{16,17} In addition to allowing rapid rewarming, pump-driven partial (femoral-femoral) or complete (right atrial-aortic) cardiopulmonary bypass provides circulatory support and oxygenation of blood, a great advantage in the management of patients in cardiac arrest or with severe cardiovascular compromise. Specialized equipment and personnel are required, however, and lack of immediate availability often precludes the use of this technique. In addition, the heparinization required for some extracorporeal techniques may cause complications in hypothermic trauma patients.

Various diathermy and radiowave techniques, although promising, have had limited use in hypothermic humans.

Finally, warm mediastinal irrigation via open thoracotomy has been used successfully in a small number of patients, although it is possible that these patients could have been resuscitated using less invasive modalities.²⁰ Thoracotomy has many potential complications and should be considered only in arrested patients.

Approach to Rewarming

No prospective, controlled studies comparing the various rewarming modalities have been done in humans. Therefore, firm guidelines for therapy cannot be given.

Patients with mild hypothermia, who are still in the "excitation" stage, generally improve spontaneously, as long as endogenous heat production mechanisms are functional. In addition, at temperatures above 30°C (86°F), the incidence of dysrhythmias is low, and rapid rewarming is rarely necessary.

By far the most important consideration is the patient's cardiovascular status; a secondary consideration is the presenting temperature. Some feel that patients with a stable cardiac rhythm (including sinus bradycardia and atrial fibrillation) and stable vital signs do not need rapid rewarming, even if the temperature is very low. They recommend passive rewarming and noninvasive rewarming modalities (e.g., forced-air rewarming, warm moist oxygen, and warm intravenous fluids) in this setting. Others argue that profoundly hypothermic patients, even if currently "stable," are at risk of developing life-threatening dysrhythmias. They recommend rapid rewarming until the temperature has reached 30° to 32°C (86°-89.6°F) to minimize the time period during which dysrhythmias may develop. The relative merits of each approach have not been studied.

Patients with cardiovascular insufficiency or instability, including persistent hypotension and life-threatening dysrhythmias, need to be rewarmed rapidly. Extracorporeal techniques offer many advantages but often are unavailable. If extracorporeal rewarming is not available, multiple other rewarming modalities can be used simultaneously.

PROGNOSIS

Many hypothermic patients have severe infections or other life-threatening illnesses. Patients with "uncomplicated" hypothermia (often purely due to cold exposure) have a fairly low mortality rate; patients with significant associated diseases have a much worse prognosis.²¹ In terms of ultimate outcome, the underlying disease process is far more important than the initial temperature or the rewarming method chosen. Therefore, evaluation and treatment of these patients must include a search for associated diseases as well as treatment of the hypothermia itself.

If asphyxia (e.g., near-drowning) precedes the development of hypothermia, the prognosis is very poor.²² If asphyxia has not occurred, the protective effect of hypothermia may have an important influence on prognosis. Decreased oxygen requirements can protect the brain and other organs against anoxic and ischemic damage. This means that the usual criteria indicating death or irreversibility of disease are not valid in the hypothermic patient, who may even survive prolonged cardiac arrest without neurologic sequelae.

Hypothermic patients may recover completely after presenting in a rigid, apneic state with fixed and dilated pupils. Recovery has been documented with core temperatures as low as 14.2°C (57.6°F)²³ and with cardiac arrest for 6.5 h.²⁴ Death in hypothermia must be defined as a failure to revive with rewarming; unless there is strong evidence that the patient is not viable, resuscitative efforts should be continued until core temperature is at least 30° to 32°C (86°-89.6°F).

Patients with mild accidental hypothermia caused purely by environmental exposure may be discharged after rewarming in the ED, provided they are asymptomatic and can return to a warm environment. Most other hypothermic patients require hospital admission, both for management of hypothermia and for evaluation and management of underlying diseases.

ties.¹ Annual heat-related death rates average one per million for those 5 to 44 years of age but increase to five per million in the population older than 85 years.² From 1979 to 1999, 8015 heat-related fatalities were reported to the Centers for Disease Control in the United States.² Of these, 3829 were listed as due to "adverse weather conditions." Analysis of the 3764 weather-related deaths with known age found that 142 (4 percent) were younger than 4 years and 1068 (28 percent) were at least 75 years.² Heat illness is a rare but preventable cause of death in young athletes during competition. Between 1995 and 2001, 15 high school students died due to heat stroke while participating in the sport of football.

Heat-related deaths have averaged approximately 400 cases per year over the past 10 years in the United States, but the rate varies significantly according to the weather.² For example, fatality rates may spike to almost 200 deaths per million population during years with heat waves and droughts of substantial severity.³ Heat waves are defined as 3 or more consecutive days of sustained temperatures above 32.2°C (90°F).⁴ The number of nonfatal heat injury cases seeking medical care on a yearly basis is not known. One California study of occupational heat injuries found 1128 cases seeking medical care in a year; there were seven (0.62 percent) deaths, a 15 percent hospital admission rate, with 40 percent of workers being off work for several days after the initial medical evaluation.⁵ Applying this ratio of deaths to heat-related illness cases from this study to the entire U.S. population produces an estimate of about 60,000 individuals each year who seek medical attention for heat-related illness.

The male-to-female ratio for heat illness is essentially equal, and any age can be affected. Some populations at higher risk include: the elderly (age >75 years), especially if they have chronic illness or take medications that interfere with heat loss; young children (<4 years), particularly if they have congenital nervous system disease or diarrheal illness; those with limited mobility; alcoholics; and people taking antipsychotics, major tranquilizers, anticholinergics, antiparkinsonian agents, cardiovascular medications (p-blockers, calcium channel blockers, and vasodilators), and over-the-counter sleeping aids or stimulants.^{6,7} In addition, individuals with a prior history of heat stroke are at greater risk for another episode. Other risk factors for exertional heat illness include obesity, dehydration, and vigorous exertion in the heat without proper training and acclimatization. Other more rare disorders, such as congenital absence of sweat glands, progressive systemic sclerosis, hyperthyroidism, and pheochromocytoma, increase heat injury risk. The major environmental risk factor is exposure to heat stress on a constant basis without air-conditioning breaks or cooling during the night. Mortality rates for the most severe form of heat illness (heat stroke) range from 10 to 75 percent.⁵ Mortality is further increased in cases with severe underlying medical conditions and in individuals who have treatment delayed for longer than 2 h after the onset of severe symptoms.

PATHOPHYSIOLOGY

Mechanisms of Heat Transfer

The body regulates heat content through four mechanisms: radiation, conduction, convection, and evaporation. Radiation and conduction are considered the dry, or sensible, methods of heat loss. Convection is usually considered a separate mechanism, but heat must first be conducted into the surrounding medium in contact with the skin (air) before it can be moved away by convection. Convection is therefore an adjunct to conduction. Evaporation represents the most efficient method of losing heat and is considered the wet, or insensible, mechanism of heat loss.

Radiation is the primary mechanism of heat loss when the environmental temperature is lower than the body temperature. Radiative loss of heat occurs through the infrared range of the electromagnetic

HEAT EMERGENCIES

James S. Walker David E. Hogan

Environmentally induced heat-related illnesses result when physiologic and physiologic adaptation mechanisms fail during a period of elevated heat stress. Heat-related illnesses can be trivial to life-threatening. In most circumstances, heat illnesses can be avoided through public education and preventative measures.

EPIDEMIOLOGY

Heat illnesses have been the most frequent cause of environmentally related death in the United States during the past decade—more than lightning-, tornado-, flood-, hurricane-, cold-, or winter-related fatali-

spectrum. Infrared radiation flowing from the body into a cooler environment may account for up to 60 percent of body cooling in these conditions. When the surrounding environment is hot compared with the body, heat will be gained by radiation. Direct sunlight alone may account for a heat burden of 100 to 250 kcal/h.

Conduction of heat occurs when the kinetic energy of moving molecules of a warm surface (skin) is transferred directly to the less kinetically active molecules of a cooler surface (solid objects, water, or air). Conduction of heat energy into solid surfaces usually accounts for less than 3 percent of the total heat loss of the body. Conduction of heat into the ambient air surrounding the skin will rapidly stop as soon as that layer acquires the same temperature as the skin surface. This results in an "insulator zone" of warmed air through which little heat may be lost. Removing the warmed air next to the skin and replacing it with cooler air may increase conductive heat loss; this process is called *convection*. When conduction is coupled with convection, rates of heat energy transfer from the body may account for up to 15 percent of the total heat loss. Conduction of heat into water is 32 times more efficient than conduction into air of the same temperature. Because the specific heat of water is greater than air by a factor of several thousand, an insulator zone of warm water next to the skin cannot form to any degree.

The cooling effect of the wind on heat loss is approximately proportional to the square root of the wind velocity: a 4-km/h wind is about twice as effective as a 1-km/h wind in removing heat. Although moving the medium of the air away from the skin by convection improves heat loss by conduction, it has limits. Above 32.2°C (90°F) and 35 percent humidity, convection does not remove heat well from the body.⁸ Fans alone have not been demonstrated to decrease the rate of heat stroke during periods of high environmental temperature and humidity. Populations with no home air conditioning (often in the lower socioeconomic strata) have an elevated risk of almost 50 percent for a serious heat injury when compared with populations with air conditioning.⁹ Taking "heat breaks" in an air-conditioned location for periods as short as 2 h a day substantially decreases the rate of heat stroke for non-air-conditioned populations. It is clear that allowing the body to decrease the heat burden at some time during the day is critical to prevent heat illness under the above conditions.

Evaporation is the primary heat loss mechanism of the body in higher temperatures. Each gram of water evaporating from the skin and lungs removes about 0.58 kcal of heat. Even in the absence of sweating, a basal level of skin and respiratory evaporation (insensible loss) accounts for about 600 mL of water daily and 12 to 16 kcal of heat loss per hour. Evaporation accounts for over 25 percent of the heat lost in cooler settings and virtually 100 percent at high environmental temperatures. To achieve heat loss, water must be able to evaporate into the atmosphere. When the atmosphere contains high levels of humidity, evaporation is impaired and heat loss by this mechanism is decreased.

Evaporation depends on the creation of adequate amounts of sweat and adequate hydration for sweat gland secretion. Dehydration of as little as 1 percent can impair heat dissipation and physiologic responses.¹⁰ Each 1 percent decrease in body weight from dehydration results in a core temperature increase of 0.1°C to 0.3°C (0.18°F to 0.54°F). Dehydration impairs cardiovascular and thermoregulatory functions by decreasing skin blood flow and sweating rate. During vigorous exercise, athletes will voluntarily ingest only 50 percent of their sweat loss and can rapidly dehydrate. In addition, studies on Olympic athletes indicate that highly acclimatized humans can achieve sweating rates that exceed gastric emptying rates. Such sweating rates outstrip the ability of the gastrointestinal tract to absorb water and result in dehydration and eventual hyperpyrexia. It is estimated that sweating rates faster than 1 L/h are not sustainable with oral hydration alone.

Although some clothing can reflect and reduce absorption of radiant heat, clothing may also act as an insulator causing heat gain by reducing the efficacy of convection and evaporation. Cloth traps air

more efficiently close to the skin, thereby allowing the rapid development of an insulator zone of warm air, and provides increased air resistance, thereby decreasing the effectiveness of convection. Evaporation through cloth depends on the gradient of vapor pressure from the skin through the cloth and into the air.⁸ Clothing that interferes with the flow of water vapor decreases evaporative efficiency. Evaporation of water from the clothing is also less effective in removing heat than evaporation directly from the skin. Wearing a hat or clothing on the trunk interferes more substantially with heat loss than covering other body areas.

Response to Heat Stress

The body tends to maintain its core temperature between 36°C and 38°C (96.8°F and 100.4°F). Native thermal regulation mechanisms begin to fail at core temperatures below 35°C (95°F) and above 40°C (104°F).¹¹ It is possible to maintain core temperatures of 40°C to 42°C (104°F to 107.6°F) for short periods without adverse effect. The highest documented core temperature in a survivor of heat stroke is 46.5°C

Physiologic response to heat stress occurs through four primary methods: dilatation of blood vessels (particularly in the skin), increased sweat production, decreased heat production, and behavioral heat control. The primary function of heat regulation mechanisms in the human body seems to be attuned to prevention of heat loss in cold environments. It is by the release or reversal of these heat-conserving mechanisms that heat loss is achieved. As the core temperature of the body rises, the sympathetic outflow of the posterior hypothalamus (the primary heat conserving center) is inhibited, leaving unopposed the sympathetic outflow from the anterior hypothalamus. Sympathetic flow from the anterior hypothalamus results in decreased vascular tone throughout the body, particularly in the cutaneous circulation. Blood flow to the skin can increase from a basal level of 0.2 L/min to a maximum of about 8 L/min. Substantial stress may be placed on the cardiovascular system during this response, because cardiac output will increase about 3 L/min for each 1°C (1.8°F) elevation of core temperature.⁹ The heart rate increases to compensate for the decrease in stroke volume from the cutaneous vascular dilation to maintain cardiac output. Any patient with underlying cardiovascular disease or a pharmacologic or physiologic impairment of these mechanisms may not be able to maintain this degree of cardiac output. Heat stress may also result in arrhythmias, myocardial ischemia, and exacerbation of congestive heart failure.

Elevated cholinergic stimulation to the skin results in increased sweat production. Elevated levels of catecholamines that occur during the heat response recruit and stimulate more sweat glands to secrete. Sharp increases in the rate of sweat production normally occur with core temperature elevations above 37°C (98.6°F).

Metabolic heat production in the body is inhibited when the core temperature rises. The major metabolic decrease in heat production is achieved when the anterior hypothalamus signals to the primary motor center in the posterior hypothalamus to inhibit shivering. Chemical thermogenesis in mammals is primarily due to the uncoupling of oxidative phosphorylation in brown fat. Because adult humans have almost no brown fat, inhibition of this mechanism is thought to have little impact on the reduction of metabolic heat production. Likewise, although increased secretion of thyrotropin-releasing hormone by the hypothalamus is seen after prolonged cold exposure, inhibition of this response in hot environments does not play a significant role in the heat response.

Behavioral control of temperature regulation is important. As individuals begin to feel hot and uncomfortable when exposed to heat stress, they may take actions to find a cool environment. Public education regarding the heat-related illness should capitalize on this response mechanism.

Acclimatization

Acclimatization is the adaptation of the body's heat stress mechanisms to increase efficiency of heat loss in a hot climate. The process does not impart a full resistance to heat illness; it only provides a maximization of the native heat removal processes. The primary methods of acclimatization occur due to changes in the onset and volume of sweating, improvement in cutaneous vascular flow and overall cardiovascular function, and alterations of the thermoregulatory set point. In most individuals, acclimatization can be achieved over 7 to 10 days.^{10,11} Moderate exercise in a hot, dry environment for 60 to 100 min each day is probably the optimal approach to achieve acclimatization. Simple exposure to a hot environment for 1 to 4 h a day also may result in acclimatization within 2 weeks. Acclimatization lowers the thermal "set point" in the hypothalamus, which triggers the onset of sweating at lower core temperatures in the acclimatized human. In addition, the maximal rate of sweat production is dramatically increased to 1.5 to 3 L/h and can be sustained for longer periods. Aldosterone secretion is boosted, and sodium conservation results due to more efficient reabsorption from the sweat. Plasma volume expands, heart rate decreases for any given heat load, and exercise tolerance improves. Dilation of cutaneous blood vessels occurs at a lower core temperature to promote earlier cooling. Once removed from the hot environment, the body will deacclimate to the original physiologic parameters within 1 to 2 weeks.¹⁰ Acclimatization protocols to decrease the frequency of heat-related illness have been developed for personnel (military, laborers, and disaster relief workers) who are preparing to deploy to hot environments.

The Path to Heat Injury

The pathway to heat injury consists of a combination of three routes: increased heat production, increased external heat gain, and decreased heat loss. Distinctions made between nonexertional (classic) and exertional heat injuries denote only the primary method by which the hyperpyrexia is achieved. Although the population characteristics, risk factors, and physiologic parameters often differ between nonexertional and exertional heat injuries, the clinical effect on the patient is ultimately the same.

Obese people are at increased risk for exertional heat illness. Adipose tissue has decreased vascularity and inhibits heat dispersal by decreasing blood flow to the skin. Obesity makes less surface area available for heat exchange, and the lower water content of adipose tissue results in the conduction of heat energy that is one third as efficient as other body tissue.

Underlying skin conditions may contribute to decreased removal of heat. Scleroderma, cystic fibrosis, eczema, psoriasis, and burns decrease sweating ability. Congenital diseases, such as ectodermal dysplasia, involving the sweat glands increase risk of heat injury. Even the presence of heat rash has been shown to decrease sweating by obstruction of sweat gland ducts with keratin debris.

Febrile illnesses with readjustment of the thermal set point above normal may contribute to the risk of heat illness. The body will use heat-conserving mechanisms to maintain the core temperature at the higher set point. Proper treatment with antipyretics such as aspirin, acetaminophen, or ibuprofen in the setting of acute febrile illnesses may decrease the risk of heat injury in individuals exposed to heat stress. However, although systemic pyrogen release has been reported due to exercise and during heat stroke, the use of antipyretics in environmental heat illness has no scientific support. Metabolic disorders, such as hyperthyroidism and pheochromocytoma, also lead to increased endogenous heat production.

Medications often interfere with heat removal mechanisms. The most notable drugs are anticholinergic agents, diuretics, phenothiazine, β -blockers, calcium channel blockers, and sympathomimetic agents.⁷ Anticholinergic agents impair sweating and impair the car-

diovascular response to heat. Diuretics lead to volume depletion and decreased cardiac output. Phenothiazines have anticholinergic properties and deplete central stores of dopamine that interfere with the hypothalamus thermoregulatory center. Medications, such as β -blockers or calcium channel blockers, decrease the cardiovascular response to heat and reduce peripheral blood flow and the ability to sweat. Sympathomimetics cause cutaneous vasoconstriction and inhibit sweating. Alcohol inhibits antidiuretic hormone, leading to dehydration and blunting the psychological heat avoidance response. Heroin, cocaine, and amphetamines disrupt the function of endogenous endorphins and adrenocorticotrophic hormones that are involved in heat adaptation mechanisms. Amphetamines and cocaine increase muscle activity and lead to heat production. Lysergic acid diethylamide and phencyclidine act on the central nervous system (CNS) to induce a hypermetabolic state.^{7,9,10}

Classic heat injury occurs during periods of high environmental heat stress.^{12,13} Physical exertion is not required, because the heat gain occurs at environmental temperatures and humidity that overwhelm the native heat loss mechanisms. Patients suffering from this form of heat illness are unable to escape from the hot environment and cannot cope with the elevated heat burden. The increase in core temperature seen in this setting is often slow, occurring over a period of hours to days. Because of this slow rise in heat burden, volume and electrolyte abnormalities have time to develop and are common. High-risk populations include the elderly, the young, and those with psychological, physiologic, and pharmacologic impairments of heat loss mechanisms.

Confinement hyperpyrexia is a special category or subtype of nonexertional hyperpyrexia and can be found in three circumstances: children left inside cars, illegal immigrants abandoned inside closed vehicles or railroad cars, and occupational heat exposure inside enclosed spaces. Between July 2000 and June 2001 in the United States, 1960 nonfatal heat injuries and 78 fatalities were reported in children after being left intentionally in motor vehicles during hot days.¹⁴ Non-ventilated vehicle compartments in a hot environment may reach temperatures of 54°C to 60°C (129.2°F to 140°F) in less than 10 min.¹⁴ Infants have less capability than adults to deal with heat stress and, if left in motor vehicles for only a matter of minutes, may obtain a critical heat burden. The second circumstance exists along the U.S. border with Mexico. During 2000, at least 418 illegal immigrants are known to have died attempting to cross the border through the desert, with more than 50 percent of these deaths due to heat stroke, and many of these individuals were locked in closed vehicle compartments by smugglers after failed attempts to enter the United States. A particularly dangerous region is through the Tucson Sector of the border, which accounts for 22 percent of all southwest border deaths of illegal immigrants. During 2000, the U.S. Border Patrol rescued more than 846 such immigrants after smugglers had abandoned them.¹⁵ In the third circumstance, during 2000, 21 workers died and 2554 others experienced heat-related occupational injuries due to confinement in hot environments.

Exertional heat injury usually affects individuals who are physically fit and participating in athletic events or performing jobs under conditions of high heat stress, such as the military or fighting fires. In this setting, heat production and heat gain from the environment exceed the capacity of heat removal processes. Physical exercise is the most common single source of internal heat production. Basal metabolism in an average human creates heat at approximately 50 to 60 kcal/h per square meter, or about 100 kcal/h in a 70-kg man. Heat production rapidly increases during physical activity due to skeletal muscle contraction. Strenuous exertion can increase the basal heat production rate by a factor of 20 in a short period. During vigorous competitions, athletes may create heat loads in excess of 1033 kcal/h, leading to core temperature increases of 0.3°C/min (0.54°F/min).¹⁰ Without an efficient cooling mechanism, progressive dehydration and hyperpyrexia continue to a level of cardiovascular and metabolic failure. Avoidance of strenuous exercise during periods of high environmental

heat stress, as judged by the heat index chart, coupled with acclimatization, hydration, breaks from the heat, and education, will prevent this form of heat illness.

CLINICAL FEATURES

Heat-related illnesses are generally divided into two categories: minor syndromes (heat edema, prickly heat, heat syncope, heat cramps, and heat exhaustion) and major syndromes (e.g., heatstroke). Although heat-related illnesses are clearly related to the exposure of an elevated environmental temperature, the magnitude or intensity of this heat source is only relative when the patient is a young child or an elderly adult with comorbid diseases.

Heat Edema

Heat edema is a self-limited process manifested by the mild swelling of the feet, ankles, and hands that appears within the first few days of exposure to a hot environment. Heat edema is due to the cutaneous vasodilatation and orthostatic pooling of interstitial fluid in gravity-dependent extremities. Also, an increase in the secretion of aldosterone and antidiuretic hormone in response to the heat stress contributes to the mild edema. In general, heat edema is found in elderly nonacclimatized individuals who are physically active after a period of sitting while traveling in a vehicle or airplane. Occasionally, it will occur after prolonged standing. It is commonly seen in healthy travelers just arriving from a colder climate. The edema is mild and does not impair or interfere with normal activities. Very rarely, pitting edema of the ankles may develop, but heat edema does not progress to the pretibial region.
