43 THE SPONDYLOARTHROPATHIES

Hani S. El-Gabalawy, M.D. and Peter E. Lipsky, M.D.

The spondyloarthropathies are a group of disorders that have certain clinical features in common and are all associated with the expression of the human leukocyte antigen (HLA)-B27 gene product (1,2,3,4,5,6,7 and 8). The similar clinical manifestations and genetic association suggest that these conditions are related and may share common pathogenic mechanisms. The spondyloarthropathies include ankylosing spondylitis, Reiter syndrome (reactive arthritis), the arthritis associated with inflammatory bowel disease, the spondylitis associated with psoriasis, juvenile-onset spondyloarthropathy, and the less clearly defined undifferentiated spondyloarthropathy. The prototypic spondyloarthropathies are on the one hand, ankylosing spondylitis, which is a chronic condition characterized by an inflammation of joints and periarticular tissues of the axial skeleton, and on the other hand, Reiter syndrome, which is a more acute inflammatory process involving primarily peripheral joints. Both conditions, as well as the other spondyloarthropathies, are notable for the tendency of those affected to develop inflammation of sacroiliac joints and a variety of extraarticular manifestations.

The spondyloarthropathies have affected human beings since antiquity, with evidence of disease noted in ancient Egyptian mummies (9). There is strong evidence that a condition similar to the spondyloarthropathies also affects nonhuman primates, including apes and Old World monkeys (10). The first clear descriptions of ankylosing spondylitis as a distinct clinical entity date from the latter part of the 19th century, whereas reactive arthritis was first described in the 18th century (11). A number of prominent historical figures, including Christopher Columbus and Benvenuto Cellini, are thought to have had reactive arthritis (12,13).

CLASSIFICATION AND DISEASE DEFINITION

The distinguishing features of the spondyloarthropathies include (a) sacroiliitis with or without associated spondylitis, (b) inflammatory asymmetric arthritis, (c) association with HLA-B27, (d) ocular inflammation, and (e) absence of autoantibodies associated with other rheumatic diseases.

The development of a set of criteria with which to capture the diverse clinical spectrum of the spondyloarthropathies has been challenging. The European Spondyloarthropathy Study Group (ESSG) proposed classification criteria for all patients with spondyloarthropathies (Table 43.1). These criteria exhibit a sensitivity of 86% and a specificity of 87% (14). The so-called Amor criteria encompass a somewhat wider spectrum of clinical features than the ESSG criteria, and include the presence of HLA-B27 as a criterion (15). The ESSG had found that inclusion of HLA-B27 did not improve the overall performance of the criteria set. These two broad-based spondyloarthropathy criteria sets have been compared in populations of patients with definite spondyloarthropathies, and both perform well (14). Their performance in heterogeneous cohorts of patients with a recent onset of musculoskeletal symptoms is less certain.

One of the following:
- A. Inflammatory back pain
- B. Synovitis
  - 1. Asymmetric
  - 2. Predominantly involving the lower extremities

Plus any one of the following:
- A. Family history
- B. Psoriasis
- C. Inflammatory bowel disease
- D. Urethritis, cervicitis, or acute diarrhea within 1 month before arthritis
- E. Alternate buttock pain
- F. Enthesopathy
- G. Sacroiliitis

TABLE 43.1. Criteria for Classification of Spondyloarthropathy Proposed By the European Spondyloarthropathy Study Group

Ankylosing Spondylitis

Criteria for the diagnosis of ankylosing spondylitis have been established (16). Although the diagnosis of long-standing disease with typical deformities is straightforward, diagnosis of early disease before the development of irreversible deformity can be difficult. Currently, the widely used criteria for diagnosis include the following: (a) a history of inflammatory back pain, (b) limitation of motion of the lumbar spine in both the sagittal and frontal planes, (c) limited chest expansion, and (d) definite radiographic evidence of sacroiliitis. The presence of radiographic sacroiliitis and any one of the other three criteria is sufficient to establish a diagnosis of definite ankylosing spondylitis (Table 43.2).

A. Criteria
- 1. Clinical
  - a. Low back pain and stiffness for >3 months, which improves with exercise but is not relieved by rest
  - b. Limitation of motion of the lumbar spine in both the sagittal and frontal planes
  - c. Limitation of chest expansion relative to normal values corrected for age and sex
- 2. Radiologic
  - a. Sacroiliitis grade ≤2 bilaterally or sacroiliitis grade 3–4 unilaterally

B. Diagnosis
- 1. Definite ankylosing spondylitis if the radiologic criterion is associated with at least one clinical criterion
- 2. Probable ankylosing spondylitis if
  - a. Three clinical criteria are present
  - b. The radiologic criterion is present without any signs or symptoms satisfying the clinical criteria

Radiologic grading of sacroiliitis: 0, normal; 1, suggestive; 2, minimal abnormality (small localized areas of erosion or sclerosis without alteration in the joint width); 3, unequivocal abnormality (erosions, sclerosis, change in joint width or partial ankylosis); 4, severe abnormality (total ankylosis).

TABLE 43.2. Modified Diagnostic Criteria for Ankylosing Spondylitis

A group of individuals has been described who are HLA-B27 positive and manifest typical symptoms of ankylosing spondylitis but who lack definite radiographic evidence of sacroiliitis (17,18). In many of these patients, radiographic changes of sacroiliitis eventually develop. However, diagnosis of these patients can be difficult, because they may not meet the criteria for classification early in the disease course. The use of more sensitive imaging modalities such as computerized tomography and magnetic resonance imaging may enhance the ability to diagnose sacroiliitis in such patients. Although more than 90% of patients with ankylosing spondylitis express HLA-B27, testing for the presence of this HLA allele is useful only as an adjunct to diagnosis, as B27 is not present in all patients, and only a very small percentage of B27-positive patients will have ankylosing spondylitis. Documentation of the presence of B27 is most helpful in patients with early disease in whom radiographic evidence of sacroiliitis has not yet developed.

Ankylosing spondylitis must be differentiated from other conditions that cause low back pain. The inflammatory back pain of ankylosing spondylitis is usually distinguished by the following features: (a) age at onset younger than 40 years, (b) insidious onset, (c) duration longer than 3 months before medical attention is sought, (d) morning stiffness, and (e) improvement with exercise or activity. The most common causes of back pain other than ankylosing spondylitis are primarily mechanical or degenerative rather than inflammatory, and do not manifest these features. It is important to note that the noninflammatory causes of back pain are substantially more prevalent than is ankylosing spondylitis, and indeed may coexist in patients with this diagnosis.

Reiter Syndrome

The classic triad of Reiter syndrome consists of arthritis, urethritis, and conjunctivitis. However, less stringent criteria for the classification of Reiter syndrome have been established by the American College of Rheumatology (ACR) because as many as two thirds of patients who appear to have Reiter syndrome do not manifest the classic triad (11). ACR criteria require the presence of peripheral arthritis of more than 1 month's duration, occurring in association with urethritis, cervicitis, or both (19). The ACR criteria exhibit a sensitivity of 84.3% and a specificity of 98.2% when used to delineate patients with Reiter syndrome from those with ankylosing spondylitis, psoriatic arthritis, seronegative rheumatoid arthritis (RA), and gonococcal arthritis. However, these criteria have not been universally accepted because a substantial number of patients, especially at the onset of disease, do not meet ACR criteria or exhibit the diagnostic triad (5,20). Attempts have been made to develop means to identify and classify those patients who exhibit lower extremity or axial inflammatory arthropathy and are often HLA-B27 positive, but who fail to meet the ACR criteria for Reiter syndrome. Proposed categories have included “incomplete Reiter” (21), “undifferentiated” (18) or “overlap” spondyloarthropathy (22), “sexually acquired reactive arthritis” (SARA) (23), “BASE syndrome” (B27, arthritis, sacroiliitis, and extraarticular inflammation) (24), and the hereditary multifocal, relapsing inflammation (HEMRI) syndrome (25). The clinical usefulness, validity, and prognostic value of these categorizations have not been proven. Indeed, a review of the published literature on “Reiter syndrome” and “reactive arthritis” indicated that 22.5% of the studies did not use any published criteria for this diagnosis (26).

EPIDEMIOLOGY

Ankylosing Spondylitis

Family studies have shown a very strong genetic component to all of the spondyloarthropathies, this being the highest for ankylosing spondylitis. The degree of disease clustering in families can be estimated by the risk ratio known as I_s (the disease frequency in relatives of affected individuals divided by the disease frequency in the general population). The value for I_s for ankylosing spondylitis is estimated to be approximately 50, with most of this genetic risk being in the major histocompatibility complex (MHC) (27). Ankylosing spondylitis shows a striking correlation with the histocompatibility antigen HLA-B27 (2,7) and occurs worldwide in approximate proportion to the prevalence of B27 in the population (28,29 and 30). In most of the populations studied, more than 90% of patients with ankylosing spondylitis are HLA-B27 positive. In the North American white population, ankylosing spondylitis has been estimated to have a prevalence of approximately 0.1%, whereas HLA-B27 has a prevalence of approximately 7%. Population surveys have suggested that 1% to 2% of adults inheriting HLA-B27 have ankylosing spondylitis (30,31). In contrast, in families of patients with ankylosing spondylitis, 10% to 20% of adult first-degree relatives inheriting HLA-B27 have the disease (32,33). Interestingly, a study comparing HLA-B27–positive and –negative blood donors in Germany found that 19 (13.6%) of 140 HLA-B27–positive blood donors had a clinically detectable spondyloarthropathy, nine of whom had ankylosing spondylitis (34). This study estimated the prevalence of ankylosing spondylitis to be 0.85% in the overall Berlin population, and 6.4% in HLA-B27–positive individuals. A similar risk was defined in Norway (35). In contrast to the 5% to 10% prevalence rate of HLA-B27 in white populations, several Native North American Indian tribes have a much higher prevalence of this HLA antigen (36). Indeed, approximately 50% of the Haida Indians living on the west coast of Canada are estimated to be HLA-B27 positive, and 10% of the adult population is estimated to have sacroiliitis (37). The prevalence of HLA-B27 is generally quite low in Asian and African populations, as is the prevalence of ankylosing spondylitis (30).

The presence of HLA-B27 does not appear to be related to the severity of the clinical manifestations of ankylosing spondylitis, although there has been some suggestion that HLA-B27 is associated with more severe radiographic disease (34). HLA-B27–negative ankylosing spondylitis is usually somewhat later in onset, is less frequently associated with acute anterior uveitis, is more frequently associated with psoriasis or inflammatory bowel disease, and is less frequently aggregated in families (38,39 and 40). It was recently shown that HLA-B39 has an increased prevalence in HLA-B27–negative patients with spondyloarthropathies in Japan (41).

Ankylosing spondylitis is uncommon before puberty, but then increases in frequency to reach a peak during young adulthood (33,42). In sporadic cases, male outnumber female subjects by about 5:1 (43,44). In contrast, in families with involvement of first-degree relatives, the male predominance is much less (1.5:1). Similarly, the aggregation of cases is greater in families with affected female members (45). These results imply that age and sex play permissive roles in the development of ankylosing spondylitis.

Reiter Syndrome

Estimates of the prevalence or incidence of Reiter syndrome are difficult to determine because of the lack of consensus regarding diagnostic criteria, the underreporting of venereal disease, and the asymptomatic or milder course in affected women. Despite these restrictions, epidemiologic information is available from military populations in which Reiter syndrome is the most common cause of inflammatory arthritis (8). Results from epidemics of dysentery in the military suggest that the incidence of Reiter syndrome is approximately four cases per 1,000 soldiers per year (46). Other studies of epidemic dysentery secondary to arthritogenic bacterial strains suggest that Reiter syndrome develops in 2% to 3% of infected individuals, whereas in nearly 20% of the HLA-B27–positive infected individuals, arthritis may develop (1,47,48). Similarly, in 1% to 3% of patients with nongonococcal urethritis secondary to infection with *Chlamydia trachomatis* a chronic arthritis will develop (4). Finally, a report from Rochester, Minnesota, identified 16 cases of Reiter syndrome between 1950 and 1980. The age-adjusted incidence rate for male patients younger than 50 years was 3.5 cases per 100,000 and was comparable to the incidence of RA (3.0 per 100,000) (49).

Reiter syndrome is a disease of young people, with its peak onset during the third decade of life. However, it also has been reported to occur in children and the aged (4,5). Male subjects are most commonly affected, with some estimates suggesting a male-to-female ratio of more than 25:1 (4,49). However, the male predominance is likely to be overestimated because Reiter syndrome in women may be associated with occult genitourinary disease. It was shown that 9% of United States female military recruits had evidence of occult genitourinary disease (50). Moreover, disease expression is usually less severe in women (4,51). Recent estimates suggest that the male/female ratio for Reiter syndrome is closer to 5:1 or 6:1 (1,4,20,21). Postvenereal Reiter syndrome is more common in men, whereas postdysenteric Reiter syndrome affects men and women equally (4,48).

HLA-B27 is found in 50% to 80% of patients with Reiter syndrome, with variations related to the frequency of the gene in the population at risk, and the organism involved (1,4,52). Thus 75% to 80% of white patients express this antigen, whereas it is seen in less than 50% of African-Americans with Reiter syndrome. Approximately 50% of patients with *Salmonella-, Campylobacter-,* and *Chlamydia*-induced Reiter syndrome are HLA-B27 positive; whereas 60% to 80% of patients with *Yersinia* and *Shigella* are positive for this antigen. HLA-B27 not only confers disease susceptibility but also seems to influence disease severity and expression. Patients with Reiter syndrome who are HLA-B27 positive are more likely to develop more prolonged and chronic disease (53). They also exhibit an increased frequency of axial involvement and systematic manifestations, such as fever, uveitis, balanitis, and oral ulcerations. These manifestations tend to be severe (25,53). In patients with psoriasis or inflammatory bowel disease, the presence of HLA-B27 or one of the cross-reactive MHC antigens, such as HLA-B7, appears to predispose to the expression of axial arthropathy (1). Likewise, arthropathies related to acquired immunodeficiency syndrome (AIDS) tend to be more severe in HLA-B27–positive individuals (54,55).

Despite the clear indication that HLA-B27 plays an integral role in the pathogenesis of Reiter syndrome, additional features of the host appear to contribute to disease susceptibility. There is a relatively low attack rate of Reiter syndrome in HLA-B27–positive individuals. Thus in epidemics of dysentery caused by known arthritogenic bacteria, only 20% or fewer of the HLA-B27–positive infected people will develop an incomplete syndrome, whereas even fewer will develop classic Reiter syndrome (1,4). Moreover, in some epidemics of dysentery with arthritogenic bacteria, the majority of Reiter syndrome has been noted in individuals who do not express HLA-B27 (56). Additionally, the observation that postvenereal Reiter syndrome predominantly occurs in men, despite B27 status, suggests that gender, as well as HLA-B27,

plays a role in its pathogenesis. Reiter syndrome is most frequent in early adulthood, with a lower incidence in other age groups, suggesting that maturational status also plays a role in disease susceptibility. Finally, studies of monozygotic HLA-B27–positive twins showed less than 50% concordance (57), indicating that host features besides this MHC allele play a role in disease pathogenesis. Epidemiologic studies of specific populations also have supported the conclusion that genetic influences other than HLA-B27 play a role in disease susceptibility. Thus, the Haida and Pima Indians have a higher frequency of HLA-B27 expression and an increased incidence of ankylosing spondylitis; however, Reiter syndrome is distinctly uncommon in these populations (58,59) but is quite common in Navajo and Eskimo populations (22). The explanations for these findings are unclear but indicate that characteristics of the target population other than B27 play a pivotal role in disease susceptibility. Despite this, the clear-cut association of HLA-B27 with the development of the spondyloarthropathies indicates a central role of this gene product in the pathogenesis of these conditions. It has been recently proposed that reactive arthritis be grouped into two categories, one that includes Reiter syndrome and is highly associated with B27, and a second that is not associated with B27. Only the former would be considered a spondyloarthropathy (60).

HLA-B27

Class I molecules of the MHC are 44-kd polymorphic proteins that are noncovalently associated with an invariant protein, b_2-microglobulin, and expressed as a heterodimer on the surface of many cell types (61). Allelic variations in the amino acids of these molecules have classically been identified by antisera. HLA-B27 is a serologically defined allele of the HLA-B locus, one of the three classic loci encoding class I MHC molecules (62). Examination of HLA-B gene products that react with HLA-B27 typing alloantisera has revealed a family of allelic subtypes. Twelve of these have been designated by the World Health Organization HLA Nomenclature Committee as *HLA-B*2701* through *HLA-B*2712* (63,64 and 65). This order is based on charge, determined by isoelectric focusing and not frequency. The prevalence of these gene products in various populations is shown in Table 43.3. *HLA-B*2705* is the predominant subtype in all populations. About 90% of HLA-B27 whites are *B*2705.* The other subtypes of B27 appear to have arisen from *B*2705* by point mutations (64). The amino acids that vary among these different subtypes are shown in Table 43.4.

Subtype	AS Association	Distribution
*B*2701*	Not known	Whites (rare)
*B*2702*	Yes	Whites (10%–15%)
*B*2703*	Yes	Blacks (west Africans)
*B*2704*	Yes	Asians (50%–70%)
*B*2705*	Yes	Whites (85%–90%) Asians (20%–50%) Amerindians (80%–100%)
*B*2706*	No	Asians (rare)
*B*2707*	Yes	Rare
*B*2708*	Not known	Rare
*B*2709*	No	Rare
*B*2710*	Yes	Rare
*B*2711*	Not known	Rare
*B*2712*	Not known	Rare

AS, ankylosing spondylitis.

TABLE 43.3. Hla-B27 Subtypes and Association with Ankylosing Spondylitis

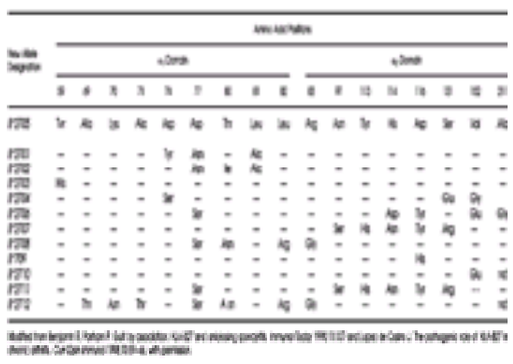

TABLE 43.4. Nomenclature and Amino Acid Differences of the Hla-B27 Subtypes

An association between many, but not all, of the HLA-B27 subtypes and the spondyloarthropathies has been demonstrated. This association has been most comprehensively analyzed for ankylosing spondylitis, as shown in Table 43.3. A number of the HLA-B27 subtypes, including *B*2701*and *B*2707* have been found only in a few individuals (63,66), and thus have not been amenable to population studies. However, *B*2701* was originally identified in an individual with advanced juvenile-onset ankylosing spondylitis (67). In general, the distribution of these B27 subtypes in patients with ankylosing spondylitis does not differ from that in healthy controls. Although it was initially shown that there was not an association between *HLA-B*2703* and ankylosing spondylitis in African blacks from Gambia (68), more recently this subtype was shown to be associated with this disease in West Africans (69). This is of interest because *HLA-B*2703* is a very unusual HLA-B molecule, containing a histidine at position 59, rather than the tyrosine that is present at this position in all other HLA class I molecules. Despite the unusual structure of *HLA-B*2703,* there appears to be an association with ankylosing spondylitis. Also, *HLA-B*2706*, an Asian subtype that was not associated with disease in Thailand (70), was subsequently detected in three Chinese patients with ankylosing spondylitis (69). With the possible exception of *HLA-B*2709*, it is likely, therefore, that ankylosing spondylitis is associated with each of the other HLA-B27 subtypes. Whether all HLA-B27 alleles are also associated with the other spondyloarthropathies is currently unknown but appears to be a likely possibility.

Transgenic animal models have provided strong evidence confirming that HLA-B27 itself is a direct disease-susceptibility factor, not merely a marker for a disease-susceptibility gene in close linkage disequilibrium with HLA-B27. Previously, indirect evidence from clinical epidemiology strongly suggested that HLA-B27 itself was the disease-susceptibility gene (71). Direct evidence that the HLA-B27 molecule itself can predispose to the spondyloarthropathies has come from studies of transgenic rats expressing *HLA-B*2705* and human b_2-microglobulin. These animals spontaneously develop a broad spectrum of disease manifestations closely resembling human HLA-B27–associated disease (72). These features include peripheral arthropathy; gastrointestinal, genitourinary tract, and cutaneous inflammation; and spondylitis. Moreover, HLA-B27 transgenic mice also have been shown to develop spontaneous inflammatory arthritis, in the absence of human b_2-microglobulin (73). These findings support the conclusion that the HLA-B27 molecule itself is the disease-susceptibility factor in the spondyloarthropathies. Therefore the association of the HLA-B27 molecule and the susceptibility to the development of spondyloarthropathy is likely to relate to one or more unique features of the structure or function of this class I MHC molecule.

Structure

The three-dimensional structure of three HLA class I molecules, HLA-A2, HLA-Aw68, and*B*2705*, has been determined by x-ray crystallography (74,75,76 and 77). The structure of HLA-B27 appears to be generally similar to that of HLA-A2 and -Aw68. The extracellular domains of these molecules consist of a membrane proximal immunoglobulin (Ig)-like structure encoded by the a_3 domain of the molecule and a receptor-like peptide-binding domain encoded by the polymorphic a_1 and a_2 domains. The a_3 domain is similar in all class I MHC molecules and is involved in the association with b_2-microglobulin. The a_1 and a_2 domains are folded into a peptide-binding cleft, with a helical regions from each domain creating the two walls and antiparallel b pleated sheets from these two domains forming the floor (Fig. 43.1). One unique feature of HLA-B27 relates to the fact that the peptide-binding cleft of this molecule is closed at both ends, creating a concave surface. This configuration has been hypothesized to have a role in the formation of tetrameric class I molecules on the cell surface (78). The unique features of each HLA-A, -B, and -C allele are, in general, determined by the amino acids of the a_1 and a_2 domains of the molecule that appear to alter the peptide-binding capacity of the molecule. Most of the polymorphic amino acid residues in class I MHC molecules are clustered along this cleft, projecting into it either from the two a helices or from the floor of the b pleated sheet. Pockets (designated A ® F) project from the cleft under the a helices (77,79). These pockets are created by amino acid residues outside the peptide-binding cleft itself. These pockets also are thought to play an important role in peptide binding. For HLA-B27, an acidic, hydrophilic pocket projecting under the superior a helix to residue 45, the so-called 45 pocket or B pocket, is thought to play a critical role in the binding of peptide (79).

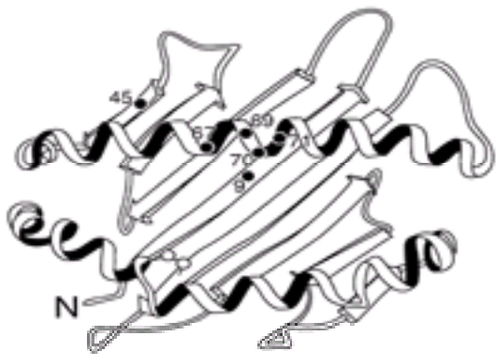

Figure 43.1. Structure of human leukocyte antigen (HLA)-B27. Highlighted are the amino acids thought to be involved in the binding of antigenic peptides. N, amino terminus. (Modified from Rothschild BM, Woods RJ. Spondyloarthropathy as an Old World phenomenon. *Semin Arthritis Rheum* 1992;21:306–316, and Chen JH, et al. A *Yersinia pseudotuberculosis* protein which cross-reacts with HLA-B27. *J Immunol* 1987;139:3003–3011, with permission.)

Class I MHC molecules bind antigenic peptides, largely derived from intracellular protein synthesis (80). Such peptides, which are generated from partial proteolytic cleavage of endogenously synthesized proteins, bind to class I MHC molecules in the endoplasmic reticulum and are transported, along with b_2-microglobulin, as a trimolecular complex to the cell surface. A number of studies have indicated that peptides consisting of nine amino acids are bound by class I MHC molecules (81,82 and 83). The amino acid sequences of peptides eluted from the HLA-B27 molecule suggest that they may potentially be derived from abundant cytosolic or nuclear proteins, such as histone, ribosomal proteins, and members of the 90-kd heat-shock protein family (82). The amino acids of the polymorphic regions of the a_1 and a_2 domains of class I MHC molecules are primarily responsible for the capacity of different class I MHC molecules to bind various peptides. After reaching the cell surface, endogenously synthesized peptide bound in the peptide-binding cleft of class I MHC molecules is presented to $CD8^+$ T lymphocytes expressing specific clonally distributed ab antigen receptors capable of recognizing the combination of polymorphic MHC molecule plus antigenic peptide (Fig. 43.2) (80).

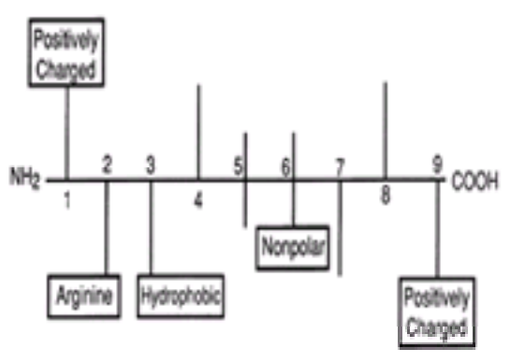

Figure 43.2. Generic structure of peptides that bind human leukocyte antigen (HLA)-B27. Nonamers with the indicated structure have been identified in the peptide-binding groove of HLA-B27. Amino acids that are pointed downward have their side chains directed into the pockets of the HLA-B27 molecule, whereas amino acids pointed upward have their side chains pointed out of the HLA-B27 peptide-binding groove. Amino acids that are centered have their side chains lying across the peptide-binding groove. (Modified from Jardetzky TS, et al. Identification of self peptides bound to purified HLA-B27. *Nature* 1991;353:326, with permission.)

The known HLA-B27 subtypes differ at specific amino acids, which are likely to be involved in the binding of specific antigenic peptides (Fig. 43.1). Of importance is the observation that susceptibility to the spondyloarthropathies does not appear to be related to the portions of the molecules that differ among the various B27 subtypes; therefore the residues that differ among the B27 subtypes are not likely to be involved in binding an arthritogenic peptide. The observation that the single amino acid change in *HLA-B*2703* (Tyr ® His at position 59) alters susceptibility to the spondyloarthropathies in some populations suggests that this residue could be important in disease pathogenesis. However, because all other class I MHC molecules possess a Tyr at position 59, it is unlikely that this amino acid plays a role in disease susceptibility. Rather, it is possible that the amino acid substitution at this position distorts the molecule in a manner to make other HLA-B27–specific amino acids unavailable for peptide binding. However, presentation of all peptides is not precluded by the change of Tyr to His at position 59, because *B*2705*-restricted, influenza-specific, cytotoxic T cells recognize infected *B*2703* cells (84). Binding of putative arthritogenic peptides, however, might be precluded by this nonconservative change in position 59 of the molecule.

Comparison of the HLA-B27 subtypes with other HLA class I sequences indicates that one amino acid residue is unique to all of the B27 subtypes (66,85,86). This is the Lys at position 70, located in the a helix formed by the a_1 domain of the molecule (Fig. 43.1). The Lys at position 70 points into the peptide-binding cleft, and, therefore, is a candidate for involvement in peptide binding. The consensus HLA-B27 sequence also shares a cluster of six amino acids within the peptide-binding cleft, including the HLA-B27 unique residue Lys70, as well as His9, Glu45, Cys67, Ala69, and Ala71. Besides HLA-B27, no other known class I HLA sequence possesses more than two of these residues. It is likely, therefore, that this portion of the HLA-B27 molecule is the disease-susceptibility element. Because these amino acids are arrayed in the antigen-binding cleft and the “45 pocket” of the molecule, it is reasonable to conclude that disease susceptibility relates to the unique capacity of these amino acids to permit HLA-B27 to bind a peptide capable of triggering or propagating the disease. The identity of such an arthritogenic peptide remains to be delineated.

A number of peptides that bind to HLA-B27 have been identified (47,65,82,87,88). In general, these peptides are positively charged and nine amino acids in length. Although an Arg residue at position 2 (P2) extending into the “45 pocket” is the best anchor for the binding of the peptides, other P2 residues such as Gln2 (65,89), as well as others (88) have been shown to be permissive for peptide binding. Other features of these peptides are shown in Fig. 43.2 and define a motif of B27-binding peptides. Because the carboxy-terminal residues interact with HLA-B27 “pockets” that feature more subtype polymorphism, it is less likely that they are relevant to disease predisposition. Interestingly, peptide ligands that bind the nonsusceptible *B*2706* (90) and *B*2709* (91) subtypes lack a carboxy-terminal tyrosine motif compared with peptides that bind susceptible subtypes such as *B*2705* and *B*2704*. Whether these differences are relevant to disease pathogenesis is still unclear. It should be pointed out that an estimated 13 million peptides might bind into the groove of HLA-B27.

Function: Peptide Binding and T-Cell Repertoire Selection

The biosynthesis of HLA-B27 is likely to be similar to that of other class I HLA molecules. The 44-kd heavy chain is synthesized in the endoplasmic reticulum, where it undergoes association with the invariant 11.5-kd b_2-microglobulin protein (92,93). Posttranslational modification of the molecule occurs in the Golgi, from which it is transported to the cell surface; there it is expressed as an integral transmembrane surface protein by most nucleated cells (61). Under physiologic circumstances, intracellularly synthesized and processed antigenic peptides become bound in the class I MHC–binding cleft within the endoplasmic reticulum. In most circumstances, the heavy chain, b_2-microglobulin, and antigenic peptide form a trimolecular complex within the endoplasmic reticulum that permits stable association on the cell surface (94). Interestingly, mice that are transgenic for human HLA-B27, but lack b_2-microglobulin, develop a spontaneous inflammatory arthritis with many of the features of spondyloarthropathies. As with the HLA-B27 transgenic rats, the arthropathy in these mice develops only after transfer from a pathogen-free environment. The fact that the mice do not express HLA-B27 on the cell surface has suggested that aberrant assembly, transport, and expression of HLA-B27 may play a role in the pathogenesis of human spondyloarthropathies (95).

Most peptides that are presented by class I MHC molecules are synthesized within the antigen-presenting cell and are encoded either by endogenous genes or by intracellular viruses or bacteria (80,96). It is the peptide/MHC molecular complex expressed on the cell surface that is recognized by $CD8^+$ T lymphocytes (80). Class I MHC molecules expressed within the thymic cortex also influence the T-cell repertoire by exerting both positive and negative selective influences on the $CD4^+$ $CD8^+$ thymocyte precursors of mature T cells (97). Thus class I MHC molecules play a dual role with regard to antigen recognition by T cells. On the one hand, they serve to select the T-cell receptor (TCR) repertoire of $CD8^+$ T cells in the thymus, and on the other, they function to bind and present antigen to $CD8^+$ T cells in peripheral tissues.

HLA-B27 and Molecular Mimicry

Several hypotheses can be constructed to account for the role of HLA-B27 in the pathogenesis of spondyloarthropathies. Although the most straightforward hypothesis is that HLA-B27 acts to bind a microbially derived peptide and that B27-restricted recognition of such a peptide leads to the pathogenic consequences recognized clinically as spondyloarthropathy, there are other potential hypotheses. One invokes the concept of molecular mimicry, which suggests that a small region of a human antigen is identical to amino acid sequences of proteins encoded by the triggering microorganism (98,99). Mimicry may be of a structural gene product or the HLA-B27 molecule itself (90,100,101). Although it is not clear how mimicry of a class I MHC molecule would lead to the anatomically localized disease characteristic of the spondyloarthropathies, there is considerable evidence for the sharing of antigenic determinants between HLA-B27 and different bacterial products.

Monoclonal antibodies against HLA-B27, B27M1, and B27M2 react with bacterial cell envelope glycoproteins from *Shigella flexneri, Klebsiella pneumoniae*, and *Yersinia enterocolitica* O:9 (102). Similarly, B27M2 identifies two cross-reactive proteins of 80 kd and 60 kd from *K. pneumoniae* (103). Another monoclonal antibody, Ye-2, derived from a mouse immunized with both HLA-B27–positive cells and with *Yersinia pseudotuberculosis*, recognizes a 19-kd envelope protein from *Y. pseudotuberculosis* as well as HLA-B27 itself (104). The monoclonal antibody failed to react with several other bacteria, including arthritogenic *Salmonella* and *Shigella* strains. Both B27M1 and B27M2 identify molecules of 23 and 36 kd from several bacterial species, including *S. flexneri, Shigella sonnei, Salmonella typhimurium, K. pneumoniae*, and *Escherichia coli* (105). Moreover, monoclonal antibodies against an isolate of *S. flexneri* cross-react with cells bearing HLA-B27 and -B7 (106). The antibodies detected bacterial antigens of 36 and 19 kd. Monoclonal antibodies against a peptide derived from amino acids 63 through 83 of *HLA-B*2705* were noted to bind HLA-B27–positive and HLA-B7–positive cell lines and appeared to bind the class I heavy chain as well as the 36- and 19-kd bacterial proteins (107). These results imply that the a_1 polymorphic region of HLA-B27 is antigenically cross-reactive with bacterial envelope proteins. However, amino acid sequencing of these bacterial proteins has indicated that there is no homology with the HLA-B27 molecules; therefore cross-reactivity is explained by the presence of similar conformational determinants or chance occurrence of particular amino acids. Inasmuch as $CD8^+$ T cells recognize linear sequences of amino acids, the significance of these antibody cross-reactivities remains unclear.

Computer searches have identified bacterial proteins with amino acid sequence homology to HLA-B27 (101,108). The nitrogenase reductase enzyme in *K. pneumoniae* contains a six–amino acid region that is homologous with *HLA-B*2705* residues 72 through 77. Moreover, a rabbit antipeptide antiserum was shown to react with intact HLA-B27, a synthetic peptide of HLA-B27 amino acids 63 through 84, the intact *K. pneumoniae* nitrogenase protein, and a synthetic peptide derived from the *K. pneumoniae* protein (98). As many as 54% of patients with reactive arthritis and 30% of patients with ankylosing spondylitis were claimed to have elevated levels of antibodies against an HLA-B27–derived peptide containing the region of homology with *K. pneumoniae* (108,109), although other investigators found such antibodies only rarely in patients with ankylosing spondylitis (110). T-cell reactivity to these peptides has not been examined. The results clearly indicate that there is amino acid sequence homology between HLA-B27 and the *K. pneumoniae* nitrogenase reductase gene product, but its relevance to disease pathogenesis is not at all clear.

Whereas several species of bacteria are capable of triggering reactive arthritis, not all isolates within a bacterial species are arthritogenic. From this observation, it was reasoned that the factor conferring arthritogenicity to a given bacterium might be a mobile genetic element, such as a plasmid. A 2-Md plasmid, termed *pHS-2*, was identified in several arthritogenic *S. flexneri* isolates, but was absent from nonarthritogenic *Shigella* (111). The nucleotide sequence of this plasmid revealed a predicted open reading frame encoding a 22-amino acid peptide potentially encoding an eight-amino acid stretch (Ala-Gln-Thr-Asp-Arg-His-Ser-Leu), seven residues of which are identical to residues 71 through 78 of the *HLA-B*2704* and *HLA-B*2706* sequences (Ala-Gln-Thr-Asp-Arg-Glu- Ser-Leu). Residues 1 through 5 and 8 of this sequence are shared by all known HLA-B27 subtypes; residue 77, this sequence corresponds to HLA-B27 residue 77, which is the most variable residue among the HLA-B27 subtypes (Table 43.4). Although the significance of this homology remains to be determined, antibodies showing high-affinity binding to the pHS-2–derived peptide, but not to the *K. pneumoniae* nitrogenase peptide, have been found in patients with ankylosing spondylitis or Reiter syndrome (112). The antibodies cross-reacted with both an HLA-B27–derived peptide and with the native HLA-B27 molecule. T-cell reactivity to this peptide has not been measured.

More recently, two independent groups isolated an RRYLENGKETL peptide from B^*2701, B^*2704, and B^*2706, a sequence that spans residues 169 to 179 of HLA-B27 (90,113). As with a very similar peptide previously identified (101), the peptide identified in these studies was demonstrated to have sequence homology with bacterial peptides. Although it can be postulated on the basis of these data that this B-27–derived peptide that mimics peptides derived from disease-associated enterobacteria can break self-tolerance, there was no correlation in these studies between presentation of this peptide and subtype association with ankylosing spondylitis. As in the case of the association with the *K. pneumoniae* nitrogenase reductase gene product, the relevance of this association to disease pathogenesis remains speculative.

ROLE OF T CELLS IN THE PATHOGENESIS OF THE SPONDYLOARTHROPATHIES

The role of antigen-specific and autoreactive T lymphocytes in the pathogenesis of spondyloarthropathies has been extensively explored, primarily in the context of reactive arthritis, in which the spectrum of antigens derived from inciting pathogens is better defined. The peripheral T-cell responses to the triggering microorganism appear to be impaired in reactive arthritis (114,115). These patients also tend to have persistent IgA antibodies to the organism (115,116 and 117). In B27-positive ankylosing spondylitis patients, the peripheral blood T-cell responses to *K. pneumoniae* were found to be impaired compared with B27-positive healthy controls (118,119). In general, though, the specificity and characteristics of the peripheral blood lymphocytes in reactive arthritis and ankylosing spondylitis have not been found to be either distinctive or informative. In contrast, the analysis of synovial tissue and synovial fluid lymphocytes has been much more informative. Both $CD4^+$ and $CD8^+$ T cells isolated from the joints of patients with reactive arthritis have been shown to respond specifically to antigens derived from the inciting microorganisms and, as has recently been shown, some clones of synovial $CD4^+$ and $CD8^+$ T cells derived from the same joint appear to respond to the same bacterial sequence (120).

$CD4^+$ T cells

The involvement of antigen-specific, class II restricted $CD4^+$ cells in the joints of patients with reactive arthritis has been demonstrated by a number of groups (120,121 and 122). Bacterial heat-shock proteins, particularly hsp60, are immunodominant antigens in these responses (123,124 and 125). A second group of immunodominant antigens includes positively charged proteins such as the *Yersinia* urease b-subunit and ribosomal protein L23 (126,127), and *Chlamydia* histone-like protein HCL (124). It is possible that these cationic proteins are bound to negatively charged structures in the joint, such as proteoglycans in the synovial lining layer and the cartilage. In ankylosing spondylitis, one study demonstrated the presence of synovial T-cell clones specifically recognizing *K. pneumoniae* antigens (118).

The cytokine patterns of both mouse and human $CD4^+$ T cells have been broadly classified as Th1 [interferon (IFN)-g] or Th2 (IL-4, IL-10). Th1 cytokines are associated with cell-mediated cytotoxicity and elimination of intracellular bacteria, whereas Th2 cytokines mediate humoral immune responses. The ratio of Th1 to Th2 responses has been explored in the synovial $CD4^+$ T cells of patients with reactive arthritis. One group of investigators who have focused on this question initially demonstrated a predominantly Th1 pattern of cytokine expression by synovial fluid T cells from patients with *Chlamydia*-induced reactive arthritis (128). Subsequently this group showed that the synovial membrane T cells from a spectrum of reactive arthritis patients tended to produce more Th2 cytokines (129,130). A particularly important role for IL-10 was noted, and it was proposed that the presence of high levels of this cytokine favors intraarticular persistence of the pathogens. It is not clear whether the discrepancies in the studies reflect differences between synovial fluid and synovial tissue T cells in various forms of reactive arthritis, or whether this simply reflects sampling bias.

$CD8^+$ T Cells

The association of HLA-B27 with the spondyloarthropathies implies a role for $CD8^+$ T cells in the pathogenesis of these conditions, as the only known functions of the polymorphic portions of class I MHC molecules are selection of the TCR repertoire of $CD8^+$ T cells in the thymus and presentation of antigen to $CD8^+$ T cells in the periphery. Bacteria-specific B27-restricted cytolytic T lymphocytes (CTLs) have been detected in the synovial fluid of ankylosing spondylitis and reactive arthritis patients (131,132 and 133). CTLs that were isolated and expanded from a number of patients with *Yersinia* reactive arthritis all reacted to a single nonamer peptide (321–329) derived from *Yersinia* hsp60, and the peptide required HLA-B27 for presentation (131). Subsequently it was shown that there are highly conserved amino acid sequences in the CDR3 region of the synovial T cells of reactive arthritis patients, despite differences in Vb. chain use (134). A $CD8^+$ synovial cell line expressing one of the shared clonotypes reacted toward several B^*2705 lymphoblastoid cell lines. Together these studies strongly suggest that $CD8^+$ T lymphocytes are responding to bacterial antigens such as hsp60 presented in the context of HLA-B27 in the synovial microenvironment. It also is possible that the $CD8^+$ T lymphocytes may be responding to autoantigens such as collagen (135).

Direct evidence to support the conclusion that $CD8^+$ T cells are involved in the pathogenesis of the spondyloarthropathies also has come from the observations made in individuals with AIDS. Despite suppression of $CD4^+$ T cells, these individuals are capable of developing reactive arthritis (55,136,137). The development of ankylosing spondylitis has not been reported. Reiter syndrome arthritis in patients with AIDS frequently follows a gastrointestinal or genitourinary infection, is usually associated with HLA-B27, and can be extremely aggressive. $CD8^+$ T-cell function is usually normal, although the number and function of $CD4^+$ T cells can be severely depleted. These observations are consistent with the conclusion that reactive arthritis and perhaps the other spondyloarthropathies are mediated by $CD8^+$ T cells responding to an antigenic peptide in the context of HLA-B27. Moreover, the finding that reactive arthritis is extremely aggressive in AIDS patients, even though it may not occur at increased frequency, suggests that $CD4^+$ T cells may function to suppress the development of reactive arthritis.

As proposed in Fig. 43.3, the spondyloarthropathies appear to be triggered by $CD8^+$ T cells responding to a bacterially derived antigenic peptide bound to HLA-B27. In this model, $CD4^+$ T cells regulate this response by recognizing other bacterially encoded antigenic peptides presented in the context of class II MHC molecules. As a result of this response, $CD4^+$ T cells may produce high levels of IFN-g and other cytokines that activate the macrophages, and thereby limit intracellular growth of the triggering microorganisms and the production of bacterially derived peptides that can associate with HLA-B27 and initiate arthritogenic responses of $CD8^+$ T cells. A relative shift toward a Th2 response in this context may favor bacterial persistence and ongoing antigen presentation to the $CD8^+$ T cells. A potential role for gd T cells also has been proposed in these disorders (138,139).

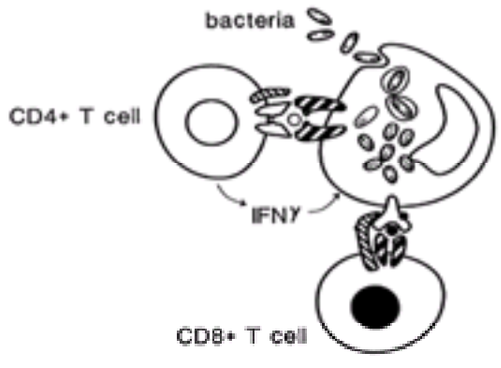

Figure 43.3. Model of cellular interactions involved in the recognition of bacterial peptides by $CD8^+$ T cells. IFN-g, interferon-g.

TRANSGENIC ANIMALS EXPRESSING HLA-B27

HLA-B27 Transgenic Mice

One means to test directly the role of HLA-B27 in the pathogenesis of the spondyloarthropathies is to generate transgenic animals that express the HLA-B27 gene product. A number of groups have generated HLA-B27–positive transgenic mice. Despite the high levels of HLA-B27 expression, spontaneous disease did not develop in these animals (140). Moreover, challenging HLA-B27–positive transgenic mice with a number of putative arthritogenic bacteria or bacterial products, including *Yersinia, Shigella*, or streptococcal cell walls, did not induce reactive arthritis, although the B27 transgenic mice appeared to be more susceptible to *Yersinia* infection than did their wild-type littermates (140). The explanation for the failure of HLA-B27–positive transgenic mice to develop reactive arthritis is unclear, especially because the human transgene is functional as an alloantigen and as an antigen-presenting structure in mice (141). More recently, it was shown that male HLA-B27 transgenic mice lacking endogenous b_2-microglobulin developed spontaneous inflammatory arthritis affecting the hind paws and resulting in joint ankylosis (95). These mice do not express B27 on the cell surface, have very low numbers of $CD8^+$ T cells, and develop the arthropathy only after transfer from a pathogen-free colony. When double transgenic mice were generated having both B27 and human b_2-microglobulin, but no mouse b_2-microglobulin, a similar phenotype developed, which also required the presence of bacterial flora. In this case, the animals did express B27 on the cell surface (142). Free B27 heavy chains were expressed by thymic epithelial cells and a subset of peripheral blood leukocytes. Treatment with antibodies to these heavy chains delayed disease development. Experiments in which the B27 transgenic mice were bred with MHC class II knock-out mice indicated that the development of disease was not dependent on MHC class II (143). These results militate against a mechanism whereby HLA-B27–derived peptides are presented by MHC class II molecules, and are in keeping with a primary role for HLA-B27 in the presentation of a relevant antigen(s).

HLA-B27 Transgenic Rats

Transgenic rats expressing the human *HLA-B*2705* gene product and human b_2 microglobulin spontaneously develop an inflammatory condition that resembles the spondyloarthropathies (72). This phenotype requires a high level of expression of the transgene on the cell surface (144). The disease features include peripheral and axial arthritis, gastrointestinal inflammation and diarrhea, psoriasiform skin changes, and male urogenital inflammation. Histologically, the joint, gut, and skin lesions closely resemble the lesions seen in HLA-B27–associated disease in humans. A number of transgenic rats expressing HLA-A2 or HLA-B7 fail to develop inflammatory disease, indicating that HLA-B27 is likely to be specifically involved in the development of this inflammatory disease. Importantly, when the rats were raised in a germ-free state, they developed neither the gut nor the joint inflammation (145). The gastrointestinal inflammation was an early and consistent finding that precedes the other disease manifestations. When normal gut bacteria were gradually introduced into the germfree B27 transgenic rats, the colitis and arthritis subsequently developed, and there appeared to be a particularly important role for *Bacteroides* species (146). Together, these observations are consistent with the hypothesis that gastrointestinal and articular inflammation are intimately related in the spondyloarthropathies, and that the commensal gut flora may play a role in the pathogenesis of these disorders.

Immunologic studies of the B27 transgenic rats have indicated that disease development requires expression of B27 on bone marrow–derived hematopoietic precursors and on peripheral $CD4^+$ T cells, but not in the thymus (147,148). Recently it was shown that male B27 transgenic rats whose B27 molecules were loaded with a high-affinity peptide derived from an influenza nucleoprotein were less likely to develop arthritis, although they did continue to develop colitis (149). Moreover, it was determined that two peptides derived from the male-specific HY minor histocompatibility antigens, which lacked an anchoring arginine residue in position 2, were specifically presented by HLA-B27 in the transgenic rats. These data support the hypothesis that B27-related arthritis requires binding of specific peptides to B27.

ROLE OF HLA-B27 IN THE IMMUNOPATHOGENESIS OF THE SPONDYLOARTHROPATHIES

Although the role of the HLA-B27 molecule in the pathogenesis of the spondyloarthropathies is not completely known, an understanding of its function suggests hypotheses about its involvement in these conditions (Fig. 43.4). One hypothesis is that infection with particular gastrointestinal or genitourinary microorganisms triggers an immune response by $CD8^+$ T cells, as these organisms are intracellular pathogens and would therefore generate peptides within infected host antigen-presenting cells. The arthritogenic response could result from the generation of a response to one or more bacterial peptides that bind to HLA-B27 and are presented to $CD8^+$ T cells. In addition to triggering immune responses, there might be dissemination of microbial antigens, including those restricted by HLA-B27, to distant tissue, such as the synovium, which is richly endowed with phagocytic cells. There is evidence that *Chlamydia, Salmonella*, and *Yersinia* antigens can be found in the synovial fluid and tissues of patients with reactive arthritis triggered by these different organisms (150,151,152 and 153). In this model, joint inflammation would result from persistent reactivity to those slowly cleared microbial products.

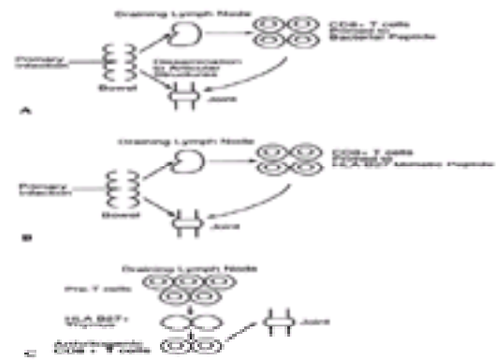

Figure 43.4. Potential immunopathogenic mechanisms in the spondyloarthropathies. The primary infectious process is shown in the bowel, although it could involve the genitourinary tract as well. **A:** Dissemination of bacterial products. **B:** Molecular mimicry. **C:** Human leukocyte antigen (HLA)-B27–mediated selection of arthritogenic T cells.

The role of HLA-B27 in bacterial invasion has been explored by a number of investigators with contradictory results (154,155,156 and 157). One group transfected murine L cells with a number of human HLA-B alleles, including B27. In contrast to all other HLA-B alleles, B27 specifically resulted in decreased invasion of a spectrum of enteric arthritogenic pathogens (154). This effect was associated with the ME1 epitope on B27, which includes a critical cysteine residue in position 67 (155). Other studies have suggested that, rather than impairing bacterial invasion, B27 was associated with enhanced intracellular survival and persistence of arthritogenic organisms such as *Salmonella enteriditis* (156,157). Thus the role of B27 in bacterial invasion and persistence remains to be clarified.

An alternative hypothesis is that the pathogenesis of the spondyloarthropathies involves the induction of autoreactivity to self-antigens because of molecular mimicry between antigens of the infecting microorganism and host tissues. In this model, infection with a bacterium expressing an HLA-B27 mimetic peptide might result in the priming of $CD8^+$ T cells to the endogenous HLA-B27–derived amino acid sequences. During the infection with the microorganism, an immune response to a variety of other bacterial antigens might provide sufficient help to overcome normal tolerance to self-peptides. Subsequently, endogenous HLA-B27 itself could be the source of the antigenic peptide. This could be produced within the synovium in increased amounts after a variety of traumatic or stressful insults that result in the local production of cytokines and increased expression of MHC molecules. This might account for the tendency of the disease to be exacerbated and to remit. In this model, HLA-B27 or another class I MHC molecule could serve as the presenting element. The critical role of HLA-B27 in this model would be to provide the endogenously derived HLA-B27 peptide.

It also is possible that the role of the HLA-B27 in the development of the spondyloarthropathies is less direct. HLA-B27 might function at the level of the thymus to select a repertoire of TCRs expressed by $CD8^+$ T cells that includes receptors uniquely capable of responding to microbial antigens in a pathogenic manner.

Additional hypotheses have been suggested. B27 might serve as a receptor for a bacterial product that alters the B27-expressing cell in a way that makes it prone to immunologic attack (76). It has been suggested that the free sulfhydryl side chain of the position 67 Cys may be altered by oxidative attack and thereby be rendered immunogenic (158,159). This unpaired cysteine residue, located in the antigen-binding B pocket of the B27 molecule, also was shown to be susceptible to modification by homocysteine, and as a result of the homocysteine modification was recognized by cytolytic T cells from patients with ankylosing spondylitis and reactive arthritis (160). An alternative hypothesis has suggested that free HLA-B27 chains can form a homodimer linked by a stable disulfide bond at the free Cys-67 (161). HLA-B27 homodimer formation has been observed at higher levels in spondyloarthropathy patients than in normal HLA-B27–positive individuals. It is hypothesized that such as homodimer may enhance the ability to present peptides. In each of these models, B27 either indirectly or directly facilitates the development of altered self-molecules that can induce persistent immunologic attack.

Each of these hypotheses is tenable, is consistent with the known structure and functions of the HLA-B27 molecule, and could explain the role of this class I MHC molecule in the pathogenesis of the spondyloarthropathies. Moreover, none is mutually exclusive of the others. Therefore, some combination of the hypothesized events might be involved in the development of the spondyloarthropathies. These hypotheses do not address a number of issues, including the unique tissue distribution of the disease; the differences in clinical manifestations between ankylosing spondylitis, Reiter syndrome, and the other spondyloarthropathies; and the immunopathogenesis of the spondyloarthropathies in HLA-B27–negative individuals.

OTHER GENETIC FACTORS PREDISPOSING TO SPONDYLOARTHROPATHIES

It is clear that the greatest genetic contribution to spondyloarthropathies comes from HLA-B27. Other HLA class I alleles have been associated with this group of diseases (162). Two studies have indicated an association between ankylosing spondylitis and HLA-B60, this being present in both HLA-B27–positive and HLA-B27–negative individuals (163, 164). HLA-B39, which has an antigen-binding B pocket similar to that of HLA-B27, has been associated with spondyloarthropathies in Japan (41).

A potential role for MHC class II alleles has been suggested (165). In a white population of ankylosing spondylitis patients in Britain, DR1 and DR8 were both found to be modestly increased, whereas DR12 was reduced in frequency compared with the frequency in a control population (27). These associations were calculated to be independent of HLA-B27. An HLA study in a heterogeneous cohort of patients with early synovitis demonstrated an association between HLA-B27 and both DR1 and DR4, although this was not specific for spondyloarthropathies (166). It should be noted that B27 and DR1 are part of an extended haplotype that is relatively common in white populations. In view of the large size of the genomic interval between the B and the DR locus, an association involving such an extended haplotype implies a potential role for a large number of other MHC genes in the susceptibility to spondyloarthropathies. It is possible that epistatic gene interactions that are unsuspected on the basis of analyzing individual MHC alleles may ultimately be quite relevant to disease pathogenesis.

Of potential importance in the class II region are genes involved in antigen processing and transport. Components of the large multifunctional protease (LMP) are encoded in this region. This complex is involved in the regulation of proteosome function at sites of inflammation, and may alter the repertoire of peptide antigens generated by the proteosome. In turn, this may affect the binding of these peptides to HLA-B27. These genes have been shown to exhibit limited polymorphism. One polymorphism in the LMP 2 gene was shown to increase the prevalence of iritis in HLA-B27–positive patients with ankylosing spondylitis, but this was not confirmed in other studies (167). Near the LMP locus are the transporters associated with antigen-processing (TAP) genes, which encode for proteins involved in the transport of peptide antigens to nascent HLA class I molecules in the cytosol. The Tap1C and Tap2A alleles have been shown to be increased in patients with B27-linked Reiter syndrome (168). Tap1B was increased in patients with ankylosing spondylitis (169). Together these findings suggest that genes involved in the processing and transport of peptides may play a role in the susceptibility to spondyloarthropathies, possibly by modifying antigen presentation by HLA-B27.

Another candidate locus that has received considerable attention is the TNF locus, which lies in the class III region between the class I and class II regions of the MHC. Several lines of investigation have indicated that TNF-a is involved in the pathogenesis of chronic inflammatory arthropathies, including the spondyloarthropathies (170,171). Considerable polymorphism has been demonstrated in the promoter region of the TNF-a locus. In particular, a polymorphism at position –308 of the TNF-a promoter has been shown to be associated with markedly increased transcription of this gene (172). Several recent studies have evaluated TNF-a polymorphisms in ankylosing spondylitis, with inconsistent results (173,174 and 175).

It has been noted in family studies that the calculated l_s for the HLA region has a value of 3.2 compared with a l_s of 50 for the overall genetic risk (165). The MHC is estimated to contribute approximately 36% of the overall genetic risk. This suggests that genes outside the HLA region make a substantial contribution to disease risk. In view of this, genome-wide linkage studies have been used to identify novel susceptibility genes outside the MHC. One study evaluated 105 British families by using 254 polymorphic microsatellite markers to identify chromosomal regions that potentially contribute to susceptibility to spondyloarthropathies (27). Although this study was rather limited in statistical power, it did reveal several genomic regions outside the MHC that showed evidence of highly significant linkage with ankylosing spondylitis. Of these, the strongest region showing linkage was located in 16q23, having a logarithm of odds (LOD) score of 2.6 compared with an LOD score of 3.8 for the MHC. Genome-wide scans of patients with psoriasis (176) and inflammatory bowel disease (177) have indicated susceptibility loci in 16q, near those associated with ankylosing spondylitis. Further identification of candidate genes will be facilitated by the completion of the Human Genome Project and the application of DNA microarray technologies.

ETIOLOGY

Ankylosing Spondylitis

Despite the association with HLA-B27, the etiology of ankylosing spondylitis is unknown. A number of features of the disease implicate immune-mediated mechanisms, including elevated serum levels of IgA (178,179 and 180) and acute-phase reactants (181), inflammatory histology (182), and close association with HLA-B27 (2,7). No specific event or exogenous agent that triggers the onset of the disease has been identified, although overlapping features with reactive arthritis and inflammatory bowel disease suggest that enteric bacteria might play a role. The possibility that enteric colonization with *Klebsiella* species plays a role in the development of ankylosing spondylitis has been suggested (183) but has not been confirmed (184). Although multiple studies have suggested the presence of specific antibody responses to *Klebsiella* in the sera of patients with ankylosing spondylitis, so far no direct association with the organism has been demonstrated. Evidence of antigenic interrelatedness between HLA-B27 and certain enteric bacteria (98,99) suggests a role for molecular mimicry in the disease, but it is not yet known whether this contributes to the pathogenesis of ankylosing spondylitis.

Reiter Syndrome

Reiter syndrome often occurs after gastrointestinal or genitourinary infection. In most instances, no identifiable infectious etiology can be identified. The most common microbial pathogens inducing Reiter syndrome are *Shigella, Salmonella, Yersinia, Campylobacter*, and *Chlamydia* (1,4,51,185,186). Although the syndromes induced by these pathogens are similar, there are differences in the pathogenic consequences, including disease severity, presence of presumed antigenic material in the synovium, and the association with HLA-B27. Whether the arthritis induced by each of these microorganisms is reactive or is related to the dissemination of microbial material to the joint is unclear because the arthritides associated with *Chlamydia, Yersinia*, and *Salmonella* are associated with the presence of microbial antigens within the synovium (150,151,152 and 153,187,188 and 189). The overall similarity of the conditions induced by these various microorganisms suggests that at least

some features of the immunopathogenesis may be common to all.

SHIGELLA

The increased incidence of Reiter syndrome after epidemics of *Shigella* dysentery has documented the potential arthritogenicity of this organism (46). Several reports suggested that 0.2% to 2.0% of infected individuals develop Reiter syndrome after epidemic shigellosis (48,49,190). Infections with *S. flexneri*2a and 1b trigger Reiter syndrome, whereas infection with the more frequent *S. sonnei* does not (4). Arthritis most commonly affects HLA-B27–positive infected individuals and has its peak onset 10 to 30 days after the onset of dysentery. In most cases, the diarrheal illness resolves before the articular inflammation appears. *S. flexneri* carries a 2-Md plasmid, pHS-2, encoding for an HLA-B27–mimetic epitope, and antibodies directed toward B27 cross-react with a peptide encoded by this sequence (112,191). This suggests that molecular mimicry may play a role in the pathogenesis of *Shigella* reactive arthritis. Interestingly, a group working a mouse model have recently shown a potential role for MHC class Ib molecules in infection-induced autoimmune recognition (192).

SALMONELLA

S. typhimurium is the most common species of *Salmonella* giving rise to Reiter syndrome. In as many as 1% to 6% of infected individuals, a sterile arthropathy develops after *Salmonella* outbreaks (48,193,194 and 195). Reactive arthritis usually develops within 3 weeks of *S. typhimurium* infection, and in some patients, the symptoms can persist for several years after the infection (195). Reactive arthritis also has been associated with infections secondary to *S. paratyphi, S. enteritis, S. heidelberg, S. infantis*, and *S. bovismorbificans* (4,193,196,197). In some patients, *Salmonella* antigens can be found in synovial tissue and fluid (150,198), although bacterial DNA was not detected (198). Like *Shigella*-associated disease, the Reiter syndrome that follows salmonellosis is associated with HLA-B27. Many of the HLA-B27–negative patients with Reiter syndrome express one of the other B27 cross-reactive antigens: B7, Bw22, B40, B42, and B60 (48,193). In some series of epidemic salmonellosis and Reiter syndrome, the incidence of B7 is greater than that of B27 (193). No important clinical differences between *Shigella*- and *Salmonella*-induced Reiter syndrome have been observed.

YERSINIA

Yersinia is a common cause of reactive arthritis in certain endemic areas, especially the Scandinavian countries (185,199,200 and 201). *Y. enterocolitica* is the most frequent isolate in northern Europe but is rarely encountered in England or America. *Y. enterocolitica* O:3 has most commonly been associated with reactive arthritis, but arthritis also has been described after infections with serotypes O:9 and O:8. *Y. pseudotuberculosis* has been reported outside of the Scandinavian countries but is still an uncommon pathogen (202). *Yersinia* infection produces an acute, mild, self-limited enteritis and mesenteric lymphadenitis, which may be associated with joint complaints in nearly 50% of patients (185,203). Men and women are equally affected. *Yersinia* arthritis is most commonly observed in young adults, although children and the elderly also have been affected.

HLA-B27 is present in 60% to 80% of patients with *Yersinia* arthritis (201,203). The arthritis is predominantly oligoarticular, affecting the lower extremities and hands. The arthritis runs a chronic or relapsing course in some patients, with chronic low back pain and chronic sacroiliitis developing in one third of patients. Five percent of patients demonstrate recurrent attacks of arthritis, often resulting from infections with other arthritogenic microorganisms such as *Salmonella* or *Chlamydia* (203). Rarely these patients progress to a clinical picture similar to that of ankylosing spondylitis. Extraarticular features, which include urethritis, ocular inflammation, mucocutaneous disease, and carditis, occur in 20% to 30% of individuals and appear most often in those who are HLA-B27 positive. Other features, including erythema nodosum and glomerulonephritis, are more common in HLA-B27–negative individuals. Active infection is associated with elevated IgA or IgG antibodies. Sustained elevations of IgA antibody titers correlate with persistent infection, chronic arthritis, and occult enteritis (204,205 and 206). *Yersinia* is commonly cultured from the stool during the acute infection. However, attempts to culture the organism from synovial fluid or tissue have been uniformly unsuccessful. *Yersinia* antigens have nonetheless been identified in both the synovial fluid (187) and tissue (151), suggesting that a persistent immune response to this material might play a role in the induction of inflammation. *Yersinia* antigens such as LPS and hsp are detectable in peripheral blood and synovial fluid leukocytes years after the initial infection (207). Moreover, it was shown that *Yersinia* 16s ribosomal RNA was present in the synovial fluid of a patient with reactive arthritis, which had occurred months after the initial episode of *Yersinia* infection (208). These data suggest that persistent subclinical infection with this pathogen may account for the chronicity of this arthropathy in some patients.

Yersinia arthritis is usually mild, and there are few long-term sequelae. The disease is more severe in a small number of patients. The presence of HLA-B27 may be of value in the identification of these individuals, as chronicity, severity, sacroiliitis, and ocular inflammation are more likely in HLA-B27–positive persons (203). In patients with persistently positive stool cultures for *Yersinia*, appropriate antibiotic therapy should be used.

CHLAMYDIA

Chlamydia trachomatis is a common urogenital pathogen that can trigger Reiter syndrome. Indeed, a study of 13,204 female army recruits in the United States indicated an overall prevalence of chlamydial infection equaling 9.2%, this prevalence being even higher in the teenage recruits (50). More than 50% of patients with Reiter syndrome have antibodies to *C. trachomatis*, although positive cultures of material from patients with active disease are seldom observed (4,23,209). An equivalent percentage of patients diagnosed with sexually acquired reactive arthritis or nongonococcal urethritis possess antichlamydial antibodies (209). These antibodies are presumably directed at *Chlamydia* antigens (chlamydial elementary bodies) that have been identified in the synovial fluid and synovial tissue of patients with Reiter syndrome, particularly in early disease (152,153,210). It also has been possible to detect chlamydial DNA in the joints of some patients with sexually acquired reactive arthritis (153,189,211,212), with synovial tissue having a higher sensitivity than synovial fluid (213). Importantly, there was a lack of correlation between antichlamydial antibodies, synovial fluid lymphocyte responses, and the presence of chlamydial DNA in the synovial fluid (212). DNA from chlamydial plasmid, major outer membrane protein (MOMP), and 16s ribosomal RNA has been detected in the synovial fluid and synovial tissue of a spectrum of arthropathies (211,212,214), and even from normal synovium (215).

In patients with sexually acquired Reiter syndrome, synovial lymphocytes have been shown to proliferate in response to chlamydial antigens (216). These responses involve both $CD4^+$ and $CD8^+$ T cells. The cytokine profile of the synovial T cells demonstrates high levels of both IFN-g and IL-10 (130,217). This has led to the speculation that this cytokine profile may have a permissive effect for the synovial persistence of *Chlamydia trachomatis*. An aberrant chlamydial gene-expression profile may result with attenuation of outer membrane proteins (218,219). This has been demonstrated *in vitro* (220). Moreover, an animal model has shown that synoviocytes can act as a reservoir for *C. trachomatis* and precipitate a chronic aseptic arthritis (221). In this model, *C. trachomatis* antigens, but not DNA, are detectable in the joint after 21 days. Studies in an HLA-B27 transgenic mouse demonstrated the recognition of chlamydial antigens by B27-restricted CTLs (222). Together these results suggest that a T cell–mediated, chlamydial antigen-specific immune response within the affected synovia may play a role in the immunopathogenesis of the disease and, unlike other forms of reactive arthritis, whole *C. trachomatis*organisms may persist in the joints of affected patients.

Chlamydial infection is thought to be responsible for as much as 10% of all cases of early inflammatory arthritis (223). Of those individuals with *Chlamydia* urethritis, in as many as 1% to 3%, arthritis ultimately develops. Of the *Chlamydia* species responsible for Reiter syndrome, *C. trachomatis* (serotypes D through K) is the most common, with primary infection involving either the urogenital or ocular tract in men and women. *C. psittaci* also produces a reactive arthropathy (224). Diagnosis is suggested by the presence of persistent arthritis in at least one joint, symptoms of genitourinary infection, detection of IgG or IgA antichlamydial antibodies, the demonstration of *Chlamydia* in genitourinary swabs or urine culture, and exclusion of other diseases (223). Recently *Chlamydia* pneumonia has been identified in the synovial tissues and synovial fluid of some patients with reactive arthritis and undifferentiated arthritis (214,225), and a number of patients with reactive arthritis demonstrated specific antibody evidence of recent infection with the pathogen (226).

The rheumatic manifestations of *Chlamydia* infections are similar to those described for classic Reiter syndrome (i.e., asymmetric oligoarthritis, enthesitis, ocular inflammation, low back pain, and sacroiliitis). However, only 20% of patients meet the criteria for the diagnosis of Reiter syndrome, and up to 15% have no urogenital manifestations at all, especially women (223). In more than half of the patients, a chronic arthropathy develops, with nearly one third having inflammatory low back pain and radiographic sacroiliitis or enthesopathy. In many patients, clinical activity is paralleled by the titer of IgA antichlamydial antibodies; sustained elevation of IgA titers suggests persistent infection with *Chlamydia* (227).

Despite similarities with classic Reiter syndrome, *Chlamydia*-induced arthritis differs in several ways. First is the identification of chlamydial antigens and even whole organisms at sites of tissue inflammation (152,153,210). Second, fewer than 50% of patients with documented disease are HLA-B27 positive (223). Finally, patients with *Chlamydia*-induced arthritis may respond to appropriate antibiotics (228,229).

OTHER AGENTS

Ureaplasma urealyticum has occasionally been implicated as a pathogenic trigger in Reiter syndrome, especially in those patients with nonchlamydial sexually acquired reactive arthritis (230,231). Gastrointestinal infections with *Campylobacter jejuni* and *C. fetus* also are associated with the development of typical Reiter syndrome (4,48).

PATHOLOGY AND IMMUNOPATHOLOGY

Ankylosing Spondylitis

Sacroiliitis is usually one of the earliest manifestations of ankylosing spondylitis. Most often, the thinner iliac fibrocartilage is eroded first, and then the thicker sacral hyaline cartilage (232). The irregularly eroded, sclerotic margins of the joint are gradually replaced by fibrocartilage and then by ossification. Ultimately, the joint may be totally obliterated. The early lesion consists of subchondral granulation tissue containing lymphocytes, plasma cells, mast cells, macrophages, and chondrocytes (233). Recently a detailed study of computed tomography (CT)-guided sacroiliac biopsies was undertaken by using immunohistology and *in situ* hybridization (234). This study demonstrated the presence of a mononuclear cell infiltrate predominated by $CD4^+$ T cells and $CD14^+$ macrophages, along with high levels of TNF-a mRNA. This picture is quite similar to that seen in rheumatoid synovitis. Small amounts of TGF-b were detected close to areas of new bone formation. A more extensive study by the same group of investigators subsequently showed that T cells become less prominent as the disease becomes more chronic, whereas numbers of macrophages continue to be high (235). Importantly, the degree of cellularity correlated with the degree of enhancement as determined by dynamic magnetic resonance imaging (MRI). This finding suggests that this imaging modality can be used to evaluate noninvasively the inflammatory process in the sacroiliac joints.

The initial lesion in the spine consists of inflammatory granulation tissue at the junction of the annulus fibrosus of the disc cartilage and the margin of vertebral bone (233,236,237 and 238). The outer annular fibers are eroded and eventually replaced by bone, forming the beginning of a bony excrescence called a *syndesmophyte*, which then grows by continued enchondral ossification, ultimately bridging the adjacent vertebral bodies. Ascending progression of this process leads to the “bamboo spine” observed radiographically. Other lesions in the spine include diffuse osteoporosis, erosion of vertebral bodies at the disc margin, “squaring” of vertebrae, and inflammation and destruction of the disc/bone border. Inflammatory arthritis of the apophyseal joints is common. Early in the course, this is characterized by the formation of pannus, which erodes cartilage. Subsequently, bony ankylosis develops.

The pathology of peripheral joint arthritis in ankylosing spondylitis shows hyperplasia of the lining layer, infiltration with lymphocytes and plasma cells, and pannus formation; however, the process is usually, but not always, less intense than that seen in RA, particularly with respect to lining-layer hyperplasia (182,239,240). The synovial lesions in ankylosing spondylitis were found to have a lower CD4/CD8 ratio than that found in RA synovial samples (241). Central cartilaginous erosions caused by proliferation of subchondral granulation tissue are common in ankylosing spondylitis but rare in RA

Reiter Syndrome

The characteristic pathologic findings in Reiter syndrome include an inflammatory synovitis, inflammation and erosions at the insertion of ligaments and tendons, the excessive production of heterotopic bone at sites of inflammation, and cutaneous changes similar to those observed in psoriasis (4). Pathologic changes in the synovial membrane are not specific, but include edema, vascular changes, and infiltration with lymphocytes, polymorphonuclear leukocytes, and plasma cells. These findings are not unique to Reiter syndrome, but are observed in many of the inflammatory arthropathies. Immunohistologic studies comparing Reiter synovitis with rheumatoid synovitis have suggested that the RA lesions tend to have higher numbers of plasma cells, cells expressing granzyme B, and cells expressing IFNg, although the differences were quantitatively modest (242). Extensive pannus formation is rare, and bone erosions are uncommon and are observed only with persistent inflammation. The overlying synovial fluid is inflammatory, with a predominance of polymorphonuclear leukocytes. There is no local complement consumption, as evidenced by the finding that synovial fluid complement levels often approach serum levels (243). The entheses are infiltrated with inflammatory cells and may be accompanied by erosions and eburnation of subligamentous bone (244,245). Bony proliferation results from subchondral osseous hyperplasia and periosteal new bone formation (245). The mucocutaneous lesions of Reiter syndrome are indistinguishable from those seen in psoriasis, with thickening of the horny layer, parakeratosis, and acanthosis (4). The outer layer of the corium is infiltrated with lymphocytes and plasma cells. Epidermal vesicles are filled with epithelial and inflammatory cells and may resemble microabscesses. Oral and genital mucosal lesions resemble cutaneous lesions with the absence of keratosis.

The intestine is characterized by subclinical inflammation in the terminal ileum and colon in approximately 60% of patients (246,247,248,249 and 250). These changes have been found regardless of the presence of HLA-B27, type of onset, clinical manifestations, or administration of nonsteroidal antiinflammatory drugs (247). Acute intestinal lesions resemble those associated with bacterial enteritis, whereas chronic lesions are similar to those observed with inflammatory bowel disease. Acute pathology is most often associated with enteropathic reactive arthritis, and chronic lesions are more commonly observed in patients with ankylosing spondylitis. Even patients with a postvenereal onset of disease develop intestinal pathology, although it is milder and less frequent (247). Follow-up studies have demonstrated that the degree of intestinal inflammation closely parallels the patient's clinical status and response to therapy (247,249). These findings, along with the demonstration of altered intestinal permeability (250,251) and elevated secretory IgA titers (4,251) in patients with active disease, suggest that occult intestinal inflammation may be central to the perpetuation of disease.

CONCLUDING REMARKS

The spondyloarthropathies represent an important opportunity to examine the interface between host genetic factors and microbial agents, and how this interface precipitates and perpetuates human pathology. The pathogenesis of conditions such as Reiter syndrome potentially encompasses a spectrum of immunologic mechanisms that includes ongoing responses to persistent pathogens and molecular mimicry between endogenous and microbial antigens. The role of HLA-B27 is at this point indisputable, and unique to this group of disorders. A more complete understanding of the role of HLA-B27 in the pathogenesis of spondyloarthropathies will be further complemented by an evolving understanding of the role played by other genes within, and outside of, the MHC.

44 RHEUMATIC FEVER AND OTHER CARDIOVASCULAR DISEASE

Clifford J. Kavinsky, M.D., Ph.D. and Joseph E. Parrillo, M.D.

There is considerable evidence that immune-mediated tissue injury is an important pathophysiologic factor in a variety of disorders affecting the cardiovascular system including rheumatic fever, collagen vascular diseases, the vasculitides, myopericarditis, endocarditis, the hypereosinophilic syndrome, and the postcardiac injury syndrome (PCIS). Cardiac tissue damage in these disorders may occur by antibody-dependent complement-mediated cytolysis or phagocytosis, effector cell chemotaxis followed by release of toxic substances, or direct T-cell–mediated cytotoxicity. Moreover, secreted cytokines such as tumor necrosis factor-a, interleukin-8 (IL-8), and IL-6 have been implicated in the pathogenesis of rheumatic fever. Whereas the inciting immune stimulus in cell injury often remains obscure, brisk B- and T-cell responses to foreign antigens having shared epitopes with host cardiac cells represent a popular theory of immune-mediated tissue destruction. Expression of foreign cell surface antigens in virus-infected cells and the development of autoimmunity to host surface and cytoplasmic molecules may also serve to induce immunologically mediated injury. In addition, the ability of certain “superantigens” to stimulate intense clonal T-cell responses may in part explain immunologic mechanisms in the expression of certain diseases such as rheumatic fever. Bacterial superantigens such as streptococcal pyrogenic toxin A act as potent exotoxins and have been shown to produce responses in both $CD4^+$ and $CD8^+$ T cells, and this may, in part, explain the immunologic mechanisms involved in rheumatic fever. Whatever the mechanisms involved, it seems clear that a derangement in immune regulation is an essential component of these autoimmune disease phenomena.

Although many of the classic collagen vascular disorders such as systemic lupus erythematosus, ankylosing spondylitis, rheumatoid arthritis, and the vasculitides have important effects on the heart and blood vessels, it is beyond the province of this chapter to discuss these diseases in detail. These disorders are specifically addressed in other chapters of this book. This chapter focuses on selected clinical syndromes producing significant heart involvement with manifestations believed to be mediated in part by immunologic mechanisms.

RHEUMATIC FEVER

Rheumatic fever is an acute inflammatory disease involving primarily the heart, joints, central nervous system, and subcutaneous tissues. It is generally a disease of children and young adults, but it may be seen in older patients (9). Rheumatic fever and acute poststreptococcal glomerulonephritis represent the nonsuppurative sequelae of pharyngitis caused by group A streptococci *(Streptococcus pyogenes),* usually after a 1- to 5-week period in immunologically and genetically susceptible persons. It is classified among the rheumatic diseases because destruction of connective tissue, which may in part be immune mediated, is a prominent feature of this disorder. It has been said that rheumatic fever “licks the joints|.|.|. but bites the heart” because of its potentially serious immediate and long-term cardiac effects and its relatively transient and reversible joint involvement. The incidence of rheumatic fever in the United States is low; approximately 1 case per 200,000 children per year (73). However, regional sporadic outbreaks have been noted (15,58). Segregated populations with limited access to medical care and overcrowded living conditions result in widely disparate trends even in developed nations. The prevalence rate of rheumatic heart disease reported in isolated, rural communities of Aborigines in northern Australia is one of the highest in the world, ranging from 9.9 to 44.1 per 1,000 (22). Overall, rheumatic fever remains a major health problem in developing and economically depressed countries.

History

The earliest descriptions of acute rheumatic fever date back to the sixteenth century when the French physician Guillaume de Baillou coined the term *rheumatism* to distinguish acute arthritis from gout. The seventeenth-century writings of Thomas Sydenham described chorea but failed to associate it with the other systemic manifestations of acute rheumatic fever. In the landmark studies of Jean-Baptiste Bouillard in 1836 and Walter B. Cheadle in 1889, clear association was drawn between rheumatic arthritis and carditis (115). In 1904, Ludwig Aschoff described the specific pathologic myocardial rheumatic lesion that now bears his name. J.K. Fowler first described the association of antecedent sore throat and rheumatic fever in 1880. Detailed clinical, bacteriologic, and epidemiologic studies by Coburn, Collis, Rammelkamp, and Stollerman during the first half of the twentieth century clearly established the causative role of group A streptococcus infection in rheumatic fever (115).

Epidemiology

Rheumatic fever remains a disease of the young, affecting primarily school-aged children at a mean age of approximately 9.8 years (130). Rheumatic fever in infants is distinctly rare, and many of the cases reported in adults may be recurrences in patients not receiving prophylaxis (84). Rheumatic fever and rheumatic heart disease display no particular gender predilection, although mitral stenosis and Sydenham chorea are reportedly more common in postpubertal women, whereas aortic stenosis is more common in men. Available data demonstrate no significant difference in the susceptibility of different races to rheumatic fever. High attack rates among various ethnic groups relate more to low socioeconomic status, conditions of overcrowding, and unavailability of health care.

Rheumatic fever remains a major worldwide health problem even though its incidence has been sharply declining in the United States. Rheumatic heart disease remains the most common form of acquired heart disease in children and young adults and is an important cause of all heart disease seen in adults. Acute rheumatic fever and rheumatic heart disease are two of the most common worldwide causes of death in young people and are responsible for 25% to 40% of all cardiovascular disease. Thirty-three to 50% of all hospital admissions for heart disease are for rheumatic heart disease (49,78). Annual attack rates as high as 140 per 100,000 population have been reported in developing countries (9). This is in stark contrast to the situation seen in the United States and Western Europe, where the occurrence of rheumatic fever has been declining since the early 1900s (Fig. 44.1). Regional data from Tennessee revealed an annual incidence of rheumatic fever of 0.5 per 100,000 among white suburban children (73). The steady decline in the prevalence of rheumatic fever has been interrupted by intermittent sporadic outbreaks beginning in the mid-1980s (42,52,84,130,137). Despite this development, rheumatic fever in the United States is largely seen only in lower socioeconomic groups. The major environmental risk factor for the development of rheumatic fever is crowding. Rheumatic fever has persisted in low-income, inner-city neighborhoods where the population density is high and crowded living conditions persist (42).

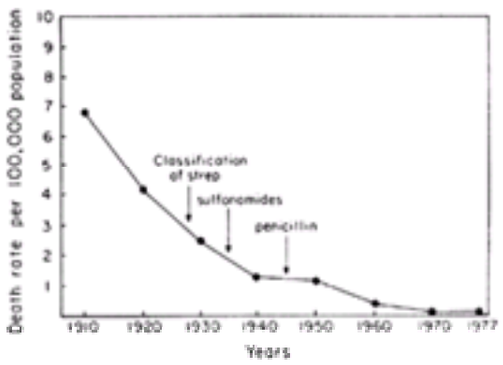

Figure 44.1. Crude death rates from rheumatic fever in the United States, 1910 to 1977. (From Gordis L. The virtual disappearance of rheumatic fever in the United States: lessons in the rise and fall of disease. *Circulation* 1985;72:1155. Copyright 1985, American Heart Association, with permission.)

As best as can be determined, all cases of acute rheumatic fever follow group A streptococcal infection of the upper respiratory tract. The attack rate after unrecognized or untreated group A streptococcal exudative pharyngitis is consistently 2% to 3% (100). Factors influencing the attack rate include (a) the severity of the antecedent pharyngeal streptococcal infection, (b) pharyngitis caused by more virulent "rheumatogenic" M protein serotypes (16,43), (c) the magnitude of the host immune response to streptococcal antigens coupled with genetic predisposing factors (132), (d) prolonged convalescent streptococcal carriage (109), and (e) a previous attack of rheumatic fever. Rheumatic fever has a recurrence rate of up to 50% during the first year after the initial attack and then decreases until 4 to 5 years later, when it levels off at approximately 10%.

Despite the high prevalence of group A streptococcal pharyngitis, the attack rate for rheumatic fever even in the presence of severe infection is only 2% to 3%. This finding implies variability in host predisposition to rheumatic fever. Genetic factors have been postulated to be important in determining susceptibility patterns to rheumatic fever. Monozygotic twins have a higher concordance rate for rheumatic fever than do dizygotic twins (36). In some studies, class II human histocompatibility leukocyte antigens (HLA) have been encountered in higher frequency in patients with rheumatic fever. The strongest associations correlate with the HLA-DR2, HLA-DR4, and HLA-DR7 phenotypes (7,54,99). No similar association has been found for the HLA class I antigens. In addition, monoclonal antibodies directed against a human B-cell alloantigen were shown to be present on the B cells of 92% of all patients with rheumatic fever in India. In contrast, this antigen occurred in only low frequency in patients without rheumatic fever (97,136). Various monoclonal antibodies developed against human B-cell alloantigen have different positive predictive values in different population groups around the world. Monoclonal D8/17, found to be 100% specific for rheumatic fever and rheumatic heart disease in patients from New York, correctly identified only 62% to 68% of north Indian patients. Thus, standardized immunochemical assays developed for specific subgroups may provide the optimal diagnostic sensitivity, specificity, and positive predictive value (72).

The reasons for the gradual decline of rheumatic fever in the United States remain obscure but are believed to be multifactorial. Certainly, the broad availability and use of antibiotics and the aggressive treatment of streptococcal pharyngitis have had a dramatic impact on the decreasing attack rate of rheumatic fever. However, because the decline of rheumatic fever predates the advent of the antibiotic era, this factor alone cannot account for the dramatic decrease in the incidence of this disease. Other possibilities include changes in the virulence of the group A streptococcal organism with a disappearance of the M serotypes associated with rheumatic fever, improvement in urban crowding conditions, and improved health care delivery (14).

The reasons for the sporadic outbreak of rheumatic fever noted in the mid-1980s remain a topic of intense debate. Most students of the field believe that these outbreaks correlate with the appearance of highly mucoid strains of group A streptococcus belonging to the previously recognized rheumatogenic M serotypes (e.g., types 1, 3, 5, 6, and 18).

Clinical Signs and Symptoms

Despite its prominence as a worldwide health problem and years of intensive basic and clinical research, rheumatic fever remains devoid of pathognomonic signs and symptoms as well as laboratory or other diagnostic tests. It is a multisystemic disease in which the clinical manifestations vary considerably not only from patient to patient, but also according to the organ systems involved, the severity of the lesions, and at what point during the course of the illness the patient presents to the physician. Rheumatic fever presents with various signs and symptoms that may occur alone, in succession, or in combination. The most important of these, in terms of diagnosis, are referred to as the *major manifestations* and consist of carditis, polyarticular arthritis, chorea, subcutaneous nodules, and erythema marginatum. Other minor manifestations are frequently present and aid in recognizing and diagnosing the disease, but they are considered too nonspecific to be of major diagnostic importance. These are referred to as *minor manifestations* and include fever, arthralgia, heart block, acute-phase reactants (C-reactive protein, erythrocyte sedimentation rate, increased total leukocyte count), and a history of an episode of rheumatic fever or rheumatic heart disease.

Upper respiratory tract infection with group A streptococcus is believed to be the necessary antecedent to the development of rheumatic fever. Nonetheless, a review of the literature revealed that up to 42% of patients had no recollection of previous pharyngitis (27). The crucial period between the time of onset of pharyngitis and the first appearance of symptoms of acute rheumatic fever averages 18.6 days, with a range of approximately 1 to 5 weeks.

The mode of onset after the latent period is highly variable. At presentation, patients may appear ill, with the onset of an acute febrile illness associated with severe, polyarticular arthritis or with the mild insidious onset of isolated carditis. With this caveat in mind, most attacks of rheumatic fever begin with polyarthritis, which may be preceded by abdominal pain. Polyarthritis and carditis constitute the most common major manifestations, occurring in approximately 77% and 54% of patients, respectively (42,105). If carditis appears, it usually does so early in the course of the illness. Sydenham chorea, subcutaneous nodules, and erythema marginatum are each present in fewer than 10% of patients (Fig. 44.2). The expression of major manifestations depends on age; carditis more commonly affects younger children, and the incidence of arthritis increases with the age of the patient.

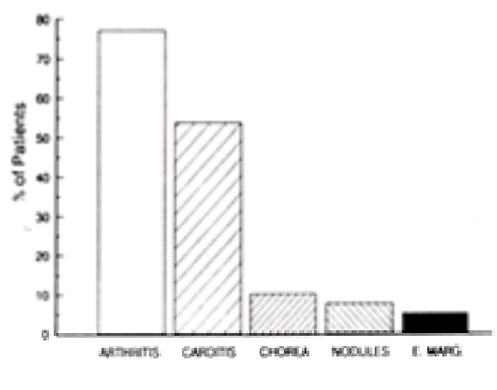

Figure 44.2. Major clinical manifestations in 39 patients with fever. E. MARG, erythema marginatum. (From Ferguson GW, Shultz JM, Bisno AL. Epidemiology of acute rheumatic fever in a multiethnic, multiracial urban community: the Miami-Dade County experience. *J Infect Dis* 1991;164:720, with permission.)

The arthritis of rheumatic fever is usually polyarticular, most commonly affecting the large joints such as the knees, ankles, elbows, and wrists. The small joints of the hands and feet are less frequently involved, and the hips and spine are rarely affected. Joint involvement ranges from mild arthralgias to severe arthritis with heat, swelling, redness, and intense pain. Severe cases of arthritis are rarely associated with the development of carditis. In the most classic presentation, several joints are usually affected in rapid succession, to create the picture of migrating polyarthritis. Once a particular joint is involved, inflammation begins to subside within a few days to a week and completely resolves within 2 to 3 weeks. The temporal course of individual joint inflammation is such that multiple joints are usually involved at any point. In most cases, the arthritis is severe for a week and completely resolves within 4 weeks without any residual long-lasting joint damage.

In contrast to polyarthritis, carditis is the most serious major manifestation of rheumatic fever because of its potential to cause death or long-term disability. Rheumatic fever frequently presents as a pancarditis with involvement of the myocardium, the endocardial structures, and the pericardium. Rheumatic carditis, in the absence of overt heart failure, acute pericarditis, or constitutional symptoms, is usually asymptomatic. Carditis, when it appears, usually does so within the first 3 weeks of the

rheumatic attack. Carditis presenting after this period is distinctly rare. The four major criteria for the clinical diagnosis of rheumatic carditis include (a) development of new organic heart murmurs not previously present, (b) cardiac enlargement, (c) congestive heart failure, and (d) pericardial friction rubs or signs of effusion (116). The presence of any one of these criteria in a patient with acute rheumatic fever justifies the diagnosis of rheumatic carditis.

In the beginning of the twentieth century, severe acute rheumatic carditis with myocarditis leading to fulminant heart failure and death was the leading medical cause of death in school-aged children (117). Fortunately, this severe form of acute rheumatic carditis has become extremely rare. More often, one sees a low-grade inflammatory process involving the myocardium and endocardium that leads in some cases to the delayed appearance of chronic rheumatic heart disease. The severity of acute rheumatic carditis does not correlate with the future development of rheumatic heart disease. During acute rheumatic endocarditis, the mitral valve is most frequently involved. Mitral valvulitis with edema and thickening of the leaflets leads to the characteristic high-pitched blowing holosystolic murmur of mitral regurgitation. This is often associated with a transient, low-pitched, apical, middiastolic flow murmur (Carey Coombs murmur). With aortic valve involvement, one may hear the soft, high-pitched decrescendo murmur of aortic insufficiency occurring just after S_2 in the aortic area. The murmurs of aortic and mitral stenosis associated with rheumatic heart disease are not heard in the setting of acute rheumatic fever.

Congestive heart failure, the least common manifestation of rheumatic carditis, occurs in approximately 5% to 10% of patients during the first attack. It is more common in recurrent bouts of rheumatic carditis. Acute pericarditis occurs in approximately 5% to 10% of patients with rheumatic carditis. It is not the sole manifestation of rheumatic carditis, but it is usually found in association with rheumatic pancarditis. Chest pain associated with pericardial friction rubs and effusions should alert the physician to the presence of pericarditis. Although pericardial effusions are common, tamponade is rare. Delayed atrioventricular (AV) conduction manifested as varying degrees of AV block is almost always transient, resolves spontaneously, and is easily reversed with atropine.

Subcutaneous nodules, although one of the major manifestations of rheumatic fever, are not pathognomonic for the disease. Similar findings are found in patients with collagen vascular disorders such as rheumatoid arthritis and systemic lupus erythematosus. Subcutaneous nodules rarely occur as an isolated finding. They most often occur in patients with severe rheumatic carditis, usually several weeks after its onset. The nodules themselves are firm, round, and painless, measuring from 0.5 to 2.0 cm. They occur in crops of one to four dozen and are usually located over bony surfaces, prominences, or tendons. Common sites are the extensor surfaces of the fingers and toes and the flexor surfaces of the wrists and ankles, as well as overlying the spinous processes of the vertebrae. They usually persist for 1 to 2 weeks, rarely more than 1 month. Erythema marginatum is an uncommon manifestation of rheumatic fever. It presents as a nonpruritic, nonpainful, macular, blanching light pink skin eruption most commonly found on the trunk and proximal portions of the extremities. Lesions rarely extend beyond the elbows and knees, and the face is generally spared. The margins spread outward in serpiginous fashion with central clearing. The lesions may change in a manner of minutes and for this reason have been likened to “smoke rings.” Although individual lesions may wax and wane, the process generally resolves within 4 weeks.

Chorea (Sydenham chorea, St. Vitus dance) is a neurologic disorder seen in fewer than 10% of patients with acute rheumatic fever. The chorea consists of involuntary, uncoordinated, purposeless, rapid movements that are associated with generalized muscular weakness and emotional lability. The choreiform moments tend to disappear with sleep and may be suppressed by sedation. Sydenham chorea often occurs together with rheumatic carditis but hardly ever with arthritis. In postpubertal women, chorea may rarely be the sole manifestation of rheumatic fever. Patients with “pure chorea” reportedly have a high incidence of rheumatic heart disease.

Chorea appears only after a relatively long latent period, as long as 1 to 6 months after the antecedent streptococcal infection. Chorea may last anywhere from 1 week to more than 2 years, but it usually is approximately 8 to 15 weeks in duration. In patients with “pure chorea,” minor disease manifestations of acute rheumatic fever such as elevated erythrocyte sedimentation rate or C-reactive protein are notably absent, most likely as a result of the long lag period before the onset of the disorder.

Pathobiology

The streptococcal origin of acute rheumatic fever is firmly established. However, proof of this relationship is indirect because group A streptococci are not recovered from the lesions of rheumatic fever, and no experimental model of the disease has been developed. Nevertheless, compelling epidemiologic, clinical, immunologic, and prophylactic treatment data strongly support a causal relationship between group A streptococcal infection of the upper respiratory tract and rheumatic fever. Epidemics of streptococcal pharyngitis and scarlet fever have a close temporal relationship with epidemics of rheumatic fever. Patients with rheumatic fever usually give a history of sore throat, and those who do not almost always have serologic evidence of recent group A streptococcal infection. Previous studies demonstrated that both initial and recurrent bouts of rheumatic fever did not occur without a significant streptococcal antibody response, the magnitude of which correlated well with the risk of subsequently developing rheumatic fever (100,109). Finally, possibly the most convincing evidence resides in the observation that initial and recurrent attacks of rheumatic fever can be prevented by either penicillin administration in the case of streptococcal pharyngitis or continuous chemoprophylaxis against future streptococcal infection in those patients with a history of rheumatic fever (35,44).

Investigators generally accept that the antecedent group A streptococcal infection leading to subsequent rheumatic fever must be located in the upper respiratory tract. Streptococcal skin infections such as pyoderma or impetigo rarely, if ever, lead to rheumatic fever (117,128). Moreover, streptococcal strains causing acute rheumatic fever and acute glomerulonephritis in the same population are different in terms of their M protein serotype (16). This finding has fostered the notion of the existence of “rheumatogenic” streptococcal strains, with the M protein serotype representing a significant virulence factor in terms of rheumatogenic potential. The hyaluronic acid capsule also represents a significant virulence factor such that highly mucoid strains of streptococci rich in M protein (e.g., types 1, 3, 5, 6, and 18) are most commonly associated with epidemics of rheumatic fever. In addition, lipoteichoic acid present on the surface of the group A streptococcus functions as an adhesion molecule by facilitating the binding of the bacterial organism to pharyngeal epithelial cell surface membranes and initiating the infection process. However, the M protein is considered to be the major virulence factor of the group A streptococcus, and more than 80 different group A streptococcal serotypes exist based on antigenic differences in the M protein molecule. Strains lacking M protein are avirulent. It is present in the cell wall of the streptococcal organism and has been shown to protrude from the cell surface as a component of the hairlike fimbriae. The M protein functions as a virulence factor by conferring resistance to phagocytosis. This is accomplished by diminishing complement activation by the alternative pathway and thus preventing activated complement from being deposited on the bacterial surface. In addition, one study demonstrated purified protein M5 to be a potent human T-cell mitogen in a process involving binding of M protein fragments to antigen-presenting cells using class II major histocompatibility complex (MHC) molecules (124). Subsequent clonal T-cell expansion then occurs in a manner similar to that described for other “superantigens” such as streptococcal enterotoxin B (13,116). This finding has implications for the autoimmune origin of rheumatic fever because clonal T-cell subsets responding to M protein may have shared specificity for cardiac or joint tissue resulting in autoimmune injury.

Despite abundant evidence of group A streptococcus as the etiologic agent in rheumatic fever, the exact pathophysiologic mechanism in which the pharyngeal infection initiates the rheumatic disease process remains unclear. Through the years, several theories have been postulated. These include (a) direct invasion by group A streptococcal organisms, (b) toxic effects of somatic and extracellular streptococcal products, (c) an immune complex–mediated serum sickness–like reaction, and (d) autoimmune phenomena through mechanisms of molecular mimicry involving cross-reactivity of streptococcal antibodies and host tissue.

The possibility that the lesions of rheumatic fever are a manifestation of direct streptococcal tissue invasion has always been an attractive hypothesis but has not been supported by experimental and clinical data. Streptococci are not visible histologically, nor can the organisms be reliably cultured from carefully prepared specimens isolated from patients with rheumatic fever. In addition, long-term antibiotic therapy administered in an effort to eradicate the streptococcal organism has not been shown to alter the course of acute rheumatic fever or the subsequent development of rheumatic heart disease.

Group A streptococcus elaborates many extracellular products including the following: streptolysins S and O; deoxyribonucleases (DNases) A, B, C, and D; hyaluronidase; streptokinase; proteinase; nicotinamide adenine deaminase; amylase; and esterase. Most of these substances are antigenic. Indeed, the most familiar of these, streptolysin O, DNase B, hyaluronidase, and streptokinase, stimulate specific antibodies that are used to obtain serologic evidence of recent streptococcal infection in patients thought to have acute rheumatic fever or glomerulonephritis. Some of these extracellular products, such as streptolysin, are capable of inducing tissue injury. However, because of the lack of an acceptable experimental model of rheumatic fever, theories concerning the direct action of toxins in the pathogenesis of rheumatic fever have been extremely difficult to confirm. Nonetheless, many students of rheumatic fever believe that some form of toxic injury to the heart and joints does play an important role during initiation of the disease process. Indeed, secreted cytokines such as tumor necrosis factor-a IL-8, and IL-6 may play a significant role in the pathophysiology of rheumatic fever (133).

The most popular theory for the pathogenesis of rheumatic fever, a theory supported by a considerable body of indirect laboratory and clinical evidence, proposes that immunologic mechanisms play a central role in the disease process. Rheumatic fever is thought to be caused by a hyperimmune host reaction to streptococcal antigenic challenge involving both the humoral and cell-mediated arms of the immune system. Production of antibodies directed against epitopes common to both streptococcal antigens and human tissue is believed to result in host cellular injury (43). Indeed, although the precise mechanisms remain unclear, rheumatic fever is believed to represent the prototypic postinfectious autoimmune disorder.

Rheumatic fever does not occur without a significant streptococcal antibody response. The mean antibody titer to just about every streptococcal antigen is elevated during an attack of rheumatic fever. Formation of immune complexes leading to a serum sickness–like syndrome with polyarthritis, rash, fever, hematuria, and elevated acute-phase reactants is postulated to occur. Indeed, the signs and symptoms of rheumatic fever bear similarities to those of other immune complex disorders such as systemic lupus erythematosus and rheumatoid arthritis. Circulating immune complexes were detected in 89% of acute-phase sera taken from patients with rheumatic fever (134). However, in contrast to other immune complex disorders, complement levels in patients with rheumatic fever tend to be normal. Although immune complex

deposition may be a contributing factor, this mechanism seems inadequate in explaining all the clinical and pathologic manifestations of rheumatic fever.

Since 1970, much attention has focused on autoimmune phenomena associated with rheumatic fever. Interest in this area arose from the finding that sera from some, but not all, patients with rheumatic fever or rheumatic heart disease contain antibodies that are reactive with human heart tissue (64). However, these antibodies are also present in low titers in the sera of patients with uncomplicated streptococcal pharyngitis. Furthermore, similar antibodies are also identified in patients with other systemic inflammatory disorders involving the heart, such as the postcardiotomy and postmyocardial infarction syndromes. Despite these problems, the observation that the myocardium of patients with severe rheumatic carditis contains surface-bound immunoglobulins and complement is irrefutable and lends credence to the importance of circulating heart-reactive antibodies in the pathogenesis of the disease process (66).

Heart-reactive antibodies appear to be directed against a variety of different antigenic determinants in heart tissue. Many of these antibodies display cross-reactivity with group A streptococcal antigens. Kaplan demonstrated that antisera to streptococcal cell wall components raised in rabbits cross-reacted with the sarcolemma and subsarcolemmal sarcoplasm of human cardiac myofibers as well as skeletal muscle and vascular smooth muscle (63). Similarly, goat antisera raised against human heart tissue showed cross-reactivity with streptococcal cell walls (67). Moreover, immunoreactivity as determined by immunofluorescence was abolished by prior absorption with streptococcal cell wall preparations. Antigenic determinants responsible for the production of heart-reactive antibodies appear to reside in the cell wall or cell membrane of the group A streptococcus (65,135). Streptococcal membrane polypeptides recognized by heart-reactive antibodies have been purified (126).

Emphasis has shifted to the epitopes residing within the M protein molecule as the source of heart-reactive antibodies possibly responsible for autoimmune tissue injury. Indeed, antisera directed against type-specific M protein recognized antigenic determinants shared by cardiac tissue. These antigenic determinants were reportedly found residing within myosin, actin, and DNA molecules of cardiac cells (30). Besides stimulation of the formation of heart-reactive antibodies, studies demonstrated cross-reactivity of M protein antisera with joint tissue. Rabbit antisera directed against purified protein M5 as well as M protein–specific antibodies from patients with rheumatic fever were found to cross-react with murine chondrocytes, cartilage, and synovium. Antibody binding was associated with complement fixation and provides further evidence that M protein cross-reactive antibodies may potentially be involved in the pathogenesis of rheumatic fever and arthritis (10). Cardiac myosin has been recognized as one of the major antigens recognized by the cross-reactive antistreptococcal autoantibodies (26). One study showed that antistreptococcal antibodies cross reactive with *N*-acetyl-D-glucosamine and myosin were cytotoxic for human valvular endothelial cells and reacted with human valvular endothelium and underlying basement membrane (46).

In addition to M protein antibodies, antibodies directed against streptococcal polysaccharide and glycoproteins have been shown to cross-react with heart valve glycoprotein (48). This finding may be significant as patients with rheumatic valvulitis have persistently elevated titers of antibodies directed against group A streptococcal carbohydrate moieties, titers that decrease after valve resection (38). Finally, sera from patients with chorea have been demonstrated by immunofluorescence to contain antibodies that cross-react with cytoplasm of subthalamic and caudate nucleus neurons; sera from patients with uncomplicated streptococcal pharyngitis were nonreactive (60).

Pathologic Findings

The acute phase of rheumatic fever is characterized by diffuse, exudative, and proliferative inflammatory reactions involving the heart, joints, and skin. The magnitude of histologic changes on tissue specimens does not correlate well with the severity of clinical manifestations. During the early stages of the disease, one sees disruption of collagen fibers, inflammatory cellular infiltrate, and principally lymphocytic and fibrinoid degeneration. It is shortly after this point that the only pathognomonic lesion of rheumatic fever appears: the myocardial Aschoff nodule (6). The Aschoff nodule is a perivascular inflammatory focus consisting of large mononuclear cells and multinucleated giant cells surrounding a central necrotic zone. The importance of Aschoff nodules is unclear because they persist for years after a rheumatic attack and do not seem to correlate with the severity of rheumatic carditis. Besides the Aschoff nodule, findings of myopericarditis and endocarditis may be present. Valvular involvement begins as swelling and inflammatory cellular infiltration of the leaflets and chordal structures with small verrucae along the lines of cusp closure. With time, the valve becomes thickened, deformed, and rigid. Chordal structure becomes shortened with fusion of valve leaflets. The end result of the process is development of valvular stenosis or insufficiency and rheumatic heart disease.

Joint involvement during the acute phase of rheumatic fever consists of swelling and edema of the articular and periarticular structures with serous effusion into the joint spaces but without erosion of the joint surface, pannus formation, or joint destruction. Histologically, one sees focal cellular infiltrates consisting of lymphocytes and polymorphonuclear leukocytes as well as fibrinoid lesions. The subcutaneous nodules consist of a central zone of fibrinoid necrotic material surrounded by histiocytes, fibroblasts, and perivascular collections of inflammatory cells. These lesions appear to resemble myocardial Aschoff bodies. Central nervous system changes include arteritis, cellular degeneration, perivascular inflammatory cell infiltration, and occasional petechial hemorrhages. These changes are generally unimpressive and are not correlated with the presence of chorea.

Diagnosis

The correct diagnosis in patients with suspected acute rheumatic fever is essential because of important implications for both prognosis and short- and long-term treatment. The diagnosis is made more difficult by the absence of pathognomonic clinical or diagnostic findings in rheumatic fever. The diffuse inflammatory nature of this disease has clinical features in common with various other disorders including systemic lupus erythematosus, serum sickness, rheumatoid arthritis, infectious arthritis, infective endocarditis, myocarditis, sickle cell crisis, Lyme disease, and drug sensitivity. The criteria for the diagnosis of acute rheumatic fever, originally formulated by T. Duckett Jones in 1944 (62) and most recently revised by the committee of the American Heart Association (93), use the major and minor disease manifestations along with documented evidence of recent streptococcal infection. These criteria are summarized in Table 44.1. If there is evidence of preceding group A streptococcal infection, then the existence of two major manifestations or of one major and two minor manifestations indicates a high probability of the presence of rheumatic fever. Because of the similarity of rheumatic fever with other systemic inflammatory disorders, the importance of documenting recent group A streptococcal infection cannot be overemphasized. The absence of such supporting evidence makes the diagnosis doubtful, except when rheumatic fever is discovered only after a long latent period from the antecedent infection (e.g., Sydenham chorea or indolent carditis) or in rare cases of suspected recurrent rheumatic fever. In patients with a reliable history of rheumatic fever or rheumatic heart disease, a presumptive diagnosis of rheumatic fever can be made with a single major manifestation or several minor manifestations as long as supporting evidence for recent group A streptococcal infection is provided.

Major Manifestations	Minor Manifestations
Carditis	Clinical
Polyarthritis	Fever
Chorea	Arthralgias
Erythema marginatum	
Subcutaneous nodules	Laboratory
	Elevated acute-phase reactants
	Erythrocyte sedimentation rate
	C-reactive protein
	Prolonged PR interval
Plus supporting evidence of antecedent group A streptococcal infection: positive throat culture or rapid streptococcal antigen test showing elevated or rising streptococcal antibody titer	

From Special Writing Group of the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease, Council on Cardiovascular Disease in the Young, American Heart Association. Guidelines for the diagnosis of initial attack of rheumatic fever. JAMA 1992;268: 2069. Copyright 1992, American Medical Association, with permission.

TABLE 44.1. Revised Jones Criteria for the Diagnosis of Rheumatic Fever

Evidence of streptococcal infection may include a positive finding on throat culture or rapid antigen test for group A streptococci or the demonstration of elevated or rising streptococcal antibody titers. Culture evidence for pharyngeal group A streptococcal infection is unreliable because only about 25% of patients have a positive culture at the time of the diagnosis of rheumatic fever. Furthermore, information from cultures does not distinguish between recent infection, which may be a prelude to rheumatic fever, and chronic nonpathologic pharyngeal colonization. Therefore, supporting evidence for recent streptococcal infection usually rests with the demonstration of elevated or rising antibody titers to streptococcal antigens, most commonly streptolysin O, DNase B, streptokinase, and hyaluronidase. Streptococcal pharyngitis elicits an antibody response to these substances in most patients. The antibody titer reaches a peak 2 to 3 weeks after the acute infection, remains at a plateau for 3 to 6 months, and then gradually declines, reaching normal levels in another 3 to 6 months (Fig. 44.3).

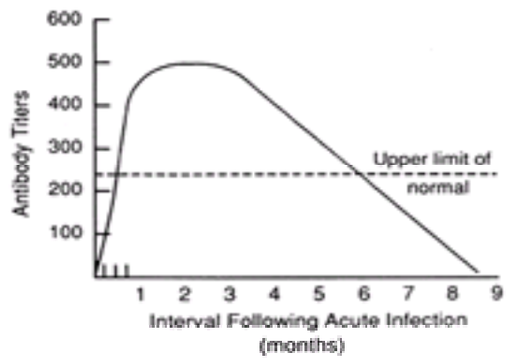

Figure 44.3. Temporal pattern of antibody response to group A streptococcal antigens. (From Ayoub E. Immune response to group A streptococcal infections. *Pediatr Infect Dis J* 1991;10:515, with permission.)

Serum samples obtained at the time of presentation usually display elevated streptococcal antibody titers. A significant increase in antibody is usually defined as a rise in titer of two or more dilution increments between acute-phase and convalescent-phase samples, regardless of the absolute magnitude of the antibody titer. The antistreptolysin O test is the most widely used and best standardized test. Titers of at least 250 Todd units in adults and 333 Todd units in children should be considered to be elevated. With this assay, approximately 80% of patients with acute rheumatic fever have an elevated antistreptolysin O titer. If a second confirmatory antistreptococcal antibody assay is used, this percentage increases to 90%. If a series of three antibody assays is used, the figure exceeds 95%.

More recently, a slide hemagglutination test using five group A streptococcal antigens attached to sheep erythrocytes was developed. Widespread availability and ease of performance have made this assay a popular office-based test for the determination of recent streptococcal infection. However, positive test results should be confirmed by more conventional antistreptococcal assays. A novel imaging technique using radiolabeled Fab fragments of monoclonal antimyosin antibodies for the detection of active rheumatic myocarditis has shown promising results but is limited by its lack of specificity (89).

Treatment

The management of patients with rheumatic fever is in part determined by the severity of the clinical manifestations of the disease. Therapy is directed toward eradicating residual group A streptococcal organisms, interrupting and suppressing the inflammatory process, and treating signs and symptoms of congestive heart failure, if they exist. None of these measures alters the course of the rheumatic attack or the probability of the subsequent development of rheumatic heart disease. However, good supportive care can affect morbidity and mortality in a positive manner.

Once the diagnosis of rheumatic fever is made, antimicrobial therapy should be instituted to eradicate any residual group A streptococcal organisms, even if cultures are negative. Parenteral therapy is preferred. A single intramuscular injection of 1.2 million units of penicillin benzathine or of 600,000 units of procaine penicillin each day for a 10-day course is considered an effective regimen. An erythromycin-based drug can be used in penicillin-allergic patients. Initial treatment should be followed by continuous long-term chemoprophylaxis to provide protection from reinfection.

All patients should be kept on bed rest for the first 3 weeks of the illness. After this initial period, the degree of physical activity should be tailored to the severity of the disease manifestations. Patients with carditis without cardiomyopathy or heart failure should be continued on bed rest for a minimum of 4 weeks after the carditis is detected. More prolonged periods of activity restriction are required in patients with severe carditis with overt signs of heart failure. The mainstay of therapy for patients with heart failure consists of the usual measures of fluid and salt restriction, supplemental oxygen, diuretics, digitalis, and probably afterload reduction.

Antiinflammatory therapy for acute rheumatic fever generally consists of salicylates and corticosteroids. The selection of a particular agent is not critical to the outcome of the rheumatic attack. Both classes of drugs are effective means of controlling the toxic manifestations of the disease and contributing to the comfort of the patient. A study comparing prednisone and acetylsalicylic acid for acute rheumatic fever did not demonstrate a significant therapeutic advantage of one agent over another (25). Patients with only mild arthralgias or arthritis without evidence of carditis are best treated with analgesics alone such as codeine or propoxyphene. Patients with more severe constitutional symptoms, arthritis, or mild carditis without overt heart failure should be treated with salicylates. A starting dose of 100 to 125 mg/ kg per day in children and 6 to 9 g per day in adults weighing 70 kg or more given in four or five divided doses is recommended. This dose of salicylate should be continued until an acceptable clinical response is achieved. Thereafter, the dose may be slowly decreased while the clinical and laboratory indices of inflammatory disease activity are closely monitored. Patients who do not obtain adequate relief with salicylates or who cannot tolerate the medication because of gastric irritation, gastrointestinal bleeding, or symptoms of salicylism should be switched to corticosteroids.

Patients with more severe forms of carditis as determined by chest x-ray studies, endomyocardial biopsy, echocardiography, or gated blood pool scanning as well as clinical signs and symptoms of heart failure should be treated immediately with corticosteroids. Starting daily doses of 40 to 120 mg of prednisone in four divided doses should be given to all patients regardless of age and should be adjusted according to clinical response. Parenteral preparations such as methylprednisolone or dexamethasone should be dose adjusted according to relative potency.

Once the clinical manifestations of the inflammatory process are under control with salicylates or corticosteroids, therapy should continue until laboratory indices of disease activity (i.e., erythrocyte sedimentation rate) approach normal. In several weeks, therapy may be slowly tapered. During this period, clinical or laboratory evidence suggesting reactivation of the inflammatory process may occur. This “rebound” phenomenon is seen more commonly with corticosteroid administration. Rebounds generally occur within 2 weeks of cessation of the antiinflammatory drugs. Rebounds occurring more than 5 weeks after cessation of therapy must be distinguished from rheumatic disease recurrence.

Patients with Sydenham chorea respond poorly to antirheumatic therapy. The use of haloperidol has been successful in some cases, and most patients respond to an initial dose of 0.5 to 1 mg per day, with increases of 0.5 to 1 mg per day every 3 days up to a maximum of 5 mg per day (123). Management of these patients is directed more toward supportive measures such as providing a quiet, nonstressful, restful environment.

Prognosis and Prevention

The natural course of rheumatic fever is highly unpredictable, and it is impossible to predict during the early stages of the disease. Approximately 75% of rheumatic attacks resolve within 6 weeks, 90% resolve within 12 weeks, and fewer than 6% persist more than 6 months. Those patients with a prolonged course of illness lasting more than 6 months usually have more slowly resolving chorea or chronic unremitting carditis (122). After a period of 2 months has elapsed after normalization of clinical and laboratory indices of disease activity and cessation of antiinflammatory therapy, rheumatic fever does not recur without recurrent streptococcal infection.

The prognosis is excellent for patients without carditis during the initial attack. Rheumatic heart disease is generally not observed in patients who did not develop carditis during the initial bout of rheumatic fever (125).

The best therapy for rheumatic fever is prevention. The goal of primary prevention is the accurate diagnosis of group A streptococcal infection and the use of appropriate antibiotics for eradicating the organism. Convincing clinical data demonstrate that acute rheumatic fever can be prevented by prompt treatment of group A streptococcal tonsillopharyngitis (44,129). Primary prevention for high-risk communities with a high prevalence of rheumatic fever can be instituted with an intramuscular injection of penicillin G benzathine as the first treatment of choice because of the poor compliance with the 10-day protocols for oral penicillin (28). A single intramuscular injection of benzathine benzylpenicillin, 600,000 units (in patients weighing less than 27 kg) or 1.2 million units (in patients weighing more than 27 kg), or oral phenoxymethylpenicillin (penicillin V), 250 mg two to three times daily for children or 500 mg two to three times daily for adolescents and adults, is effective (28). Erythromycin may be given for patients allergic to penicillin. Throat culture or tests for group A streptococcal antigen may provide a reliable negative predictive test in patients at sufficiently low clinical risk and may preclude the need for unnecessary antibiotics. False-positive tests are the result of subclinical colonizing strains or non–group A streptococci (groups C and G). Follow-up cultures are not recommended when appropriate treatment and compliance are documented (118).

Patients who have experienced a bout of rheumatic fever are at high risk of recurrent bouts of rheumatic fever. Recurrence rates decline with the length of time since the last attack (121,122). Nevertheless, patients with a history of rheumatic fever are at increased risk of recurrence well into adult life. Features influencing rheumatic fever recurrences include the presence of residual rheumatic heart disease and the magnitude of the immune response to the antecedent streptococcal infection. The committee of the American College of Cardiology/American Heart Association recommends the following for the duration of secondary rheumatic fever antibiotic prophylaxis: (a) rheumatic fever with carditis and persistent valvular disease: more than 10 years since last episode of rheumatic fever and at least until age 40 years of age, occasionally lifelong prophylaxis if at high risk and likely to come into contact with populations with increased prevalence of streptococcal infection (i.e., day care

workers, teachers); (b) rheumatic fever with carditis but no residual valvular disease: 10 years since last episode or well into adulthood, whichever is longer; and (c) rheumatic fever without carditis: 5 years or until age 21, whichever is longer (11,18). Continuous long-term antimicrobial prophylactic therapy may be instituted using one of the regimens shown in Table 44.2. The decision to withdraw antibiotics should be carefully individualized after assessment of the patients' overall risk for repetitive exposures. This prophylactic regimen for the prevention of recurrent rheumatic fever, however, does not substitute for the standard bacterial endocarditis prophylaxis required for patients with documented valvular rheumatic heart disease (29).

Agent	Dose	Mode
Penicillin G benzathine	1,200,000 units	intramuscula every 4 wk
	or	
Penicillin V	250 mg b.i.d.	Oral
	or	
Sulfadiazine	0.5 g q.d. for patients <60 lb; 1.0 g q.d. for patients >60 lb	Oral
For patients allergic to penicillin and sulfadiazine:		
Erythromycin	250 mg b.i.d.	Oral

TABLE 44.2. Secondary Prevention of Rheumatic Fever

Work continues on identifying rheumatogenic strains of group A streptococcus in an effort to develop an effective multivalent vaccine. Research has focused on identifying and characterizing the streptococcal M protein, the antigenic stimulus that produces antibodies that confers immunity to the streptococcus organism (119). However, the development of an effective vaccine has been hindered by the vast number of M protein serotypes and the potential for producing possible adverse autoimmune reactions. Emerging strategies for overcoming these problems include identifying and combining multiple epitopes from the N terminus and the conserved carboxy-terminal regions of the M protein, and eliminating host cross-reactive epitopes (21). Identifying a genetic marker for rheumatic fever susceptibility is also on the horizon, and this would be useful in identifying those patients at highest risk for acquiring this disease and those who would benefit most from aggressive prophylactic regimens (80).

MYOCARDITIS

Myocarditis is defined as an inflammatory process involving the heart. The inflammation may be restricted to the heart, or, more commonly, it represents the cardiovascular component of a systemic disease process. Inflammation is often not restricted to the myocardium but may involve the endocardial structures or pericardium to varying degrees, in which case terms such as *pancarditis and myopericarditis* are occasionally applied.

The incidence, prevalence, and predisposing factors for myocarditis are difficult to ascertain for several reasons, including the following: (a) the existence of multiple, distinct, infectious and noninfectious causes; (b) the finding that most cases are mild and subclinical and are not brought to the attention of the physician; (c) the lack of highly sensitive and specific diagnostic criteria; (d) the unresolved antecedent relationship with the pathogenesis of cardiomyopathy; and (e) differing opinions on the histologic diagnosis of myocarditis. Nonetheless, retrospective analysis of unselected autopsy data suggests that myocarditis is far more prevalent than expected. Autopsy studies performed on young, healthy soldiers during the course of World War II demonstrated histologic evidence of myocarditis in 3.5% to 10.0% (50,106). More recent studies using more stringent histologic guidelines for the diagnosis of myocarditis supported a much lower prevalence (51). Studies of children experiencing sudden, unexpected, nonaccidental death revealed myocarditis in 17% to 21% (8,91).

Clinical Signs and Symptoms

The clinical presentation of myocarditis is variable and in part depends on the severity of myocardial involvement. Signs and symptoms range from asymptomatic to rapidly progressive florid congestive heart failure leading to death. Patients often complain of nonspecific, constitutional symptoms including fever, weakness, fatigue, dyspnea, palpitations, and chest discomfort. A history of viral prodrome during the preceding 1 to 3 weeks can sometimes be elicited. Chest pain usually reflects concomitant pericarditis. Occasionally, the clinical presentation may be confused with acute myocardial infarction.

On physical examination, fever and tachycardia are usually present. The first heart sound is often diminished and may be associated with an S_3 gallop and an apical systolic murmur. Signs consistent with right-sided or left-sided heart failure with pulsus alternans, pulmonary congestion, jugular venous distention, hepatomegaly, ascites, and peripheral edema may be present in patients with more severe disease. A pericardial friction rub may be audible with concomitant pericarditis. Pulmonary and systemic emboli have also been noted to occur. Arrhythmias may appear and are occasionally associated with sudden death.

Pathobiology

Unlike rheumatic fever, in which the group A streptococcus is the singular etiologic agent, myocarditis has been associated with many infectious agents as well as with collagen vascular disorders, drugs, heavy metals, toxins, and hypersensitivity reactions. Myocardial inflammation may well represent a final common pathway response to a host of different insults. The many potential causes of myocarditis are summarized in Table 44.3. In North America, viral agents are believed to be by far the most commonly identified causative agent in myocarditis. Moreover, myocarditis resulting from more recently identified agents such as human immunodeficiency virus (HIV) or *Borrelia burgdorferi* is becoming increasingly recognized. In South America, *Trypanosoma cruzi,* the causative agent of Chagas disease, is considered the most common cause of myocarditis and cardiomyopathy.

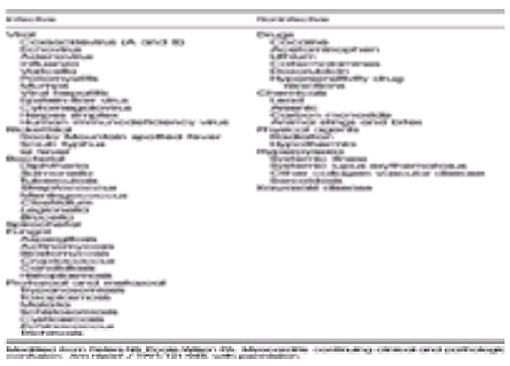

TABLE 44.3. Causes of Myocardial Inflammation

Of the viruses, the picornaviruses, notably the enteroviruses such as coxsackievirus A and B and echovirus account for most cases of myocarditis. Coxsackievirus B may cause up to 50% of all cases (53). Other viruses such as cytomegalovirus, influenza A and B, rubella, mumps, and varicella virus have also been associated with myocarditis. However, definitive evidence of a viral origin in individual patients is difficult to obtain and is usually based on the demonstration of rising titers of virus-specific antibodies. Isolation and culture of virus from tissue specimens are unusual, and immunohistochemical techniques attempting to localize viral antigens in myocardial tissue have proved unreliable. However, studies using recombinant DNA techniques have detected enteroviral RNA in a subset of patients with myocarditis and cardiomyopathy (20,61). For most cases of myocarditis, no specific etiologic agent can be identified. These cases, referred to as *idiopathic myocarditis* are presumed to be viral in origin (81). Myocarditis, unless referred to in more specific terms, generally implies a viral origin.

Theories concerning the pathogenesis of virus-induced myocardial inflammation and injury include (a) cardiotropic viral infection leading to viral replication and cell lysis, and (b) humoral and cell-mediated autoimmunity directed against both normal myocytes (through shared epitopes) and virus-infected cardiac cells expressing structurally altered antigens or neoantigens. Viral infection may lead to active intracellular viral replication, with ultimate cytolysis and myocyte necrosis. This

mechanism is believed to be particularly important during the early phases of the disease before specific immune responses occur. However, virus particles are hardly ever seen by electron microscopy, and the ability to culture virus or to detect virus-specific antigens from myocardial tissue of patients with myocarditis lacks reproducibility. Nevertheless, most investigators believe that the myocarditic process begins with a cardiotropic viral infection, replication, and cell lysis. Convincing animal data using a murine model of coxsackievirus B–induced myocarditis support this theory (59). During this initial phase of the disease, before mounting a significant immune response, inflammatory cellular infiltrates are absent. After the initial phase of the infection, the humoral and cell-mediated arms of the immune system are activated. Virus-specific antibodies are produced, resulting in clearance of virus through the monocyte-macrophage system. During this initial phase of the inflammatory process, the mechanisms of autoimmunity are believed to be implicated. Humoral and cell-mediated autoimmunity may be directed against normal and virus-infected myocytes. This results in mononuclear cell infiltration of the myocardium, and this, along with myocyte cell death, constitutes the histologic criteria for the diagnosis of myocarditis.

Sera taken from patients with myocarditis were found to contain antibodies reactive with both cardiocytes and viral antigens, and they were found to be cytotoxic in the presence of complement (76). In addition, suppressor T-cell activity is postulated to be reduced in these patients (39). More recently, sera from patients with myocarditis were found to have an autoantibody reactive with the adenosine diphosphate–adenosine triphosphate carrier protein of the inner mitochondrial membrane and were found to impair the performance of isolated guinea pig hearts (108). Further evidence for immune-mediated mechanisms is the demonstration of increased expression of the MHC antigens within the myocardium of patients with active myocarditis (56). Studies have implicated the role of cytokines such as tumor necrosis factor-a and ILs in the induction of apoptosis of myocardial cells (20).

The importance of T-lymphocyte–mediated autoimmunity in myocarditis is best demonstrated in the murine model. T-cell–deficient, athymic mice, or mice treated with antithymocyte serum, demonstrated less myocardial inflammation in response to injection of coxsackievirus B3 than did mice with normal T-cell function. T-cell–deficient mice reconstituted with coxsackievirus B3–sensitized T cells developed a more severe form of myocarditis (71).

Pathologic Findings

The pathologic findings in myocarditis are varied and depend on the etiologic agent and the severity of the inflammatory process. In patients with severe disease, the myocardium may be flabby with focal hemorrhages. In patients with chronic disease, the heart may be hypertrophied with four-chamber dilatation. Histologically, the presence of an inflammatory infiltrate associated with myocyte necrosis is characteristic of myocarditis (Fig. 44.4). The inflammatory infiltrate consists of a variety of cell types including polymorphonuclear cells, lymphocytes, macrophages, plasma cells, eosinophils, and giant cells. Myocyte damage may be manifested as necrosis with myocyte debris, degeneration, vacuolization, or cell disruption with infiltration of inflammatory cells (77).

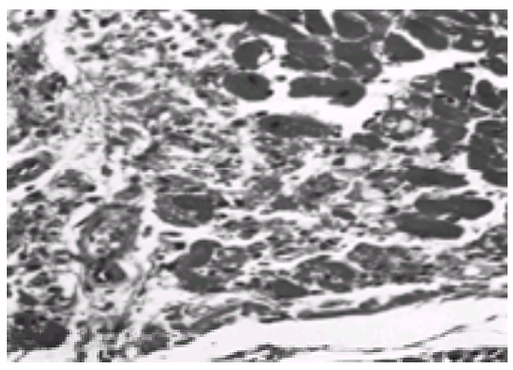

Figure 44.4. Hematoxylin and eosin–stained section from a patient with myocarditis. Note the extensive inflammatory cellular infiltrate with myocyte necrosis. (Original magnification ×250)

Diagnosis

Rigid criteria for the diagnosis of myocarditis based on clinical, laboratory, or diagnostic test findings do not exist. Such information serves to suggest the diagnosis but not to confirm it. Presentation of a patient with a compatible clinical syndrome of constitutional symptoms, weakness, fever, dyspnea, palpitations, and chest pain 1 to 3 weeks after a viral illness should alert the physician to the possibility of the diagnosis. Physical findings of tachycardia, new heart murmurs, a pericardial friction rub, or findings consistent with acute heart failure serve to support the diagnosis further.

Elevation in acute-phase reactants (erythrocyte sedimentation rate, total leukocyte count) is often noted. Serum levels of cardiac enzymes (creatine phosphokinase, lactic dehydrogenase) may be normal or elevated, depending on the extent of myocardial damage. Virus may rarely be isolated from various tissue or body fluid samples. A fourfold rise in viral type–specific neutralizing antibodies in paired acute-phase and convalescent-phase sera is sometimes observed. The chest x-ray film may show signs of cardiac enlargement or pulmonary vascular engorgement. The electrocardiogram usually reveals nonspecific changes in the ST segments and T waves. Arrhythmias and AV conduction disturbances are common, particularly in cases associated with severe heart failure. Echocardiography is helpful in assessing chamber enlargement, depression of ventricular performance, valvular involvement, and the presence of pericardial effusions.

Technetium-99m pyrophosphate and gallium-67 citrate scanning may occasionally demonstrate increased myocardial uptake. Newer nuclear imaging techniques using indium-111–radiolabeled Fab fragments of monoclonal antimyosin antibody preparations show promise in identifying patients with suspected myocarditis (32).

In the end, definite proof of the presence of myocarditis requires histologic examination of myocardial biopsy material. However, the sensitivity of endomyocardial biopsy in detecting suspected myocarditis has been questioned. In one study, definitive histologic evidence of myocarditis was found in only 30% of patients with clinical myocarditis (4). In another study, only 11% of patients with biopsy-proved myocarditis were suspected clinically to have myocarditis (90). The difficulties associated with the histologic diagnosis of myocarditis are believed to be related to the focal nature of the inflammation process and variability in histopathologic criteria used to establish the diagnosis. With general acceptance of the Dallas classification system, the histologic diagnosis of myocarditis can only be applied when an inflammatory cellular infiltrate is noted in the myocardium in association with myocyte necrosis or degeneration not typical of the ischemic damage associated with coronary artery disease (5).

Course

Most bouts of myocarditis of any cause either are subclinical or result in a self-limited illness that resolves without any long-term sequelae. Patients with more acute, fulminant myocarditis with heart failure either recover or die within weeks of the onset of the disease. Arrhythmias and progressive congestive heart failure are the usual causes of death in this group of patients.

A third group of patients, estimated to represent between 10% and 15% of patients who recover from diagnosed viral myocarditis, are believed to go on to develop chronic cardiac dysfunction indistinguishable from that of idiopathic dilated cardiomyopathy. Indeed, numerous studies of patients with dilated cardiomyopathy reported biopsy evidence of myocarditis in a significant number of these patients (86,95). Many investigators believe that autoimmune processes activated during the early phases of myocarditis are maintained through persistent and low-level viremia or periodic reactivation of latent virus infection, leading to expression of autoantigens, chronic autoimmune injury, and myocardial damage. Multiple bouts of reactivation myocarditis ultimately result in the development of a cardiomyopathic picture. Indeed, enterovirus RNA has been detected in myocardial biopsy specimens from patients with congestive cardiomyopathy using gene amplification by polymerase chain reaction (61). In summary, some patients with myocarditis develop cardiomyopathy, and some patients with cardiomyopathy have evidence of antecedent myocarditis. How frequently these two processes overlap awaits further study.

Treatment

The therapy for patients with myocarditis is largely supportive and is directed at the major manifestations of the disease process. Patients with myocarditis should have bed rest during the acute phase of this illness. Experimental evidence suggests that exercise worsens myocardial inflammation. Patients with congestive heart failure respond to conventional therapy consisting of supplemental oxygen, diuretics, and digitalis preparations. Animal studies suggested a beneficial effect of angiotensin-converting enzyme inhibitors (85). Rhythm disturbances should be treated with specific antiarrhythmic therapy. Patients with intractable New York Heart Association class IV failure may require inotropic agents (dobutamine, milrinone), and patients with the most severe disease should receive circulatory support devices.

Heart transplantation remains an option for patients with impending death from progressive heart failure or arrhythmias unresponsive to conventional therapy.

The role of antiinflammatory agents remains controversial. Nonsteroidal antiinflammatory agents such as indomethacin, salicylates, and cyclosporine have classically been contraindicated during the early phases of viral myocarditis because they worsen the myocardial damage. Many different immunosuppressive agents such as steroids, cyclosporine, FK-506, and cyclophosphamide have been examined in both animal models and human patients with varying results (69). Several small early studies suggested a beneficial effect in terms of improving clinical signs and symptoms of inflammation as well as histologic evidence of myocarditis on biopsy specimens (77,82). A prospective, randomized trial of patients with idiopathic dilated cardiomyopathy and severe left ventricular dysfunction revealed a modest improvement in left ventricular ejection fraction in those patients with cellular infiltrate observed in myocardial biopsy specimens who were treated with prednisone (96). This study suggested that some patients with cardiomyopathy and a cellular infiltrate in myocardial biopsy specimens have a corticosteroid-responsive inflammatory process in their myocardium. The largest controlled clinical trial to date has been the Myocarditis Treatment Trial, which was a randomized multicenter trial of immunosuppressive therapy for biopsy-proven myocarditis with prednisone and either cyclosporine or azathioprine versus conventional therapy for congestive heart failure. This study revealed no significant differences in left ventricular ejection fraction or left ventricular end-diastolic diameter at 28 or 52 weeks and no significant difference in survival during follow-up between the patients receiving conventional therapy and those receiving immunosuppressive therapy (83). However, this study had significant limitations in execution of its protocol and case selection.

Selected Specific Myocarditides

LYME DISEASE

Lyme disease is a multisystemic infectious disease caused by the spirochete *B. burgdorferi,* which is transmitted by the bite of the *Ixodes dammini* tick (113) (Chapter 79). It is endemic to most regions of the United States and is the most common vectorborne disease in the United States. From 1982 to 1996, more than 99,000 cases were reported to the United States Centers for Disease Control and Prevention, and during this time the incidence of reported cases increased by at least 32 times (23). Disease involvement includes the skin, joints, central and peripheral nervous systems, and the heart. The disease usually begins during the summer with a characteristic skin rash (erythema chronicum migrans), followed in days to months by signs and symptoms of disseminated infection including constitutional symptoms resembling a flulike illness with neurologic, arthritic, and cardiac manifestations. A persistent infection may be seen months to years after the onset of the illness. This late stage of Lyme disease expresses itself as chronic arthritis with persistent neurologic and cutaneous manifestations.

Carditis has been associated with Lyme disease in 4% to 10% of patients. It is usually seen in the second stage of the illness during the disseminated infection. Cardiac involvement may manifest itself as myopericarditis with varying degrees of AV block and myocardial dysfunction (87). AV block, often requiring temporary placement of a pacemaker, is the most common manifestation. Myocardial biopsy specimens may show areas of dense lymphocytic infiltrate with myocyte necrosis. Persistence of the spirochete organism within the myocardium is thought to be an important pathophysiologic mechanism in Lyme carditis. This concept is supported by identification of spirochetes in myocardial biopsy specimens of patients with Lyme carditis (33). In contrast, the late manifestations of Lyme disease including chronic arthritis and neurologic impairment are believed to be, in part, immune related. Studies demonstrated a significant association between class II histocompatibility molecules, particularly HLA-DR2 and HLA-DR4 haplotypes, and the development of chronic Lyme arthritis (112). Specific T-cell subsets directed against spirochetal antigens are postulated to be either clonally deleted, resulting in an ineffective immune response, or cross-reactive with shared tissue epitopes, resulting in autoimmune injury.

The diagnosis of Lyme disease relies on isolation of the spirochete organism or detection of increased or rising titers of specific antispirochetal antibodies (98). The prognosis in Lyme carditis is excellent, with complete resolution of conduction disturbances and cardiac dysfunction the rule. Administration of antibiotics to all patients with this form of carditis is generally recommended (98). Some authors recommend prednisone specifically for those patients with persistent heart block lasting more than 1 week, associated meningoencephalitis, or cardiomegaly. However most of the data to support this recommendation are anecdotal (88).

Vaccination has shown to be effective in preventing Lyme disease in several animal and human studies. In 1990, a whole-cell inactivated *B. burgdorferi* vaccine was licensed for use in dogs. In a 20-month postlicensure study, Lyme disease developed in (1%) of 1,969 vaccinated dogs versus 211 (4.7%) of 4,498 unvaccinated dogs (74). However, because whole-cell vaccines may be associated with severe local reaction in humans, a recombinant immunogenic *B. burgdorferi* protein was chosen for human trials. Antibodies against this protein in the outer coating of the organism (outer surface protein A or Osp A) have been found to be protective and active inoculation with Osp A have prevented *B. burgdorferi* infection. The results of the adult Osp vaccine trial were published in 1998 (114). In this large, multicenter, randomized, double-blind study involving 10,936 persons who lived in Lyme disease–endemic areas in the United States, administration of three injections of the vaccine at 0, 1, and 12 months prevented most definite cases of Lyme disease or asymptomatic *B. burgdorferi* infection. After the third injection, Lyme disease developed in 66 (1.2%) of 5,467 placebo recipients versus 16 (0.3%) of 5,469 vaccine recipients (p = .009), and the vaccine efficacy was 76% (95% confidence interval, 58%, 86%). The Advisory Committee in Immunization Practices has recommended that the Lyme disease vaccine should be considered for patients 15 to 70 years of age who live, work, or travel in moderate-risk to high-risk areas (24). The availability of the vaccine should not detract from the importance of personal precautions for tick bite prevention because the vaccine does not protect against other tickborne disease such as ehrlichiosis and babesiosis. The shortest and the most efficacious dosing schedule for vaccination including boosters has not been clearly defined, and accelerated dosing given in 3 to 6 months have shown encouraging results. Large trials using the vaccine in the pediatric population are currently under way.

CHAGAS DISEASE

Chagas disease (American trypanosomiasis) is the most common form of heart disease in Central and South America. It is also becoming increasingly recognized in the United States, largely because of increased numbers of infected immigrants from endemic regions (55,70). The disease is caused by the protozoan *T. cruzi,* which is transmitted to humans through the bite of an insect vector (reduviid bug). During the acute phase of illness, the patient may be asymptomatic or may experience constitutional symptoms such as fever, diaphoresis, myalgias, nausea, vomiting, diarrhea, dizziness, and palpitations. Signs of congestive heart failure, tachycardia, lymphadenopathy, hepatosplenomegaly, and meningeal irritation may be present. In a few patients, myocarditis develops and may be characterized by cardiomegaly or heart failure. Patients may experience progressive heart failure leading to death over a short period. In this setting, parasites are generally found in the myocardium.

Patients surviving acute infection may enter a latent phase. Up to 30% of patients eventually develop the chronic form of Chagas heart disease, leading ultimately to a clinical picture characterized by a dilated cardiomyopathy. Clinical manifestations of biventricular heart failure are frequently seen, with right ventricular failure usually dominating. Ventricular arrhythmias are frequently found and may result in syncope or sudden death. Classic electrocardiographic abnormalities of right bundle branch block and left anterior hemiblock are seen in up to 80% of patients (103). Examination of myocardial biopsy specimens usually reveals mononuclear cell infiltration and fibrosis, particularly in the area of the sinoatrial and AV nodes, and myocyte degeneration. Myocardial involvement may lead to the formation of left ventricular aneurysms at the apex or adjacent to the mitral annulus, associated with apical thrombus.

The slowly progressive, often indolent nature of Chagas cardiomyopathy that occurs in the absence of parasitic organisms is believed to be autoimmune mediated (104). Animal models have demonstrated the presence of self-reactive cytotoxic T cells after acute infection that were able to lyse normal noninfected heart cells (2).

The diagnosis of Chagas disease usually rests on demonstration of a positive result on complement fixation test or detection of the parasite in the blood during the acute phase of the illness. No specific therapy exists for Chagas cardiomyopathy, although antiparasitic agents such as nifurtimox and benznidazole may be helpful in select patients. The long-term prognosis correlates with the degree of impairment of ventricular function. Patients with mild ventricular dysfunction have a 5-year mortality of 20%. The mortality exceeds 60% in patients with more severe cardiac impairment.

HUMAN IMMUNODEFICIENCY VIRUS–RELATED HEART DISEASE

Cardiac involvement is being increasingly recognized in association with *HIV infection* in the setting of acquired immunodeficiency syndrome (AIDS) and has been extensively reviewed in the literature (1,68). Approximately 50% of patients with AIDS are estimated to experience some form of cardiac involvement during the course of their disease. Mortality from cardiac complications is estimated to be as high as 18% and is usually the result of progressive heart failure or arrhyth- mias. The spectrum of etiologic agents includes a large range of infectious, noninfectious, and neoplastic causes involving any of the myocardial, pericardial, or endocardial structures (Table 44.4). The common cardiac manifestations of AIDS include pericardial effusion, myocarditis, dilated cardiomyopathy, drug-related cardiotoxicity, endocarditis, pulmonary hypertension, and malignant neoplasms. All these cardiac sequelae are expected to increase in prevalence with the improved survival of HIV-infected patients receiving the newer antiretroviral medical regimens (102).

TABLE 44.4. Cardiac Involvement in Acquired Immunodeficiency Syndrome

Reports demonstrated myocarditis to be a common finding in patients with AIDS. Up to 46% of patients with AIDS were found to have histologic evidence of myocarditis at necropsy (101). Most of these patients were asymptomatic, and in most, no clear etiologic agent could be identified. Biopsy specimens usually reveal mononuclear cell infiltrates with focal myocyte necrosis. The origin of AIDS-related myocarditis is unclear. HIV-1 is not usually identified in biopsy tissue from patients with myocarditis by recombinant DNA techniques (12). Many investigators believe that myocarditis is not initiated by HIV-1 but rather by virus strains usually associated with myocarditis in non-HIV–infected individuals such as coxsackievirus B. Myocardial injury is believed to occur by the same mechanism of virus- and immune-mediated injury as described for other forms of viral myocarditis. Besides myocarditis, AIDS is associated with dilated cardiomyopathy. Current thought concerning the pathogenesis of AIDS-related cardiomyopathy suggests that it represents the end point of chronic persistent viral myocarditis and myocardial injury. Indeed, in some series, myocarditis was present in all cases of AIDS-related death with gross evidence of cardiac dilatation (3). Besides infectious myocarditis, antiretroviral drugs have also been implicated with the development of reversible cardiac dysfunction (57).

POSTCARDIAC INJURY SYNDROME

PCIS encompasses a group of disorders characterized by a pericarditis syndrome occurring several days to several months after a myocardial insult as a result of infarction (postmyocardial infarction syndrome, Dressler syndrome), surgery (postcardiotomy syndrome), or trauma (postcardiac trauma syndrome). A similar syndrome is occasionally observed after pulmonary embolism. PCIS was first reported in 1953 in patients undergoing mitral commissurotomy for rheumatic heart disease (110). It was later noted in patients undergoing a variety of cardiac surgical procedures. Investigators recognized that the syndrome did not occur without surgical manipulation of the pericardium. A similar syndrome in patients after myocardial infarction was described by Dressler in 1956 (37). Factors such as young age, previous episode of pericarditis, and a recent viral infection are said to predispose to the development of PCIS. The extent of myocardial injury does not correlate with PCIS. The incidence of PCIS is estimated to be 4% of patients after myocardial infarction and up to 30% of patients after cardiac surgery.

PCIS is characterized by the onset of constitutional symptoms, fever, and pleuritic chest pain occurring 2 to 3 weeks after the initial insult (infection, surgery, or trauma) with a range of 1 week to several months. Physical examination may often reveal pericardial and pleural friction rubs. In the postcardiac surgery setting in which pericardial friction rubs are the rule, the persistence of fever and chest pain suggests of PCIS. Pleural effusions, pulmonary infiltrates, and enlargement of the cardiac silhouette may be noted on chest x-ray studies. The electrocardiogram may reveal ST-segment elevation or T-wave inversions suggestive of pericarditis. Echocardiography is useful in identifying pericardial effusion and tamponade. Elevation of acute-phase reactants, particularly the erythrocyte sedimentation rate and total leukocyte count, is frequently observed.

The precise mechanisms responsible for the pathogenesis of PCIS are unknown. However, an immunologic component has been proposed. This is supported by the following: the presence of a latent period between the initial myocardial insult and the onset of symptoms; the often dramatic response to antiinflammatory drugs, particularly corticosteroids; and the occasional associated relapse after tapering or cessation of steroid therapy. Investigators have proposed that entry of blood into the pericardium induces cellular injury, which after a latent period triggers an autoimmune response to heart cell antigens that leads to release of cellular mediators of inflammation. This concept is supported by several studies demonstrating the occurrence of antiheart antibodies in patients who developed PCIS after infarction and cardiac surgery (40,127). Further studies identified reactive antigenic determinants residing within the major contractile proteins, actin and myosin (31). Finally, some investigators believe that reactivation of latent virus may provide an immune stimulus that serves to initiate the cascade of events leading to inflammation (40).

The diagnosis of PCIS relies largely on clinical criteria. Laboratory and diagnostic test data may provide supportive evidence. The syndrome is usually self-limited and resolves slowly over time, but it may recur. Oral anticoagulants should be discontinued because of the risk of pericardial hemorrhage. Patients with severe symptoms should be placed on bed rest and treated with aspirin or a nonsteroidal antiinflammatory agent such as indomethacin, ibuprofen, or naproxen. In patients with severe incapacitating chest pain or chest pain unresponsive to aspirin or nonsteroidal antiinflammatory agents, corticosteroids are the agents of choice. Patients treated with 60 mg of prednisone per day usually respond dramatically with rapid defervescence, relief of chest pain, and increased sense of well-being. The other indices of disease activity such as the erythrocyte sedimentation rate, white blood cell count, and pleural and pericardial effusions normalize. Recurrence may occur during steroid tapering and may be treated with nonsteroidal antiinflammatory agents or reinstitution of higher doses of corticosteroids.

The most serious complication of PCIS is cardiac tamponade, which occurs in approximately 0.1% to 6.0% of patients and should be treated with prompt pericardial drainage. Pulmonary infiltrates thought to be inflammatory pneumonitis are also reported. These patients usually require corticosteroid therapy.

EOSINOPHILIC HEART DISEASE

Loeffler endocarditis, first discovered in 1936 in two patients with new-onset heart failure and peripheral eosinophilia, is now thought to represent the cardiovascular manifestations of the *hypereosinophilic syndrome* (75). It has been referred to by a variety of terms including *eosinophilic leukemia, eosinophilic endocarditis, idiopathic collagen vascular disease,* and *idiopathic eosinophilia* and is believed by many investigators to be a variant of endomyocardial fibrosis, which has similar cardiac manifestations and primarily affects patients in tropical and subtropical Africa.

The hypereosinophilic syndrome is primarily a disease of men in their fourth decade. More than 75% of patients with this disorder experience heart failure. The principal clinical, noncardiac features of the disease include constitutional symptoms, weight loss, fever, cough, and skin rash. Cardiac involvement may be asymptomatic, but more often signs and symptoms of heart failure are present. The cardiovascular manifestations in 26 patients with documented hypereosinophilic syndrome are summarized in Table 44.5 (94). Common symptoms include cough, dyspnea, palpitations, and chest pain. Signs of congestive heart failure often associated with the murmur of mitral regurgitation are seen. Systemic emboli may occur. The chest x-ray film may reveal cardiac enlargement or pulmonary edema. The electrocardiogram may demonstrate left atrial enlargement, T-wave inversions, or first-degree AV block (94). The echocardiogram frequently shows increased ventricular wall thickness as a consequence of endocardial fibrosis, apical thrombus, or abnormal motion of the posterior leaflet of the mitral valve with mitral regurgitation. Dense endomyocardial fibrosis and scarring lead to a hemodynamic picture of restrictive cardiomyopathy with increased stiffness and reduced ventricular cavity size resulting in abnormal diastolic filling properties.

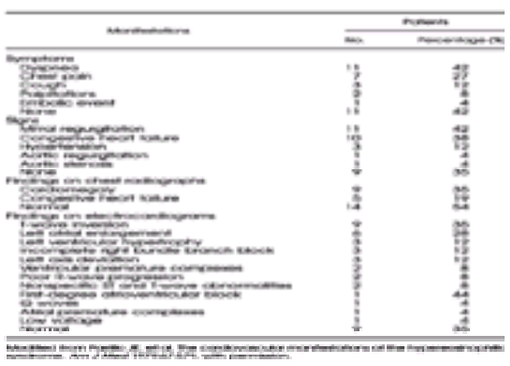

TABLE 44.5. Cardiovascular Manifestations of 26 Patients with the Hypereosinophilic Syndrome

Investigators have postulated myocardial involvement in the hypereosinophilic syndrome to consist of three stages (92). The first stage is an acute necrotic phase that is characterized by intense myocarditis with exuberant eosinophilic infiltration and associated arteritis and occurs within the first few months of the illness. It is followed by a thrombotic-necrotic stage occurring months to years after the initial presentation, at which time resolution of the myocarditic component with myocardial thickening and a variable amount of endocardial thrombus is seen. The third stage is that of late progressive endocardial fibrosis with findings consistent with restrictive cardiomyopathy (Fig. 44.5).

Figure 44.5. Extensive endocardial fibrosis and thickening of the left ventricular wall in a patient with eosinophilic heart disease.

Current thought concerning the origin of eosinophilic heart disease postulates a cardiotoxic effect produced by release of eosinophil granule products. The finding of intense eosinophilic infiltration in the setting of severe myocardial inflammation makes this an attractive theory. Major basic protein, the primary component of eosinophil granules, has been demonstrated to be cytotoxic to a variety of parasites and human cells *in vitro* (47). Eosinophilic infiltrates have been found associated with focal myocardial abscess formation and granuloma (107). More recently, DeMello et al. found deposits of eosinophil major basic protein within necrotic myocardium of two patients with the severe form of acute eosinophilic necrotizing myocarditis (34). The initial stimulus for the profound eosinophilic response in this disorder is unknown, but investigators have speculated that certain viral, occult parasitic, or allergic causes may be involved (92).

Patients with eosinophilic heart disease often have a beneficial response to the administration of corticosteroids or cytotoxic agents, particularly hydroxyurea. Such therapy may slow progression of the disease and may improve symptoms as well as survival (93). Such therapy may be combined with conventional therapy for heart failure including diuretics, digitalis, and afterload reduction. Long-term anticoagulation therapy should be considered when ventricular thrombi are noted. Patients with significant mitral or tricuspid regurgitation may benefit from endocardial resection and valve replacement. The course of the illness is variable. Patients with severe, acute necrotizing myocarditis may rapidly drift into severe heart failure and cardiogenic shock. Other patients may experience a more chronic, slowly progressive course of worsening heart failure.

45 VASCULITIS

Paul Katz, M.D.

Vasculitis is the term applied to a large and heterogeneous group of clinical disorders characterized by inflammation and damage to blood vessels. The injury to the vascular lumen results in distal ischemia to the tissues supplied by a given involved vessel. This reduction in blood flow causes an array of symptoms and clinical expressions of the underlying syndrome. Depending on the pathologic entity, vasculitis can exist as the major manifestation of the disease process, or it may be present as a lesser feature of a variety of illnesses. For example, vasculitis is the most prominent feature of Wegener granulomatosis (WG), yet it may be a minor component of diseases such as rheumatoid arthritis or systemic lupus erythematosus. This chapter addresses primarily those clinicopathologic processes in which the sole or major feature of the disease is secondary to vasculitis. In addition, remarks are confined to those vasculitic syndromes that are systemic, that is, those characterized by multisystem disease involving organs other than or in addition to the skin. The reader is referred to Chapter XX for a discussion of those syndromes in which vasculitis is confined to the skin or is predominantly expressed in the skin and to Chapter 37 and Chapter 39 for in-depth reviews of those entities in which vessel inflammation may be a secondary process. The following entities in the systemic vasculitis group are discussed:

1. Systemic necrotizing vasculitis
   a. Polyarteritis nodosa (PAN)
   b. Allergic angiitis and granulomatosis (AAG) (Churg-Strauss syndrome)
   c. Polyangiitis "overlap" group
2. WG
3. Lymphomatoid granulomatosis (LG)
4. Giant cell arteritis
   a. Takayasu arteritis
   b. Temporal arteritis
5. Miscellaneous vasculitides
   a. Mucocutaneous lymph node syndrome (MLNS) (Kawasaki disease)
   b. Isolated central nervous system vasculitis
   c. Behçet disease

The American College of Rheumatology (ACR) published classification criteria for the vasculitides (1), and the Chapel Hill Conference in 1992 also proposed a scheme based on clinical and histologic aspects, vessel size, and autoantibodies (2). Any classification scheme, including the one used in this chapter, is probably imperfect. For example, Rao and colleagues used the ACR criteria to categorize 198 patients referred for evaluation of possible vasculitis (WG, giant cell arteritis, PAN, or hypersensitivity vasculitis) (3). The positive predictive value for these four syndromes using ACR criteria was only 29% to 75% for patients with the final, proven diagnosis of vasculitis. Nonetheless, classification schemes provide a framework for approaching patients with these syndromes.

PATHOGENESIS

Although blood vessel inflammation may be apparent in seemingly unrelated and distinct clinical disorders, the events leading to vasculitis are thought to be similar irrespective of the nature of the particular disease (4). Investigators generally believe that the primary immunopathogenic mechanism responsible for the development of most vasculitic syndromes is an immune complex model similar to that first noted in the Arthus reaction (5) and in experimental serum sickness (6). Based on the animal data of Cochrane and Dixon (7), one can construct a theoretic model of immune complex–mediated vasculitis, which appears applicable to many of these diseases in human patients. The extrapolation of these elegant animal models to human vasculitis is largely based on similarities in histopathologic features and the demonstration of circulating and tissue-bound immune complexes (8) (Chapter 25). Unfortunately, only rarely has a causative antigen been clearly implicated in any of these clinical syndromes, one exception being the association of some cases of PAN with hepatitis B antigenemia (9). Thus, although it is possible to demonstrate circulating and even deposited immune complexes in many of the vasculitic syndromes, the causal relationship of these complexes with the pathophysiologic events in most of the vasculitides remains speculative.

Investigators have postulated that circulating antigen-antibody complexes, formed in a state of relative antigen excess, are deposited in blood vessel walls. This deposition is enhanced by the release of vasoactive amines from platelets and immunoglobulin E (IgE)–triggered basophils. In this regard, the vasculitis of experimental models of serum sickness can be abrogated by pretreatment of the animals with antihistamines and serotonin antagonists (6,10). Additionally, complex deposition is augmented by mechanical factors such as blood flow turbulence and hydrostatic forces, which explain the preferential localization of immune complexes at vessel bifurcations and in the lower extremities, respectively.

After localization in the blood vessel wall, the antibody component of the complex activates the classical complement cascade, with the resultant generation of complement-derived chemoattractants, particularly C5a (4,11). After neutrophil egress into the blood vessel wall, these cells release a variety of lysosomal enzymes after cellular interaction with the immune complex (12). These highly damaging enzymes (e.g., collagenase, elastase) result in necrosis and compromise of the vessel lumen and lead to distal ischemia. The failure to demonstrate immune complex components in vasculitic tissue specimens or in the circulation may be explained on the basis of the following mechanisms: (a) circulating immune complexes may be present for only a brief time and may be cleared rapidly by the reticuloendothelial system, and (b) the Ig and complement components of immune complexes may only be detectable in tissue for 24 to 48 hours after deposition (13).

In addition to the immune complex models and, as discussed later, in some forms of vasculitis, circulating autoantibodies may contribute to the pathogenesis of blood vessel inflammation. Antineutrophil cytoplasmic autoantibodies (ANCAs) have been isolated from sera from patients with WG as well as from patients with other systemic vasculitic and nonvasculitic conditions (14). Apart from serving as possible diagnostic markers, these antibodies, which diffusely stain the cytoplasm or the perinuclear areas of neutrophils (C-ANCAs and P-ANCAs, respectively), may activate these inflammatory cells. C-ANCA reacts with proteinase 3 localized within primary granules. After cell activation, proteinase 3 may be expressed by neutrophils and monocytes. *In vitro,* C-ANCA can bind to proteinase 3 and initiates degranulation and stimulation of the respiratory burst (15), thereby injuring endothelial cells. ANCAs could participate in the pathogenesis of vessel inflammation by a variety of mechanisms including activation of leukocyte effector cells and alteration of the physiologic activity of the antibody-bound antigen. Both paths could lead to endothelial cell damage. Antibodies to myeloperoxidase (MPO), that is, although not specific for vasculitic syndromes, could also participate in this process. Like proteinase 3, MPO can be located in ANCA-positive tissue specimens.

Serum antiendothelial cell antibodies (AECAs) can be found in some vasculitic syndromes. Although the target antigen is uncertain, AECAs have been associated with various syndromes such as the small vessel vasculitis of rheumatoid arthritis, systemic lupus erythematosus, Kawasaki syndrome, and WG. Investigators have speculated that AECAs could injure endothelial cells through the complement cascade with the formation of the membrane attack complex, by antibody-dependent cellular cytotoxicity (ADCC), or by altering endothelial cell function (16). Endothelial cells may also be actively involved in immune-mediated injury, because these cells can secrete cytokines, such as interleukin-1 (IL-1), IL-6, and IL-8 and colony-stimulating factors, and they can express class I and II major histocompatibility complex (MHC) and adhesion molecules (17). Additional information regarding the possible contribution of endothelial cells to the pathogenesis of vasculitis is anticipated to

accrue.

Cell-mediated immune reactions may also contribute to the development of certain forms of vasculitis and, in particular, those characterized by concomitant granulomatous inflammation (e.g., WG). In this scheme, antigen-sensitized lymphocytes interact with circulating antigen and result in the release of soluble mediators or lymphokines. These mediators induce the accumulation and activation of monocytes in a manner similar to neutrophils, which may release vessel-damaging lysosomal enzymes. Additionally, these same activated macrophages could transform into epithelioid cells, which then evolve into the multinucleated giant cells characteristic of granulomas (18). These mechanisms may explain the mononuclear cell infiltration and perivascular granulomas observed in certain forms of vasculitis that also display features of immune complex–mediated diseases. Finally, immune complexes themselves can directly induce granuloma formation either by being phagocytosed by the macrophage or by activating this cell through surface membrane receptors for Ig. Both processes can trigger the cascade of epithelioid cell transformation and ultimate granuloma formation (8).

Additional examples exist in temporal arteritis. Histologic specimens of temporal arteries in affected patients show $CD4^+$ T cells, with associated monocytes and macrophages, as well as epithelioid and giant cells. This latter group of cells express adhesion molecules such as intercellular adhesion molecule-1 (ICAM-1), lymphocyte function antigen-1 (LFA-1) and LFA-3, and human leukocyte antigen (HLA)-DR. The $CD4^+$ T cells express IL-1 and interferon-g, typical of the Th1 T-helper cell type, as seen in cell-mediated immune reactions. Conceivably, interferon could activate macrophages and could lead to giant cell and granuloma formation.

CLASSIFICATION

As noted, this chapter focuses on those clinical entities in which vasculitis is the major and, in some cases, sole feature of the disease. The classification scheme used is based on the clinical, pathologic, and therapeutic characteristics of these syndromes (8). Excluded from the present chapter are the predominantly cutaneous vasculitides, which are often referred to as the *hypersensitivity vasculitides,* and vasculitis secondary to an underlying disorder.

Systemic vasculitis refers to those syndromes in which blood vessel inflammation will likely progress to significant and often life-threatening end-organ dysfunction without therapeutic intervention. This condition is in contradistinction to those diseases in which cutaneous vasculitis predominates and significant end-organ failure is unusual. For each subgroup of systemic vasculitis, the pertinent clinical characteristics, histologic features, laboratory features, and therapeutic approach are presented. Emphasis is placed on those characteristics that make each syndrome unique and clearly distinguishable from other types of vasculitis.

SYSTEMIC NECROTIZING VASCULITIS GROUP

This large group of disorders has perhaps presented the most difficulty in classification. Included in this category are classic PAN, AAG (Churg-Strauss syndrome), and the polyangiitis “overlap” syndrome (4,8).

Classic Polyarteritis Nodosa

The first description of necrotizing vasculitis was that of Kussmaul and Maier, who, in 1866, presented the case report of a patient with what is now called *classic PAN* (19). This term is now applied to those syndromes with necrotizing vasculitis of small and medium-sized muscular arteries in which the lesions tend to be segmental. There appears to be a predilection for this process to involve the bifurcation of vessels with some distal involvement of arterioles and adjacent veins (20).

This disease is truly multisystemic, often with nonspecific and protean early clinical manifestations. Initially, symptoms may include malaise, fatigue, fever, myalgias, muscle weakness, abdominal pain, and head and extremity pain. Less frequent signs include neurologic and joint abnormalities. Both the insidious nature of these symptoms and the rarity of this disorder may contribute to delays in establishing the diagnosis.

Renal disease is present in 70% of patients, it is the major cause of mortality, and it may be present as vasculitis with glomerular ischemia, glomerulonephritis, or a combination of both processes. Hypertension may accompany renal disease and may contribute to the underlying vasculitic process. Although investigators had thought that the hypertension of PAN was associated with the healing stages of renal disease (21), it is now apparent that this hypertension may occur early in the course of the illness and may, in fact, antedate apparent kidney involvement. Urinary findings may include hematuria, cellular casts, and proteinuria.

Apart from hypertensive cardiovascular disease, PAN may directly involve the coronary arteries and may be a major cause of death (22). Clinically, PAN-related cardiac disease is present in one third of patients and in two thirds of subjects at autopsy. Most commonly, this condition is manifested by heart failure secondary to coronary arteritis or hypertension. Additionally, evidence of myocardial infarction may be found at autopsy despite no clinical evidence of such an event (23). Other manifestations of PAN can include pericarditis, which is seen in up to 14% of patients (22), and involvement of the conduction system secondary to nutrient arteritis (24,25).

Gastrointestinal symptoms are reported in up to 75% of patients with PAN and are related to visceral artery vasculitis (4). This involvement may be manifested by abdominal pain, nausea, vomiting, diarrhea, ileus, bleeding, infarction, and perforation of visceral organs. Additional signs may include abdominal angina and steatorrhea related to superior mesenteric artery inflammation. Acute presentations of abdominal pain may resemble appendicitis, cholecystitis, or pancreatitis (26). At autopsy, gastrointestinal tract involvement is noted in 50% of subjects and may involve any segment of the bowel (4).

Liver disease in PAN secondary to hepatitis B antigenemia can range from mild, subclinical disease with minimal elevation of transaminases to chronic active hepatitis (9). Vasculitis of the liver may be seen in one half of patients in the absence of evidence of hepatitis infection and may lead to massive hepatic infarction and necrosis (27). Hepatitis C antigenemia can be found in some patients with PAN, although the precise role in pathogenesis, except when associated with cryoglobulinemia, is unclear (28).

Neurologic manifestations are observed in 80% of patients with PAN, with greater involvement of the peripheral rather than the central nervous system (29). Approximately two thirds of patients have peripheral neuropathy as mononeuritis multiplex, extensive mononeuritis, cutaneous neuropathy, or polyneuropathy. These conditions are thought to arise from inflammation of the vasa nervorum. Peripheral neuropathy may be relatively refractory to therapy and, in fact, may remain as some degree of functional impairment in patients otherwise in remission. Forty percent of subjects have central nervous system signs or symptoms made evident by diffuse and focal abnormalities of higher cortical, cerebellar, or brainstem activity. Cranial nerve involvement is unusual. Ocular abnormalities secondary to PAN may be present as typical hypertensive changes or as retinal vasculitis manifested by cytoid bodies.

Classic PAN, by definition, does not involve the lung. When lung disease is present, it is usually found in association with granulomatous inflammation in an atopic patient and is included under the category of AAG (Churg-Strauss syndrome) (4), as discussed later. Theses two entities may overlap, a finding that has led to the designation polyangiitis “overlap” syndrome (30).

Skin involvement is reported in 20% to 30% of patients with PAN secondary to small muscular arteritis of the subcutaneous tissue, which may be clinically manifested by tender erythematous nodules from a few millimeters to several centimeters in size (31) or as livedo reticularis. Unfortunately, the term *cutaneous PAN* has been applied to vasculitis of the small arteries of the subcutaneous tissue without systemic involvement (32). Histopathologically, the vessel involvement is indistinguishable from classic PAN; however, the disease is limited to cutaneous vessels. I prefer to consider this a form of cutaneous vasculitis (8), rather than a manifestation of classic PAN.

Although arthralgias are frequently observed in patients with PAN, true arthritis is uncommon. Myalgias, which may herald the onset of the disease (4), are secondary to vasculitis, and they may be found in blind muscle biopsy specimens from symptomatic sites. Testicular epididymal pain may likewise be a presenting manifestation of PAN, and vasculitis of the testes is observed in 30% of postmortem specimens. The clinical manifestations of classic PAN are listed in Table 45.1.

TABLE 45.1. Clinical Profile and Clinical Manifestations in Patients with Classic Polyarteritis Nodosa

No diagnostic laboratory tests are specific for classic PAN. However, various laboratory abnormalities largely reflect the nonspecific findings of any chronic inflammatory disease as well as those resulting from immune complex deposition. Elevations in C-reactive protein may be useful in monitoring disease activity (33). Approximately 30% of patients with PAN are ANCA positive, most of whom are P-ANCA, rather than C-ANCA, positive.

The diagnosis of classic PAN is based on the histologic finding of necrotizing vasculitis of small and medium-sized muscular arteries (Fig. 45.1) in patients with a compatible clinical picture. Biopsy sites are best determined on the basis of accessibility and clinical or laboratory evidence of disease activity. Blind biopsies of asymptomatic sites rarely establish the diagnosis; preferred anatomic locales include skin, muscle, and peripheral nerve.

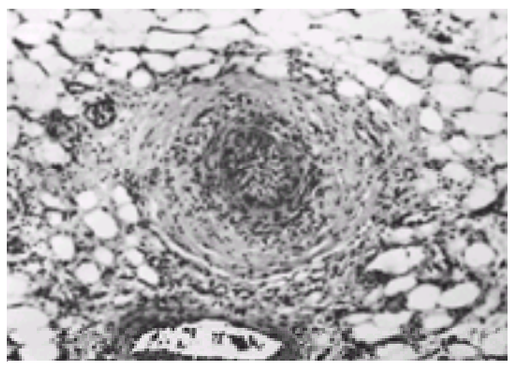

Figure 45.1. Biopsy specimen of a subcutaneous nodule in a patient with classic polyarteritis nodosa. A small muscular artery is involved with an inflammatory process, early fibrinoid necrosis, and obliteration of vessel lumen (hematoxylin and eosin stain, ×200).

The angiographic finding of small, aneurysmal dilatations *(pseudoaneurysms)* in renal, hepatic, and visceral vessels may be helpful in establishing the diagnosis (Fig. 45.2). Although initially thought to be diagnostic of PAN (34), these aneurysms may also be demonstrable in the polyangiitis “overlap” syndrome, systemic lupus erythematosus (35), and fibromuscular dysplasia (36). However, in a patient with a clinical picture compatible with classic PAN but without an easily accessible biopsy site, a positive angiogram substantiates this diagnosis.

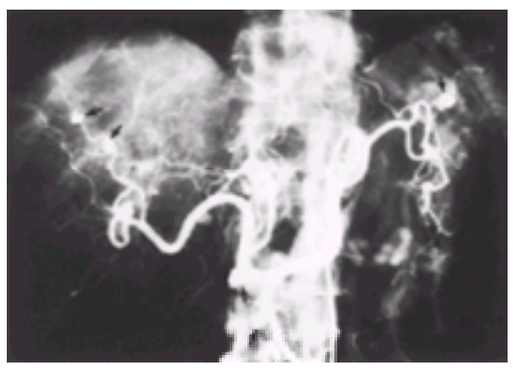

Figure 45.2. Celiac axis angiogram in a 47-year-old man with classic polyarteritis nodosa. The *arrows* indicate typical aneurysm formation in visceral arteries.

Without therapy, the prognosis of classic PAN is extremely poor. In untreated patients, the 5-year survival rate is 13%, and it increases to only 48% with corticosteroid therapy (37). These figures are considerably worse for patients presenting with hypertension or renal disease. Renal failure or a cardiovascular or gastrointestinal event is the usual cause of death. The therapy of classic PAN is described later, in the discussion of treatment of the systemic necrotizing vasculitis group.

Allergic Angiitis and Granulomatosis (Churg-Strauss Syndrome)

AAG is a disease similar to classic PAN in many respects. Unlike classic PAN, however, pulmonary vascular involvement is the *sine qua non* of this syndrome (13,38,39). Additionally, the following features distinguish AAG from classic PAN: (a) vasculitis of blood vessels of different sizes and types (small and medium-sized arteries, veins, and venules), (b) granulomatous inflammation (intravascular and perivascular), (c) peripheral blood and tissue eosinophilia, and (d) a strong association with severe atopic disease (usually asthma). As such, it is probably identical to “PAN with pulmonary involvement” as described by Rose and Spencer (21).

Patients generally present with nonspecific findings including fever, malaise, and weight loss. Pulmonary symptoms are usually the most notable and may include bronchospasm and evanescent pulmonary infiltrates (Table 45.2). There is a high incidence of skin lesions in AAG secondary to small vessel vasculitis. As shown in Table 45.2, the multisystemic nature of this syndrome is similar to that of classic PAN.

Category	Value
General considerations	Results
Age (mean)	46 yr
Sex ratio (male to female)	1.3:1
Duration (mean) of pulmonary symptoms before systemic symptoms	2 yr
Fever	Majority of patients
Organ system involvement	Percentage (%)
Pulmonary	95
Infiltrate on chest radiograph	93
Wheezing	82
Cutaneous	67
Purpura	37
Nodule	35
Peripheral neuropathy	63
Hypertension	54
Gastrointestinal	42

TABLE 45.2. Clinical Profile and Manifestations in Allergic Angiitis and Granulomatosis

Like PAN, AAG has no specific laboratory tests. Most patients have elevated erythrocyte sedimentation rates and white blood cell counts that, in 80% of cases, include absolute eosinophilia (more than 1,000 cells/µL). The presence of peripheral blood eosinophilia excludes the diagnosis of classic PAN but not the polyangiitis “overlap” syndrome. As may be anticipated from the strong allergic history in many patients with AAG, serum IgE levels may be elevated (5).

Histologically, vascular inflammation similar to that of classic PAN is characteristic of AAG. As previously noted, vessels of differing types and sizes may be involved. Unlike in PAN, eosinophils and granulomas may be found in and near involved vessels (21). Biopsy of involved tissues with characteristic pathologic features in concert

with the appropriate clinical setting establishes the diagnosis of AAG.

Without treatment, the 5-year survival rate for AAG is 4%; with corticosteroid treatment, this figure is increased to approximately 60%. The therapeutic recommendations for AAG are the same as for classic PAN.

Polyangiitis "Overlap" Syndrome

In examining large numbers of patients with the characteristics of classic PAN or AAG, it becomes evident that one syndrome of necrotizing vasculitis does not easily fit into these or other clinical categories (8,30). This has been referred to as the *polyangiitis "overlap" syndrome* (4,8). Typically, a patient in this group may have features of both classic PAN and AAG with or without the small vessel cutaneous venulitis characteristic of cutaneous "hypersensitivity vasculitis." Such patients may or may not have pulmonary involvement, an atopic history, eosinophilia, and tissue granulomas. This syndrome is a systemic vasculitis with the potential to progress to end-organ failure and death. Treatment of this subgroup is identical to that of PAN and AAG. Evidence suggests that long-lasting remissions are possible with early diagnosis and prompt institution of therapy (30).

Treatment of the Systemic Necrotizing Vasculitis Group

As noted in the preceding sections, the prognosis of patients with these entities before the advent of corticosteroids was extremely poor (37). Nonetheless, even with these drugs, the overall 5-year survival rate of the group was less than 50% (37). The heterogeneity of patients in this group has contributed to the difficulties in devising successful therapeutic regimens. In this regard, a few patients may do well with only corticosteroid treatment. Conversely, in some patients with rapidly progressive and fulminant disease, combination therapy with corticosteroids and cytotoxic drugs is mandatory to prevent irreversible organ dysfunction and, perhaps, death.

In patients with less severe disease without impending organ failure, a trial of corticosteroids appears justified. Therapy is initiated with prednisone, 1 mg/kg per day in divided doses with consolidation over several weeks to a single daily dose (8). This regimen is continued for 1 to 2 months, followed by an attempt to convert the patient to an alternate-day schedule over the ensuing 1 to 2 months. If this conversion is successful without evidence of relapse, alternate-day corticosteroids are continued for months up to 1 year, with tapering of this dose until the drug is discontinued or until a dosage is reached that is needed to suppress disease activity.

In patients failing to respond to this regimen within a month of its institution or in patients presenting with fulminant disease and end-organ dysfunction, a cytotoxic drug should be begun. Using the protocol originally devised for WG (see later), excellent results have been achieved with cyclophosphamide administered orally at 1 to 2 mg/kg per day. In patients unable to take the drug orally, it can be administered intravenously at the same dose. Prednisone therapy should always be administered together with the cyclophosphamide regimen, particularly early in the course, because cyclophosphamide in the regimen outlined takes 2 weeks to 1 month to achieve a significant immunosuppressive effect. The prednisone regimen should be administered as outlined earlier, with ultimate conversion to an alternate-day regimen after approximately 1 month of daily therapy. The alternate-day regimen should be maintained for at least 3 to 6 months, with gradual tapering until discontinuation or until a dose is reached beneath which disease activity flares. The dose of cyclophosphamide is adjusted to maintain the white blood cell count at approximately 3,000 to 3,500 cells/µL, with an absolute neutrophil count of greater than 1,000 to 1,500 cells/µL (8). At these levels, infection is extremely unlikely. Cyclophosphamide therapy is continued for 1 year after complete remission has been achieved; the dose is then tapered in 25-mg decrements every 2 months until it is discontinued. Using this regimen, we have achieved long-term remissions in most patients with systemic necrotizing vasculitis (40).

Although other cytotoxic drugs have been used in some of these syndromes (e.g., azathioprine, chlorambucil), it does appear that cyclophosphamide is the most efficacious agent for inducing long-term remissions in systemic necrotizing vasculitis (41). As discussed later, cyclophosphamide therapy may result in serious side effects, especially when therapy is prolonged. Enthusiasm for the use of intermittent "pulse" cyclophosphamide, as successfully employed in lupus nephritis, has been dampened by difficulties in inducing and maintaining remissions.

WEGENER GRANULOMATOSIS

WG is characterized by the clinical complex of (a) necrotizing granulomatous vasculitis of the upper and lower respiratory tracts, (b) glomerulonephritis, and (c) varying degrees of disseminated small vessel vasculitis (42,43). As with most of the systemic vasculitides, the cause of WG is unknown; however, it is believed to represent an exaggerated and aberrant hypersensitivity reaction to an unknown antigen that may have entered through the respiratory tract.

A reported series of 158 patients with WG provided a comprehensive review of the clinical, laboratory, and pathologic manifestations of the disease (44). The mean age at onset was 41 years, yet 15% of patients presented before the age of 19 years. No gender differences were noted, and only 3% of affected persons were not white.

The presenting signs and symptoms of WG are listed in Table 45.3. Most patients present with nonspecific complaints (malaise, fatigue) in concert with symptoms referable to the upper airways such as rhinorrhea, sinusitis, nasal mucosal ulcerations, and otitis media. Sinus roentgenograms often appear abnormal, with early signs of mucosal thickening. This may progress to total opacification of air-fluid levels. Nasal septal perforation and loss of supporting nasal structures may lead to the characteristic saddle nose deformity. Most patients with WG develop secondary infection of damaged upper airway structures, almost invariably with *Staphylococcus aureus.* This infection may occur even in patients who are in complete remission from their underlying disease and often represents an increased susceptibility of previously damaged upper airway mucosa to becoming secondarily infected. Such infections may complicate the clinical picture in patients in remission who may initially be misdiagnosed as having a relapse. Clearly, this critical distinction cannot be overemphasized, and in such patients, the appropriate cultures or surgical procedures to establish the diagnosis are recommended.

TABLE 45.3. Presenting Signs and Symptoms in 158 Patients with Wegener Granulomatosis

Pulmonary symptoms in the absence of upper respiratory tract signs are unusual. Respiratory complaints such as cough, hemoptysis, and chest pain may herald the onset of WG. Chest radiographs generally reveal multiple, bilateral nodules that may cavitate (Fig. 45.3). Approximately 10% of patients have demonstrable pleural effusions, but hilar adenopathy is rare (45). Pulmonary dysfunction manifested as airflow obstruction, decreased lung volumes, and decreased diffusing capacity is frequently noted.

Figure 45.3. Chest roentgenogram of a 38-year-old woman with Wegener granulomatosis. Note the bilateral nodular cavitary infiltrates.

Patients with WG rarely present with renal failure in the absence of significant disease in other organ systems. Signs of kidney disease may range from minimal urinary sediment abnormalities with normal renal function (e.g., in mild focal and segmental glomerulonephritis) to markedly progressive renal dysfunction with diffuse necrotizing glomerulonephritis including proliferative and crescentic changes. Because of the morbidity and eventual mortality associated with renal disease in WG, and because extrarenal WG usually precedes kidney diseases, it is impernative to establish the diagnosis and to initiate appropriate therapy as early as possible (43).

Ocular disease may occur either early or late in the course of WG. This may range from mild conjunctivitis through episcleritis and scleritis to scleromalacia perforans (46). Proptosis secondary to nasal sinus involvement or retroorbital granulomatous vasculitis may be seen in some patients.

Cutaneous lesions may develop early in the course of WG and are usually secondary to small vessel vasculitis (47). These may be present as ulcerations, papules, vesicles, or subcutaneous nodules.

No diagnostic laboratory studies are available for WG; however, some characteristic abnormalities may be useful. The erythrocyte sedimentation rate is invariably elevated, often greater than 100 mm per hour. This test is perhaps the most sensitive indicator of disease activity in WG and is useful in detecting active disease even in the absence of clinical symptoms. Autoantibodies against extranuclear components of neutrophils may be present in sera from patients with WG (48). As noted earlier, sera from patients with WG frequently contain ANCAs, which diffusely stain the cytoplasm of fixed neutrophils (C-ANCAs) (15,49). These autoantibodies are directed against a 29-kd serine proteinase, termed *proteinase 3.* Additionally, some sera from patients with WG, as well as sera from patients with microscopic PAN, Churg-Strauss syndrome, necrotizing crescentic glomerulonephritis, or Kawasaki syndrome, may stain neutrophils in a perinuclear pattern (P-ANCAs) (49). P-ANCA staining results from autoantibody reactivity with myeloid lysosomal enzymes, most importantly MPO, as well as elastase. Approximately 90% of sera from patients with active WG are C-ANCA positive; with disease remission, this falls to 40% (44). Frequently, low-grade anemia and thrombocytosis are encountered secondary to the inflammatory nature of the disease. Most patients have leukocytosis, often with a left shift. Increased levels of serum IgG and IgA are observed in most patients, a finding reflecting hyperactivity of the immune system (42). Rheumatoid factor and circulating immune complexes can be demonstrated in some patients with WG. We described an increased frequency of HLA-B8 in WG (50).

The pathologic hallmark of WG is necrotizing granulomatous vasculitis (Fig. 45.4). Biopsy of the upper airways, although accessible, may reveal only acute and chronic inflammation. Lung biopsy produces an extremely high diagnostic yield because large tissue specimens can be obtained. In addition to demonstrating the typical granulomatous vasculitis of WG, one can usually rule out other diseases in the differential diagnosis such as pulmonary neoplasms and infectious diseases. The vasculitis primarily involves small arteries and veins. Granulomas may be within, adjacent to, or distant from sites of vascular inflammation. Renal involvement is histologically variable but may range from focal and segmental glomerulonephritis to fulminant crescentic glomerulonephritis (51). Less frequently encountered are vasculitis and granulomas. Histologic evidence of immune complex components can be demonstrated in some, but not all, biopsy specimens.

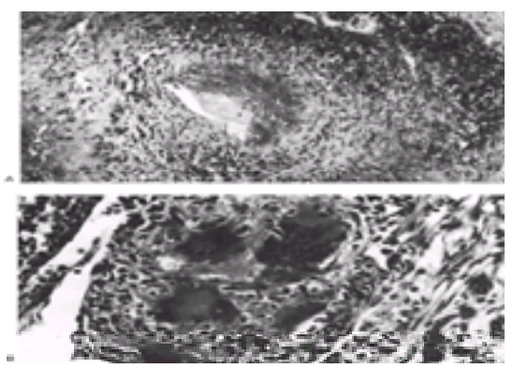

Figure 45.4. Lung biopsy specimen from a patient with Wegener granulomatosis. **A:** Typical pulmonary vasculitis with fibrinoid necrosis of a vessel wall and surrounding inflammatory infiltrate (hematoxylin and eosin stain, ×170). **B:** Multinucleated giant cells within infiltrate in alveolar spaces (hematoxylin and eosin stain, ×270).

Before the advent of cytotoxic therapy, WG was an almost uniformly fatal disease with a particularly rapid and progressive course in the presence of renal disease. In the absence of treatment, the mean survival time was 5 months, with a mortality rate at 1 year of 82%, which rose to more than 90% after 2 years (52). These dismal results were not substantially influenced by corticosteroids. This was the first vasculitis syndrome shown to respond successfully to long-term low-dose cyclophosphamide therapy, because it was demonstrated that this drug, together with alternate-day corticosteroids, could induce long-lasting remissions in most patients (42).

The treatment outcomes of 158 patients with WG were reported (44). Eighty-four percent received standard treatment of daily low-dose cyclophosphamide and corticosteroids, 5% were treated with low-dose cyclophosphamide alone, 6% received only corticosteroids, and 4% received other cytotoxic drugs and corticosteroids. The standard protocol produced marked improvement or partial remission in 91% of recipients; 75% experienced complete remissions, with a median time of 12 months. Fewer than 10% of patients so treated experienced remission as late as 6 years after beginning this protocol. Although almost all patients eventually had disease remissions, nearly one half had relapses. Morbidity, secondary to the disease or its therapy or both, occurred in nearly 90% of patients; most prominent was chronic renal insufficiency, affecting 40%. Hearing loss, nasal deformity, tracheal stenosis, and visual impairment were experienced by up to one third of subjects.

Cyclophosphamide-related morbidity included cystitis (43%), carcinoma of the bladder (3%), and myelodysplasia (2%). Overall, malignant diseases were nearly 2.5 times more frequent in cyclophosphamide-treated patients than in the general population; notably, this was skewed toward bladder cancer (33-fold) and lymphoma (11-fold). Infectious complications, occurring in 46% of the cohort, were observed secondary to immunosuppressive treatment and disease-related tissue injury; one half of these were seen in association with daily corticosteroid treatment. Thirteen percent of the patients died as a direct consequence of WG, its sequelae, or therapy.

Despite the efficacy of low-dose cyclophosphamide-corticosteroid treatment, the considerable toxicity has prompted interest in alternate therapies. Based on the success and relatively low toxicity of high-dose, monthly intravenous cyclophosphamide in systemic lupus erythematosus, this same protocol was employed in 14 patients with WG (53). Patients received cyclophosphamide monthly and tapering doses of corticosteroids for 6 months; if successful, the regimen was continued, but less often. Although initial improvement was observed in more than 90% of patients, nearly 80% had disease exacerbations or were intolerant of this regimen; only 20% had prolonged remissions. Therefore, this protocol is less efficacious than the standard regimen.

Twenty-nine patients with less severe disease were treated with weekly methotrexate and daily or alternate-day corticosteroids, with marked improvement observed in approximately 75% and remission in 70% (54). This protocol has been employed in patients with less than immediately life-threatening illness. Methotrexate is begun at 0.3 mg/kg per week, with a gradual increase in dose as needed and as tolerated up to a dose of 25 mg per week. Seventeen percent displayed continued and accelerating disease activity during the first 6 months of this regimen. Over time, 36% of patients experienced a relapse requiring repeat therapy. Thus, in selected patients, this therapeutic option may be appropriate.

Finally, scattered reports have noted success with trimethoprim-sulfamethoxazole (55). However, these results were not confirmed in a study from the National Institutes of Health. Given the potential role of tumor necrosis factor in WG, studies are under way to look at the possible efficacy of anti–tumor necrosis factor therapy using etanercept and infliximab. These newer therapies certainly hold promise, particularly in view of the limited toxicity of this drug.

LYMPHOMATOID GRANULOMATOSIS

In 1972, Liebow et al. published their landmark description of *LG,* an unusual form of granulomatous vasculitis characterized by an angiodestructive and angioinvasive infiltration of blood vessels with atypical lymphocytoid and plasmacytoid cells (56). Currently, this disease is included with the angiocentric immunoproliferative lesions, as are benign lymphocytic angiitis and granulomatosis and angiocentric lymphoma. The pathogenesis of this syndrome is obscure, and it may differ from other vasculitides in that an immune complex origin may not be apparent. There is a predilection for this disease to involve many of the same organ systems as WG (lung,

skin, kidneys, and central nervous system) (57), and this may cause some confusion between these syndromes. Approximately 50% of patients with LG do not respond to the accepted therapeutic regimen (see later) and go on to develop non-Hodgkin lymphoma (58).

Usually, patients in the fourth or fifth decade present with nonspecific signs including malaise, fever, fatigue, and weight loss (4). More specific symptoms are referable to pulmonary involvement including cough, dyspnea, and chest pain and are manifested by the radiographic finding of bilateral nodular densities. Approximately one fifth of patients with LG have either peripheral or central nervous system signs. Cutaneous disease occurs in up to 40% of patients, as either erythematous macules or indurated plaques. One third of patients with LG have renal involvement secondary to parenchymal infiltrates with atypical mononuclear cells rather than glomerulonephritis. Less frequent manifestations include splenomegaly (18%), hepatomegaly (12%), and lymphadenopathy (8%).

Again, no specific laboratory tests hallmark LG. One half of patients may have leukocytosis, whereas 20% have leukopenia. The erythrocyte sedimentation rate is either normal or minimally elevated, in contrast to the invariable elevations in WG (56).

The unique histologic appearance of LG includes angiocentric and angioinvasive infiltration of arteries and veins with pleomorphic, atypical lymphocytes (primarily T cells) and plasmacytes. Associated atypical B lymphocytes may be infected with Epstein-Barr virus. The granulomas are less frequent and less distinct than in WG. In addition to cellular atypia, mitosis of the infiltrating cells may be observed. Differentiation between LG and frank lymphoma may be difficult; however, the clinical absence of splenic, bone marrow, and lymphatic disease favors the diagnosis of LG. Furthermore, the pathologic appearance of the infiltrating cells is extremely important in establishing the diagnosis.

Without therapy, LG is nearly always fatal (56,59). We described our experience with 15 patients with LG who were treated with the protocol mentioned earlier for systemic necrotizing vasculitis (58). In 50% of patients, long-term remissions were achieved, and therapy was discontinued. The remaining one half who failed to respond evolved into the lymphomatous phase of LG and eventually died. The best indicator of significant long-standing remission and survival is a successfully induced, early and complete remission. In patients with disease limited to the lungs and skin, cyclophosphamide and prednisone may be adequate; however, more extensive and histologically aggressive disease likely deserves more extreme chemotherapy. This situation emphasizes the need for early diagnosis and treatment if remissions are to be realized.

GIANT CELL ARTERITIDES

Within the broad category of *giant cell arteritides* are two distinct disorders: temporal arteritis (or cranial arteritis) and Takayasu arteritis (“pulseless” disease). Although these syndromes are distinct clinically, they are histologically similar and are characterized by vasculitis of medium-sized and large arteries, often accompanied by granuloma or giant cell formation.

Temporal Arteritis

The classic signs and symptoms of *temporal arteritis* include fever, high erythrocyte sedimentation rate, and anemia often accompanied by polymyalgia rheumatica in a person more than 55 years old (60). Although usually involving branches of the carotid artery, temporal arteritis is truly a systemic vasculitis, and virtually any medium-sized or large artery may be involved, including the renal artery and aorta.

Temporal arteritis is a common disorder, with an incidence of 17.4 cases per year per 100,000 people older than 50 years. Rarely, this disease may present in younger adults and even adolescents (61). There appears to be a 2:1 female predominance. Genetic studies have suggested that HLA-DR4 frequency is increased in patients with temporal arteritis or polymyalgia rheumatica.

The presenting symptoms of temporal arteritis are usually nonspecific and include headache (44%), malaise (20%), fatigue (12%), and fever (8%) (60). The only early sign that may be specific is jaw claudication, reported in 12% of patients (60). In one half of patients, physical abnormalities of the temporal artery, such as tenderness, nodules, and decreased pulse, may be found. However, an absence of these findings does not decrease the chances of a positive finding on biopsy because one third of patients have no clinical changes in the area of the temporal artery (62). Approximately 40% of patients with temporal arteritis develop visual impairment (63), although it is unusual for this to be the presenting manifestation with associated blindness. Blindness generally occurs 3 to 4 months after the onset of symptoms, a finding emphasizing the need for early diagnosis and therapy.

Polymyalgia rheumatica, with its characteristic proximal myalgias, periarticular pain, and morning stiffness, is seen in approximately 50% of patients with temporal arteritis (64). Conversely, 40% to 50% of patients with polymyalgia rheumatica have positive temporal artery findings even in the absence of symptoms (64). Clearly, the distinction between these two syndromes may be difficult, but necessary.

Typical laboratory findings in temporal arteritis include mild normochromic, normocytic anemia and a high erythrocyte sedimentation rate. A review of the literature indicated that temporal arteritis may be seen in the absence of elevations in erythrocyte sedimentation rate (65). Headache and jaw claudication were seen less frequently in these patients than in those with elevated values. These findings in an elderly patient with the aforementioned symptoms should alert the clinician to this diagnosis. Elevated acute-phase reactants and serum Igs have been observed in some patients. Frequently, abnormal findings on liver function tests, especially increased alkaline phosphatase levels, are noted (66); less commonly, there may be only slight elevations of serum transaminases. Patients with polymyalgia rheumatic and antiphospholipid antibodies appear to have a greater chance of developing temporal arteritis. Furthermore, levels of anticardiolipin antibodies may drop precipitously after corticosteroid therapy.

Typically, the diagnosis of temporal arteritis is established by the finding of panarteritis of the vessel with mononuclear cell infiltration. Giant cells may or may not be present, and their absence does not exclude the diagnosis. Ig deposits on the internal elastic membrane are found in fewer than 50% of biopsy specimens (67). Infiltrating lymphocytes are primarily T cells of the helper-inducer CD4 subset. Some of these cells are positive for HLA-DR, the integrin receptor very late antigen-1, and IL-2 receptors, indicative of activation (68). Accompanying giant and endothelial cells and macrophages express HLA-DR and LFA-1, LFA-3, and ICAM-1. These same histologic findings are frequently demonstrable in vessels other than the temporal artery, and this situation may result in systemic signs and symptoms.

Investigators have suggested that multiple sections of bilateral temporal artery biopsy specimens should be examined because of the focality and segmental nature of the vasculitis (69). Additionally, it has been proposed that superficial temporal arteriography could assist in identifying high-yield biopsy sites, although the angiographic changes are not diagnostic of this syndrome (70). In general, this is not recommended.

Patients with temporal arteritis generally respond dramatically to corticosteroid therapy. Usually, after several days of 40 to 60 mg of prednisone daily, patients report an improved sense of well-being with a diminution in fever, malaise, and myalgias (71). Concomitant with this is a decrease in vascular symptoms including headache and jaw claudication. Because of the risk of blindness, the diagnosis should be established quickly, and proper therapy should be instituted. The symptoms of polymyalgia rheumatica frequently improve with lower doses of corticosteroids; unfortunately, these are inadequate to prevent the development of visual impairment. Gradually, prednisone can be tapered to 7.5 to 10.0 mg per day, with readjustment should symptoms recur. Therapy should be continued for 1 to 2 years (60). The erythrocyte sedimentation rate may increase during tapering even in the absence of clinically apparent disease. Under these circumstances, tapering can be carefully continued because some symptoms generally reappear before relapse. It appears that many patients can be converted to alternate-day corticosteroid therapy once remission has been induced. This schedule should not be instituted at the onset of therapy because it is unlikely to completely improve symptoms (72). Although nonsteroidal antiinflammatory drugs may relieve some symptoms, they do not prevent blindness. In this regard, visual impairment is generally irreversible, although a few patients may have some restoration of function (72). Alternate corticosteroid regimens have been employed in patients with impending visual loss (73). Resolution of ischemic optic neuropathy with high-dose, “pulse” intravenous methylprednisolone, similar to that administered for optic neuritis, may be useful in these circumstances, although experience is limited. Fortunately, most patients remain in remission even after cessation of an adequate trial of corticosteroid therapy.

A report of nine patients who died of temporal arteritis indicated that myocardial infarction, dissecting aneurysm, and stroke were implicated. No patient in this group was receiving “adequate” corticosteroid treatment (74).

Takayasu Arteritis

Takayasu arteritis (“pulseless” disease), a disease primarily of young women, is characterized by vasculitis and stenosis of intermediate-sized and large arteries with a predilection for the aortic arch and its branches (75,76). Because of the increased incidence in female patients, genetic factors are believed to be important; furthermore, an association with the HLA antigens B5, A10, B52, and DHO has further substantiated this possibility (4). Nonetheless, a study of 21 white North American patients showed no correlation with class I or II antigens (77); DR1 was negatively associated with the disease.

Takayasu arteritis is biphasic. The acute phase is heralded by symptoms of a systemic inflammatory disease; the chronic stage has signs of an occlusive vascular process with insufficiency. The mean time between these phases is 8 years, but it may be as short as several months (78). In 70% of patients, an acute stage can be identifiable historically, whereas in the remainder, ischemic signs and symptoms herald the diagnosis in the absence of prior recognizable systemic inflammatory

disease. In the early period, fever, night sweats, fatigue, myalgias, arthralgias, and weakness are common. Ischemic symptoms dominate the late stage of disease; this most frequently involves the aortic arch and its branches, but any intermediate-sized or large vessel may be involved. In this stage, physical examination may reveal absent pulses or vascular bruits. In addition to vascular insufficiency, claudication or Raynaud phenomenon may be apparent. Renal artery involvement may produce hyperreninemia with resultant hypertension. Other findings may include visual disturbances, syncope, paresthesias, and cerebral infarction. Cardiac signs such as congestive heart failure, angina, aortic insufficiency, myocarditis, and pericarditis may be noted.

Up to 14% of patients with Takayasu arteritis die of the disease, usually secondary to congestive heart failure resulting from myocardial infarction (79). Laboratory studies are nondiagnostic. Most patients have elevations of the erythrocyte sedimentation rate; mild anemia, leukocytosis, and increased serum Igs may likewise be present.

The diagnosis is usually established by the characteristic arteriographic changes ranging from narrowing to occlusion of large arteries with formation of collateral circulation (80). Usual vessels involved are the subclavian artery, descending aorta, renal artery, and carotid artery, although, as noted earlier, any intermediate-sized or large vessel may be involved.

Because biopsy material is usually not available for study, the diagnosis is less frequently made by the histologic finding of panarteritis of large elastic arteries with mononuclear and giant cells in all vessel wall layers (81). Secondary atherosclerotic changes may be observed in previously damaged vessels. Histologically, this vasculitis syndrome suggests a cell-mediated pathogenesis with lesions infiltrated with natural killer and cytotoxic T lymphocytes and gd T cells. Furthermore, adhesion molecule expression in the vessel wall adds additional support to this pathogenic model.

The initial inflammatory stage of Takayasu arteritis can be frequently suppressed by corticosteroids; however, it is not clear that such therapy prolongs life. The effect of these agents on the ultimate outcome of the disease is particularly difficult to interpret in view of the variable course; that is, patients with Takayasu arteritis generally deteriorate gradually, but spontaneous remissions or acute decompensation may occur. Some data suggest that long-term low-dose prednisone therapy (5 to 10 mg per day) may reduce late complications and may prolong life. A report of 20 patients indicated that patients not responding to corticosteroids often benefited by the addition of cyclophosphamide (82). Additionally, methotrexate may be effective in patients in whom corticosteroid therapy fails. In patients with vascular insufficiency secondary to this process, percutaneous angioplasty may be useful for renal, aortic, and coronary vessels.

MISCELLANEOUS SYSTEMIC VASCULITIDES

Mucocutaneous Lymph Node Syndrome (Kawasaki Disease)

MLNS, or Kawasaki disease, is an acute illness of children characterized by the clinical signs of prolonged fever, conjunctivitis, involvement of the oral mucosa and lips, cutaneous changes in the distal extremities, truncal exanthem, and acute cervical lymphadenopathy (27,83). Although initially described in Japan, the disease is now recognized with increased frequency in the United States, where it has been reported in children from 3 months to 13 years old (84).

The cause of MLNS is unknown; initial enthusiastic reports about the possible relationship with *Rickettsia,* Epstein-Barr virus, and streptococci have not been conclusively verified. The disease is seen with greatest frequency in persons of Japanese descent, but HLA associations have not been clearly identified.

Ninety-five percent of patients are febrile during the first week of illness, with gradual defervescence during the ensuing week (83). A common manifestation is marked reddening of the skin of the palms and soles (88% of patients) during the initial 7 days, much like that of scarlet fever. Concomitant with a decline in fever, desquamation of the involved skin occurs, beginning at the distal end of the affected digits. Nonspecific maculopapular dermatitis develops within 3 to 5 days of the onset of fever, with eventual progression to confluence. Patients invariably develop dry erythematous and fissured lips and oral mucous membranes in association with congested conjunctivae and a “strawberry” tongue. Tender, nonsuppurative anterior and posterior cervical lymphadenopathy is present in three fourths of patients.

An infrequent, yet potentially life-threatening, complication of MLNS is cardiac involvement with signs of cardiomyopathy or mitral or aortic valve regurgitation (85). Late cardiac events such as coronary artery vasculitis and aneurysm formation may be responsible for the 1% to 2% case-fatality rate (86). Less common manifestations may include arthralgias or arthritis, liver function abnormalities, diarrhea, and aseptic meningitis (87).

Nondiagnostic laboratory studies such as leukocytosis and increased erythrocyte sedimentation rate are frequently observed in patients with MLNS. Elevations of serum IgE may be present for 1 to 2 months. With myocarditis, electrocardiographic abnormalities may be noted, but these may not necessarily be apparent even in the presence of coronary artery aneurysms. These aneurysms are usually demonstrable angiographically or by echocardiography.

Histologically, panarteritis of the coronary vessels with mononuclear cell infiltration is noted. Aneurysm formation generally occurs at the sites of greatest vasculitic inflammation. Other vessels may be involved less frequently, but usually only endothelial proliferation is observed. Lymph node biopsy generally reveals necrosis, thrombosis, small vessel vasculitis, and immunoblast-like leukocytes. The syndrome originally labeled *infantile (or childhood)* PAN likely represented MLNS with severe coronary arteritis (88).

The diagnosis of MLNS is made by the presence of five of the six criteria described earlier. The striking clinical signs and symptoms of this entity usually make the diagnosis readily apparent.

Although normally MLNS is a self-limited disease without long-term morbidity or mortality, the risk of coronary arteritis and of subsequent aneurysm formation has favored treatment. Initial enthusiasm for corticosteroids or aspirin has not been sustained. Currently, intravenous immune globulin is considered the therapy of choice, particularly with regard to the prevention of late complications (89).

Isolated Central Nervous System Vasculitis

Rarely, vasculitis may be restricted to *vessels of the central nervous system* without evidence of extracranial involvement (90). Although intracranial vasculitis may be observed in patients with certain bacterial infections, syphilis, tuberculosis, fungal infections, and viral illnesses, isolated idiopathic central nervous system vasculitis may occur. Patients usually present with mental confusion, headache, or focal neurologic deficits. Systemic signs and symptoms such as arthralgia and arthritis, myalgias, and fever, which are frequently observed in many systemic vasculitides, are conspicuously absent in isolated central nervous system vasculitis.

Although routine laboratory tests are rarely helpful, cerebrospinal fluid examination may reveal increased opening pressure, mononuclear pleocytosis, and slightly increased protein; however, normal fluid does not exclude the diagnosis. Radiographic examinations, except angiography, are of little value. Cerebral arteriography may demonstrate vessel “beading” with narrowing and dilatation of small blood vessels, vessel cutoff, or aneurysm formation, although these studies may appear entirely normal. Biopsy of involved vessels, usually small arteries and arterioles, reveals mononuclear cell infiltration and occasionally giant cells.

In the absence of therapy, this disease is nearly always fatal (91), with either an abrupt, fulminant course or slow deterioration. Although the precise treatment modality is unproved, corticosteroids alone are the initial drugs of choice. When a corticosteroid regimen fails, or in patients who are intolerant of corticosteroids, the aforementioned regimen of cyclophosphamide plus corticosteroids appears to improve this dismal prognosis significantly.

Behçet Disease

Behçet disease is an unusual clinical syndrome hallmarked by recurrent episodes of oral ulcerations, ocular lesions, genital ulcerations, and skin lesions. Histologically, the basic process is that of venulitis, although virtually any size vessel in any location may be involved. The cause of Behçet disease is unknown. Immune complex deposits in involved tissues (92) and lymphocyte-mediated cytotoxicity against oral epithelial cells (93) have suggested an immune pathogenesis.

The disease is found with increased frequency in eastern Mediterranean and Far Eastern countries; additionally, the incidence of the histocompatibility antigen HLA-B51 is greater than expected in affected patients, especially those with the most severe disease (94). Recognized with higher frequency in people living along the “silk route,” affected patients away from this area do not have the associated HLA-B51 frequency.

The initial manifestation of Behçet disease is usually oral ulcers, noted in 75% of patients. These painful lesions may be multiple and may be found anywhere in the oral cavity; healing is generally spontaneous within 2 weeks of onset. Twenty-five percent of patients present with ocular signs, usually iridocyclitis and hypopyon, which are usually self-limited and without late complications. Posterior eye disease (e.g., choroiditis, retinal vasculitis) may be recurrent and can result in visual loss.

Genital ulcers are clinically similar to oral ulcerations. In male patients, these are most frequently found on the scrotum and less commonly on the penis. Vulvar lesions are more common than vaginal ulcers in female patients. Scar formation after healing is noted. Skin lesions may occur as pyoderma, pustules, papules, vesicles, and

erythema nodosum. Cutaneous nodules may be noted after minor skin trauma such as venipuncture. Superficial thrombophlebitis and deep thrombophlebitis are noted in one third of patients. Heparin may have little effect on this condition and, in some instances, may in fact worsen vessel inflammation.

Although infrequently encountered, neurologic involvement, usually manifested as paralysis, headache, or meningoencephalitis, is associated with increased mortality. These findings occur late in the course of Behçet disease, and recurrences may be noted. Renal involvement manifested as proteinuria or hematuria, cardiac involvement manifested as pericarditis, and gastrointestinal ulcerations are observed in a few patients.

Laboratory tests are of little assistance in establishing the diagnosis. Leukocytosis, increased erythrocyte sedimentation rate, and hypergammaglobulinemia may be present. Mononuclear cell infiltration of small vessels is the typical histologic pattern, with a tendency toward perivascular involvement and thrombosis. The diagnosis, however, is usually made on the basis of clinical findings.

No clearly satisfactory therapy for Behçet disease exists. Chemotherapeutic agents, blood transfusions, colchicine, corticosteroids, and nonsteroidal antiinflammatory drugs have all been tried with varying degrees of success. Without large vessel, gastrointestinal, or central nervous system involvement, the prognosis is good. Posterior ocular involvement, usually refractory to therapy, may improve with cyclosporine. In a 2-year trial of daily azathioprine (2.5 mg/kg of body weight per day), improvement was noted in existing ocular and extraocular disease (95); additionally, the development of new eye disease was substantially less than that in patients receiving placebo.

APPROACH TO THE PATIENT WITH SYSTEMIC VASCULITIS

The systemic vasculitides encompass a wide variety of diverse clinical entities. Many of these are clearly separable, whereas others may overlap in their clinical, pathologic, and immunologic considerations. The clinician must correctly categorize the type of vasculitic syndrome and must delineate the extent and nature of the process. Early diagnosis and proper treatment are necessary if severe and often permanent end-organ failure is to be avoided.

46 ANTIPHOSPHOLIPID SYNDROME

Stephen Reddel, MB, BS, and Steven A. Krilis, Ph.D.

The *antiphospholipid syndrome* (APS) is an uncommon condition characterized by thrombosis and miscarriage, in the presence of autoantibodies to specific plasma phospholipid (PL)-binding proteins. The diagnosis of APS requires both clinical and laboratory findings. Patients have a range of clinical findings generally attributable to vascular events in both the arterial and venous circulations, and women are also subject to recurrent miscarriage. The autoantibodies are called antiphospholipid antibodies (aPLs) for historical reasons, but they are actually directed against phospholipid-binding plasma proteins, specifically b_2-glycoprotein I (b_2-GPI) and prothrombin (1,2).

The tests for aPL fall into two groups. *In vitro* coagulation tests may be prolonged by aPL in which case the aPL is called a lupus anticoagulant (LA). The most commonly used enzyme-linked immunosorbent assay (ELISA) for aPL uses cardiolipin-coated wells and buffer containing bovine serum: this is called the anticardiolipin (aCL) assay.

HISTORICAL FEATURES

The appreciation of what is now generally known as APS followed from the intersection of several coincident findings (3). Widespread premarital syphilis screening unveiled a group of young women with biologic false-positive tests for syphilis, many of whom had systemic lupus erythematosus (SLE) (4). These patients frequently had thromboses despite prolonged *in vitro* coagulation tests (5). The coagulation tests generally require the addition of anionic PL, providing a surface to which many coagulation factors must bind to be fully active. Cardiolipin is the antigen detected in the Wassermann reagent (the “reagin” of syphilis tests) and is also an anionic PL. Coating the cardiolipin directly onto a microtiter plate (initially as a radioimmunoassay, now as an ELISA) was found to have greater sensitivity than the syphilis screening tests for detecting the population with thrombosis within SLE (6). Autoantibodies, whether LA or aCL, are therefore known as aPLs, and the syndrome has generally become known as APS. Synonyms include the aCL syndrome, the anti-PL protein syndrome, and the eponymous Hughes syndrome.

Contrary to the name of the syndrome, PL itself is not the target for clinically significant antibodies. Autoantibodies occurring in APS generally do not bind to anionic PL in the absence of human or bovine plasma in the buffer (7). Investigators have shown that most aCLs from patients with APS actually bind b_2-GPI, a plasma protein that binds anionic PL (8,9 and 10). On the contrary, aCLs from patients with infections (not limited to syphilis) without clinical features of APS bind directly to cardiolipin (11). Antibodies with an LA effect generally bind either prothrombin or b_2-GPI (12,13). The two major autoantigens in APS are therefore b_2-GPI and prothrombin, not PLs.

IMMUNOLOGIC HIGHLIGHTS

APS is widely accepted as an autoimmune disease. Support for this concept derives from the following: the presence of autoantibodies, the occasional reports of neonatal thrombosis associated with maternal-fetal transfer of antibodies (14), the results of some experiments in the passive transfer of antibody to mice (15), and reports of T-cell reactivity to b_2-GPI (16,17). The association of APS with SLE indirectly supports an autoimmune basis, as does the development of some features of APS in spontaneous mouse models of SLE.

APS was originally recognized in patients with SLE, but it may also occur without other features of a connective tissue disease. This has led to a dichotomy of secondary APS and primary APS, although in practice a continuum may be seen, and individual patients may move from one state to the other over time (18,19). A patient may also experience deterioration, relapse, or remission; because thrombotic events occur infrequently, assessment of the clinical course should be viewed as stochastic, unlike the more progressive changes in symptoms of a condition such as rheumatoid arthritis.

Although SLE is the most frequent connective tissue disease associated with APS, other disorders in which APS may occur do not exactly parallel those disorders that may overlap with SLE. The American College of Rheumatology (ACR) included a positive routine aCL, LA, or false-positive test for syphilis, but not clinical events such as thrombosis, as classification criteria for SLE (20). We disagree with this inclusion, both for reasons of the test method suggested by the ACR and because it seems illogical to diagnose one condition from the presence of another condition (21).

APS nevertheless remains a curious immunologic disorder. Although autoantibodies are present, the typical pathologic finding is of bland thrombosis in the absence of overt inflammatory change. Paradoxically, although the disease is one of thrombosis, the effect of the autoantibodies is to prolong *in vitro* coagulation assays.

EPIDEMIOLOGY

APS occurs in a population similar to that of other connective tissue diseases; the most commonly affected group comprises women of reproductive age. In secondary APS, the female-to-male gender ratio of 7 to 9:1 mirrors that of SLE, whereas primary APS has a lesser female predominance of about 4:1 (18,22). Cases in the young and old are described. The diagnosis in elderly patients is confounded by the frequent occurrence of aCLs or LA in members of this group without APS (23,24) and the frequency of thrombosis from other causes such as atherosclerosis, cardiac embolism, malignant disease, or immobility.

Several sets of diagnostic criteria for APS have been proposed and are discussed further later in this chapter (19,25). Because the formal diagnostic criteria for APS are not fully accepted and there is no current standard test, it is not possible to establish a true prevalence. Nevertheless, by the criteria of a large single study of patients with SLE in Mexico, up to 23% of patients develop “definite” APS over 15 to 18 years (26). A prevalence within an SLE population of about 25% is consistent with the frequency of thrombosis within SLE in other studies (1,27). Not all patients with SLE and aPL have thrombosis; of patients with SLE, 44% have a positive aCL and 34% have an LA. Robust epidemiologic data on primary APS are lacking, but this variant appears to be less frequent; a particular difficulty is that in an unselected non-SLE population, approximately 80% of aCL and LA detected will be unassociated with thrombosis of any sort (27).

APS may also be a heterogenous disorder: many women may only ever have fetal loss; and in patients with a first arterial or venous thrombosis, any subsequent thrombosis tends to be of the same type (28). Some patients present with or develop fulminant, widespread thromboses described as catastrophic APS (29).

Autosomal dominant inheritance appears to account for a small number of cases of APS (30). Case reports have linked factor V_{Leiden} mutation and APS, but neither this nor any other candidate gene was found consistently to segregate with the disease in a larger study of familial APS (30). Human leukocyte antigen (HLA) studies have identified associations between APS and HLA class II haplotypes, but these associations have not held for interracial evaluations (31).

CLINICAL ASPECTS

The manifestations of APS are largely the consequence of thrombosis in the affected organ (2). The pattern of thromboses in APS is unique; both small and large

vessels are affected in both the venous and arterial circulations. A “full house” case is therefore characteristic and easily recognizable clinically. However, not all aspects are present in every case, especially on presentation, and clinicians prefer not to wait for further thromboses despite their utility in confirming the diagnosis. In addition, the aPL tests are regarded as sensitive but not specific for APS. The careful exclusion of differential diagnoses is therefore paramount even in the presence of positive tests for aPL. Conversely, the diagnosis of APS should only be considered (but not conclusively made) in typical clinical cases in the absence of aPL and anti–b_2-GPI; a caveat is that aPL may transiently disappear at the time of a thrombosis (32).

The ACR proposed criteria for the diagnosis of APS in a general population, with the proviso that “… the classification criteria are not intended to be used outside of the context of clinical and scientific investigations of APS” (25). The ACR criteria regard the diagnosis of “definite antiphospholipid syndrome” to be present if at least one significant aPL is detected on two occasions and one clinical criterion is present; there are no strict exclusion parameters. This is a more generous use of “definite” than in previously proposed criteria for APS within SLE (19), which used “definite” for two or more clinical events plus a moderate-titer or high-titer aCL (see later). We also believe that it is essential to exclude other conditions associated with aPL (drugs, malignant disease, infections) that in the presence of thrombosis may otherwise lead to a fallacious diagnosis of APS.

Signs and Symptoms

The three major clinical features of APS are venous thrombosis, arterial thrombosis, and miscarriage. The signs and symptoms reflect the site of the clinical event and the severity. Because almost any organ may be affected in APS, the range of presentations is protean (2).

The sites particularly commonly affected are as follows: the deep pelvic and leg veins, often causing painful leg swelling with or without the symptoms of pulmonary emboli; the cerebral arteries, causing stroke; and the cutaneous small vessels, causing small painful nodules, ulceration, and, more commonly, an unsightly but generally asymptomatic mottling of the skin termed livido reticularis. Miscarriage may present with bleeding or pelvic pain, or it may be detected ultrasonographically while asymptomatic. Thrombocytopenia is rarely severe enough to cause bleeding and is therefore asymptomatic. Chorea may be frequently unreported and is often noticed informally by the physician.

Neuropsychologic conditions secondary to any chronic disease are frequent in APS and include depression, anxiety, and headache. These conditions should not be dismissed because they may also represent cerebral venous or arterial thrombosis or cerebral lupus.

Clinical Features

The major clinical findings positively correlated with the presence of aCL in patients with SLE from the most comprehensive single study by Alarcón-Segovia et al. are detailed in Table 46.1. The clinical features associated with the presence of aCL in this series have generally been supported by other studies. However, a comparison of primary and secondary APS groups suggests that hemolytic anemia may be a feature of SLE *per se* rather than APS (22). Additionally, the term “transverse myel*itis* ” is presumptive; myelo*pathy* is preferable. Other clinical features suggested to be part of APS are detailed by system in Table 46.2. Some of these features are uncommon enough to escape statistical recognition but are nonetheless characteristic of APS; others have not been borne out by later studies but are included for clarification.

Manifestation	n	Percentage (%)
Livido reticularis	202	30
Thrombocytopenia	132	20
Recurrent fetal loss	45[a]	17
Venous thrombosis	76	11
Hemolytic anemia	59	9
Arterial occlusion	21	3
Leg ulcer	21	3
Pulmonary hypertension	11	2
Transverse myelitis	5	1

TABLE 46.1. Frequency of Clinical Manifestations Associated with Antiphospholipid Antibodies Applied to 667 Patients with Systemic Lupus Erythematosus

	Manifestation
Central Nervous System (99)	**Chorea**
	Multi-infarct dementia
	Deep white matter lesions, mimicking multiple sclerosis
	Epilepsy
	Sinus thrombosis/intracranial hypertension
	(Migraine (100))
Skin (54)	**Painful skin nodules or macules**
	Acrocyanosis
	Sneddon syndrome
Renal	**Thrombotic microangiopathy**
Respiratory	**Pulmonary hemorrhage**
Cardiac	Vegetations/Libman-Sacks endocarditis
Bone	Avascular osteonecrosis
Obstetric	Infertility/in vitro fertilization failure

In our opinion, features in bold have been generally supported by the literature, features in regular type remain uncertain, and features in parentheses have been discounted by later studies.

TABLE 46.2. Other Clinical Features of Antiphospholipid Syndrome

Venous thrombi are found most commonly in the deep or superficial leg veins, the vena cava, the renal, adrenal, hepatic veins, and the cerebral venous sinuses, but they may occur elsewhere; secondary pulmonary emboli are common. Arterial thrombi are less common and typically affect the cerebral, ophthalmic, coronary, mesenteric, and leg arteries, with the aorta also occasionally involved. Hypertension and other risk factors for atherosclerotic arterial disease may contribute to or account for some arterial thrombi in patients with APS. Most, but not all, studies do not support an association between aPL and stroke or coronary occlusion in unselected populations (33,34). This finding illustrates the rarity of APS such that in unselected populations the rare cases of arterial thrombosis induced by APS are statistically overwhelmed by more common causes.

Miscarriage in APS often occurs in the second trimester, which is unusual for other causes of miscarriage. Some authors suggest that despite the trend to the second trimester, most miscarriages in APS still occur in the first trimester of pregnancy.

Bleeding is unusual in APS despite the prolongation of *in vitro* clotting time. When bleeding is present, it suggests the presence of a high-avidity antiprothrombin antibody with hypoprothrombinemia (35), but it may rarely be caused by thrombocytopenia.

Laboratory Investigations

The diagnosis of APS requires the presence of aCL or LA positivity. A patient with APS may have an abnormality in either the aCL or LA, or both: testing and retesting should therefore be performed for both. Each test has various methods, with varying standardization and performance (36,37): it is therefore reasonable to send samples to a second or reference laboratory if any doubt exists. Syphilis testing offers little extra benefit for the diagnosis of APS, although it may be useful to exclude syphilis with specific serology. The attributes of the specific aCL and LA tests are summarized in Table 46.3.

Test	Antigen Detected	Disorder
aCL	β_2-GPI	APS
"	Phospholipid	Infection, other
anti-β_2-GPI	β_2-GPI	APS
antiprothrombin	Prothrombin	?APS
LA (aPTT,KCT,DRVVT)	Prothrombin (low avidity)	APS
"	Prothrombin (high avidity)	Hemorrhage
"	β_2-GPI	APS

aCL, anticardiolipin assay; APS, antiphospholipid syndrome; aPTT, activated partial thromboplastin time; DRVVT, dilute Russell viper venom time; β_2-GPI, β_2-glycoprotein I; KCT, kaolin clotting time; LA, lupus anticoagulant.

TABLE 46.3. Tests Used in the Antiphospholipid Syndrome

The aCL assay relies on the binding of b_2-GPI to CL, which is, in turn, bound by anti–b_2-GPI autoantibodies. Cardiolipin in organic solvent is evaporated onto the wells of a microtiter plate. Test serum along with the appropriate controls is incubated in the presence of buffer, without calcium ions. Bovine serum is an essential component of the buffer because it contains b_2-GPI, the actual antigen (8). The plate is developed using subclass-specific second antibody and a standard ELISA substrate. The strongest associations with disease are for immunoglobulin G (IgG), and then IgM, aCL, although there is some support for also testing IgA aCL (19,25). The result is often expressed in "GPL" or "MPL" units in which one unit is the activity of 1 µg/mL of standard affinity purified antibody. Positive results are divided into low, medium, and high ranges, representing 2 to 5 standard deviations (SD), 5 to 10 SD, and greater than 10 SD higher than the mean, respectively. An important variation to the aCL is using a serum-free buffer with and without b_2-GPI and assessing the difference; this is termed a b_2-GPI–dependent aCL assay (11). Many variations of the aCL ELISA use other PLs, without clear superiority (37,38).

LAs (previously called "lupus coagulation inhibitor," still the Medline subject title) are antibodies that prolong the *in vitro* coagulation time of platelet-free plasma after the addition of an activating substance plus a limited quantity of PL (39). Another negatively charged surface such as kaolin may be substituted for PL. Studies for LA should be done using at least two different methods because no one method detects all LA. The dilute Russell viper venom time activates the common coagulation pathway directly. The intrinsic clotting cascade may be activated through the contact system by the kaolin clotting time or the activated partial thromboplastin time (Fig. 46. 1). When a test result is prolonged, further checks must be performed. The mixing of LA with normal plasma does not normalize the clotting time, unlike in a clotting factor deficiency. The prolongation of the clotting time by an LA diminishes or normalizes with the addition of excess PL, called the PL (or platelet) neutralization procedure. It is also necessary to exclude inhibitory anticoagulants such as heparin and specific factor inhibitors such as anti-factor VIII (40). The degree of prolongation of the clotting time is usually not considered. Autoantibodies with an LA effect may be shown to bind either b_2-GPI or prothrombin (41).

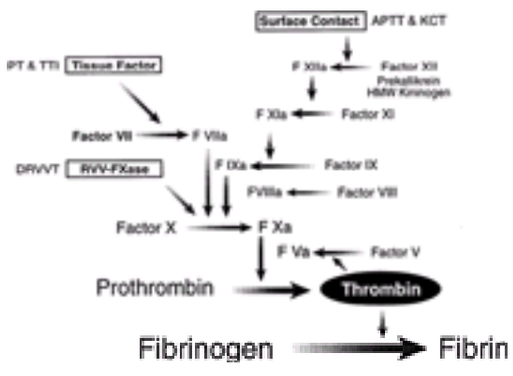

Figure 46.1. The components of the procoagulant pathway as assessed by *in vitro* clotting assays. The prothrombin time (PT) and tissue thromboplastin inhibition test (TTI) assess the tissue factor (extrinsic) pathway; the activated partial thromboplastin time (aPTT) and kaolin clotting time (KCT) assess the contact (intrinsic) pathway; and the dilute Russell viper venom time (DRVVT) assesses the prothrombinase (common) pathway. The DRVVT and the KCT are the most commonly used for the detection of lupus anticoagulant. (Modified with kind permission from T. Exner, Gradipore, Australia.)

A direct anti–b_2-GPI ELISA also has been developed (10). Close homology exists between human and bovine forms of b_2-GPI, and most APS antibodies bind bovine b_2-GPI in the aCL ELISA, but a few bind only to human b_2-GPI (42). Most patient anti–b_2-GPI sera bind only when the b_2-GPI has been coated on irradiated, negatively charged, "high-binding" plates, although the optimal method is not yet clear (43,37). Significant association with APS has been found for IgG, IgM, and IgA isotypes of anti–b_2-GPI, although IgG is the best studied (43,44). Although it is not an ACR accepted test for the diagnosis of APS, the presence of anti–b_2-GPI adds considerably to the confidence of the diagnosis.

The development of an antiprothrombin ELISA for LA-positive samples is proceeding with conflicting evidence of clinical utility to date, although it will probably become a useful secondary test to clarify the antigen in LA-positive plasma (45,46). Antiprothrombin antibodies are not detected by the standard aCL ELISA.

INTERPRETATION OF ANTIPHOSPHOLIPID ANTIBODY ASSAY RESULTS

The quoted predictive power of the aCL, LA, and anti–b_2-GPI tests varies considerably among studies. Because the tests are usually defined in terms of a normal mean +2 to 5 SD, a percentage of a general population will be arbitrarily abnormal. Thrombosis in a general population is also common. Because APS is rarer than either of the foregoing, it follows that some cases of thrombosis associated with aPL are not truly cases of APS. As best as can be determined, the likelihood ratio (pretest-posttest probability of disease after a positive result) of the foregoing tests is around 2–5 (37). In a condition such as SLE in which the pretest probability of APS is 1:3 (25%), these tests will, if positive, raise the probability into the range in which the disease is likely as not or better. However, in many other cases of thrombosis, the likelihood that the cause is APS may be less than 1:10. In this case, a positive result (giving less than 1:1 posttest probability) should not give a clinician confidence in the diagnosis of APS.

The utility of the aCL depends on the cutoff used. Approximately 80% of patients with SLE who have any manifestation of APS, and virtually all with more than three manifestations, have a detectable elevation of aCL (19). However, the false-positive rate is such that SLE patients with aCL in the low positive range have a relative risk for APS little different from that of the baseline SLE population (47). At higher cutoffs, the test is more specific, but approximately 40% of SLE patients with thrombosis have an aCL less than 5 SD higher than the mean (48). Nevertheless, the presence of any elevated aCL titer in a venous thromboembolism study has been shown to predict both recurrence and death (49).

The presence of an LA (by various methods) has been shown in several multivariate analyses of SLE populations to be of greater significance than aCL (50). However, a prospective study of pregnant women found a high proportion of dilute Russell viper venom time results just outside the normal range, without significant consequences (51).

The anti–b_2-GPI assay is less sensitive but has a strong positive predictive value. This test should therefore be used if aPL and clinical features of APS are present but the diagnosis remains equivocal or in the typical clinical case in the absence of aCL or LA (37).

Pathology

The characteristic arterial lesion in APS consists of fibrin thrombus with endothelial changes and intimal proliferation; a variable degree of recanalization may be present (52). Whether intravascular thrombosis or endothelial injury is the primary event is in debate (53). Inflammatory or vasculitic arterial changes are rarely described and should be taken to suggest an alternative diagnosis. Small vessel arterial or arteriolar thrombosis, sometimes with hemorrhage or dermal hemosiderin deposits, is the usual cause of the skin manifestations of APS that, despite their sometimes inflammatory appearance (i.e., painful skin nodules, which look vasculitic),

have an ischemic origin (Fig. 46.2) (54).

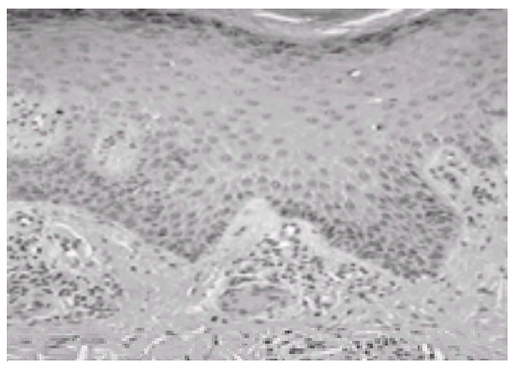

Figure 46.2. Cutaneous small vessel thrombosis in the antiphospholipid syndrome. Skin biopsy from the painful skin nodules of a 33-year-old woman with anticardiolipin, lupus anticoagulant, anti–b_2-glycoprotein I, deep venous thrombosis, and miscarriage. The hematoxylin and eosin–stained section of a skin biopsy shows a small dermal vessel in the center of the lower third of the frame that contains bland fibrin thrombus without inflammation. (Courtesy of Dr. K. Georgeous.) (See Color Figure 46.2.)

The placenta after miscarriage shows uteroplacental vascular disease, with fibrinoid necrosis and sometimes “atherosis” (not atherosclerosis), leading to secondary villous changes including abruption and villous infarcts. Intraplacental vessels may show fibrin thrombi. Less commonly (20%), vasculitis and chronic villitis are present and may occur in the absence of SLE (55). Neither the arterial lesions nor the placental lesions are specific and in particular are similar to those found in malignant or pregnancy-induced hypertension.

Venous thrombi have not been adequately studied histologically despite their frequency in APS. The rare cases of alveolar hemorrhage may be caused by either pulmonary arteriolar thrombosis or pulmonary capillaritis (56).

Therapy

Treatment of APS is with anticoagulation rather than with immunosuppression. Retrospective studies have suggested that patients with APS who have a thrombotic event should receive indefinite anticoagulation with coumarin anticoagulants and that recurrences have occurred at less than an international normalized ratio (INR) of 2.85 to 3 (57,58). With some reagents, the prothrombin time/INR may be falsely prolonged by an LA. This may have the effect of raising the INR of a patient receiving inadequate anticoagulation into the apparently therapeutic range (59). This may have contributed in the foregoing studies to the occurrence of thromboses at INRs of 2 to 3. Anticoagulation to an INR of 3 to 4.5 therefore is not uniformly accepted because of doubts concerning the true degree of anticoagulation and the significant risk of bleeding.

Miscarriage and gestational thrombosis are prevented with the combination of aspirin and low-dose subcutaneous heparin, because coumarin anticoagulants are teratogenic. This regimen has support from randomized clinical trials (60, 61), and it is administered throughout pregnancy after a viable fetus is confirmed by ultrasound until 1 to 2 weeks before term. Low-molecular-weight heparins may be adopted in due course. Consideration should be given to counteracting the osteoporotic effect of heparin. Aspirin is present with regular dosage in breast milk and can affect closure of the *ductus arteriosus;* if required for postnatal prophylaxis of thrombosis, warfarin is minimally present in breast milk (62). Intravenous Ig has not yet been shown to provide significant extra benefit; corticosteroid therapy is not useful and has deleterious effects on the mother.

Immunosuppression does not generally affect outcome in APS. The exceptions are in the treatment of pulmonary hemorrhage, with corticosteroid, and in the rare case of catastrophic APS, when both corticosteroid and plasmapheresis may appear to be of benefit (29). The use of hydroxychloroquine as prophylactic therapy in APS has shown utility in a mouse model and is being tried in human patients (63).

IMMUNOPATHOLOGY

Humoral Response

The major antigens bound by autoantibodies in APS are the plasma proteins b_2-GPI and prothrombin. In APS, b_2-GPI and prothrombin are readily accessible to circulating autoantibody, unlike the nuclear autoantigens generally detected in SLE. Kininogen, annexin V, and protein S have also been cited as autoantigens in isolated cases with features of APS.

Why these proteins should become autoantigens is unclear. The anionic PL phosphatidylserine (PS) moves to the outer layer of the bilaminar cell membrane during apoptosis and necrosis (64). One explanation therefore is that b_2-GPI or prothrombin, bound to PS, may be concentrated on apoptotic blebs with viral proteins from infected cells and may be processed abnormally in individuals with disordered self-tolerance (17,65).

b_2-GLYCOPROTEIN I

b_2-GPI (sometimes apolipoprotein H) is a 326-amino acid glycoprotein present at approximately 200 mg/L in plasma that is able to bind to anionic PL without calcium ions. It is composed of five structurally similar short consensus repeat (SCR, sometimes “sushi”) domains, and this feature characterizes it as a member of the complement control protein family (66,67). Persons without detectable b_2-GPI have been identified who appear clinically well.

The anionic PL binding properties of b_2-GPI are mediated by a cluster of positively charged lysine residues and a hydrophobic loop on domain V (Fig. 46.3) (68,69 and 70). The central portion (domains III and IV) is heavily glycosylated, separating the PL binding site from domains I and II; these domains are of unknown function and project away from the PL surface into the plasma space (69,70). Both domains I and IV have been suggested to contain the major epitopic region for most anti–b_2-GPI autoantibodies (71).

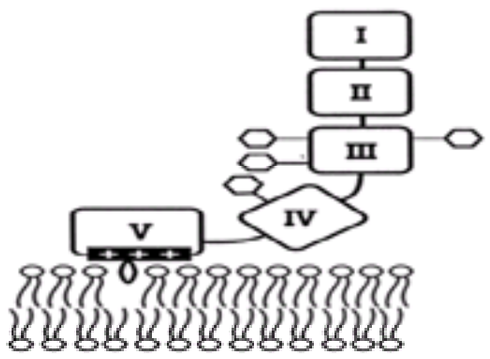

Figure 46.3. Structure of b_2-glycoprotein I (b_2-GPI). Schematic illustration of the structure of b_2-GPI as determined by x-ray crystallography, showing the five domains, the four glycosylation sites, and the positively charged phospholipid binding site with a hydrophobic insertion loop. (Modified from Bouma B, de Groot PG, van den Elsen JMH, et al. Adhesion mechanism of human b_2-glycoprotein I to phospholipids based on its crystal structure. *EMBO J* 1999;18:5166–5174, with permission.)

Autoantibodies are seldom detected when b_2-GPI is coated directly on a standard ELISA plate (Fig. 46.4) (43). This has been interpreted as indicative of a cryptic epitope appearing only when b_2-GPI is bound to PL or the negatively charged surface of an irradiated plate (8,10). Contrary evidence suggests that most antibodies are in the low avidity range and require dimeric binding to b_2-GPI; this concept is supported by higher avidity to a dimer construct of b_2-GPI (72,73 and 74).

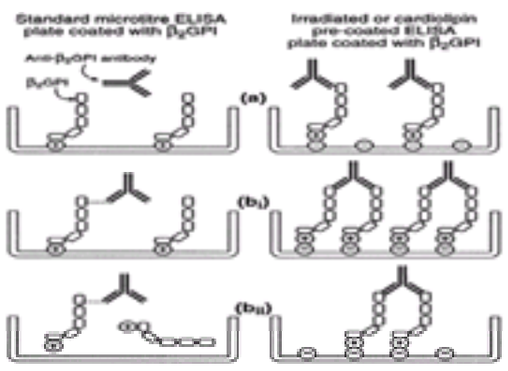

Figure 46.4. Why does anti–b_2-glycoprotein I (b_2-GPI) not bind b_2-GPI on a standard microtiter plate? Anti–b_2-GPI autoantibodies bind b_2-GPI coated on enzyme-linked immunosorbent assay plates only when the plate has been irradiated, inducing a negative charge, or precoated with a negatively charged phospholipid. Theories for this include the following: an unknown conformational change reveals a hidden (cryptic) epitope when b_2-GPI binds to a charged surface *(a);* or the anti–b_2-GPI autoantibodies have a low avidity that requires divalent binding to remain attached to b_2-GPI. On negatively charged plates, an increased antigen density *(b_i)* or uniform orientation of the antigen and its epitope *(b_{ii})* may bring two epitopes sufficiently close that divalent binding occurs.

The physiologic function of b_2-GPI is unknown. Because b_2-GPI may displace other coagulation system proteins from a PL surface, an *in vitro* effect will depend on whether procoagulant or anticoagulant parts of the coagulation system are being evaluated. The plasma level of b_2-GPI is unchanged or increased in APS (75). Anti–b_2-GPI autoantibodies increase the avidity of b_2-GPI for anionic PL (73).

PROTHROMBIN

Prothrombin is well known as the zymogen precursor of thrombin. It is a 579-amino acid glycoprotein present at approximately 100 mg/L in plasma (76). A complete prothrombin deficiency has not been identified in humans and is lethal in mice (77). The amino-terminal region of prothrombin contains a cluster of glutamic acid residues binding PL in a Ca^{++}-dependent manner (gla domain). This region and two kringle domains are cleaved from the thrombin (protease) region by factor Xa in the prothrombinase complex (factors Xa, Va, Ca^{++}, PL^{-}), releasing free thrombin. The major epitopes on prothrombin appear to be on the gla and kringle domains rather than on the thrombin domain (78).

Autoantibodies to prothrombin show wide ranging avidity. Most are low avidity and require similar ELISA conditions (with the addition of calcium) to those required for the detection of anti–b_2-GPI (45,79). Occasional antiprothrombin antibodies are high avidity and result in hypoprothrombinemia, often with bleeding (35). Much of the *in vitro* evidence does not suggest that antiprothrombin directly facilitates the production of thrombin: indeed, it is generally retarded.

Cellular Response

The cellular response in APS has only recently been investigated. T-cell clones reactive to b_2-GPI have been identified by one group in patients with APS but not others: this process may lead to procoagulant activity by expression of monocyte tissue factor (16). Conflicting data have also been published showing T-cell reactivity only to chemically reduced b_2-GPI, but not the protein in native form (17).

Immunopathogenesis

The presence of a physiologic anionic PL surface leads to the production of thrombin and local clot generation in the presence of tissue factor. At the same time, the activation of the protein C pathway and plasmin prevents the clot from spreading away from the exposed surface. Patients with APS have evidence of an ongoing increase in the production of thrombin, despite the inhibition of this *in vitro* by LA (80). One group has reported that purified anti–b_2-GPI may accelerate the *in vitro* prothrombin time (81).

Most groups have shown that the addition of b_2-GPI to purified protein C pathway proteins leads to a slowing in activation of protein C and a diminished effect of activated protein C on factor Va. This effect is potentiated by anti–b_2-GPI (82). However, adding b_2-GPI to a purified procoagulant pathway has a similar slowing effect. One disputed hypothesis is that the anticoagulant protein C pathway may be more inhibited than the procoagulant pathway under certain conditions (83,84).

Annexin V, like b_2-GPI, is an anionic PL binding protein that, presumably by competing with coagulation factors for limited PL, has an *in vitro* anticoagulant effect (85). Previous reports that annexin V is displaced from the placenta in APS by the b_2-GPI/anti–b_2-GPI complex have been debunked (86).

b_2-GPI may also have a direct role in apoptosis by binding to apoptotic cell membrane and functioning as a target protein for phagocytic cells; this may be enhanced by the presence of anti–b_2-GPI (87). It is unclear whether this is the mechanism by which anti–b_2-GPI binds to some endothelial cell preparations or whether there is a specific endothelial cell receptor for b_2-GPI (88). It is debated whether aPL can bind to healthy endothelial cells and, if so, cause either activation or apoptosis, both of which may reasonably be prothrombotic (89).

APS sera reacting to both aCL and oxidized low-density lipoproteins have suggested a link with atherosclerosis, although it has been reported that arterial thromboses correlate with anti–b_2-GPI but not antioxidized low-density lipoproteins (90). The demonstration of the binding of b_2-GPI and the atherothrombotic risk factor lipoprotein (a) is interesting but of uncertain significance (91).

ANIMAL MODELS

Several spontaneous mouse models of SLE may develop aPL and anti–b_2-GPI; they have thrombocytopenia and fetal loss, but not venous thrombosis (92,93). In nonautoimmune mice, anti–b_2-GPI may be induced by immunization with human b_2-GPI, but it is unclear whether they develop any disease (94). Rabbits immunized with human b_2-GPI also develop aPL and anti–b_2-GPI, but they do not develop disease (95).

Passive transfer to mice of purified aPL from women with fetal loss does not routinely lead to murine fetal loss (96). Conversely, passive transfer of purified or monoclonal aPL has been reported to potentiate an induced thrombosis model in mice (15).

A mouse model of APS with fetal loss and thrombocytopenia has been generated by immunization with polyclonal or monoclonal aPL to induce antiantiidiotype antibodies (97). Subsequent studies reported on the treatment of this model. In the SLE version of this model, the findings were not reproducible by an independent group (98).

FUTURE DIRECTIONS

Great progress has been made since the term “antiphospholipid syndrome” was coined in the mid-1980s. It is now a widely recognized syndrome and may even be in danger of being overdiagnosed. There are, however, shortcomings in our ability to deal with this disease. The most important is the requirement for a surrogate marker

of disease activity. This would enable the clinician to titrate the requirement for anticoagulation to the current disease activity. The situation at present in which the clinician and the patient wait for the next thrombosis or hemorrhagic complication before changing therapy is deeply unsatisfactory. The other major shortcoming is the absence of a gold standard test, without which early or less typical cases of APS are difficult to distinguish from other causes of thrombosis or miscarriage in the presence of nonspecific aPL. Current clinical and basic science research is addressing these problems.

ACKNOWLEDGMENTS

This research unit receives ongoing support from the National Health and Medical Research Council of Australia and from the Clive and Vera Ramaciotti Foundation. We thank Michael Barnett and Suzanne Reddel for their critical readings of the manuscript.

47 SARCOIDOSIS

A. Brent Carter, M.D., and Gary W. Hunninghake, M.D.

Sarcoidosis is a systemic granulomatous disorder that can affect essentially any tissue in the body, but it primarily affects the lung and lymphatic systems. The presence of epithelioid granulomas in more than one organ system is necessary to make the diagnosis of sarcoidosis. In addition, other causes of granulomas must be excluded to make the diagnosis. Although the disease was first described in 1877, the cause remains unknown. The immunologic and pathologic features, however, are well understood and are emphasized in this discussion.

PATHOLOGY

The pathologic hallmark of sarcoidosis is a noncaseating epithelioid cell granuloma (Fig. 47.1). The central portion is composed primarily of $CD4^+$ lymphocytes, whereas the peripheral portion consists of $CD8^+$ lymphocytes, macrophages, and fibroblasts (1,2). The mononuclear phagocytes may also form giant cells in which cytoplasmic asteroid bodies, Hamazaki-Wesenberg bodies, and Schaumann bodies may be found (1,2,3,4,5 and 6).

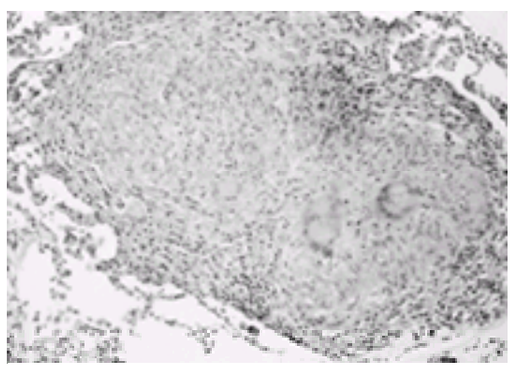

Figure 47.1. Histologic section of a transbronchial biopsy revealing a typical well-formed noncaseating granuloma with multinucleated giant cells and perigranulomatous fibrotic changes (hematoxylin-eosin stain, original ×100).

The presence of cytoplasmic inclusion bodies may be seen in other granulomatous disorders and thus is not specific for sarcoidosis (2). Asteroid bodies are stellate inclusions composed of a collection of cellular organelles in giant cells that have formed by fusion (7). Hamazaki-Wesenberg bodies appear as yellow-brown spirals, which represent extracellular lysosomes or residual bodies (3). Schaumann bodies are a mixture of mucopolysaccharides, calcium salts, and iron, and they appear as concentrically lamellated bodies (8).

Epithelioid granulomas occasionally contain areas of focal necrosis. This may represent a variant of the disease (1,9). Investigators have estimated that slightly less than half the granulomas in sarcoidosis may contain some focal necrosis (10,11). Because infectious diseases are important in the differential diagnosis of sarcoidosis, special microbiologic stains and cultures are necessary, especially when macroscopic necrosis is present. Other causes, however, also need to be considered, such as a tumor-related granulomatous lesion (12,13,14 and 15) and granulomatous lesions of unknown significance (GLUS syndrome) (13). Table 47.1 summarizes the differential diagnosis of sarcoidosis based on specific organ involvement.

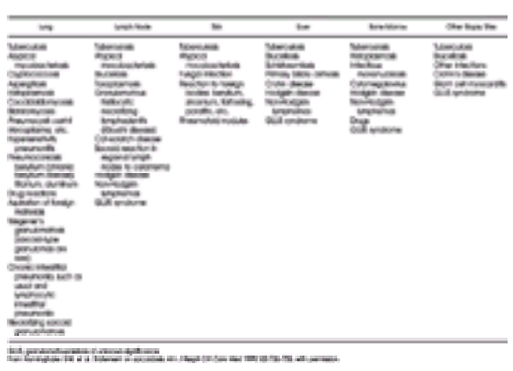

TABLE 47.1. Major Pathologic Considerations in the Differential Diagnosis of Sarcoidosis at Biopsy and Surgical Pathology

The most common tissues that contain granulomas in sarcoidosis are the lung, lymph nodes, skin, liver, and spleen (1,2,4,6,16,17). In the lung, granulomas are typically localized in areas of lymphatic drainage, such as in bronchovascular bundles, perilobular spaces, or subpleural spaces (Fig. 47.2).

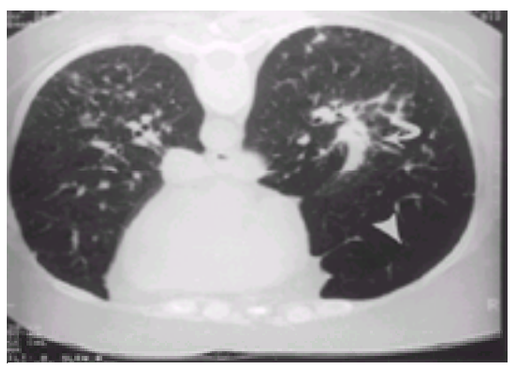

Figure 47.2. Disease activity is intracompartmentally localized in sarcoidosis. High-resolution computed tomography scan of the lung of a patient with sarcoidosis. The disease is localized predominantly around the central bronchovascular bundles *(curved arrow)* while sparing the peripheral gas-exchanging parenchyma *(arrowhead).* This intracompartmentally localization of inflammation suggests that sarcoidosis has a patchy distribution, and in the lung, the lymphatics are found in the bronchovascular bundles.

The course of granulomas is either complete resolution or the development of fibrosis. Most patients have complete resolution of granulomas, but those whose lesions undergo fibrosis may eventually develop honeycombing of the lung. At this time, the factors that initiate the development of fibrosis are unknown (1,2).

EPIDEMIOLOGY

Sarcoidosis occurs worldwide, but it has a predilection for certain areas, especially those with temperate climates (18). The prevalence of sarcoidosis in Sweden, for example, is 60 per 100,000. Africa and Southeast Asia, on the other hand, have an extremely low prevalence (18). The disease has a peak incidence in adults between 20 and 29 years of age (19). In Scandinavia and Japan, however, a second peak incidence occurs in women older than 50 years of age (20,21 and 22). In the United States, the prevalence is highest in the Southeast and averages 10 per 100,000 (18). There is a slightly higher incidence of sarcoidosis in women, and in a population-based incidence study in the United States, the rates were 5.9 per 100,000 person-years for men and 6.3 per 100,000 for women (23). The highest prevalence rates are found in Sweden, in Denmark, and in African Americans (24). In comparison with the white population of the United States, African Americans have an age-adjusted annual incidence rate 3.3 times higher and a lifetime risk of developing sarcoidosis that is 2.8 times higher (23,25,26).

Familial clustering of sarcoidosis has been reported in the United States, Ireland, and Japan (27,28 and 29). In the United States, familial clustering is found more commonly in African-American families (27). Genetic studies in familial clustering of sarcoidosis suggest that the most common genotype inherited in these families include human leukocyte antigen (HLA) class I HLA-A1 and HLA-B8 and class II HLA-DR3 (30,31 and 32).

Although the specific etiologic factor that is responsible for the development of sarcoidosis is unknown, several studies suggest that the disease occurs in persons with a genetic susceptibility who are exposed to certain environmental agents. Some of these studies have suggested the possibility of person-to-person transmission or simultaneous exposure to a specific agent. For example, a study of residents of the Isle of Man reported that 40% of cases occurred in persons with prior interaction with a resident known to have the disease (33,34). These interactions were noted to occur in the same household, at work, and between friends who did not live in the same household. The development of disease within the same household, especially between spouses, suggests the possibility of a mutual infectious or environmental exposure.

Environmental exposure, whether infectious, inorganic, or organic, has long been suggested to be involved in the origin of sarcoidosis. Several of the agents considered to be etiologic factors in sarcoidosis are listed in Table 47.2. Some of the early studies relied on the increased prevalence of sarcoidosis in the southeastern United States. These studies evaluated exposure to pine, lumberyards and mills, soil, pets and farm animals, and water supply (35,36,37,38,39,40,41,42,43,44 and 45). Studies evaluating occupational exposure were subsequently developed; however, no direct association with the development of sarcoidosis was made in these studies (46,47,48 and 49). Unlike with many other pulmonary diseases, nonsmokers have a higher incidence of sarcoidosis or severity of the inflammatory response than smokers (50,51 and 52). The reason may be the decreased number of alveolar macrophages or the increased number of $CD8^+$ lymphocytes recovered from the bronchoalveolar lavage fluid of smokers (51).

Infectious agents
Viruses (herpes, Epstein-Barr, retrovirus, Coxsackie B virus, cytomegalovirus)
Borrelia burgdorferi
Propionibacterium acnes
Mycobacterium tuberculosis and other mycobacteria
Mycoplasma
Inorganic agents
Aluminum
Zirconium
Talc
Organic agents
Pine tree pollen
Clay

TABLE 47.2. Examples of Agents Suggested to be Involved in the Etiology of Sarcoidosis

The infectious agents currently proposed to be involved in the development of sarcoidosis include several viruses, *Borrelia burgdorferi, Propionibacterium acnes, Mycoplasma,* and both tuberculous and nontuberculous mycobacteria. Mycobacteria are the most heavily studied among all of these infectious organisms because they are known to cause granulomatous inflammation during infection (53). In fact, two different studies measured antibodies to mycobacteria and found these antibodies in 50% to 80% of patients with sarcoidosis (54,55). Other antigenic components of mycobacteria, such as tuberculostearic acid, muramyl dipeptide, and portions of cell wall–deficient forms, have been measured in patients with sarcoidosis (56,57 and 58). As an aggregate, these studies did not provide evidence that an infectious organism is the etiologic agent in sarcoidosis. Specifically, mycobacteria, although often present in granulomatous inflammation in sarcoidosis, were not shown to represent the antigen that causes development of the disease.

IMMUNOLOGY AND PATHOGENESIS

Although the cause of sarcoidosis is unknown, much of the immunology of this disease has been studied in detail. The initial discernment of the immunology and pathogenesis occurred in 1941, when Ansgar Kveim found that the intradermal injection of lymph node tissue from patients with sarcoidosis resulted in a papular eruption in 12 of 13 patients with sarcoidosis (59). Louis Siltzbach organized an international study after he found similar results using a suspension from spleen cells (60). The Kveim-Siltzbach test, which recognizes these investigators' contributions to understanding the pathogenesis, is positive in up to 80% of patients with sarcoidosis (61,62). A positive reaction requires the presence of epithelioid granulomas 4 to 6 weeks after the inoculation.

Granuloma formation depends on the accumulation of activated $CD4^+$ cells and macrophages (Table 47.3). The increase in activated $CD4^+$ cells in areas of inflammation occurs secondary to both proliferation at the site of inflammation and accumulation of cells derived from the peripheral blood (63,64). Interleukin-2 (IL-2) mediates proliferation of $CD4^+$ cells at the site of inflammation. T lymphocytes obtained from patients with sarcoidosis release increased amounts of IL-2 and express IL-2 receptors (65,66 and 67). In fact, IL-2 has been shown to enhance T-lymphocyte proliferation in areas of inflammation in patients with sarcoidosis (68,69). Not only does this mechanism increase the proliferation of $CD4^+$ cells, but the release of IL-2, in addition to interferon-g, also results in the differentiation of Th0 T-helper cells into a Th1 phenotype (70).

Intraalveolar and interstitial accumulation of $CD4^+$ cells with helper-inducer activity and release of IL-2
Expansion of T cells bearing a restricted TCR repertoire in involved tissues; this pattern is consistent with a TCR oligoclonality; expansion of the lung α/β TCR cell pool in a subset of patients
Increased *in situ* production of Th1 cell–derived cytokines (IL-2 and IFN-γ) during granuloma formation
Increased expression of members of TNF ligand and TNF receptor superfamilies by sarcoid T cells
B-cell hyperactivity and spontaneous *in situ* production of immunoglobulins
Increased spontaneous rate of proliferation of lung immunocompetent cells
Accumulation of monocyte-macrophages with antigen presenting cell capacity and expressing increased levels of activation markers (HLA-DR, HLA-DQ, CD71) and adhesion molecules (CD49c, CD64, CD102)
Increased release of macrophage-derived cytokines (IL-1, IL-6, IL-8, IL-15, TNF-α, IFN-γ, GM-CSF) and chemokines (IP-10, RANTES, MIP-1α, IL-16); most of these cytokines favor granuloma formation and lung damage
Increased production of macrophage-derived fibrogenetic cytokines (TGF-β and related cytokines, PDGF, and IGF-1), favoring evolution toward fibrosis

GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN, interferon; IGF, insulin-like growth factor; IL, interleukin; MIP, macrophage inflammatory protein; PDGF, platelet-derived growth factor; RANTES, regulated on activation normal T cell expressed and secreted; TCR, T-cell receptor; TGF, transforming growth factor; TNF, tumor necrosis factor.

TABLE 47.3. Immunologic Abnormalities Observed in Patients with Sarcoidosis

The accumulation of cells derived from the peripheral blood at sites of inflammation is induced by cytokines and chemokines, such as IL-8, IL-15, and RANTES (regulated on activation normal T cell expressed and secreted), released from macrophages (65,71 and 72). The bronchoalveolar lavage fluid from patients with sarcoidosis has elevated levels of IL-8 and has been correlated with the degree of granulomatous inflammation (73,74). In addition, alveolar macrophages from patients with sarcoidosis and a $CD4^+$ cell alveolitis express high levels of IL-15 (75). RANTES protein levels are increased in bronchoalveolar lavage fluid from patients

with sarcoidosis when compared with control subjects (76,77), and RANTES mRNA levels are increased in alveolar macrophages obtained from patients with sarcoidosis (78,79). Furthermore, increased RANTES expression has been correlated with $CD4^+$ redistribution into the lung. This interaction of activated $CD4^+$ lymphocytes and macrophages is summarized schematically in Fig. 47.3.

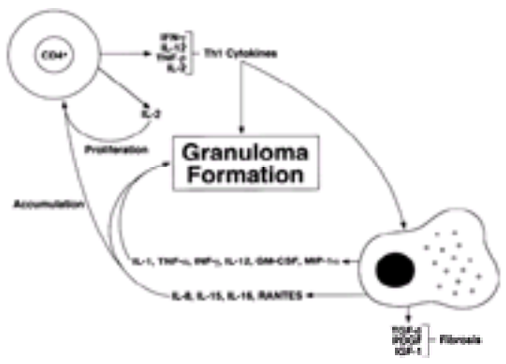

Figure 47.3. Schematic diagram of the classic Th1 immune response.

Most $CD4^+$ and $CD8^+$ lymphocytes use the T-cell receptor (TCR) to identify specific antigens, and exposure of cells to these antigens results in the expansion of T lymphocytes that bear a restricted TCR. More specifically, $CD4^+$ cells use the a/b-chain variable region of the TCR to recognize specific antigens, and the expansion of this restricted variable portion of the TCR results in the oligoclonality of $CD4^+$ cells in areas of inflammation. Several studies involving patients with sarcoidosis have shown the presence of $CD4^+$ cells with a restricted TCR gene expression (80,81,82,83,84,85 and 86). Investigators have demonstrated in patients with sarcoidosis that the oligoclonality of the restricted TCR in $CD4^+$ cells disappears when the granulomatous inflammation resolves (86). These studies showing restricted TCR usage during the period of inflammation suggest that a specific antigen triggers sarcoidosis.

Other nonspecific immunologic abnormalities that can be found in sarcoidosis include polyclonal hypergammaglobulinemia and immune complex formation with elevated levels of rheumatoid factor and antinuclear antibodies (87,88,89,90 and 91). Similar cell-cell interactions that result in granuloma formation drive the increase in antibody production in sarcoidosis (92). Activated T lymphocytes release B-cell growth factors and B-cell differentiation factors, which induce immunoglobulin production by B lymphocytes (93). It is unclear how frequently hypergammaglobulinemia occurs in sarcoidosis, but investigators have shown that T lymphocytes from the lungs of patients with active sarcoidosis can spontaneously activate B lymphocytes to secrete immunoglobulins, and a correlation exists between the number of activated T lymphocytes and the number of immunoglobulin-secreting B lymphocytes in sarcoidosis (88).

Although not clinically relevant, immune complex formation in patients with sarcoidosis has been reported to be as high as 50% (89,94). Elevation of rheumatoid factor and antinuclear antibodies has also been seen in patients with sarcoidosis (89,94), whereas other studies have demonstrated no elevation in these serum factors (90). One other study measured serum factors in patients with inactive sarcoidosis and found that their levels were similar to those of control subjects (95). Thus, the increase in serum factors, such as rheumatoid factor, antinuclear antibodies, and erythrocyte sedimentation rate, is a nonspecific finding and does not appear to be clinically important.

Although many studies propose that a specific antigen is necessary for the development of sarcoidosis, the genetic susceptibility of those who develop the disease is an important factor as well. The basis of evaluating the role of genetic factors in the development of sarcoidosis is that cases of sarcoidosis have occurred in families, and certain races appear to be predisposed to develop the disease (26,43). As discussed previously, studies of familial clustering of sarcoidosis have revealed a high prevalence of certain HLA genotypes in family members who develop the disease (30,31 and 32). These genes may be important in regulation of antigen presentation and signal transduction in the cells that process the antigen and initiate the inflammatory response. Other studies, however, suggest that genetic factors are important in determining the prognostic features—presentation and progression—of sarcoidosis. One study compared 126 cases of sarcoidosis from the Czech Republic with 107 cases from Italy (96). These investigators found a positive association with disease in both populations with HLA-A1, HLA-B8, and HLA-DR3 and a negative association with HLA-B12 and HLA-DR4. Early onset of sarcoidosis occurred in patients with HLA-B13 and HLA-B35, and late onset was found in those with HLA-A30, HLA-B8, HLA-DR3, and HLA-DR4. The primary difference between these ethnic groups was that in the Czech Republic, HLA-B13 was found in patients with extrapulmonary localization of disease. In Italy, conversely, systemic disease was associated with HLA-B22. These findings support the notion of clinical heterogeneity in sarcoidosis (96).

Another study that determined genotypes in Scandinavia, which has a relatively homogeneous population, found that patients with HLA-DR17 had a better prognosis than those with HLA-DR14 or HLA-DR15 (97). HLA-DR17 was present in a high percentage of Scandinavian patients, but it was also shown to be associated with a favorable outcome in other studies (31,96). As an aggregate, these genetic studies indicate that certain genotypes may be related to the development of sarcoidosis and others may be related to the clinical outcome of the disease. In addition, the effect of specific genotypes varies, depending on the ethnic population.

CLINICAL PRESENTATION

Sarcoidosis can affect any organ of the body, so physicians from a variety of specialties may make the initial diagnosis or may be involved in the care of a patient with sarcoidosis. As discussed earlier, the ethnic and genetic background of a patient has a significant influence on the disease manifestation. For example, persons of Swedish, Puerto Rican, or Irish descent often present with Löfgren syndrome, which is characterized by erythema nodosum, polyarthritis, iritis, and fever (98). Another study compared patients of West Indian descent with white patients who lived in the same area (99). These investigators found that the patients from the West Indies had more disseminated disease, and respiratory symptoms were common at presentation. Whites, on the other hand, presented more commonly with erythema nodosum. The effect of various genotypes—specifically, HLA antigens—is discussed earlier and has been associated with variability in disease presentation and overall prognosis.

Constitutional symptoms are common at presentation in sarcoidosis, and they occur more frequently in African Americans and Asian Indians than in whites. Fever is typically low grade and is occasionally associated with night sweats. Sarcoidosis has been known to present as a fever of unknown origin (100). Weight loss, although significant, is usually limited to less than 6 kg. Fatigue and malaise do not occur as frequently as other constitutional symptoms, but they can be incapacitating when present initially.

The lungs are the organs most frequently involved in sarcoidosis; at least 90% of patients have evidence of granulomatous inflammation, even if they are asymptomatic. If symptoms are present, they usually include dyspnea, nonproductive cough, and chest pain (101). Radiographic staging of pulmonary sarcoidosis is an internationally accepted means of classifying the disease. Stage 0 is normal without evidence of pulmonary disease. Stage I is bilateral hilar lymphadenopathy. Stage II is bilateral hilar lymphadenopathy accompanied by diffuse parenchymal infiltrates. Stage III is diffuse parenchymal infiltrates without hilar adenopathy. Stage IV is advanced parenchymal disease with evidence of end-stage fibrosis with honeycombing (18,102). Sarcoidosis involving the airway, which includes the larynx, trachea, and bronchi, is less common than parenchymal disease.

Pulmonary function tests in patients with sarcoidosis show primarily restrictive physiology. Abnormal gas exchange with resultant hypoxemia may be seen in patients with stage IV radiographic disease (102). Sarcoidosis involving the airway often gives a different pattern on pulmonary function tests. These patients may have obstructive physiology and airway hyperreactivity (103,104).

The lymphatic system is the second most common organ system involved in sarcoidosis. Besides the hilar and mediastinal lymph nodes, the most frequently involved are lymph nodes in the cervical, axillary, epitrochlear, and inguinal regions. Lymph nodes in sarcoidosis are nontender and easily movable. Pancytopenia may be present if spleen involvement is significant (105).

The liver is frequently involved in sarcoidosis. Although these lesions are usually insignificant clinically, studies have estimated that between 50% and 80% of patients have granulomas in the liver (106,107 and 108). Treatment is usually not required for mild hepatic dysfunction, but patients with severe abnormalities and evidence of hepatic failure may benefit from corticosteroids or cytotoxic therapy (107,109,110).

Cardiac involvement in sarcoidosis is rare, but if present, the risk of mortality is substantial. Granulomas in the heart can result in both benign and lethal arrhythmias and cardiomyopathy if myocardial involvement is significant. Cardiac sarcoidosis may be detected by several different tests, but thallium-201 imaging has been shown to be the preferred study to detect segmental contractile dysfunction (111,112). If thallium-201 imaging shows contraction abnormalities, coronary artery catheterization

should be performed to exclude coronary artery disease. Endomyocardial biopsies are typically not helpful because of patchy involvement of the myocardium with granulomas. Electrocardiograms may be normal in patients with arrhythmias, but Holter monitoring may be used to detect arrhythmias in patients suspected of having conduction abnormalities.

Ocular sarcoidosis is often asymptomatic, but all patients with sarcoidosis should have an ophthalmologic examination because ocular involvement can result in blindness (113). Although any part of the eye or orbit may be involved, the most commonly affected structure is the anterior uveal tract. Anterior uveitis is the primary disorder in ocular sarcoidosis, and it can be diagnosed with slit-lamp examination. It is usually treated adequately with corticosteroid drops applied locally. When the posterior chamber or the retina is affected, more invasive testing is necessary for detection (114).

The two most important cutaneous manifestations of sarcoidosis are erythema nodosum and lupus pernio. Skin involvement is reported to occur in about 25% of patients with sarcoidosis (115). Erythema nodosum, which is one of the clinical findings in Löfgren syndrome, appears as raised, red, tender nodules on the anterior surface of the lower legs. Joints near the affected skin may also be painful. Erythema nodosum is typically self-limiting and resolves in 6 to 8 weeks. This cutaneous manifestation is primarily seen in European, Puerto Rican, and Mexican patients.

In contrast to erythema nodosum, lupus pernio is a chronic manifestation of cutaneous sarcoidosis, and resolution is extremely rare. It is most commonly seen in African Americans. Lupus pernio appears clinically as indurated plaques associated with discoloration of the nose, cheeks, lips, and ears. It is also associated with bone cysts and pulmonary fibrosis.

Sarcoidosis can involve any portion of the nervous system in the form of diffuse inflammation or a mass lesion (116), but this manifestation occurs in fewer than 10% of patients (117,118). Neurosarcoidosis is difficult to diagnose clinically, and, therefore, histologic samples are often required. Laboratory testing is nonspecific, but both computed tomography and magnetic resonance imaging can be used to support the diagnosis. The presentation is also variable and may include cranial nerve palsies, polyneuritis and polyneuropathy, meningitis, mass lesions, pituitary and hypothalamic syndromes, and memory loss (119).

Hypercalcemia is seen in fewer than 10% of patients, whereas hypercalcuria is seen in as many as 50% (120,121). The mechanism for both hypercalcemia and hypercalcuria is increased production of 1,25-dihydroxycholecalciferol (calcitriol) by granulomas (120,121). Persistent hypercalcuria can result in nephrolithiasis, nephrocalcinosis, and renal failure (122).

THERAPY

The therapeutic regimen used to treat patients with sarcoidosis needs to be individualized because of the variability in the prognosis. In fact, sarcoidosis is often a self-limited disease, so frequent observation, rather than specific drug therapy, is often the best approach (123). In patients with mild skin, ocular, or airway disease, topical therapy, including inhaled corticosteroids, may be sufficient. Systemic therapy is indicated in patients with progressive disease and in those with hypercalcemia and cardiac, neurologic, or ocular sarcoidosis.

Corticosteroids, whether topical or systemic, are the first-line drugs used for treatment of sarcoidosis. Topical therapy may be used in patients with skin involvement, uveitis, nasal polyps, and airway disease (124,125,126,127,128 and 129). Many studies have shown that topical therapy is beneficial (124,125 and 126,129,130 and 131), but there has been some disagreement in the efficacy of this type of therapy (128).

Systemic corticosteroids have been shown in clinical trials to be beneficial in patients with pulmonary sarcoidosis, as measured by symptoms, radiographic studies, and pulmonary function studies (132,133,134,135,136,137,138,139 and 140). Some reports, however, have noted that symptoms and radiographic abnormalities return with cessation of therapy (135,141). The duration of therapy needs to be individualized, but patients should be expected to have some response after 3 months. Patients who respond to corticosteroids should gradually have the dosage tapered over a minimum of 12 months. If relapses occur, patients with sarcoidosis may require long-term, low-dose corticosteroids (135,141).

Because of the many side effects of systemic corticosteroids, many studies have been undertaken to evaluate the efficacy of steroid-sparing agents. These agents primarily fall in the category of cytotoxic agents. These drugs, specifically methotrexate and azathioprine, are useful in some patients with sarcoidosis, but often no clear indication exists regarding when to initiate therapy with these agents. Methotrexate has been used to treat chronic forms of the disease. One study found a response in 66% of patients taking methotrexate alone, and another 18% responded when low-dose corticosteroids were added to the regimen (142,143). Relapse of sarcoidosis has been shown to occur when this agent is discontinued (143). Like methotrexate, azathioprine has been used in the treatment of chronic disease. In fact, two studies found a response to therapy in chronic sarcoidosis when azathioprine was used in the treatment regimen (144,145).

SUMMARY

Sarcoidosis is a systemic disorder that is characterized by a classic Th1 immune response. In fact, sarcoidosis was the first human disease in which the Th1 response was clearly delineated. This immune response appears to be modified by genetic factors, and it likely occurs in response to exposure to an environmental agent. Therapy of the disease is directed at the immune response. Further advances in the understanding and therapy of this disease are likely to depend on defining the cause of the disorder.

48 DIABETES MELLITUS

Norio Abiru, M.D., David T. Robles B.S., and George S. Eisenbarth, M.D., Ph.D.

CLASSIFICATION

In the broadest sense, *diabetes mellitus* can be defined as a group of disorders characterized by hyperglycemia resulting from defects in insulin secretion, insulin action, or both. The long-term sequelae of the chronic hyperglycemia associated with diabetes mellitus include damage to the small blood vessels (microangiopathy) of various organs, especially the eyes, kidneys, and nerves, and damage to large arteries (macroangiopathy) (1). These complications of diabetes mellitus are among the leading causes of blindness, lower extremity amputation, and end-stage renal disease and are a major factor contributing to premature death (2). Classifications of diabetes mellitus have been based on the requirement for insulin therapy (e.g., insulin-dependent or IDDM, non–insulin-dependent or NIDDM), the age of onset (adult onset, juvenile onset), and the pathogenesis (e.g., malnutrition related, “other types,” gestational). IDDM signified a form of diabetes in which, in the absence of insulin therapy, a patient died. It was realized, however, that insulin dependence could not be tested; many patients early in the course of type 1 diabetes had significant endogenous insulin secretion, and most patients with type 2 diabetes eventually are treated with insulin. A newer classification of diabetes mellitus, put forth by the American Diabetes Association, serves to encompass the increasing knowledge of the etiology and natural history of diabetes (1). This classification system is based on our current understanding of etiology, and the terms IDDM and NIDDM are no longer used. The four major categories for diabetes are as follows: *type 1 diabetes,* characterized by b-cell destruction that often progresses to absolute insulin deficiency); *type 2 diabetes,* which ranges from primarily insulin resistance to insulin secretory defect with insulin resistance; *other specific types of diabetes,* a group that includes mutations such as those causing maturity-onset diabetes of the young (MODY) (MODY2-glucokinase, MODY3 hepatocyte nuclear factor (HNF)-1a mutation), pancreatitis, endocrinopathies, drug-induced diabetes, diabetes associated with “stiff man” syndrome or antiinsulin receptor antibodies, and chromosome abnormalities associated with diabetes (e.g., trisomy 21); and *gestational diabetes mellitus,* defined as diabetes with onset or first recognition during pregnancy.

Type 1 diabetes is divided into type 1A (immune-mediated) and type 1B diabetes (idiopathic loss of insulin secretion), depending primarily on the presence or absence of antiislet autoantibodies. In type 1A diabetes, the rate of b-cell destruction is variable, rapid in some persons (mainly infants and children) and slow in others (mainly adults). With current autoantibody assays, adults with immune-mediated but slowly progressive diabetes, termed latent autoimmune diabetes of adults (LADA) (3) or slowly progressive IDDM (4), can be classified as having type 1A diabetes (1). A report from Japan suggests that a form of type 1B diabetes can be extremely rapid in onset and is associated with pancreatic exocrine inflammation (5). This chapter concentrates on what has been termed type 1A diabetes or the form of diabetes resulting from immune-mediated destruction of the cells that produce insulin.

HISTORICAL FEATURES OF TYPE 1A(IMMUNE-MEDIATED) DIABETES

Recognition of distinct forms of diabetes and appreciation of the immunologic basis for a subset of the disease are relatively recent. Without the separation of diabetes into type 1 and type 2 forms, lymphocytic invasion of the islets (which is associated only with type 1 diabetes) was rarely observed (6,7,8,9 and 10).

A major advance was the recognition of genetically distinct forms of diabetes. Studies of monozygotic twins (MZTs) with diabetes revealed different patterns of disease expression (earlier age of onset for type 1 diabetes) and lower concordance for childhood onset diabetes compared with adult-onset diabetes. Specific HLA alleles were found to be associated with the insulin-dependent, usually childhood-onset, form of diabetes (what we now term type 1A diabetes) (11,12). It was proposed that type 1A diabetes was predominantly a disorder of acute viral origin, whereas for some patients, it was of autoimmune origin. In particular, patients with other autoimmune diseases such as Addison disease were thought to have the autoimmune form of diabetes (13,14). In 1974, cytoplasmic islet cell autoantibodies were found in the sera of patients with diabetes who had polyendocrine autoimmunity (e.g., Addison disease) (15). Islet cell autoantibodies were then found to be present before the development of diabetes for most patients with insulin-dependent diabetes. Studies of MZTs of patients with type 1A diabetes led to the observation that years before the development of type 1A diabetes, associated with the presence of islet autoantibodies, insulin secretion was progressively lost (16,17 and 18).

IMMUNOLOGIC HIGHLIGHTS

Over the past decade, type 1A diabetes has become one of the best studied autoimmune disorders. Prospective studies of large populations beginning at birth now track disease development. Evaluation of antiislet autoantibodies in these studies reveal that they often appear before 1 year of age. Depending on the spectrum of autoantibodies present, hyperglycemia develops within several years.

Although the detection of antiislet antibodies is useful for disease prediction, the consensus among investigators is that b-cell destruction is mediated by T cells, and not by autoantibodies (19,20 and 21). With the discovery of two spontaneous animal models of type 1A diabetes, the NOD mouse and the BB rat, studies of animal T cells have contributed to our understanding of the immunopathogenesis of this disease (21,22). Islet-specific T-cell clones have been isolated from the spleen, lymph node, and islets of Langerhans of NOD mice, and such islet-specific T cells are capable of inducing diabetes after adoptive transfer into young NOD mice (23). Evidence of disease “transfer” in human patients is also available with the recurrence of islet b-cell destruction in pancreas transplanted from a nondiabetic identical twin into a twin with long-term diabetes (24). The development of diabetes in the transplanted pancreas was remarkable in that diabetes recurred within a matter of weeks after organ transplantation. This finding suggests that the immune process that leads to type 1A diabetes remains intact for years after the development of diabetes. In contrast, the development of diabetes usually occurs over years. One hypothesis, which we favor, is that the development of type 1A diabetes is a chronic process with long-term immunologic and progressive metabolic abnormalities. This hypothesis allows the development of diabetes to be divided into a series of stages, beginning with genetic susceptibility and ending with essentially complete b-cell destruction, as shown in Fig. 48.1. In human patients, not only is there progressive loss of insulin secretion after intravenous glucose before the diagnosis of diabetes, but also, after the diagnosis of diabetes, C-peptide secretion is progressively lost (Fig. 48.2).

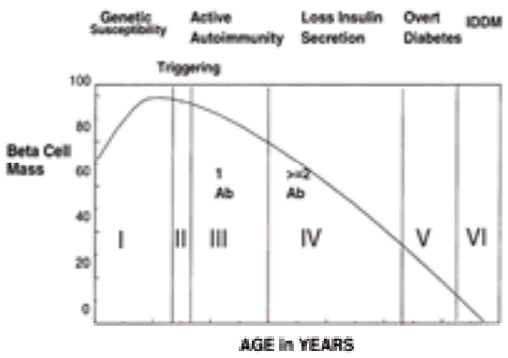

Figure 48.1. Stages in the development of type 1A diabetes. (Adapted from Eisenbarth GS. Type I diabetes mellitus: a chronic autoimmune disease. *N Engl J Med* 1986;314:1360–1368, with permission.)

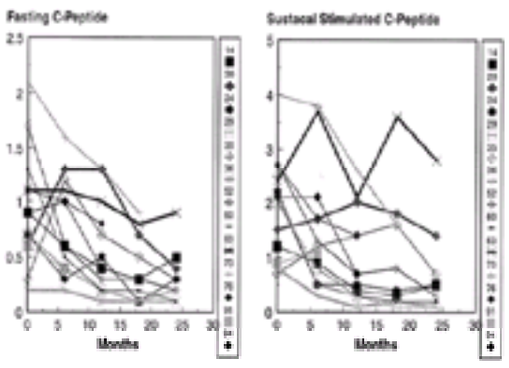

Figure 48.2. Example of progressive loss of C-peptide secretion in children after the diagnosis of type 1A diabetes. Younger children often lose C-peptide secretion even more rapidly.

Investigators have suggested that b-cell destruction in NOD mice occurs just before the onset of overt diabetes. This suggestion is based on the observation that the splenocytes change from a predominantly Th2-cell (T-helper) phenotype to a predominantly Th1-cell phenotype just before the development of hyperglycemia (25), as well as on evidence of accelerated islet graft rejection 2 weeks before the onset of diabetes (26). However, a study of b-cell mass and rate of b-cell proliferation in NOD mice by Sreenan and co-workers found that b-cell proliferation (which could be a compensatory response to ongoing autoimmune b-cell destruction) was observed in mice at 8 weeks of age. Despite the compensatory b-cell proliferative response, b-cell mass was significantly reduced by 13 weeks of age; only 11% of NOD mice at this age were overtly diabetic, and most mice did not become diabetic until after 16 weeks of age (27). These data suggest that b-cell destruction occurs gradually, eventually progressing to overt diabetes in NOD mice. We reported that insulin autoantibody (IAA) expression at 8 weeks in NOD mice can predict the early development of diabetes at 16 to 18 weeks (28). Identifying a cohort of NOD mice expressing IAA at 8 weeks should facilitate the study of heterogeneity of the timing of b-cell destruction.

EPIDEMIOLOGY

Genetics

Similar to most autoimmune disorders, type 1A diabetes develops in persons with genetic susceptibility (29,30,31 and 32). In the general population, the risk of type 1A diabetes by the age of 15 years is approximately 1 in 400 for children (33). This is in marked contrast to the risk to a child of a father with type 1A diabetes (1 in 40) or the risk of a child of a mother with type 1A diabetes (1 in 66) (34). For siblings of a patient with type 1A diabetes, the risk of diabetes is 1 in 20. Although the risk of diabetes is greatly increased for first-degree relatives of patients with type 1A diabetes, 85% to 90% of persons who develop diabetes do not have a relative with the disorder.

The concordance among MZTs of patients with type 1A diabetes (50%) differs markedly from the concordance of dizygotic twins (DZTs) (5%), in whom the risk is similar to that of other siblings (35). Although the probability that a discordant MZT will develop diabetes decreases with the duration of discordance, twins can become concordant more than 40 years after the development of diabetes in their twin (Fig. 48.3). This difference in concordance between MZTs and DZTs reflects a significant role for inherited factors. However, the finding that the concordance among MZTs is not closer to 100% suggests that environmental factors, somatic mutation, or stochastic events may also play a role in pathogenesis. Expression of antiislet autoantibodies is similarly much greater for the discordant MZT as compared with the DZT mate of patients with type 1A diabetes. Most MZTs of patients with type 1A diabetes expressing antiislet autoantibodies develop diabetes (36).

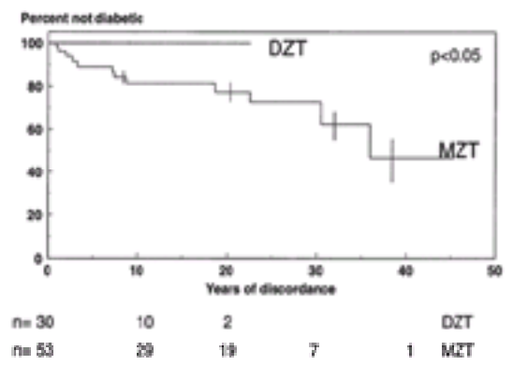

Figure 48.3. Progression to diabetes of initially discordant monozygotic twins by life-table analysis. *X-axis:* years of discordance. (Adapted from Redondo MJ, Rewers M, Yu L, Garg S, Pilcher CC, Elliott RB, et al. Genetic determination of islet cell autoimmunity in monozygotic twin, dizygotic twin, and non-twin siblings of patients with type 1 diabetes: prospective twin study. *BMJ* 1999;318:698–702, with permission.)

One study suggested that either serum interleukin-4 (IL-4) levels or IL-4 production by natural killer (NK) T cells could aid in the definition of risk of diabetes among twins (37). The serum IL-4 assay used in this work artifactually measured heterophile antibodies directed against the murine monoclonal anti–IL-4 antibodies used in the IL-4 assay (38,39). The presence of such heterophile antibodies are correlated with diabetes-protective human leukocyte antigen (HLA) alleles (e.g., DQB1*0602) and thus correlated with lack of disease progression. Prospective study of NK T cells will be necessary to determine whether their lack of IL-4 secretion is causally related or is a result of the development of type 1A diabetes.

HUMAN LEUKOCYTE ANTIGEN GENES (IDDM 1)

The association between autoimmune diseases and genes of the major histocompatibility complex (MHC) has been well documented. The establishment of large repositories with DNA (e.g., Human Biologic Disease Interchange, British Diabetes Association Warram Repository) from hundreds of complete families with type 1A diabetes and developments in genetic analysis have led to large studies of HLA alleles and other genetic loci (40,41,42 and 43).

Class II molecules, in particular, DQ alleles, are most strongly associated with diabetes risk, but DR, DP, and class I alleles can influence diabetes risk and age of diabetes onset. DQ and DR alleles are in linkage dysequilibrium. For example, the DR3 allele DRB1*0301 is almost always associated with DQA1*0501, DQB1*0201,

whereas the DR4 allele DRB1*0401 is commonly associated with DQA1*0301 and one of three DQB1 alleles, DQB1*0301, DQB1*0302, DQB1*0303. The highest risk for type 1A diabetes is associated with persons expressing both DQA1*0501-DQB1*0201 (DQ2) and DQA1*0301-DQB1*0302 (DQ8) (DR3/4 or DQ8/DQ2 heterozygotes).

Using a rapid method for screening HLA alleles from umbilical cord blood samples, we have typed more than 20,000 newborns in Denver, Colorado. The high-risk genotype (DRB1*03/DRB1*04, DQB1*0302) is present in 2.4% of newborns (44). Both relatives of patients with type 1A diabetes and infants from the general population are studied. As many as 40% of siblings of patients with type 1A diabetes with DR3/4 (DQB1*0302) develop antiislet autoantibodies by the age of 3 years, in contrast to fewer than 5% of general-population children with DR3/4 (DQB1*0302).

In addition to these high-risk HLA haplotypes, less common HLA haplotypes are associated with diabetes risk. From our analysis of the transmission of DQ haplotypes to affected children of the Human Biological Data Interchange family collection, DQA1*0501-DQB1*0201 and DQA1*0301-DQB1*0302, when present in a parent, were transmitted to more than 80% of affected children, as expected. The DQA1*0401-DQB1*0402 haplotype was transmitted to 82% of diabetic children when a parent had this haplotype (without DR3 and DR4 as the alternative parental haplotype). This haplotype is uncommon in the general population, although it is important to a person or family in which this haplotype occurs (Table 48.1) (45). DQB1*0402 contains an aspartic acid residue at position 57 of the DQ b chain that has been reported to be associated with protection from type 1A diabetes (46,47). In Korean and Japanese patients with type 1A diabetes, an allele related to DQB1*0402 also with Asp57 is commonly present, a finding suggesting that similar HLA alleles contribute to type 1A diabetes risk in all populations, but specific alleles differ in frequency for different ethnic groups (48).

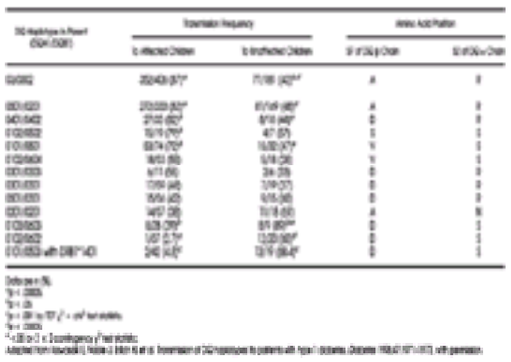

TABLE 48.1. Transmission Frequencies DQ Haplotypes to Affected and Unaffected Children from Heterozygous Parents

The HLA haplotype DQA1*0102-DQB1*0602 is present in 20% of the general population and provides dominant protection from type 1A diabetes (49). DQA1*0102-DQB1*0602 was transmitted to only 1 of 37 (2.7%) children with diabetes (Table 48.1). In contrast, 60% of unaffected children received this haplotype (45). Further analysis indicates that rare alleles such as DRB1*1401 and DQA1*0201, DQB1*0303 may be as protective as the protective DQ molecule DQA1*0102, DQB1*0602 associated with DR2. It appears that in humans, as in the NOD mouse, both DQ and DR alleles (mouse I-A and I-E, respectively) can protect from type 1A diabetes. We have evidence that DQB1*0602 does not prevent the expression of antiislet autoantibodies, although most autoantibody-positive persons with DQB1*0602 express only a single autoantibody.

At present, it is not possible to encapsulate the protection and susceptibility associated with the foregoing alleles by reference to a single polymorphic amino acid residue. For example, the hypothesis that aspartic acid at position 57 of DQb alleles is associated with diabetes risk (47) fails to account for the high-risk allele DQB1*0402 or to differentiate a series of alleles with dramatically different “protection” (e.g., DQB1*0602 versus DQB1*0301, both having Asp 57) or the influence of HLA DR alleles (50). The “most” diabetogenic HLA DQ allele, DQ8 (DQA1*0301, DQB1*0302), when associated with DRB1*0403 does not form a high-risk haplotype. For the haplotype DRB1*1401, DQA1*0101, DQB1*0503, it is the DRB1 allele rather than DQ that is protective (e.g., when DQA1*0101, DQB1*0503 is present without DRB1*1401, it is transmitted to children with diabetes approximately 50% of the time).

HLA-DR and DQ alleles in type 1A diabetes have been well studied; however, the role of the DP allele or class I allele is less well documented. Erlich and co-workers reported an association of type 1A diabetes with the DPB1 allele 0301 in a population of Mexican Americans by an association study between patients and control subjects (51). An increased frequency of DPB1*0301 among patients was observed in the group excluding DRB1*0405 subjects (which is one of the susceptibility alleles in Mexican Americans), a finding suggesting that polymorphisms at the DPB1 locus may also influence diabetes risk.

DQA1*0301 is associated with susceptibility to type 1A diabetes in Japanese patients (52,53). Nakanishi and co-workers have reported the association of the HLA class I allele, A24, with less residual b-cell function (54). They studied the association of the HLA-A24 with type 1A diabetes in Japanese persons who did not have DQA1*0301. All patients with type 1A diabetes without DQA1*0301 had HLA-A24, whereas 60% of normal control subjects or 58% of patients with type 1A diabetes with DQA1*0301 had HLA-A24 (55). This finding suggests that HLA class I may contribute to susceptibility to type 1A diabetes independent of HLA class II alleles.

A major unanswered question is how HLA alleles contribute to the development of diabetes and autoimmunity. Although this question has no definitive answer, several hypotheses and data are provided by studies in humans, by spontaneous animal models of type 1 diabetes, and by transgenic animal models. One hypothesis is that high-risk class II molecules may be unstable, and protective molecules may be more stable. The I-A^{g7} molecule (NOD murine homolog of DQ) is reported to be unstable (56,57), and the protective DQA1*0102/DQB1*0602 is reported to be more stable than other HLA-DQ molecules (58). It is proposed that such a lack of stability may allow autoreactive T lymphocytes to escape negative selection in the thymus. The observation that the haplotype DRB1*1501, DQA1*0102/DQB1*0602 allele is associated with a high risk of multiple sclerosis but protection from type 1A diabetes argues against a global association of DQ allele stability with protection from autoimmunity.

Schmidt and co-workers studied an animal model with diabetes that developed subsequent to introduction of a transgenic T-cell receptor (TCR) (59). These animals are protected from diabetes by several different class II HLA molecules, all of which induce thymic deletion of this T-cell clonotype. Thus, mechanisms of central tolerance may play an important role in preventing autoimmunity and diabetes. Wen and co-workers described a fascinating murine model in which the high-risk human DQA1*0301/DQB1*0302 allele was introduced into the mice (60). When this DQ8 transgene was combined with islet expression of a costimulatory molecule (B7-1), spontaneous diabetes occurred. This finding suggests that the DQ8 allele directly influences the development of type 1A diabetes. Such an influence on diabetes susceptibility may result from presentation of a critical islet peptide to T cells or the shaping of the TCR repertoire.

INSULIN GENE (IDDM 2)

Studies of the genetics of type 1A diabetes may provide an indication of how expression of a target autoantigen, namely, insulin, can affect tolerance induction and susceptibility to autoimmune disease. The insulin gene on chromosome 11 (IDDM 2) contributes to diabetes susceptibility. The promoter region of this gene has a variable nucleotide tandem repeat *(VNTR)*, which is associated with risk of type 1A diabetes (61,62). Such repetitive sequences often undergo expansion or contraction. Given its location in the 5' regulatory region of the insulin gene, such length polymorphisms have been reported to affect and to correlate with intrathymic expression of insulin messenger RNA (63,64). The insulin gene polymorphism with a larger repeat region results in greater thymic expression of insulin mRNA (presumably favoring more efficient negative selection and tolerance) and is associated with protection from diabetes. This finding is in contrast to the smaller repeat region of susceptible persons, in which there is a lowered intrathymic expression of the insulin gene (63,64). Thus, a lack of central tolerance to insulin as a result of altered thymic expression may underlie part of the pathogenesis of type 1A diabetes.

Thymic expression of peripheral and sequestered antigens (e.g., insulin, myelin basic protein) has been determined to be a normal event (65), and it is believed to be critical for the establishment of central tolerance (66,67). These data are further supported by the work of Egwuagu and colleagues, who studied the differences in susceptibility to experimental autoimmune uveoretinitis (EAU), an animal model for human intraocular inflammation (uveitis). These investigators reported that thymic (mRNA and protein) expression of ocular autoantigens in the thymus correlated with resistance to autoimmune disease (EAU) (68). These data (together with the data on the insulin gene) suggest that thymic malfunction, in particular, alterations of thymic antigen expression, may be necessary but not sufficient for the development of autoimmunity.

OTHER NON–MAJOR HISTOCOMPATIBILITY COMPLEX GENES

Investigators believe that the combined effects of haplotype sharing for the HLA and insulin (INS) regions account for, at most, 60% to 70% of the familial aggregation of type 1A diabetes. However, in some populations, the combined effects of HLA and INS contribute less than 50% of the familial risk, a finding suggesting that other

non-MHC loci contribute to the genetic risk. To identify regions that may contain susceptibility genes, several genomewide linkage studies have been undertaken. There has been great difficulty in reproducibly identifying specific genes underlying diabetes susceptibility outside of MHC alleles and the insulin gene. Most of genetic studies have implicated only large chromosomal regions in diabetes susceptibility, and for most of these putative loci, confirmation by multiple groups is lacking. Currently, three major modes of inheritance may account for the majority of type 1A diabetes: polygenic, oligogenic, and monogenic inheritance. (If the disorder is oligogenic or monogenic, there must be heterogeneity.) The existence of all three modes of inheritance in different families, we believe, is likely because of animal models with different modes of inheritance.

Evidence for Polygenic Inheritance

More than 20 candidate regions associated with type 1A diabetes have been reported in studies evaluating pairs of siblings with diabetes (69,70,71,72,73,74,75,76,77,78 and 79) (Table 48.2). Most of the known or suspected susceptibility loci have been designated IDDMn, where n is a numeric identifier. The associations reported to date are relatively weak and have proved difficult to confirm (79,80 and 81). Although the non-MHC loci described to date have a weak influence on diabetes risk in a mixture of families, extremely potent and important regions may confer a diabetes risk in specific families.

Locus	Region	λ-s	Candidate gene or closely linked marker
IDDM1	6p21.31	1.7–4.2	HLA class II
IDDM2	11p15.5	1.6	5′ VNTR insulin gene
IDDM3	15q26	<1.5	D15S107
IDDM4	11q13	1.0–1.5	FGF3
IDDM5	6q25	1.0–3.0	ESR
IDDM6	18q21	1.0–1.5	D18S64
IDDM7	2q31–33	1.0–1.6	D2S152
IDDM8	6q27	1.0–2.1	D6S446/D6S264
IDDM9	3q21	1.0–1.7	D3S1300
IDDM10	10p11–q11	1.1–2.2	D10S193
IDDM11	14q24.3–14q31	<1.5	
IDDM12	2q33	<1.5	CTLA-4/CD28

TABLE 48.2. Insulin-Dependent Diabetes Mellitus (IDDM) Candidate Regions Identified by Linkage/Association Studies

Evidence for Oligogenic Inheritance (IDDM17)

We performed linkage and haplotype analysis in a large Bedouin Arab family with 20 members with type 1A diabetes (Fig. 48.4) (82). In this family, homozygosity (suggesting autosomal recessive inheritance) at a locus on chromosome 10 (now termed IDDM17) and HLA alleles DR3 or DR4 convey a risk of diabetes of approximately 40% (nonparametric linkage score greater than 4). When the gene underlying this association is identified, based on the genetic heterogeneity model, we predict that this gene contributes to the development of diabetes in a subset of families from other populations.

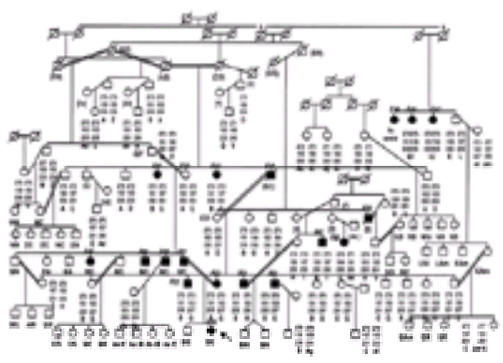

Figure 48.4. Family tree in which 18 members have developed type 1 diabetes, and diabetes appears to be inherited as an autosomal recessive mutation at a locus on chromosome 10 plus typical type 1 HLA alleles. The B haplotype on chromosome 10 occurs in most patients with diabetes (*numbers* refer to chromosome 10q25.1 microsatellite alleles), and patients with diabetes have homologous B-like 10q 25.1 regions for other diabetic haplotypes (e.g., haplotypes, Ae, O, I, J, C, T, G, and H).

Evidence for Monogenic Inheritance: Autoimmune Polyendocrine Syndrome Type I: A Mutation of the Autoimmune Regulator Gene

The two distinct autoimmune polyendocrine syndromes are termed autoimmune polyendocrine syndrome type I (APS-I) and type II (APS-II) (13,14 and 15,83,84,85,86 and 87). APS-II is strongly associated with type 1A diabetes and Addison disease as well as autoimmune thyroid disease. HLA alleles, in particular DR3 and DR4 haplotypes, contribute to disease, but given the familial aggregation of the syndrome, other genes contributing to susceptibility are likely. In contrast, the APS-I results from a recessive mutation of a gene on chromosome 21 (21q22.3), termed the autoimmune regulator gene (AIRE) (88,89). APS-I is a distinctive syndrome, with the major disorders being mucocutaneous candidiasis, hypoparathyroidism, and Addison disease and, less frequently, autoimmune hepatitis. Other endocrine and nonendocrine disorders may also develop in these patients and include type 1A diabetes, gonadal failure, alopecia, vitiligo, pernicious anemia, nail and dental enamel dystrophy, and keratopathy. Approximately 18% of patients with APS-I develop type 1A diabetes. More patients express glutamic acid decarboxylase 65 (GAD65) autoantibodies (almost 50%) than develop diabetes (90,91). Both type 1A diabetes and Addison disease are strongly associated with the HLA-DR3 and DR4 alleles, but patients with APS-I show no susceptibility to class II HLA association. This finding suggests that the mutation that results in APS-I is able to bypass the influence of HLA alleles on disease risk. The syndrome is so distinctive that essentially all families with the clinical syndrome, when studied, have mutations of the AIRE gene (92).

The manner by which mutations of the AIRE gene influence autoimmunity is unknown. Analysis of the AIRE gene revealed that it harbors several domains (two zinc fingers, a nuclear targeting signal, four nuclear receptor binding motifs, and a putative DNA binding domain), a finding that suggests a role in transcriptional regulation (93). Bjorses and co-workers demonstrated that AIRE activated transcription of a reporter gene in a eukaryotic transactivation assay (94). Which cells express the AIRE protein remains controversial. mRNA for the AIRE gene has been detected in the thymus, lymph node, and fetal liver (92,95). By immunohistochemical analysis, the AIRE protein was detected in the nuclei of several immunologically relevant tissues, namely, thymus, spleen, lymph node, and peripheral leukocytes (93,95). Given its putative role in regulating transcription and its restricted cell and tissue expression, it is likely that the AIRE protein regulates genes important for the development of immunologic tolerance.

Environment

The incidence of type 1A diabetes varies worldwide, with some populations having remarkably high incidence rates, such as in Scandinavia, which has a rate of approximately 45 in 100,000 (96), whereas others, particularly Asian countries such as Japan, have a low incidence of approximately 1.8 in 100,000 (97). In the United States, the incidence in children is approximately 15 in 100,000. The incidence of type 1A diabetes also varies among members of different racial backgrounds living in the same geographic region, although they are not of the same magnitude as the geographic differences. In the United States, for example, non-Hispanic whites are approximately one and a half times more likely to develop type 1A diabetes than other racial groups.

Geoethnic variation in type 1A diabetes risk probably reflects differences in the frequencies of modifier genes (susceptibility or protective) or environmental factors (causative or protective) or some combination thereof. The precise role that these factors have on the variation in the incidence of type 1A diabetes has been difficult to establish. Several studies suggest that most of the intercountry variation in diabetes risk may relate to genetic differences and not environmental factors. Investigators found that MZTs and first-degree relatives of patients with type 1A diabetes in Japan had a risk of diabetes similar to that of twins and relatives of patients in the United States (98). The island of Sardinia has one of the highest incidences of type 1A diabetes in the world. On migration from Sardinia to mainland Italy (a lower-incidence region), the risk of diabetes is unchanged (99). In contrast, data indicate that Yemenite Jews who came to Israel now have the highest incidence of type 1A diabetes in Israel. In Yemen, childhood diabetes is reportedly rare (100).

The incidence of type 1A diabetes has been increasing in many countries over the past 40 years, with the greatest differences occurring in the youngest children

developing diabetes. Some studies reported an early peak in diabetes incidence around age 5 years (33,34,101,102). The risk of developing diabetes in children increases until puberty (reaching a peak onset at 12 to 13 years). The incidence peak at this time may be related to physiologic changes (increases in sex hormones) associated with insulin resistance or lifestyle changes and the associated change in the pattern of infection (34). Type 1A diabetes can occur at any age, even in the eighth and ninth decades of life. Only a few studies have examined the incidence or prevalence of type 1A diabetes in older groups, mainly because of the difficulty of distinguishing slowly progressive type 1A diabetes from insulin-requiring type 2 diabetes in older persons. Many patients, particularly adults, presenting to their physician with what appears to be non–insulin-requiring diabetes have an early stage of type 1A (immune-mediated) diabetes (103). The diagnosis of diabetes in such adult patients is now possible because of the availability of autoantibody assays with high sensitivity and specificity (48). Asian adult patients are likely to have a lower prevalence of adult-onset type 1A diabetes compared with the reports from Finland (3,48,104).

Several European countries such as Great Britain and Finland have experienced more than a doubling in incidence of type 1A diabetes over the past three decades (105,106). This increase in the incidence of type 1A diabetes is almost certainly the result of environmental factors. What may be changing in the environment is unknown, but one hypothesis is that sanitation and vaccination create a “cleaner” environment that results in reduced exposure to microbial antigens postnatally. Such postnatal infection may protect from autoimmunity by shaping the immunologic repertoire. BB rats and NOD mice raised in a germ-free environment develop more diabetes than those raised in standard animal rooms (107). It is not yet clear whether type 1A diabetes is actually increasing in incidence or whether the age of onset of the disorder is decreasing. An alternative hypothesis to that of a decrease in environmental factors that protect from diabetes is that a diabetogenic factor is increasing. Many investigators believe that viral infections contribute to diabetes development.

A common observation is that the incidence of diabetes increases in the fall and winter. With the long prodrome preceding type 1A diabetes, many investigators now believe that this seasonal variation results from stress associated with infections precipitating metabolic decompensation and diagnosis. Thus, more recent studies have searched for viruses that may initiate the development of diabetes rather than merely precipitate hyperglycemia (34,108). Previous studies linked the risk of type 1A diabetes to congenital rubella infection, but intriguingly, noncongenital infection does not appear to convey this risk (109,110). Approximately one fourth of children with congenital rubella will develop diabetes. As many or more of these children also develop autoimmune thyroiditis, a finding suggesting that the virus has altered the immune system and has thereby increased the risk of developing a series of autoimmune disorders (109,111). No other viral infection is as clearly linked to diabetes.

One manner in which viral infection may influence diabetes risk is thorough molecular mimicry. In this model, a peptide of the virus with homology to an islet antigen can induce the proliferation of T cells that cross-react with the islet antigen, thus leading to antiislet autoimmunity. Coxsackieviruses have been of particular interest because of a molecular homology involving six amino acids (PEVKEK) with the antigen GAD65 (112,113 and 114). A series of studies related anticoxsackie antibodies to type 1A diabetes, either at onset or during the development of diabetes, but both negative and positive results were reported (115,116,117,118,119 and 120). Viral infection of the mother may also contribute to the development of diabetes (116,121). A possible explanation for the lack of definitive association may derive from the finding that viral infections are ubiquitous and are not unique to persons with diabetes.

Microbial superantigens that act by bridging between class II MHC and the Vb portion of specific subsets of TCRs have been implicated in the pathogenesis of autoimmune disease (122). One study reported the isolation of an endogenous retrovirus from patients with type 1A diabetes and proposed that this superantigen may initiate b-cell destruction (123). However, other groups could not confirm the association between the viral gene and type 1A diabetes (124,125).

A potential environmental trigger of type 1A diabetes is ingestion of dietary proteins. This is analogous to celiac disease in which the ingestion of the wheat protein gliadin is essential for antiintestinal autoimmunity, and in particular the presence of antitransglutaminase autoantibodies. Celiac disease is frequently found in patients with type 1A diabetes (approximately 1 in 20). Of patients with diabetes who have the HLA genotype DR3/3, almost one third express antitransglutaminase autoantibodies, and one half of these patients have celiac disease on biopsy (126). For most such persons, the disease is asymptomatic and is detected only with autoantibody screening.

Milk proteins have garnered most of the attention of investigators studying the role of dietary proteins in the development of type 1A diabetes. Both antibodies and T-cell responses to milk proteins have been reported to be increased among children with type 1A diabetes. In one study, investigators suggested that certain forms of milk casein vary in their protein sequence and can be converted to peptides with immunomodulatory properties (127). Investigators also suggested that milk albumin introduced in a neonate's diet may increase the risk of type 1A diabetes. The link between milk albumin and type 1A diabetes has been suggested to result from the homology between a milk albumin peptide and the islet autoantigen, ICA69 (128,129 and 130).

Insulitis and diabetes in BB rats can be triggered by exposure to wheat and cow's milk protein at the time of weaning (131). Borch-Johnsen and co-workers reported that a nationwide decrease in breast-feeding correlated with an increase in incidence of the type 1A diabetes (132), and retrospective studies have implicated early milk ingestion in the development of diabetes (133,134 and 135). The increased risk in most of these studies was small, and prospective studies following healthy children until the expression of autoimmunity (Baby-Diab study of Munich and DAISY study of Denver) have failed to find an association between milk ingestion and antiislet autoimmunity (136).

Given the high penetrance of the disorder for MZTs and relatives of patients with type 1A diabetes with HLA DR3/4, and a similar risk of diabetes and autoantibody expression for DZTs and other siblings (36), if a triggering environmental factor is important, it is likely to be ubiquitous. This would be similar to celiac disease, in which most persons are exposed to wheat gliadin, but only a few of those exposed develop celiac disease. Current studies indicate that each TCR can be triggered by as many as 1 million different peptides. Many peptides able to trigger the same receptor have little or no linear sequence in common (137). Thus, the number of peptides that may be mimotopes of an important islet autoantigen and may potentially contribute to disease could be enormous. As the target molecules and immune pathogenesis are better defined, it should become easier to identify relevant environmental factors.

CLINICAL CONSIDERATIONS

Signs and Symptoms

The classic signs of type 1A diabetes are polyuria, polydipsia, and weight loss. At diagnosis, most patients who present with type 1A diabetes have had overt hyperglycemia for many months, some for more than a year, as evidenced by the presence of an elevated level of hemoglobin A_{1c} (HbA_{1c}). Despite the classic signs and symptoms of diabetes, the diagnosis is often missed by the first health care provider to see the child. Such children are at increased risk of developing ketoacidosis. Even with institution of insulin therapy, some of these children develop cerebral edema, which has a high mortality.

Diagnostic Criteria

DIAGNOSIS OF DIABETES

The American Diabetes Association 1997 revised guidelines for the diagnosis of diabetes include a fasting plasma glucose level of more than 126 mg/dL (7 mmol/L) or a plasma glucose level of more than 200 mg/dL (11.1 mmol/L) taken randomly (with symptoms of diabetes) or 2 hours after an oral glucose load (1.75 g glucose/kg up to a maximum of 75 g). Confirmation of such abnormalities on more than one occasion is recommended. “Impaired” fasting glucose values are from 110 to 125 mg/dL (6.1 to 6.9 mmol/L), and impaired 2-hour values are from 140 to 200 mg/dL (7.8 to 11.1 mmol/L). Transient hyperglycemia, though uncommon, can occur particularly with severe illness. Children with such transient hyperglycemia do not usually have antiislet autoantibodies and usually have a normal HbA_{1c}.

DIAGNOSIS OF TYPE 1A DIABETES

At present, the best indicator of type 1A diabetes in a patient with hyperglycemia is the presence of antiislet autoantibodies (see later). In addition, HLA genotypes can suggest the presence or absence of type 1A diabetes. A child, for instance, without antiislet autoantibodies and with the protective HLA allele DQA1*0102, DQB1*0602 is unlikely to have type 1A diabetes. More often, such children have type 2 diabetes. Approximately one half of Hispanic and African-American children presenting with diabetes have type 2 and not type 1A diabetes (138). Some of these children, after initial treatment with insulin, can be treated with oral hypoglycemic agents.

Laboratory Tests

The laboratory tests used for the prediction and diagnosis of type 1A diabetes relate to hyperglycemia, insulin secretion by islet b cells, autoimmunity and genetic polymorphisms. Standard laboratory tests of blood glucose and HbA_{1c} are readily available. The HbA_{1c} test provides a determination of average blood glucose for approximately 3 months. Because type 1A diabetes develops slowly, it is unusual for a child to present with hyperglycemia with a normal HbA_{1c}. This situation can occur with fulminant type 1B diabetes (5), children presenting with transient hyperglycemia associated with stress (139), and children followed to the development of diabetes such that diabetes is diagnosed soon after the earliest abnormalities of glucose metabolism.

In a nondiabetic person expressing antiislet autoantibodies, the best predictor of type 1A diabetes and approximate time of onset of diabetes is loss of insulin secretion

after a bolus of intravenous glucose. The intravenous glucose tolerance test has been standardized, and insulin levels are usually measured at 1 and 3 minutes after the glucose bolus. Loss of rapid secretion of insulin precedes loss of the ability of the pancreas to secrete insulin after a meal. Once diabetes is diagnosed, patients are treated with insulin. Thus, after diagnosis, C-peptide, rather than insulin, is the measurement of choice to define remaining b-cell function. C-peptide (connecting peptide) of the proinsulin molecule is stored in insulin secretory granules after cleavage from the proinsulin molecule. It is then secreted by pancreatic b cells in amounts equal to that of insulin. Within 3 years of the onset of type 1A diabetes, most children have a severe impairment of insulin secretion such that fasting C-peptide is no longer detectable. The maintenance of C-peptide secretion is also used as a measure of effective immunotherapy in clinical trials.

The initial assay for antiislet autoantibodies (detection of cytoplasmic islet cell antibodies) consisted of indirect immunofluorescent detection of antibodies binding to frozen sections of human pancreas (15,140). Assays for autoantibodies reacting with the surface of islet cells were also studied but lacked disease specificity and are rarely performed today (141). The ICA or islet cytoplasmic autoantibody assay can provide important diagnostic and prognostic information. Unfortunately, the assay is difficult to standardize, and dramatic variation in the sensitivity and specificity among laboratories has been observed. The development of “biochemical” fluid-phase radioassays to detect a series of autoantibodies reacting with islet antigens replaced the immunofluorescence assay. The ICA assay detects a subset of autoantibodies reacting with glutamic acid decarboxylase, the molecule ICA512 (also termed IA-2), and additional poorly characterized islet antigens, but it does not detect antiinsulin autoantibodies. Assays for autoantibodies reacting with insulin, glutamic acid decarboxylase, or ICA512 (IA-2), when performed with fluid-phase assays (not enzyme-linked immunosorbent assays), can be set with high specificity such that less than 1 in 100 nondiabetic persons have positive results. These autoantibody assays are now usually performed in 96-well filtration plates. Labeled antigens are either purchased or obtained through *in vitro* transcription and translation of cDNAs of the respective molecules (28,142,143,144 and 145). Antibody-bound labeled antigen can be detected with b counting directly in the 96-well plate making the assay easier to perform and more cost-effective. With such semiautomated assays, the assay costs can be reduced to less than $10 per sample. One or another of the three autoantibodies is present in approximately 95% of children with recent-onset type 1A diabetes.

Pathology

The hallmark of type 1A diabetes is the presence of insulitis (lymphocytic invasion of islets) and the selective loss of islet b cells. Islets comprise approximately 1% of the pancreas; exocrine pancreatic cells comprise most of the pancreas. Islets contain multiple endocrine cells, including cells secreting insulin (b cells), glucagon (a cells), somatostatin (d cell), and pancreatic polypeptide. Type 1A diabetes leads only to the complete loss of b cells. This selective b-cell loss occurs despite the presence of two islet autoantigens in human a cells, namely, GAD and ICA512. Pancreatic tissues from a large series of patients who died shortly after the development of type 1A diabetes were analyzed by Foulis and Clark (10). These investigators described three types of islets: (a) insulin-deficient islets with no insulitis, which make up the largest fraction (approximately 70%), (b) insulin-containing islets with a chronic inflammatory cell infiltrate, and (c) insulin-containing islets that appear normal. The diversity of islet types likely represents chronic progressive invasion and destruction of b cells of single islets. This type of autoimmune-mediated destruction may be analogous to the “spotty” lesions of vitiligo, whereby patches of skin melanocytes are destroyed over time. Once all the b cells within an islet have been destroyed, the insulitis disappears. The study of biopsy specimens from the pancreas of patients with newly diagnosed type 1A diabetes revealed that the infiltrating mononuclear cells consisted of T cells ($CD4^+$ and $CD8^+$), B lymphocytes, and macrophages. Among them, $CD8^+$ T lymphocytes were the predominant cell type, whereas macrophages were the next most prevalent (146). However, $CD4^+$ T cells made up the predominant cell type in adult type 1A diabetes patients with residual b-cell function (147). These data suggest that the subtype of the islet infiltrating cells may be variable, depending on the phenotype or the stage of diabetes. Interferon-g (IFN-g) mRNA transcripts have been shown to be highly expressed in the pancreas of the patients, whereas IL-4 mRNA was deficient (148). Huang and co-workers emphasized the presence of IFN-a (149).

Treatment and Prognosis

The discovery of insulin in 1921 was one of the most important medical discoveries of our time. Insulin therapy has saved millions of lives, but it remains an inadequate form of therapy, primarily because of the limited therapeutic window. A major risk with insulin therapy of type 1A diabetes is severe hypoglycemia, which can result in coma, seizure, or death. Therapies are, however, improving with genetically engineered (rapid-acting and long-acting) insulins. In addition, devices capable of measuring cutaneous glucose continuously have been approved by the United States Food and Drug Administration and are likely to have a major beneficial impact on improving glycemic control.

Hypoglycemia becomes more of a problem as blood glucose is lowered toward normal. Normal blood glucose, associated with a lower HbA_{1c}, is essential for prevention of renal failure and proliferative retinopathy (150). Approximately 30% to 40% of persons with type 1A diabetes eventually develop renal failure or loss of vision. Both complications can be decreased if patients are monitored for early eye disease (annual ophthalmologic exam) or early nephropathy (annual determination of microalbuminuria).

IMMUNOPATHOLOGY OF TYPE 1A DIABETES

Humoral Response

Studies of antiislet autoantibodies have filled an important gap in our knowledge concerning the development of type 1A diabetes. Children have been followed from birth until the development of type 1A diabetes (28,44,151,152 and 153). From these studies, it is apparent that antiislet autoantibodies in genetically susceptible persons (e.g., HLA DR3/4 heterozygous persons) can develop in the first 6 to 9 months of life. Autoantibodies often develop sequentially over 6 months to 1 year, with antiinsulin autoantibodies appearing first. GAD65 autoantibodies also occur early, and ICA512 (IA-2) autoantibodies often develop after GAD65 and IAAs (151,153,154).

Many biochemically defined autoantigens have been found to be targets of the autoimmune process that precedes type 1A diabetes (155). The association of autoantibodies to GAD65 with the stiff man syndrome, a rare neuromuscular disease characterized by muscle spasms, contributed to the identification of GAD65 as the elusive islet 64-kd autoantigen (156). The antiislet autoantigen ICA512 was identified by screening an islet cDNA library with sera from patients with type 1A diabetes (157,158,159 and 160). Autoantibodies reacting with 40- and 37-kd tryptic fragments of labeled islet proteins were identified by Christie (161). It was later realized that the 37-kd protein is ICA512 and the 40-kd molecule is a fragment of a molecule termed phogrin by Hutton and co-workers, IA-2b by Notkins and co-workers, and IAR by other investigators (162). ICA512 and IA-2b are both molecules associated with secretory granules. Both ICA512 and I-A2b have tyrosine phosphatase-like domains and are homologous in their C-terminal intracytoplasmic domains. Essentially all the autoantibodies in patients with type 1A diabetes are directed to this intracytoplasmic domain. Most of the anti–IA-2b reactivity can be absorbed with synthetic ICA512 antigen, a finding suggesting that most autoantibodies directed against IA-2b cross-react with ICA512. Approximately 10% of children with diabetes express antibodies that react with ICA512 but fail to react with phogrin (163). We have found that only 1% of children with diabetes who have anti–IA-2b autoantibodies are negative for ICA512 autoantibodies.

Although insulin was the first autoantigen biochemically characterized (164), the assay for antiinsulin autoantibodies has been much less convenient than assays for GAD65 and ICA512. The conventional IAA assay uses 600 µL of serum per determination and is performed in centrifuge tubes. International workshop comparisons of the conventional assay indicated that IAA assays that used less than 600 µL were significantly less sensitive in detecting relevant antiinsulin autoantibodies (165). Williams and co-workers described an IAA radioassay that uses protein A rather than polyethylene glycol and requires much less sera (20 µL) than the conventional assay (153,166,167). Modifications of this assay by our laboratory now allow IAAs to be determined with the same throughput as for GAD and ICA512 autoantibody assays (28). In addition, several laboratories have reported that the polyethylene glycol precipitation of the conventional assay produces false-positive results for hemolyzed sera. Such false-positive results are abrogated with the protein A assay.

COMBINATORIAL AUTOANTIBODY DETERMINATION

The detection of autoantibodies, when combined with the measurement of insulin secretion, is important for the accurate prediction of diabetes (168). For three of the islet-cell autoantibodies (anti-GAD65, antiinsulin, and anti–ICA512/IA-2), the frequency of positivity is high (approximately 95% of children with recent-onset type 1A diabetes express one or more of the three autoantibodies). The assays are in a form that allows sensitive and specific testing of thousands of samples (Table 48.3). Expression of multiple autoantibodies confers a high risk for progression to type 1A diabetes (Fig. 48.5).

Antigen	Sensitivity (Specificity)	Comment
Insulin	40–95% (99%)	Prevalence inversely correlated with age of onset
GAD	70% (99%)	Prevalence increases with age
ICA512 (IA-2)	60% (99%)	Islet tyrosine phosphatase homolog
IA2β (Phogrin)	55% (99%)	These autoantibodies predominantly a subset of ICA512/IA-2 autoantibodies

TABLE 48.3. Biochemical Antiislet Autoantibody Assays

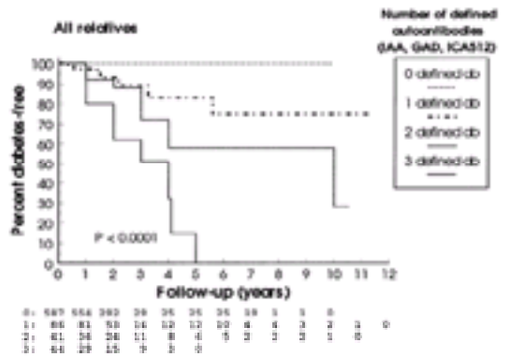

Figure 48.5. Life-table analysis of the risk of type 1 diabetes in first-degree relatives according to the number of autoantibodies to insulin, GAD65, and ICA512/IA-2. (Adapted from Verge CF, Gianani R, Kawasaki E, et al. Prediction of type I diabetes in first-degree relatives using a combination of insulin, GAD, and ICA512bdc/IA-2 autoantibodies. *Diabetes* 1996;45:926–933, with permission.)

A study examining the risk of type 1A diabetes in first-degree relatives according to the number of autoantibodies found that, in relatives not expressing 1 of the autoantibodies, only 1 relative out of approximately 600 developed diabetes. Fewer than 20% of relatives expressing only a single autoantibody (usually GAD65 or IAAs) developed diabetes. In contrast, expression of 2 or 3 autoantibodies was associated with high risk. Most persons expressing only a single autoantibody may not be destroying b cells. For example, an adult patient with expression of only GAD65 autoantibodies at autopsy was found to have a normal pancreas. Many of the relatives at autopsy with a single autoantibody at initial testing in Fig. 48.5 and who went on to develop diabetes eventually expressed multiple autoantibodies before the onset of diabetes (151). Autoantibody reactivity “spreading” to multiple autoantigens and to multiple epitopes of a given autoantigen can be readily observed in children less than the age of 5 years (169). Expression of multiple autoantibodies appears to be associated with a high diabetes risk for even the general population. Less than 1 in 300 persons in the general population expresses more than a single autoantibody. This is similar to the risk for type 1A diabetes in the United States. In contrast, 80% of children at the time of type 1A diabetes onset express two or more autoantibodies.

INSULIN AUTOIMMUNE SYNDROME

Nearly all patients with diabetes develop antibodies to insulin after subcutaneous insulin therapy. These “induced” IAAs are distinct from those produced spontaneously in that they have a lower affinity for insulin. These induced IAAs usually do not interfere with insulin therapy. In 1970, Hirata and co-workers identified the first patients with antibodies to insulin who had not been treated with insulin. These patients had spontaneous hypoglycemia associated with the production of IAAs with the designation, insulin autoimmune syndrome or Hirata disease (170). Insulin autoimmune syndrome is characterized by a combination of fasting hypoglycemia and polyclonal (rare monoclonal not HLA associated) antibodies to insulin and is associated with HLA-DR4 (DRB1*0406) (171). Since 1970, at least 226 cases in Japanese patients and 26 cases in whites have occurred.

The IAAs in these patients appeared spontaneously or after administration of drugs such as methimazole, penicillamine, or a-mercaptopropionylglycine (172,173). The mechanism of induction of antiinsulin antibodies by these drugs is not well understood, but all these drugs contain a sulfhydryl (S-H) group. Investigators have suggested that the treatment with reducing agents may cleave disulfide bonds of the insulin molecule *in vivo* and may expose insulin-derived peptides to the DRB1*0406 allele (173).

Cellular Response

Although islet autoantibodies predict the development of type 1A diabetes, no evidence indicates that these antibodies themselves are pathogenic (174). Rather, the disease appears to result from cell-mediated immunity. Cell-mediated autoimmunity has not been easy to study in humans because the autoimmune process is well advanced by the time of diagnosis and because diseased human islets are difficult to obtain. Several studies in human patients have reported abnormalities in peripheral T-cell function (175,176,177,178,179,180 and 181). Early studies suggested that differences in the ratios of T-cell subsets, CD4/CD8, could be detected between patients and control subjects. A common abnormality noted across many of these studies is an increase in activated T cells. The data on T-cell reactivity to various candidate autoantigens have been inconsistent (182), and international workshops with “blinded” antigens have highlighted the difficulties. Many explanations have been offered for the reason that this reactivity has been difficult to detect reproducibly. Explanations include a low frequency of circulating autoreactive T cells (183), peripheral immune regulation of autoreactivity (184), assay systems with a low signal-to-noise ratio (elevated background reactivity), or undue reliance on proliferation of T cells as the sole determinant of reactivity.

Effector Mechanisms for b-Cell Destruction

Pathogenic CD4 and CD8 T cells in type 1A diabetes are believed to express a Th1 phenotype. A substantial amount of evidence in the NOD mouse supports the hypothesis that protection from diabetes is associated with nondestructive inflammation and a shift in the cytokine pattern to one exhibiting Th2 cytokines (IL-4, IL-5, IL-10, and transforming growth factor-b) (185,186,187,188,189 and 190).

Diabetogenic CD4+ or CD8+ T-cell clones are capable of mediating b-cell destruction independently in certain experimental situations. However, in human and in rodent models, evidence indicates a complex interaction between antigen-presenting cells (dendritic cells, macrophages, and B cells) and T lymphocytes in the destruction of b cells. For example, depletion of B cells (191) or macrophages (192) in the NOD model blocks development of diabetes. Numerous studies have determined that certain proinflammatory cytokines, including TNF-a, IL-1, IL-6, and IFN-g, play an important role, as well as Fas-FasL interactions, perforin, and granzymes and reactive oxygen intermediates.

Programmed cell death or apoptosis has a role in the normal regulation of the immune response (193,194). Investigators have been examining apoptosis to determine both how b cells die and whether abnormalities in apoptosis may be found in the pathogenic lymphocytes that cause b-cell destruction (195,196). NOD mice express Fas on the surface of b cells during the development of insulitis and diabetes. b cells can die by programmed cell death through the engagement of Fas by Fas-ligand expressed on lymphocytes. In human type 1A diabetes, data are conflicting regarding b-cell–specific Fas expression. One group noted Fas expression on b cells only, a finding suggesting a direct role for Fas in b-cell apoptosis. In contrast, two groups using confocal microscopy found Fas expression on all islet cells including a and b cells. When intracellular mRNA message for apoptotic pathway molecules was assessed, it appeared that critical caspases needed for signaling through the Fas pathway were reduced in diabetic islets, but not in control islets. If this observation is verified, then it would suggest that other pathways of apoptosis, such as mediated by TNF receptor, may be more important for b-cell death.

Loss of Insulin Secretion

First-phase insulin secretion after the administration of intravenous glucose is a parameter that aids the prediction of the time to development of clinically overt diabetes

(197). One to 3 years before the onset of type 1A diabetes, most persons have lost first-phase secretion.

The unique association of the levels of IAAs with the age of development of type 1A diabetes and rate of progression to diabetes is not found for GAD65 autoantibodies and ICA512 autoantibodies. For example, infants less than 5 years of age usually have remarkably elevated levels of IAAs (thousands of nanounits per milliliter), whereas children presenting with diabetes after the age of 15 years have levels in the hundreds, and most are negative for IAAs with current assays. This association of IAAs with a young age of onset may relate to a faster progression to diabetes with high levels of IAAs. We model the approximate time of onset of type 1A diabetes with a dual-parameter model using first-phase insulin secretion on intravenous glucose tolerance testing and levels of IAAs. The model was used to analyze two independent data sets from Boston and Melbourne patients. As illustrated in Fig. 48.6, for both groups, ICA-positive relatives with a predicted time to diabetes of less than 2.5 years (by this formula) had a much more rapid and greater progression to diabetes, in contrast to relatives with a predicted time of greater than 2.5 years (198).

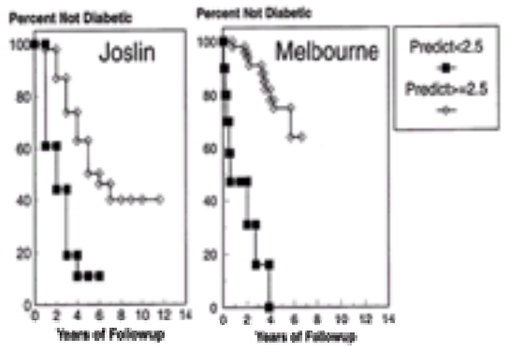

Figure 48.6. Dual-parameter model for prediction of diabetes onset. Levels of insulin autoantibodies and loss of first-phase insulin secretion on intravenous glucose tolerance testing correlate with progression to diabetes. (Adapted from Eisenbarth GS, Gianani R, Yu L, et al. Dual parameter model for prediction of type 1 diabetes mellitus. *Proc Assoc Am Physicians* 1998;110:126–135, with permission.)

Investigators have estimated that at the time of diagnosis of type 1A diabetes, 80% to 90% of the b cells have already been destroyed. Examination of pancreas of patients who died shortly after the onset of type 1A diabetes revealed that insulitis is observed only within the islets that still contain b cells.

In some patients newly diagnosed with type 1A diabetes, initial insulin therapy may be accompanied by a brief metabolic remission, termed the “honeymoon phase.” During this time, low doses of insulin are sufficient to achieve glycemic control. This brief metabolic remission usually lasts for less than 1 year, and it probably reflects decreased insulin resistance after treatment of severe hyperglycemia. The ability to induce this temporary metabolic remission makes the search for an agent that can maintain long-term remission an important goal.

ANIMAL MODELS

Spontaneous Rodent Models

Our understanding of the pathogenesis of type 1A diabetes has been greatly facilitated by the availability of rodent models. Although most animal models of autoimmune disease are experimentally induced (e.g., through chemical toxins, autoantigens, infections, immunotherapy), the NOD mouse and the BB rat both spontaneously develop diabetes. Because the study of diabetes in humans is hampered by the limited access to the target organ, the use of animal models allows investigators to study immunopathologic features at various stages of the disease process. Furthermore, the relative ease of genetically manipulating and breeding mice has allowed better characterization of the role of specific immune mediators and has facilitated the study of disease prevention.

NOD MOUSE

A spontaneous model of diabetes, the NOD (nonobese diabetic) mouse, was discovered in Japan by Makino and colleagues (22). Disease in the NOD mouse is similar to the process in humans in that b-cell destruction is autoimmune mediated. Cellular and humoral immune responses specific for b cells are present, antiislet autoantibodies precede overt diabetes, and a strong association with MHC genes exists. Lymphocytic infiltration of the islets, termed insulitis, can be detected in the NOD mouse at 4 to 5 weeks by light microscopy.

Genetic studies in the NOD mouse reveal that diabetes in this model is characterized by multiple genetic loci determining disease susceptibility. The MHC (termed idd-1) plays a key role but is necessary and not sufficient for disease. The class II region in NOD mice encodes the I-A^{g7} molecule, the homolog of human diabetes-associated HLA-DQ molecules. The I-A^{g7} molecule is unusual in that it has a histidine at position 56 and a serine (instead of an aspartic acid) at position 57 of the b chain, which differs from I-A molecules of most other mouse strains. The a chain of I-A^{g7}, however, is identical to the a chain expressed by nondiabetes-prone mice (e.g., BALB/c). Susceptibility to diabetes in the NOD mouse is strongly influenced by this unique I-A^{b} chain because transgenic NOD mice expressing a “normal” I-A or with amino acid substitutions of position 56 and 57 of the NOD I-A^{g7} are protected from disease. The NOD mouse does not express I-E (the murine homolog of HLA-DR) because of a mutation in the Ea promoter. Transgenic replacement of a normal I-Ea gene blocks diabetes development (198).

NOD mice housed and maintained in standard environmental conditions display a high frequency of diabetes, which predominantly affects female mice (approximately 80% of females and 30% of males at 30 weeks of age). Despite being genetically identical, only certain mice develop diabetes.

With the development of a micro-IAA assay, prospective evaluation of IAAs in NOD mice has become possible. Our studies of IAAs in NOD mice revealed heterogenous expression of IAAs. IAAs appeared between 8 and 24 weeks and often disappeared before the onset of diabetes. Early appearance of IAAs at 8 weeks of age was strongly associated with early development of diabetes, which occurred at 16 to 18 weeks of age (Fig. 48.7). These data suggest that a high risk of early development of diabetes is often determined by 8 weeks of age, and the program for developing diabetes of NOD mice is “fixed” relatively early in life (28).

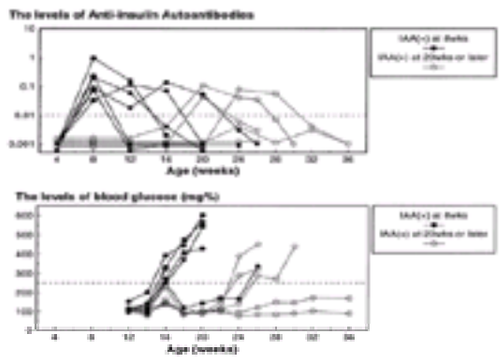

Figure 48.7. Insulin autoantibodies in NOD mice. Insulin antibodies and blood glucose for the NOD mice expressing insulin autoantibodies (IAAs) at 8 weeks of age and at 20 weeks or later followed from 4 weeks of age until diabetes or 36 weeks. Positive index of IAAs > .0. (Adapted from Yu L, Robles DT, Abiru N, et al. Early expression of anti-insulin autoantibodies of man and the NOD mouse: evidence for early determination of subsequent diabetes. *Proc Natl Acad Sci USA* 2000;97:1701–1706, with permission.)

In the NOD mouse, multiple investigators have isolated T-cell clones reactive to islet antigens (199). Islet cell–reactive T-cell clones are able to transfer diabetes (200). The TCR of the clone BDC2.5 (autoantigen unknown), when introduced transgenically into SCID mice, is associated with accelerated development of diabetes (201,202). Of the many CD4+ T-cell clones isolated from NOD islets, we concentrate on *insulin*-reactive T-cell clones that have been well characterized with regard to

the peptide recognized. Wegmann and co-workers isolated T cells from islets of prediabetic NOD mice and created T-cell lines using irradiated whole islets as antigen. These lines were later discovered to react with insulin (203). More than 95% of the insulin-reactive clones recognize a dominant peptide of insulin that spans the amino acid residues 9 to 23 of the insulin B chain (B:9-23 peptide) (204). These clones accelerate disease in young NOD mice, and one was able to transfer disease into NOD/*scid* mice (204). The B:9-23 peptide of insulin can be administered subcutaneously or intranasally to prevent diabetes (205). Molecular characterization of the known B:9-23 reactive CD4+ T-cell clones derived from the NOD islet reveals that the TCR a chain is highly restricted to AV13S3 and Ja 45 or Ja 34. This TCR motif is expressed by approximately 60% of insulin-reactive T-cell clones (206). Despite use of the same Va chain (AV13S3), B:9-23 reactive T-cell clones can recognize two different peptides (B:9-16 and B:13-23) sharing only four amino acids B:13-16 EALY (207).

NOD CD8 T cells reacting with islet antigens have also been cloned (208,209). Schmidt and Verdaguer and their colleagues produced a panel of CD8 T-cell clones that accelerated the development of diabetes when transferred to NOD mice but not to NOD SCID mice (59,210). A “mimotope” of the unknown antigen for these T cells has been identified. The T cells are restricted by K^d. A tetramer with the mimotope peptide is apparently able to detect T cells in early insulitic lesions. Wong and co-workers developed a CD8 T-cell clone with transgenic islets that express the B7-1 costimulatory molecule (208). The clone reacted with a B-chain peptide of insulin, B:15-23. The T cells were restricted by the K^d molecule, and a K^d tetramer with the insulin peptide reacted with a proportion of CD8 T cells in young NOD mice (211). These T-cell clones are able to transfer diabetes to NOD/SCID mice (208).

The relative importance of $CD8^+$ versus CD4 T^+ cells is controversial (212). Data from Christianson et al. indicated a greater contribution of $CD4^+$ than of $CD8^+$ T cells for the adoptive transfer of diabetes into NOD/SCID mice (213). The $CD8^+$ T-cell clone developed by Wong et al. can induce disease in NOD/SCID recipients. Wang and co-workers found that anti-CD8 antibody treatment is only effective in inhibiting diabetes when administered between 2 and 5 weeks of age, a finding suggesting that CD8 T cells are required in the early phase of disease (214). b_2-Microglubulin–null NOD mice, which lack $CD8^+$ T cells, do not develop insulitis or diabetes (215). In adoptive transfer to the NOD/SCID-b2m (null) mice, the disease can be transferred by spleen cells from older, but not young, NOD mice (216). Class I antigen recognition by $CD8^+$ T cells is likely to be required for early activation of islet-reactive CD4 T cells.

There has been considerable emphasis on GAD as a potential primary autoantigen (217,218 and 219). Suppression of GAD expression in b cells of NOD islets by antisense GAD constructs prevented diabetes in two of five strains (219). However, deleting the GAD65 gene failed to protect NOD mice from diabetes, and apparently with further breeding of the antisense transgene constructs onto NOD mice, diabetes occurs in “protected strains” (220). Expression of proinsulin transgenically in NOD mice, driven by a class II promoter, prevents diabetes (221). Similar studies with widespread GAD expression did not protect NOD mice (222).

BB RAT

The BB rat, discovered at the Bio-Breeding laboratory in Canada, is another spontaneous diabetes model. Diabetes in BB rats develops with equal frequency among male and female animals, with 90% of both sexes developing insulitis and then overt diabetes between 50 and 90 days of age. Selective breeding of BB rats resulted in the production of a diabetes-prone (DP) and a diabetes-resistant (DR) BB rat. The BB rat differs from the NOD mouse in that only two to four genetic loci contribute to susceptibility for most crosses. The DP-BB rats are T-cell lymphopenic, a characteristic not shared by NOD mice or humans with type 1A diabetes.

Genetic susceptibility for type 1A diabetes in the BB rat is also determined by MHC genes. In the BB rat, diabetes is independent of class I alleles but requires the MHC class II haplotype $RT\text{-}1^U$ (iddm2). At least one $RT\text{-}1^U$ allele must be present for diabetes development. A second locus *lyp* (lymphopenia), also termed iddm1, is inherited in an autosomal recessive manner and is responsible for the T-cell lymphopenia. Thus, spontaneous disease requires homozygosity at this locus. The lymphopenia in these animals involves the loss of $CD8^+$ T cells, NK T cells, and $RT6^+$ T cells (223). RT6 is a T-cell glycosylphosphatidylinositol-anchored alloantigen with both enzymatic and signal transducing capabilities (224). The RT6 surface antigen marks a subset of T cells capable of immunoregulation.

The DR-BB rats are immunocompetent and nonlymphopenic (225), but they do have autoreactive cells. Adoptive transfer of DR-BB splenocytes (226) or thymocytes (227) to histocompatible athymic rats can induce diabetes. DR-BB rats express normal numbers of $RT6^+$ T lymphocytes. Depletion of $RT6^+$ lymphocytes with anti-RT6 monoclonal antibodies can induce diabetes in DR-BB rats (228). In addition, infection with the Kilham rat virus can induce diabetes in these mice. The Kilham rat virus does not infect the b cells but is believed to alter immune regulation.

LONG-EVANS TOKUSHIMA LEAN (LETL) RAT

The Long-Evans Tokushima Lean (LETL) rat, an inbred spontaneous diabetes rat model, was established from an outbred colony of Long-Evans rats at the Otsuka Pharmaceutical Laboratory in Japan. These animals develop diabetes between 90 and 120 days, with no gender bias. As in the DP-BB rat model, destruction of b cells is autoimmune mediated; however, diabetes in the LETL rat differs from the DP-BB rat model in that T-cell lymphopenia is not present. Genetic analysis of these animals indicates that at least two recessive genes are involved in the pathogenesis of insulitis, one of which is closely linked with the rat MHC $RT1^U$ allele (229). Yokoi and Komeda and co-workers isolated a diabetes substrain of the LETL rat, the Komeda diabetes-prone (KDP) rat. The KDP rat showed a 100% development of insulitis, with 82% of animals progressing to diabetes within 220 days of age. A genome-wide scan for non-MHC type 1 diabetes susceptibility genes in the KDP rat revealed that a non-MHC gene, termed *iddm/kdp1,* on rat chromosome 11 is essential for the development of insulitis and diabetes (230).

LYMPHOPENIA-INDUCED PVG.$RT1^U$ RAT

Fowell and Mason developed a lymphopenia-induced model of diabetes in a nonautoimmune rat that shares the same MHC genotype ($RT1^U$) as the BB rat. They used a protocol of adult thymectomy and sublethal g irradiation (231). Neonatal tolerization with insulin B-chain peptides protected the rat from diabetes. The epitope recognized by the insulin-reactive T-cell line was mapped to residues 1 to 18 of the insulin B chain. As observed in the NOD mouse, diabetes can be adoptively transferred to syngeneic recipients by T-cell lines specific for insulin B:1-18 peptide (232).

Transgenic and Gene Targeting Models

Transgenic and knock-out technologies have been used to study the role of cytokines in the development of diabetes. Local pancreatic expression of proinflammatory cytokines using transgenes under the control of the rat insulin promoter have been well studied. NOD mice expressing IFN-g specifically in the islets (under the control of the rat insulin promoter) developed a massive inflammatory infiltrate with complete destruction of islets b cells (Table 48.4) (233).

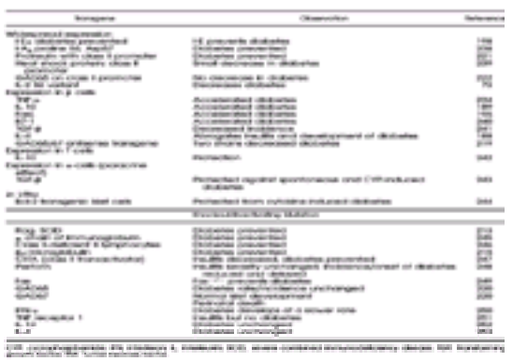

TABLE 48.4. Summary of Transgenic and Knock-Out Studies on the NOD Background

The role of TNF-a provides an example of how the progression to diabetes is determined in part by the temporal regulation of proinflammatory cytokines. TNF-a is not expressed in the neonatal period in TNF-a transgenic NOD mice. Systemic administration of TNF-a in neonatal NOD mice or islet-specific expression of TNF-a (234) accelerates the disease process, whereas neutralization of TNF-a at this stage (235) or expression later, at 7 weeks (236), protects against diabetes.

Studies of the TCR transgenic mouse (BDC2.5) developed by Katz and colleagues shed light on the progression of diabetes in the NOD mouse (201). The BDC2.5 transgenic T cells are CD4+, bear a TCR that is reactive to an unknown antigen, and are diabetogenic. Insulitis develops in the BDC2.5 transgenic NOD mouse at 3 weeks and rapidly progresses to a massive infiltrate. Despite the development of a massive lymphocytic infiltrate, diabetes onset occurs at a relatively normal period (10 to 25 weeks). Based on these observations, Andre and Mathis and colleagues proposed a hypothesis that suggests that the development of diabetes occurs through two critical checkpoints (237). Checkpoint 1, which marks the appearance of insulitis, occurs at 3 weeks of age. The time leading up to checkpoint 1 is believed

to be important for the recruitment and activation of self-reactive T cells. Checkpoint 2 involves the conversion from insulitis to overt diabetes. At this time, the regulatory factors responsible for keeping the autoreactive T cells in check (e.g., inhibitory cytokines, regulatory T cells, inhibition of costimulatory signals) are no longer in place, and the result is destruction of b cells.

Several studies provide evidence for the importance of B lymphocytes in the pathogenesis of type 1A diabetes in NOD mice. NOD mice genetically deficient in B lymphocytes are resistant to diabetes (245,246,247,248,249,250,251,252,253 and 254). Noorchashm and co-workers developed NOD mice with a MHC class II ($I\text{-}A^{g7}$) deficiency confined to the B-cell compartment. This NOD mouse with $I\text{-}A^{g7}$–deficient B cells were resistant to development of diabetes, a finding suggesting that B cells are critical antigen-presenting cells (246).

The idea that a Th1-dominant response is destructive, whereas a Th2-dominant response is protective to islet b cells, provides the basis for efforts to skew the T-cell response toward the Th2 phenotype. In support of this hypothesis, administration of IL-4 (255) or IL-10 (256) is associated with protection from diabetes in NOD mice, whereas systemic administration of Th1-type cytokines, IL-12 (257) and TNF-a (235), accelerates disease progression. However, studies of transgenic and knock-out NOD models involving these cytokines provided conflicting results and suggest that the Th1-Th2 paradigm for the development of type 1A diabetes is oversimplified. For example, NOD mice expressing an IL-4 transgene specifically in islet b cells are protected from diabetes, whereas IL-4 knock-out NOD mice do not develop diabetes at an accelerated rate. Treatment of NOD mice with anti–IFN-g prevents diabetes development in NOD mice (258), but NOD mice made genetically deficient in IFN-g continue to develop diabetes, albeit at a reduced rate (250). Furthermore, whereas NOD mice administered IL-10 are protected from diabetes (256), mice expressing an IL-10 transgene specifically in the islet b cells develop accelerated diabetes (189). Although the reasons for these differences are not yet clear, the foregoing observations suggest that the ability to dissect the role of individual cytokines may be difficult. There is significant redundancy in cytokine action, individual cytokines can affect the expression of other cytokines, and significant temporal differences may exist in the cytokine influence on the disease process.

FUTURE DIRECTIONS

Prediction

With current autoantibody assays, genetic typing and metabolic testing, it is relatively easy to identify persons with a risk of type 1A diabetes exceeding 90% in a given period. For example, relatives of a patient with type 1A diabetes expressing more than two of GAD65, ICA512, or antiinsulin autoantibodies and with first-phase insulin release below the tenth percentile and lacking DQB1*0602 have a high risk (144). Identifying a high-risk group of persons (e.g., a risk of 90% within 5 years) does not imply that the remaining 10% will not develop diabetes. It is much more likely that a significant proportion of the remaining persons will develop diabetes within 10 years. Similarly, a moderate-risk group (e.g., risk of approximately 50% within 5 years: more than autoantibodies, preserved first-phase insulin secretion, lacking DQB1*0602) does not mean that the remaining 50% will not develop diabetes. It is likely that the 50% of patients in this group who do not develop diabetes within 5 years and whose first-phase insulin secretion declines to less than the tenth percentile have a 90% risk of diabetes within the next 5 years.

Prevention

With accurate prediction, studies aimed at preventing or at least delaying the onset of diabetes are now being conducted worldwide. A few investigators are not participating in current trials (259).

IMMUNOSUPPRESSIVE THERAPY

The first major trial of general immunosuppressive therapy for newly diagnosed subjects evaluated cyclosporine (260,261). Cyclosporine suppressed antiinsulin autoantibodies but not cytoplasmic ICA and preserved C-peptide secretion. After discontinuation of cyclosporine, the preservation of C-peptide secretion was rapidly lost. Hyperglycemia recurred in patients who could discontinue insulin therapy even though cyclosporine therapy continued. The recurrence of hyperglycemia appeared to be metabolically mediated in a setting in which most b cells had been destroyed. The failure of immunosuppression to “cure” diabetes and to preserve C-peptide secretion after discontinuing the drug led to relatively little interest in generalized immunosuppression. The most efficacious drug, cyclosporine, required large doses, and it can be associated with both renal toxicity (apparently no permanent toxicity from follow-up of patients in these trials) and a significant risk of malignant disease with long-term therapy.

ADJUVANT THERAPY

Studies in the NOD mouse and BB rat models suggested that injection of either complete Freund's adjuvant or bacille Calmette-Guérin (BCG) prevents diabetes (262). The success of such therapy in the rodent models, however, has not been matched in human subjects. Several randomized trials of BCG treatment of newly diagnosed patients indicate that BCG is not effective in preserving C-peptide secretion or inducing remission of type 1A diabetes (263,264).

NICOTINAMIDE

Treatment with nicotinamide, a free radical scavenger, reduces the development of diabetes in NOD mice but not in BB rats. Its mechanism of action may relate to reduction of free radical-induced islet destruction or blockade of lymphokine-mediated islet destruction. A pilot trial of nicotinamide treatment in human patients was associated with a reported 50% delay in the development of diabetes (262). In the first population-based trial involving nicotinamide intervention, a large cohort of New Zealand schoolchildren were screened for expression of cytoplasmic islet cell antibodies, whereas a matched group of schoolchildren were not screened. ICA-positive children were then treated with nicotinamide and were compared with the nonscreened and nontreated children. Results from this trial suggested a 50% delay in progression to diabetes after an average 7-year follow-up. These nonrandomized trials were followed by two randomized trials of diabetes prevention among ICA-positive relatives. In the smaller “DENIS” trial in Germany, nicotinamide did not have any protective effect in a high-risk group of relatives, and the trial was terminated (approximately 25% of the treated and placebo group developed diabetes) (265). The larger European Nicotinamide Trial (ENDIT) is under way, with outcome data expected in the next few years.

ANTIGEN-SPECIFIC THERAPIES

Insulin is currently being used for antigen-specific therapy in human patients (266). Trial design and implementation followed the reports that insulin, given subcutaneously, intranasally, or orally could prevent diabetes of NOD mice. The mechanisms by which insulin-based immunotherapy protects are not fully defined. Hypotheses include downregulation of islet antigens by the metabolic activity of intact insulin, alteration of lymphocyte function by insulin binding to insulin receptors on lymphocytes, and induction of “regulatory” T cells capable of secreting “antiinflammatory” cytokines (IL-4, IL-10, transforming growth factor-b). Metabolically inactive insulin analogs or insulin B chain can also prevent diabetes (267,268). This indicates that the metabolic activity is not essential for prevention. Zhang and co-workers reported that oral administration of insulin delays the onset and reduces the incidence of diabetes in NOD mice (269). Bergerot et al. studied the mechanisms of protection by oral insulin treatment and reported that insulin-reactive $CD4^+$ T cells induced by oral treatment protect from diabetes by blocking Th1 cytokine secretion and migration of diabetogenic effector T cells to the pancreas (270). Small pilot trials of insulin therapy for diabetes prevention have been reported (271). In a trial from the Joslin and Barbara Davis Center, all eight nontreated persons developed diabetes within 3 years of follow-up. In contrast, three of nine relatives treated with intravenous and subcutaneous insulin remain nondiabetic, and six of nine remained nondiabetic for longer than 4 years, with one nondiabetic relative now followed for 10 years. In the group treated with subcutaneous insulin alone, six of eight persons remain nondiabetic, with the longest follow-up now at 6.6 years and six of eight followed for longer than 4 years.

The National Institutes of Health initiated a randomized trial of parenteral insulin therapy and a placebo controlled trial of oral insulin (the Diabetes Prevention Trial-1 or DPT-1) in 1994. The goal of DPT-1 is to determine whether insulin therapy can prevent or delay the development of disease in relatives at risk for type 1A diabetes. Entry criteria for DPT-1 include the expression of cytoplasmic ICA in relatives of patients, the absence of DQB1*0602, the loss of first-phase insulin secretion, and the expression of IAAs. More than 90,000 relatives throughout the United States have been screened for participation in the trial; 339 have been entered into the parenteral portion of the trial, and more than 223 (target 490) entered into the oral portion of the trial. First-degree relatives can be screened for the DPT-1 trial at centers throughout the United States and Canada (call 1-800-HALT-DM1).

Many adults have slowly progressive type 1A diabetes (3). A study from Japan suggests that insulin therapy may be of help in preserving C-peptide secretion in autoantibody-positive patients presenting with non–insulin-dependent diabetes (272).

It is likely that insulin peptides without the risk of hypoglycemia will be preferable to insulin for diabetes prevention. Muir and co-workers studied insulin B chain, and Daniel and Wegmann found that a single subcutaneous injection of the insulin B:9-23 peptide prevented 90% of diabetes in NOD mice (205). The company Neurocrine has developed an altered peptide ligand of B:9-23 peptide with alanines at position 16 and 19. Administration of this peptide prevents diabetes in NOD mice, and phase I clinical trials are under way. Additional phase I trials for prevention of diabetes with peptides or full-length protein are under way or are planned, such as heat shock

protein (Peptor) and glutamic acid decarboxylase (Diamyd).

CONCLUSION

Type 1A diabetes is highly predictable, has multiple animal models in which disease is preventable, and has reached the stage at which multiple trials of prevention in human patients are under way. Despite this progress, many fundamental questions remain unanswered. It is hoped that as preventive therapies are developed, an interplay between advances in fundamental knowledge and clinical trials will lead to effective therapies.

49 Autoimmune Thyroid Disease, Addison Disease, and Autoimmune Polyglandular Syndromes

Ramzi A. Ajjan, Ph.D., and Anthony P. Weetman, M.D., D.Sc.

Autoimmune endocrine diseases represent the prototypes of organ-specific autoimmune disease. This chapter reviews these endocrinopathies, which comprise autoimmune thyroid disease (ATD), Addison disease, premature ovarian failure, and autoimmune pituitary disease; often, these conditions are associated in autoimmune polyglandular syndromes. The predisposing factors, clinical presentation, and treatment are discussed briefly, whereas special attention is given to the immunopathology of these disorders. The key features of animal models of ATD and Addison disease are summarized.

AUTOIMMUNE HYPOTHYROIDISM

In 1912, Hashimoto identified a condition in which goiter developed in four women as a result of lymphoid infiltration (1). More than 40 years later, thyroid antibodies were identified in patients with a similar clinical presentation (2), and this goitrous form of chronic autoimmune thyroiditis is now known as *Hashimoto thyroiditis*. Some patients are euthyroid at presentation because their concerns resulted from the goiter. An atrophic form of ATD also exists and is referred to as *atrophic thyroiditis* or *primary myxedema*. These patients are identified because of hypothyroid features.

Epidemiology

Autoimmune hypothyroidism is a common disease that affects 1% of women but no more than 0.1% of men, generally between 40 and 60 years of age (3). As with other autoimmune diseases, susceptibility to autoimmune hypothyroidism is thought to be influenced by an interaction of genes and environment in addition to endogenous factors such as age and pregnancy.

GENETICS

Human leukocyte antigen (HLA) alleles have been studied extensively in autoimmune hypothyroidism (4), and an association of HLA-DR3, -DR4 and -DR5 with autoimmune hypothyroidism has been recognized in most studies of white subjects. Negative associations (HLA-DQB1), offering protection from the disease, also have been reported (4); however, variability between different ethnic groups has been noted, and in all cases, these associations have been rather weak with inconsistent linkage results, suggesting that HLA genes play only a minor role in the susceptibility to autoimmune hypothyroidism.

Non-HLA loci also have been studied, including polymorphisms of immunoglobulin and T-cell receptor (TCR) genes. Studies of immunoglobulin allotypes in patients with autoimmune hypothyroidism have produced conflicting results (5,6), and a recent comprehensive family study excluded any linkage between immunoglobulin (IgG) heavy chains, TCR polymorphism, and autoimmune hypothyroidism (7,8), and therefore these genes are unlikely to play a major role in the pathogenesis of the disease.

Currently, attention is focused on genes controlling other components of the immune system. Cytotoxic T-lymphocyte-associated molecule-4 (CTLA-4) is found on T-cell surface and binds the B7 family of receptors, thereby regulating T-cell activation. Although an association between polymorphisms of the CTLA-4 gene and autoimmune hypothyroidism in white patients has been documented (9), linkage was excluded recently (8), again indicating that CTLA-4 is not a major determinant of genetic susceptibility to autoimmune hypothyroidism.

Recent linkage studies suggested new susceptibility loci, in particular one locus on chromosome 13 (HT1; 96cM) was linked to Hashimoto thyroiditis with a maximum logarithm of odds (LOD) score (MLS) of 2.1. Another locus (HT-2, 97cM) showed linkage to Hashimoto thyroiditis in a subgroup of families with an MLS of 3.8 (10). Interestingly, only one locus (AITD-1) was found to confer susceptibility to both Graves disease and Hashimoto thyroiditis (MLS of 2.2), indicating that these two diseases are genetically heterogeneous.

ENVIRONMENT

Age probably plays an important role in susceptibility through increasing exposure to environmental agents, in addition to the changes in immunoregulation associated with aging (11). Furthermore, the possibility of cryptic antigen release, secondary to tissue damage (for example, from infection or ischemia), increases with aging and may be a factor in the development of autoimmune hypothyroidism.

Sex hormones are highly likely to be involved in the etiology of ATD in general, and hormone changes also may be responsible for the fact that pregnancy ameliorates the disease, with exacerbation of thyroiditis (or even *de novo* appearance of disease) occurring in the postpartum period (12). Moreover, estrogens exacerbate experimental autoimmune thyroiditis, whereas testosterone ameliorates it (13). In addition to sex hormones, prolactin may play a role because autoimmune thyroiditis is more common in women with hyperprolactinemia (14).

The involvement of infectious agents in the etiology of autoimmune diseases has always been an attractive concept, but their role in autoimmune hypothyroidism remains debatable (15). Epidemiologic data point to iodide as an important factor in enhancing thyroid autoimmunity (16). For example, a study demonstrated a correlation between high iodine intake and the development of autoimmune hypothyroidism (17). Furthermore, a high iodine diet exacerbates thyroiditis in animal models of autoimmune hypothyroidism, whereas a low iodine diet results in amelioration of the disease (18). The mechanism of these effects is unclear, but high concentrations of iodide are directly toxic to thyroid follicular cells (19), possibly leading to release of autoantigens. This toxicity may be mediated by the formation of highly reactive compounds with oxygen metabolites (20). Another possible explanation is the increased iodination of one of the major thyroid autoantigens,

thyroglobulin (TG), which may enhance its immunogenicity (21,22). In addition, iodide forms highly toxic species with oxygen metabolites (22), which could precipitate autoimmunity in a genetically predisposed person.

Exposure to sublethal radiation predisposes to thyroid autoimmunity (23), and lithium exacerbates autoimmune thyroiditis (24). Both probably mediate these effects by altering the function of regulatory T cells. Treatment with amiodarone can result in thyroid dysfunction, particularly in the presence of preexisting thyroid abnormalities. Thyroid dysfunction is due mainly to metabolic abnormalities arising from a disturbance of iodide organification or secondary to the high iodine load; however, direct toxic effects of the drug on thyroid follicular cells have been shown repeatedly but with only inconsistent evidence of autoimmune involvement (25).

Clinical Presentation

Symptoms and Signs

Table 49.1 summarizes the symptoms and signs of autoimmune hypothyroidism. The changes are usually subtle and insidious in onset and may be rather nonspecific, such as complaints of tiredness, lassitude, and weight gain. Although often the most severe symptoms occur in patients with the most severe hypothyroidism, the progression of thyroid failure over several years allows patients to adapt to their altered hormone status, leading to a paucity of complaints in some subjects who have obvious hypothyroidism. Patients are forgetful and may have psychological problems, ranging from mild depression to frank psychosis (*myxedema madness*). In severe cases, patients may present with myxedema coma, a life-threatening complication of hypothyroidism that necessitates urgent treatment.

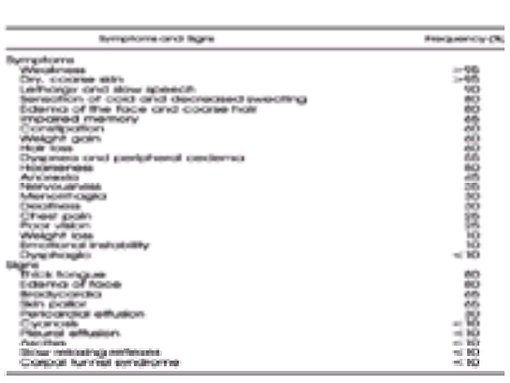

TABLE 49.1. Main Symptoms and Signs in Autoimmune Hypothyrodism

PHYSICAL FINDINGS

In obvious cases, the facial appearance (dull expression, facial puffiness, and periorbital swelling) together with a hoarse voice and slow speech will suggest the diagnosis. Yellowish skin resulting from hypercarotenemia, particularly notable on palms and soles, is not unusual, and slow relaxing reflexes may be present. Fluid accumulation in the middle ear may cause deafness, and there may be fluid accumulation in serous cavities.

LABORATORY TESTS

The diagnosis is usually established easily by finding a low thyroxine (T_4) and elevated thyroid stimulating hormone (TSH) levels. An elevated TSH with normal T_4 suggests subclinical hypothyroidism (Table 49.2), in which there is early evidence of thyroid damage. About 2% of such patients progress to overt thyroid failure annually, but the rate is 5% if the elevated TSH is accompanied by detectable thyroid antibodies in the serum. The autoimmune nature of hypothyroidism is confirmed by the presence of thyroid antibodies against TG or thyroid peroxidase (TPO) (Table 49.3). TSH-receptor (TSH-R) blocking antibodies can be detected in up to 20% of patients, but assay for these is not routinely performed (see later). Antibodies against the Na^+/I^- symporter (NIS) have been described in a minority of patients with autoimmune hypothyroidism (see later) but have no diagnostic value.

	Serum TSH	Serum free T4	Symptoms
Subclinical hypothyroidism	Elevated	Normal	Usually absent
Grade 1	Upper limit of reference range—10 mU/L	Normal	
Grade 2	10.1–20 mU/L	Normal	
Grade 3	>20 mU/L	Normal	
Clinical or overt hypothyroidism	Elevated	Low	Usually present

T4, thyroxine; TSH, thyroid-stimulating hormone.

TABLE 49.2. Definition of Hypothyroidism

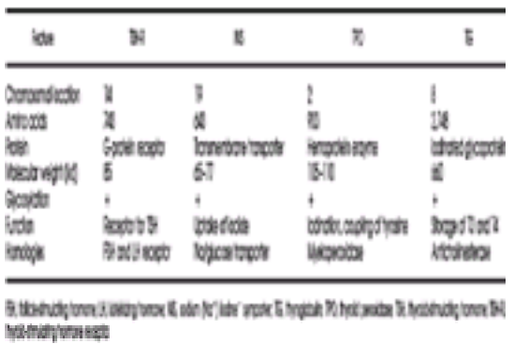

TABLE 49.3. Key Features of the Thyroid Autoantigens

A number of nonspecific laboratory abnormalities can be found in patients with autoimmune hypothyroidism, including raised cholesterol, creatinine phosphokinase, and lactate dehydrogenase levels. A normochromic, normocytic anemia is often present and a macrocytic anemia also can be found, which in some but not all cases is due to the association of pernicious anemia with autoimmune hypothyroidism.

TREATMENT

This is generally straightforward with replacement T_4. Synthetic preparations of thyroxine (L-thyroxine) provide optimal treatment. Triiodothyronine (T_3, liothyronine) has too short a half-life to provide replacement, even though it is the active metabolite of T_4. The place of combined T_3 and T_4 replacement is being reevaluated but is not generally necessary. The goal of T_4 replacement is to return TSH levels to normal. Myxedema coma is a medical emergency treated with intravenous T_4 or T_3 and

intensive supportive therapy, including ventilation.

PATHOLOGY

Hashimoto thyroiditis is characterized by a lymphocytic infiltrate with many plasma cells and the formation of germinal centers (Fig. 49.1); $CD4^+$ T cells predominate over $CD8^+$ T cells (26) The thyroid follicles are small and contain some macrophages, plasma cells, and occasional multinucleated giant cells. The epithelial cells are enlarged with a distinctive eosinophilic cytoplasm resulting from an increased number of mitochondria (Fig. 49.2). A variable amount of fibrosis can be identified. The primary myxedema variant shows extensive replacement by fibrous tissue and atrophy of the gland. Scattered islands of lymphoid cells and enlarged epithelial cells can be identified between areas of fibrosis. It is unclear whether this simply represents an end stage of Hashimoto thyroiditis, a variant of the fibrosis seen in Hashimoto thyroiditis, or a distinct pathologic entity.

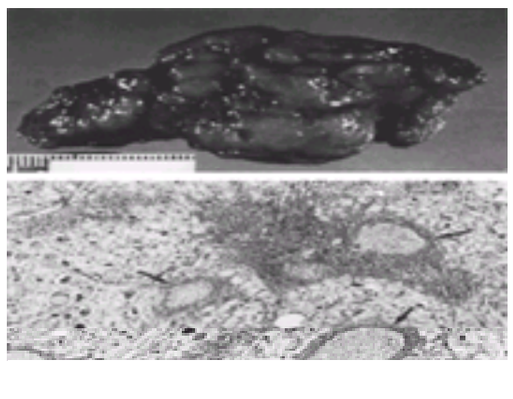

Figure 49.1. Pathology of Hashimoto thyroiditis. **Top:** Gross appearance of thyroid gland. The lobe of the gland is enlarged and has lobulated, freshly appearance. **Bottom:** Low-magnification photomicrograph showing prominent lymphoid infiltrate with multiple reactive germinal centers *(arrows)*. Many of the follicles are atrophic, and there is scanty colloid. (From Mendelsohn GF. Pathology of thyroid disease. In: Mendelsohn GF, ed. *Diagnosis and pathology of endocrine diseases.* Philadelphia: JB Lippincott, 1988:56, with permission.)

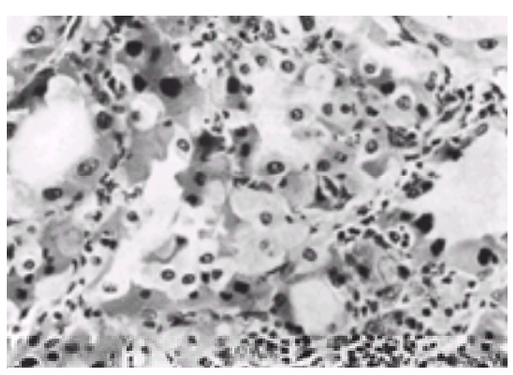

Figure 49.2. Typical Hürthle or Askanazy cells in Hashimoto thyroiditis. These are mitochondrion-rich, altered follicular cells that give an oxyphil staining pattern and indicate thyroid damage. These cells show a moderate degree of pleomorphism and cytologic atypia. A lymphoplasmacytic infiltrate can be seen in the lower right corner. (From Mendelsohn GF. Pathology of thyroid disease. In: Mendelsohn GF, ed. *Diagnosis and pathology of endocrine diseases.* Philadelphia: JB Lippincott, 1988:58, with permission.)

Immunopathology

The three major autoantigens in ATD are TSH-R, TPO, and TG (Table 49.3). Accumulating evidence indicates that the NIS is an autoantigen. TSH-R is a member of the G-protein-coupled receptor family (27). It is 764 amino acids long and comprises three extracellular loops that contain the amino terminus, seven transmembrane segments, and three intracellular loops, ending with a carboxyl terminus. The extracellular domain contains six potential glycosylation sites that are important for the correct function of the receptor. Stimulation of the receptor by TSH causes generation of cyclic adenosine monophosphate (cAMP), stimulating both growth and function of thyroid follicular cells. High concentrations of TSH also can stimulate the phosphatidyl-inositol (PI) cascade, but this pathway seems to have only a minor role in signal transduction in the thyroid (28).

Because iodine is an essential component of T_3 and T_4, its accumulation by the thyroid gland is of utmost importance. Although the thyroid proteins involved in hormonogenesis are now well characterized, relatively little is known about the NIS. The NIS gene in humans encodes a protein of 643 amino acids arranged in a structure with 12 probable transmembrane domains (29,30).

Previously known as the microsomal antigen, TPO is the primary enzyme involved in iodination of tyrosine residues and, in their coupling, to form thyroid hormones (31). It belongs to the family of mammalian peroxidases and has a high sequence homology with myeloperoxidase. In man, TPO is a membrane-associated protein of 933 amino acids with five potential glycosylation sites. An alternatively spliced variant of TPO mRNA giving a 57-residue smaller protein (876 amino acids) has been described and termed TPO-2. TPO-2 usually coexists in the thyroid with the full-length TPO of 933 amino acids (TPO-1). TPO-2 lacks enzymatic activity and is believed to have a different conformation to TPO-1 and hence different antibody reactivity (32). The importance of this observation in relation to ATD is unclear at present. TPO-2 may be expressed earlier than TPO-1 during the embryonic stage of thyroid development, and therefore immunologic tolerance could occur to TPO-2, but not TPO-1, in some persons (33).

Thyroglobulin serves as the precursor and storage form of thyroid hormones and is the major intrathyroidal store of organified iodide. It consists of two monomers of 2,750 amino acids extensively disulfide-linked to form a globular homodimer. TG is secreted primarily into the thyroid follicles, although small amounts gain access to the circulation. In response to demand, TG is endocytosed by the thyroid follicular cells and hydrolyzed, liberating T_3 and T_4 into the circulation. Although some studies suggested an abnormal TG structure in patients with autoimmune hypothyroidism, others failed to confirm these findings (34,35), and in animal models, altered TG structure is not responsible for the induction of autoimmune thyroiditis (36), making a role for TG mutations in the pathogenesis of autoimmune hypothyroidism unlikely. The degree of iodination of TG correlates with its immunogenicity in experimental models of ATD (37), and antibody epitope recognition is highly dependent on the iodination state of the molecule (20,21).

HUMORAL RESPONSES

Patients with autoimmune hypothyroidism almost always have serum antibodies (Ab) to TG and TPO (Fig. 49.3) and less commonly to NIS and TSH-R. Low titers of TG Ab can be found in normal individuals (especially in elderly patients or following viral infections) (3,11), and these antibodies are usually of the immunoglobulin M (IgM) or IgG class. In contrast, patients with autoimmune hypothyroidism have high titers of TG Ab with high affinity, and they are mainly of the IgG class (13). TG Abs are predominantly IgG_1 and IgG_4, although all four subclasses are typically present, with IgG_2 showing the highest functional activity (38). TG Abs are relatively restricted to two major and one minor epitope on each subunit, but many minor epitopes are recognized by TG Abs as titers rise (39). In some patients, there is restricted heavy-chain variable (V) region gene use, with only a moderate restriction of light chains (40).

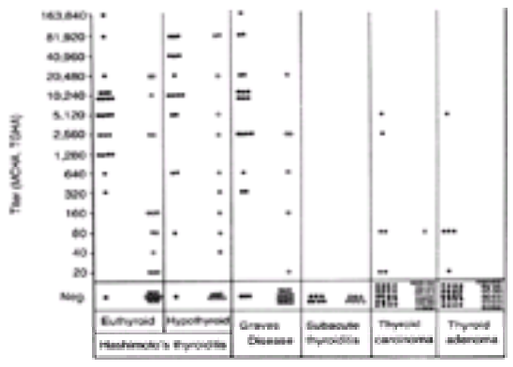

Figure 49.3. Titers of thyroid microsomal hemagglutination antibodies (MCHA, *closed circles*) and thyroglobulin hemagglutination antibodies (TGHA, *open circles*) in patients with various thyroid diseases. (Modified from Amino N. Measurement of circulating thyroid microsomal antibodies by the tanned RBC hemagglutination technique: its usefulness in the diagnosis of autoimmune thyroid disease. *Clin Endocrinol* 1976;5:115, with permission.)

The detection of TG Ab in apparently normal individuals, together with the inability of TG Ab to fix complement (probably because of wide separation of epitopes on the TG molecule preventing IgG cross-linking) casts some doubt on their importance in ATD. TGAb can mediate antibody-dependent cell-mediated cytotoxicity (ADCC) *in vitro* (41), however, and a catalytic role for TG Ab also has been described (42), which could be important in liberating cryptic epitopes for T-cell recognition.

In about 5% to 10% of clinically normal persons, TPO Abs also are detected; the exact figure depends on assay sensitivity. As with TG Ab, IgG_1 and IgG_4 subclasses predominate in TPO Ab (38); although a clear restriction in light chains is not evident, a predominance of light-chain use has been observed in most patients (43). TPO Abs from patients with Graves disease and Hashimoto thyroiditis exhibit similarity in sequences and reactivities to native TPO, indicating a similar antibody response in both types of ATD (44). Conformational TPO Abs in ATD sera are restricted mainly to two closely spaced overlapping epitopes on TPO (45,46). Antibodies in ATD sera occasionally also react with linear TPO epitopes (47), but their significance in ATD pathogenesis is difficult to ascertain. The assumption is that these antibodies arise at a late stage in disease. TPO Abs are able to mediate ADCC, and unlike TG Ab they can also fix complement. The ability of TPO Ab to cause enzymatic inhibition *in vitro* indicates a potential direct role for these antibodies, but it seems most unlikely that TPO inhibition by antibodies occurs at any significant extent *in vivo* (48).

Bispecific Abs interacting with both TG and TPO have been termed TGPO Abs. These Abs are present in sera with high TGAb and TPOAb titers, and they are more frequently detected in patients with Hashimoto thyroiditis than in patients with other ATD (49). Their role in the pathogenesis remains to be resolved, but their existence may help to explain why TG and TPO antibodies frequently coexist.

Several types of Abs to TSH-R have been identified. Thyroid-stimulating antibodies (TS Abs) are dominant in patients with Graves disease, whereas thyroid-blocking antibodies (TB Abs), which prevent TSH-mediated signaling, are found mainly in patients with Hashimoto thyroiditis or primary myxedema. A minority of patients with autoimmune hypothyroidism and patients with Graves disease have reactivity to TS Abs and TB Abs, respectively. Whereas assays for TS Ab and TB Ab measure functional activity, usually in terms of cAMP production by thyroid cells *in vitro*, assays for TSH-binding inhibiting immunoglobulins (TBIIs) measure binding to the receptor (via displacement of radiolabeled TSH) and hence detect the broad range of TSH-R antibodies. TBIIs are present in both Graves disease and autoimmune hypothyroidism, but levels of TBII do not correlate with TS Ab or TB Ab activities; the latter two activities can be determined only by bioassay (27). It is worth noting that Graves disease can develop in patients who have hypothyroidism (and vice versa), and this appears to be related to the balance between TB Abs and TS Abs. The existence of TB Ab was first demonstrated by the development of transient neonatal hypothyroidism secondary to transplacental transfer of these antibodies (50), but subsequent studies showed the association of TB Abs with autoimmune hypothyroidism in Japanese, Korean, and white patients (36). The existence of autoantibodies that increase or inhibit thyroid follicular cell growth independently of the TSH-R (51), potentially resulting in goiter formation or thyroid atrophy respectively, remains debatable.

Numerous studies recently demonstrated the presence of antibodies in Hashimoto thyroiditis patient sera that bind to the rat NIS peptides and recombinant protein (52,53), and antibodies that bind the human symporter have been detected in 24% of autoimmune hypothyroidism sera (54). These antibodies inhibit the function of the rat and human NIS (54,55) and this may have important clinical implications. NIS-inhibitory antibodies could contribute to hypothyroidism in the initial phases of the disease before widespread tissue destruction takes place.

CELLULAR IMMUNITY

T cells play a critical role in the development of autoimmune hypothyroidism. These cells migrate from the periphery to the thyroid gland, where they interact with thyroid follicular cells and extracellular matrix. Many studies found a reduction in the proportion of circulating $CD8^+$ T cells in autoimmune hypothyroidism, and the concept of an antigen-specific T-suppressor cell defect as a factor in the development of autoimmune hypothyroidism has attracted considerable debate (56). Defects in the putative T-suppressor cell response to TPO and TG (but not to irrelevant antigens) have been demonstrated in autoimmune hypothyroidism, but these assays have not been reproducible or physiologic (57), and therefore the role of suppressor cells in the pathogenesis of autoimmune hypothyroidism remains unclear.

Restricted use of TCR by intrathyroidal T cells has been the focus of several studies. If T-cell autoreactivity is clonally limited, this would permit the application of novel therapeutic approaches based on inactivation of selected subpopulations of T cells. Marked restriction in TCR Va gene use by intrathyroidal T cells in ATD (58) has not been confirmed even after analyzing interleukin-2 (IL-2) receptor positive T cells (59,60). Using cell-fractionation studies, Va restriction in the intrathyroidal $CD8^+$ T cells from three Hashimoto thyroiditis patients has been observed, suggesting a role for clonally restricted T-cell-mediated cytotoxicity in Hashimoto thyroiditis (61).

T cells may destroy thyroid follicular cells in Hashimoto thyroiditis and primary myxedema by direct cytotoxicity or indirectly via cytokine secretion. The presence of perforin in Hashimoto thyroiditis-derived $CD8^+$ T cells indicates that these cells are activated *in situ* (62). Furthermore, $CD8^+$ cytotoxic T-cell clones, capable of killing autologous thyroid follicular cells in an HLA class I-restricted fashion, have been raised from Hashimoto thyroiditis patients, but T-cell stimulation in culture by IL-2 favors the expansion of nonspecific natural killer (NK) cells, rendering the study of thyroid-specific $CD8^+$ cells difficult and often inconclusive (63,64).

The involvement of apoptosis in causing tissue destruction in autoimmune hypothyroidism has been suggested by the high frequency of apoptotic thyroid follicular cells in thyroid tissue from patients with Hashimoto thyroiditis (65). An increased expression of Fas by thyroid follicular cells from Hashimoto thyroiditis tissue has been shown (66,67), and this may increase the chance of Fas interacting with its ligand (FasL), for example, on T cells, to trigger thyroid cell apoptosis. *In vitro* studies have shown that Fas expression by thyroid follicular cells is upregulated by cytokines and inhibited by TSH (67). This may explain why apoptosis is uncommon in Graves disease as a result of the protective effects of TS Abs (mimicking TSH action) on Fas expression. FasL expression also has been detected on thyroid cells from Hashimoto thyroiditis thyroid (67), which may provide a protective mechanism against apoptosis, by eliminating Fas^+ autoaggressive T cells. On the other hand, the coexpression of Fas and FasL by thyroid cells may result in these cells killing each another or even committing suicide (67). The massive apoptosis that would occur in such a case is not seen *in vivo*, casting doubts about the relevance of this hypothesis, and there is considerable debate over the specificity of thyroid cell staining for FasL (67). Iodide excess can also induce thyroid cell apoptosis through a p53-independent pathway (68).

Cytokines produced by the infiltrating T cells in Hashimoto thyroiditis have diverse effects on thyroid follicular cells. Cytokines may modulate thyroid cell growth and function and can alter the immunologic properties of these cells, for instance, by inducing HLA class II and adhesion molecule expression (69). *In vitro* studies showed that Hashimoto thyroiditis-derived T cells have a high potential for tumor necrosis factor-a (TNF-a) and interferon-(IFNg) but not IL-4 production (69), consistent with a T-helper cell (Th1) pattern of cytokine production in this condition, capable of mediating delayed-type hypersensitivity and cytotoxicity. Because thyroid antibodies can be detected in almost all patients with autoimmune hypothyroidism, a Th2 response is clearly also important in disease pathogenesis, and some Hashimoto thyroiditis-derived $CD4^+$ T clones produce a mixed Th1/Th2 cytokine pattern (70).

The reverse transcription-polymerase chain reaction (RT-PCR) technique demonstrated IL-1, IL-2, IL-4, IL-6, IL-8, IL-10, IFNg, and TNF-a mRNA in Hashimoto thyroiditis thyroid tissue samples (71,72), but a quantitative RT-PCR showed the predominance of a Th1 response (73). By applying cell fractionation techniques to Hashimoto thyroiditis-derived thyroidal lymphocytes, mRNA for all these cytokines has been detected in infiltrating $CD4^+$ and $CD8^+$ T cells, except for IL-1 (72). Besides the infiltrating inflammatory cells, thyroid follicular cells have been shown to produce a number of cytokines *in vitro*, including IL-1, IL-6, IL-8, IL-12, IL-13, IL-15, and TNF-b and transforming growth factor-b (TGF-b), suggesting an interplay between cytokine production by these cells and infiltrating lymphocytes in the autoimmune process (69) (Fig. 49.4).

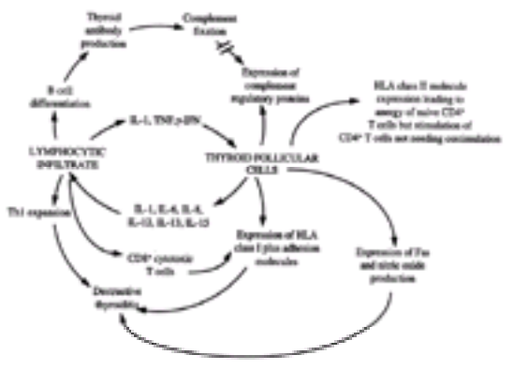

Figure 49.4. Interaction of cytokines and other factors with thyroid cells in the pathogenesis of autoimmune thyroid disease. (From Weetman AP, Ajjan R, Watson PF. Cytokines and Graves' disease. *Baillieres Clin Endocrinol Metab* 1997;11:418, with permission.)

Further evidence for a critical role of cytokines in ATD comes from observations following experimental or therapeutic administration of cytokines. Animals with experimental autoimmune thyroiditis (EAT) induced by immunization with thyroid antigen plus adjuvant develop a disorder similar to Hashimoto thyroiditis in humans, characterized by lymphocytic infiltration of the thyroid gland (see later). IL-1b administration accelerates the onset of thyroiditis in this model of EAT and blocks the induction of tolerance by TG treatment (74,75). A mild thyroiditis, but not hypothyroidism, can be induced by IFN-g administration to normal mice (76), whereas anti-IFN-g antibody treatment reduces disease severity in EAT (77). In humans, IFN-a treatment for malignancy or chronic hepatitis is associated with impairment of thyroid function, ranging from the appearance of thyroid autoantibodies alone to the development of frank thyroid dysfunction (78). The frequency of thyroid dysfunction after IFN-a treatment ranges from 2.5% to 40%, with most patients developing hypothyroidism and a minority hyperthyroidism. A study on euthyroid patients treated with IL-2 alone documented the development of thyroid dysfunction, including both hypothyroidism and hyperthyroidism, in 41% of patients (79,80). It should be noted that these studies were conducted on patients already suffering from serious diseases, and the effects of exogenous cytokine administration on thyroid function in the normal population remains unknown.

Peripheral and intrathyroidal T-cell responses to thyroid antigens have been analyzed *in vitro* and epitope mapping carried out using overlapping peptides. Because TG generates only a weak proliferative response in AITD-derived T cells, attention has focused on TPO and TSH-R, the latter considered in detail in the section on Graves disease that follows. T-cell proliferation in response to TPO epitopes is heterogeneous both within and between patients (81,82 and 83), and this makes therapeutic intervention with modified TPO peptides unrealizable. The immunodominant T-cell epitopes on TPO are predominantly, although not exclusively, located on amino acid residue 100 through 119 and 625 through 644 in patients with Hashimoto thyroiditis (84). The diversity of T-cell responses to TPO peptides presumably is due to determinant spreading whereby diversification of the immune response to antigenic epitopes occurs as disease progresses (85).

IMMUNE-MEDIATED TISSUE DESTRUCTION

Cellular events leading to tissue destruction as well as thyroid cell dysfunction have been considered already. Antibodies to thyroid antigens exacerbate but do not initiate this process. Deposition of early components of complement was identified in the thyroid of Hashimoto thyroiditis patients and elevated levels of thyroidal and circulating terminal complement complexes are found in ATD (36). The contribution of complement activation to thyroid cell destruction is limited by the expression of a number of membrane attack complex regulatory proteins expressed on thyroid cells, most importantly CD59 (86). Sublethal complement attack can impair thyrocyte function, for instance, resulting in suppression of the cAMP response to TSH (87). Also, complement-attacked thyroid cells release a range of proinflammatory molecules, including reactive oxygen metabolites, prostaglandin (PG)-E_2, IL-1, and IL-6 (88); thus, the complement system could play an important role in tissue damage in ATD indirectly by mediating the release of a variety of inflammatory mediators.

Antibody-dependent cellular cytotoxicity is mediated by the interaction of NK cells with the Fc portion of the antibodies that are, in turn, attached to thyroid follicular cells, resulting in cell lysis. Initially, antibodies that mediate ADCC were detectable in Hashimoto thyroiditis but not in Graves disease (89), and an inconsistent correlation between anti-TPO titers and cell lysis has been reported (90). Although a unique antibody, not reactive with TPO, has been proposed to account for the detection of ADCC activity in Hashimoto thyroiditis but not Graves disease sera (90), it now seems clear that TPO antibodies in any type of ATD sera, including Graves disease, mediate the bulk of ADCC activity (91).

IMMUNOPATHOGENESIS OF DISEASE

The main factors involved in the immune pathogenesis of autoimmune hypothyroidism are T-cell-mediated cytotoxicity directed against thyroid cells, including thyroid cell apoptosis and thyroid cell dysfunction, particularly that from cytokines. Antibodies play a secondary role except in a small proportion of patients with TB Abs. The role of thyroid cells may be critical in these processes. ATD-derived thyroid follicular cells show increased expression of HLA class I and II molecules, which is regulated by cytokines, most importantly IFN-g (92). Class II-expressing thyroid cells may enhance the activation and proliferation of certain autoreactive lymphocytes, but the inability of thyroid cells to express costimulatory signals, necessary for naive T-cell activation, may also render these latter cells anergic and thus induce peripheral tolerance (93). Class II-expressing thyroid cells may perpetuate ATD after autoimmunity is firmly established and B7 dependence is no longer important for continued T-cell responses.

Thyroid cells also express a number of adhesion molecules, such as intercellular adhesion molecule (ICAM-1) and lymphocyte function antigen-3 (LFA-3) (69), which have a central role in disease pathogenesis through leukocyte activation and localization to the inflammatory sites. Cytokine-mediated modulation of such adhesion molecule expression in the thyroid could be crucial to the perpetuation, if not initiation, of the disease. Furthermore, the ability of thyroid cells to produce cytokines and nitric oxide (94) emphasizes the potential role of these cells in augmenting the inflammatory process. In addition to these proinflammatory effects, thyroid follicular cells express complement-activation regulatory proteins, enhancing resistance to complement-mediated cell lysis. The possible effector mechanisms operating on thyroid follicular cells in ATD are summarized in Fig. 49.5.

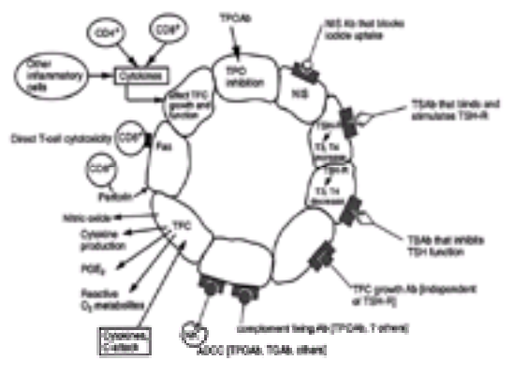

Figure 49.5. Mechanisms underlying thyroid cell destruction and dysfunction in autoimmune thyroid disease. Ab, antibody; ADCC, antibody-dependent cell-mediated cytotoxicity; C-attack, complement attack; NIS, Na^+/I^- symporter; T_3, triiodothyronine; T_4, thyroxine; TBAB, thyroid blocking antibody; TFC, thyroid follicular cells; TG, thyroglobulin; TPO, thyroid peroxidase; TSAB, thyroid-stimulating antibody; TSH, thyroid stimulating hormone; TSH-R, TSH receptor.

Animal Models

In some animal models, EAT occurs either spontaneously or is immunologically induced. The Buffalo and Bio-Breeding (BB) strains of rats, the nonobese diabetic (NOD) mouse, and the obese strain (OS) of chicken develop spontaneous autoimmune thyroiditis (95,96). The incidence of thyroiditis in Buffalo rats does not exceed 25%; however, this can be enhanced by immunologic modulation (i.e., neonatal thymectomy) and toxin administration (3-methylcholanthrene). A higher incidence of spontaneous thyroiditis in seen in BB rats, which is usually, but not necessarily, associated with diabetes in these animals. The animal model closest to Hashimoto thyroiditis remains the OS chicken (96). These birds develop severe thyroiditis with overt hypothyroidism requiring T_4 supplementation to thrive. Thymectomy at birth

prevents thyroiditis, indicating that the disease is T cell dependent. All the above models develop TG antibodies, but TPO reactivity is generally absent. MRL-*lpr/lpr* mice develop thyroiditis with both TG and TPO antibodies as well as a lupuslike syndrome (97).

Thyroiditis can be induced in monkeys, rabbits, guinea pigs, rats, and mice by immunization with TG in complete Freund's or other types of adjuvant or even by TG alone (98). The strength of the thyroid autoimmune response is influenced by class II and, to a lesser extent, class I genes. Nonmajor histocompatibility complex (MHC) genes, such as those encoding immunoglobulin heavy chains, also can play a role in the susceptibility of the disease in rats and mice (99). Disease can be transferred by T cells but inconsistently or not at all by TG antibodies, showing that TG antibodies are not directly involved in the pathogenesis of the disease (100). The importance of T cells to pathogenesis is further demonstrated by the development of thyroiditis after neonatal thymectomy (with or without irradiation) in genetically susceptible strains of mice and rats, presumably due to failure of central tolerance or the generation of immunoregulatory T cells (101). Treatment of neonatal mice with cyclosporin A also can induce thyroiditis (102). The development of thyroiditis in these animals can be prevented if they are kept in pathogen-free conditions; disease then can be induced by the transfer of normal gut flora (103), emphasizing the importance of environmental factors in development of the disease.

Future Directions

Although treatment of autoimmune hypothyroidism is relatively simple, it is not curative. Establishing the exact pathogenic mechanisms that result in autoimmune hypothyroidism may allow the development of new therapeutic strategies that offer a cure, not only for autoimmune hypothyroidism but also for other organ-specific autoimmune disease. It is well accepted now that numerous genetic and environmental factors are important in the susceptibility to autoimmune hypothyroidism. The exact contribution of each and the pattern of combination that leads to the emergence of the disease remain largely unknown. The recent development of automated linkage analysis should allow a precise identification of the genes that are directly involved in disease pathogenesis.

T cells play a central role in the pathogenesis of autoimmune hypothyroidism. Most studies found a polyclonal T-cell response to thyroid antigens, probably because study of these cells was performed when the disease is well advanced and earlier epitope-specific T-cell responses are lost. If the genetic basis of the disease is established in the future, it should be possible to predict the development of the disease, allowing study of the evolution of T-cell autoreactivity. More work is also needed to establish the exact role of thyroid antibodies in disease pathogenesis. The investigation of the role of NIS antibodies is of particular interest. These antibodies have been shown to inhibit the symporter function *in vitro*, potentially resulting in clinical hypothyroidism even before tissue destruction becomes evident.

Postpartum Thyroiditis

Transient thyroid dysfunction during the year after childbirth is termed *postpartum thyroiditis* (PPT). The population prevalence is around 5%, although this figure includes many patients diagnosed during surveys of biochemical changes postpartum; clinically apparent disease is much less common. The pathology resembles that of Hashimoto thyroiditis or primary myxedema. PPT starts usually with a thyrotoxic phase 2 to 3 months postpartum, followed by a hypothyroid phase at 5 to 6 months. The thyrotoxic or hypothyroid phase can occur alone. After a euthyroid interval, up to a quarter of patients become hypothyroid 3 to 4 years after onset of postpartum thyroiditis (12,104), indicating that this disease represents an early manifestation of autoimmune hypothyroidism.

The usual feature of this disorder is a postpartum rise in TPO Abs; occasionally, TG Abs accompany TPO Abs, and rarely they represent the only marker of the disease. The presence of TPO Abs antepartum can serve as a predictive marker of the disease because it has been shown that 50% to 75% of TPO Ab-positive pregnant women will develop PPT (105).

The complement system is activated in postpartum thyroiditis PPT, and this activation is related to the extent of thyroiditis and correlates with the severity of thyroid dysfunction (106,107). Therefore, TPO Abs may play an important role in this disease through their complement-fixing properties, but the occurrence of PPT in the absence of TPO Abs in some women suggests that T-cell-mediated events are at least as important. In keeping with this, PPT is associated with an elevated ratio of $CD4^+$:$CD8^+$ circulating T cells, both during pregnancy and in the postpartum period, and an increase in the circulating $CD45RA^+$ lymphocyte subset has been found in pregnant women who subsequently developed PPT (108).

GRAVES DISEASE

Although Caleb Parry first described a case suggestive of Graves disease and its associated eye signs, it was not until 10 years later that Robert Graves identified the disease in 1835. An autoimmune basis of the disease was subsequently revealed by the discovery of a long-acting thyroid stimulator (24), now known as the thyroid-stimulating antibody (27). This antibody binds the TSH-R, mimicking the effects of TSH and resulting in hyperthyroidism. More than 90% of patients with Graves disease have thyroid-associated ophthalmopathy (TAO), which can be detected using a number of scanning techniques. Clinically apparent TAO is evident in about 50% of patients with Graves disease. Thyroid dermopathy is found only in a minority of patients with Graves disease (1%–5%), and this usually occurs in the presence of severe TAO.

Epidemiology

Hyperthyroidism affects up to 2% of women and 0.2% of men, with a peak age of onset in the fifth decade of life (3). About 80% of hyperthyroid patients have Graves disease.

GENETICS

Recent data suggest that the role of genetic factors in the susceptibility to Graves disease is less than previously thought (109,110). There is only a 22% concordance in monozygotic twins and 0% in dizygotic twins (111). The risk in HLA-identical siblings is generally less than 10% (112), indicating that HLA has a modest genetic effect on disease pathogenesis. A detailed review of HLA associations with Graves disease can be found elsewhere (9,113), and only key features are summarized here. An association of HLA-DR3 with Graves disease has been recognized in most studies of white subjects, with a relative risk of 2 to 3. Studies of white populations have described HLA-DQA1*0501 as an important risk factor in Graves disease over and above that of HLA-DR3, with which there is linkage disequilibrium (114). In contrast, inheritance of HLA-DRB1*07 appears to be protective (115). As with autoimmune hypothyroidism, the association of Graves disease with polymorphisms of immunoglobulin or TCR genes has been conflicting, but, on balance, there are no firm data to indicate a true association (5,6 and 7,116). Association between Graves disease and TSH-R polymorphisms has been inconclusive, and association with TNF polymorphisms have not been reproducible (111). In contrast, an association between polymorphisms of the CTLA-4 gene and Graves disease has been repeatedly shown (9,117,118). Furthermore, the inheritance of thyroid autoantibodies has been recognized, suggesting that immunoglobulin genes may play a role in the susceptibility to the disease (119).

Linkage studies showed that Graves disease is linked to a locus on chromosome 14 (GD-1; 99cM) and chromosome 20 (GD-2; 56cM), with an MLS of 2.5 and 3.5, respectively, and, in addition, a locus on the X chromosome has been linked (GD-3; 114 cM) with an MLS of 2.5 (10). This latter finding poses the question of whether the X-inactivation mosaic is involved in disease pathogenesis (120).

ENVIRONMENT

As in autoimmune hypothyroidism, Graves disease affects mainly women, indicating a role for sex hormones in disease pathogenesis. Iodine intake exacerbates thyroid autoimmunity in general (13), and increased iodine intake can precipitate Graves disease by the synthesis of excess thyroid hormones (the Jod–Basedow phenomenon).

Some patients with Graves disease have antibodies to *Yersinia* antigens, proposed to be attributable to TSH-R cross-reactivity (121). Most patients with *Yersinia* infection, however, do not develop Graves disease, and the role of this organism in the pathogenesis of Graves disease is still controversial. Retroviral sequences have been detected in both the thyroid and peripheral blood mononuclear cells of patients with Graves disease (122), but others subsequently failed to confirm these findings (123). Thyroid biopsies from Graves disease patients showed reactivity to human foamy virus antibodies (124,125), but again this could not be repeated (126). Although these data are interesting, such viruslike particles also have been detected in normal thyroids and other tissues, and therefore a role in the development of Graves disease is unlikely.

Stress appears to be an important factor in the development of Graves disease (127), but the evidence is indirect because studies are retrospective and unfavorable life events could be a consequence rather than a cause of the disease. Disease-independent life events are more frequent than disease-dependent life events in patients with Graves disease, however, implying a real effect of stress (128). Stress causes a wide array of neuroendocrine changes that may alter the immune response through loss of suppressor cell function, T-helper cell subset imbalance, and defective clonal inactivation of self-reactive, immature B-lymphocytes.

Clinical Presentation

SYMPTOMS AND SIGNS

The common symptoms and signs of Graves disease are summarized in Table 49.4. Many symptoms are similar to those of adrenergic excess. The clinical presentation of the disease may be dramatic or subtle. In its extreme form, namely thyroid storm, it may manifest with atypical symptoms, including fever, cardiovascular collapse, confusion, psychosis, severe weakness, or even coma. This is a life-threatening emergency that requires urgent medical treatment. On the other hand, Graves disease may manifest atypically, particularly in elderly patients, with apathetic hyperthyroidism that can be confused with depression.

Symptoms	Frequency (%)
Symptoms	
Nervousness, irritability	>95
Increased perspiration	90
Change in temperature preference	90
Palpitations and dyspnea	90
Fatigue and weakness	90
Increased frequency of stools	80
Weight loss with increased appetite	78
Symptoms of TAO	50
Insomnia	30
Pruritis	20
Menstrual irregularities	20
Increased pigmentation or vitiligo	<5
Signs	
Hyperkinetic behavior, thought, and speech	>95
Tachycardia or atrial fibrillation	>95
Restlessness, hoarseness	>95
Goiter	90
Fine, warm, moist skin	90
Thrill and bruit	70
Signs of TAO	50
Thinning of hair and loss of curl	50
Hyperreflexia	50
Tachypnea on exertion	30
Pretibial myxedema	5
Onycholysis and clubbing	<5
Lymphadenopathy	<5
Splenomegaly	<5
Hyperpigmentation or vitiligo	<5

TAO, thyroid-associated ophthalmopathy.

TABLE 49.4. Symptoms and Signs of Graves Disease

PHYSICAL FINDINGS

A diffuse goiter of variable size can be found in most patients. The presence of TAO with hyperthyroidism is diagnostic of Graves disease. The most common signs of TAO are lid retraction or lag and periorbital edema (Table 49.5.) Exophthalmos can be demonstrated in about one third of patients, whereas diplopia and visual field loss resulting from optic nerve compression are unusual. Thyroid dermopathy occurs in fewer than 5% of patients and almost always in the presence of TAO. It is found most frequently over the anterolateral aspects of the shin but can occur anywhere in the body, especially at sites of trauma.

Symptoms
Irritation of the eye or pain in the globe
Limitation of movement of the eyeballs, especially upward
Diplopia
Blurred vision due to inadequate convergence and accommodation
Decreased visual acuity due to papilledema, retinal edema, retinal hemor
images or optic nerve damage
Signs
Lid reaction and lag
Wide palpebral opening
Periorbital swelling and puffiness of the lids
Staring or frightened expression
Infrequent blinking
Absence of forehead wrinkling on upward gaze
Inability to keep the eyeballs converged
Chemosis, corneal injection, or ulceration
Visible and palpable enlargement of the lacrimal glands
Visible swelling of lateral rectus muscles as they insert into the globe and
injection of the overlying vessels
Exophthalmos

TABLE 49.5. Symptoms and Signs of Thyroid-Associated Ophthalmopathy

DIAGNOSTIC STUDIES

The diagnosis of primary hyperthyroidism biochemically relies on demonstrating high T_4 levels with undetectable TSH levels. Because T_4 levels may be normal in the early phases of the disease, T_3 measurement should be carried out if TSH is suppressed with normal T_4.

Radionuclide scans with ^{123}I, ^{131}I, or ^{99m}Tc are helpful in difficult cases (e.g., without TAO), showing a diffuse goiter typical of Graves disease. The detection of TPO antibodies (positive in 80% of Graves' disease patients) further aids the diagnosis. The measurement of TS Ab is not done in many centers, but as assays improve and become less expensive, they will become the test of choice for diagnosis.

Usually, TAO is diagnosed clinically, but computed tomography or magnetic resonance imaging is indicated in cases of uncertainty or to rule out other pathologies, such as a retroocular mass or arteriovenous malformation. Several methods, such as octreotide scanning, were developed to assess orbital disease activity, which may help in selecting patients for immunosuppressive treatment, but further evaluation still will be necessary.

PATHOLOGY

The thyroid gland is diffusely enlarged from twice to several times normal size. Thyroid follicles show marked epithelial hypertrophy and hyperplasia (Fig. 49.6). Blood vessels are large and congested. A variable degree of lymphoid infiltration of the gland with both T and B cells is usually seen. The formation of germinal centers is not uncommon, whereas fibrosis is unusual (26). These changes reverse with antithyroid drug treatment.

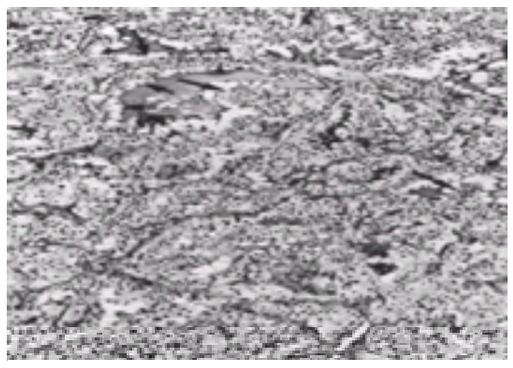

Figure 49.6. Histology of Graves disease. The thyroid is markedly hyperplastic. The follicular cells are tall, cuboidal to columnar, with pale cytoplasm. Colloid is depleted and shows a moth-eaten appearance where present *(short arrows)*. Papillary projections in the follicles are noted (*long arrows*). (From Mendelsohn GF. Pathology of thyroid disease. In: Mendelsohn GF, ed. *Diagnosis and pathology of endocrine diseases.* Philadelphia: JB Lippincott, 1988:65, with permission.)

Treatment

Reversal of the autoimmune process in Graves disease, thereby restoring thyroid function, would be the ideal treatment of the disease; however, this is not an option at present. Current treatment of the disease consists of antithyroid drugs, radioiodine, or surgery.

ANTITHYROID DRUGS

These drugs can be given either as reducing doses (*titration regimen*) or as a high dose with the combination of T_4 (*block-and-replace regimen*). The former usually is not applied for more than 24 months, whereas in the latter, treatment is limited to 6 months. Long-term remission is achieved in up to 50% of patients. The drugs not only inhibit TPO activity, thereby lowering T_3 and T_4 levels, but also alter the autoimmune response and lower TS Ab levels, which explains this remission. The mechanisms are discussed subsequently here. The most serious, albeit rare, complication of these drugs is agranulocytosis. Hepatotoxicity that may continue despite stopping the drug is rare but life threatening. Antithyroid medications may cause thrombocytopenia and lupuslike syndromes. Less serious side effects include urticaria, arthralgia, and gastrointestinal symptoms (129).

RADIOIODINE (^{131}I) THERAPY

This is an increasingly popular first-line treatment for Graves disease. Contraindications are pregnancy and breastfeeding, and caution is required in TAO as ^{131}I may worsen eye signs. Early fears of an increase in malignancies after radioiodine treatment is unfounded (130); however, a minimal increase in death rates from thyroid cancer and other individual malignancies after radioiodine treatment has been documented, which may be related to the disease itself rather than the treatment. This type of treatment is probably best avoided in children with Graves disease until the risks are clearly established in this group. In most patients, the main long-term side effect of radioiodine is the development of hypothyroidism.

SURGERY

Some patients prefer subtotal thyroidectomy, especially in the presence of a large goiter or the coexistence of a nodule whose nature is unclear. In specialized centers, the cure rates are usually more than 95% with low operative complication rates. It is worth noting that surgery has no effects on TAO.

Immunopathology

HUMORAL IMMUNITY

It is now accepted that TSH and TS Ab interact with the extracellular domain of the receptor (27), but the existence of epitopes on the extracellular surface of the transmembrane domains cannot be ruled out completely. Several difficulties have been encountered in the study of TSH-R antibodies. The absence until recently of an animal model of Graves disease and the inability to purify the native, functional TSH-R in sufficient quantities have hampered research into TSH-R antibody interactions. Rather than using primary cell cultures or cell lines as a source of autoantigen (which would provide very little TSH-R protein), prokaryotic and eukaryotic expression systems for TSH-R have been developed, but none is ideal for the assay of antibodies. TSH-R expressed in *Escherichia coli* does not bind TSH (131), whereas TSH-R extracellular domain expressed in baculovirus remains intracellular and must be purified from cell homogenates and does not bind TSH (132). In addition, TSH-R expression in different systems has often shown inconsistent or insufficient binding of autoantibodies, recently attributed to the important relationship between autoantibody recognition and TSH-R maturation associated with glycosylation (27).

Substitution studies have shown that epitopes for TS Ab and TBII in Graves disease are located primarily on the N-terminal region of the extracellular domain (27,133,134). TB Ab binding sites are found mainly on the C-terminal portion of TSH-R and, to a lesser extent, on the N terminus and midregion of the extracellular domain (27,133). TSH-R Abs are often light-chain restricted and predominantly of the IgG_1 subclass (135), suggesting an oligoclonal B-cell origin for these antibodies in at least some patients. On the other hand, TS Ab activity (based on cAMP production and PI activity) can differ from one patient to another, with antibodies activating both pathways found in patients with the most severe disease, implying a heterogeneity in the activity of TS Ab (136). Attempts at a molecular analysis of TSH-R antibodies have been both limited and disappointing (137,138), probably because of low levels of TSH-R Abs compared with TPO Ab and TG Ab levels (139) as well as the lack of a pure TSH-R molecule suitable for the study of antibody interactions.

Recent studies of TSH-R-antibody interactions should be interpreted with care. Most TSH-R B-cell epitopes appear to be conformational, rendering the results of the peptide studies questionable (27). In addition, chimeric substitution studies in a particular region of TSH-R may induce overall conformational changes in the remaining receptor molecule, with the possibility of obtaining false-negative results in antibody binding assays. Moreover, recent evidence suggests that glycosylation of the receptor is an important factor in antibody recognition, which casts doubts on the validity of bacterial expression systems and peptide studies. Finally, recombinant TSH-R is “sticky” and may bind to irrelevant immunoglobulin molecules.

A recent bioassay using Chinese hamster ovary (CHO) cells transfected with NIS showed that 30% of Graves disease sera possess antibody-mediated NIS inhibitory activity (140). Using an *in vitro* translation and transcription system for NIS synthesis, 22% of Graves disease sera were found to bind this recombinant form of the symporter (55). Antibodies against TG and TPO can be detected in up to 80% of Graves disease patients, and their properties are similar to those found in autoimmune hypothyroidism (discussed previously).

CELLULAR IMMUNITY

A defect in TSH-R-specific T-suppressor cells was proposed to underlie Graves disease, akin to the thyroid-specific defect proposed in autoimmune hypothyroidism (56), but clear evidence using recombinant TSH-R is so far lacking, and the exact mechanism of suppression is poorly defined. As in Hashimoto thyroiditis, TCR restriction of the intrathyroidal T cells has been investigated in Graves disease with contradictory results (58,59). Similarities in the intrathyroidal, pretibial, and retrobulbar Va and Vb TCR repertoire were shown in two patients, but there was heterogeneity in TCR use between the patients (141), which suggests recognition of similar antigenic determinants at the different sites of Graves disease complications in the same patient, but it is obvious that more patients at different stages of disease need to be studied to obtain a comprehensive picture of T-cell restriction in Graves disease. The antigens recognized by these T cells are unknown.

Thyroid-infiltrating $CD8^+$ cells in Graves disease do not seem to have a role in cell-mediated cytotoxicity because they fail to express perforin, whereas Graves disease-derived ab^+, $CD4^-$, $CD8^-$ T cells do contain perforin. This pattern of perforin expression differs from autoimmune hypothyroidism, and of course in Graves disease there is no clinical ground to suspect that tissue destruction occurs, although 10 years after onset, up to 15% of Graves patients successfully treated with antithyroid drugs develop autoimmune hypothyroidism. In addition, thyroid follicular cells and reactive cytotoxic gd^+ T cells have been grown from the Graves disease infiltrate; these cells are not HLA restricted and preferentially express IL-4, indicating a Th2-like phenotype (142). The importance of these cells in pathogenesis is unclear.

Thyroid-derived T cells from Graves disease patients produce IL-4, indicating a Th2 response, which one would predict in this exemplar par excellence of autoantibody-mediated disease. Furthermore, quantitative RT-PCR has shown predominance of Th2 cytokines in Graves disease tissue samples (72). The failure to detect IL-4 in some Graves disease tissue samples (69), together with the detection of IL-13 expression, indicates that the latter is also involved in priming toward a Th2 response in Graves disease. The importance of the Th2 response is demonstrated by the development of Graves disease in a patient treated with IL-4 for metastatic malignant melanoma (143). Moreover, more than 30% of multiple sclerosis patients treated with a monoclonal antibody to CD52 (resulting in an immune deviation away from Th1) developed Graves disease (144), further emphasizing a pivotal role for the Th2 cells in this disease.

Using recombinant techniques, T-cell responses to full-length TSH-R extracellular domain have been shown in Graves disease, but positive reactivity (albeit at lower levels) was also evident in patients with focal thyroiditis (145). To define T-cell epitopes on TSH-R, peripheral and intrathyroidal T-cell responses to a series of overlapping peptides covering the entire extracellular domain of TSH-R have been investigated in proliferation assays. A heterogeneous response has generally been detected, and occasional responses are found using T cells obtained from normal individuals (146,147). TSH-R amino acids 158 through 176, however, have been defined as an immunodominant T-cell epitope in Graves disease in a number of studies (84,148). Furthermore, a loss of T-cell reactivity to this peptide was demonstrated after the successful treatment of Graves disease with thyroidectomy or radioiodine administration (149). Residues 207 through 222 and 343 through 376 also contain important T-cell epitopes in Graves disease (84), which are also recognized by T-cell clones from apparently healthy subjects (150).

Antithyroid drugs may induce remission by a number of mechanisms, detailed elsewhere (13). In brief, treatment with antithyroid drugs leads to a fall in thyroid but not other antibody levels, and a reduction in thyroidal lymphocytic infiltration that is independent of any change in thyroid hormone status produced by the action of these drugs on TPO. The most likely explanation of these immunologic effects is that the drugs are concentrated by thyroid cells and reduce their expression of a number of proinflammatory molecules, including cytokines and reactive oxygen metabolites (88). This will have the effects of suppressing the intrathyroidal autoimmune process, specifically reducing thyroid autoantibody production (Fig. 49.7).

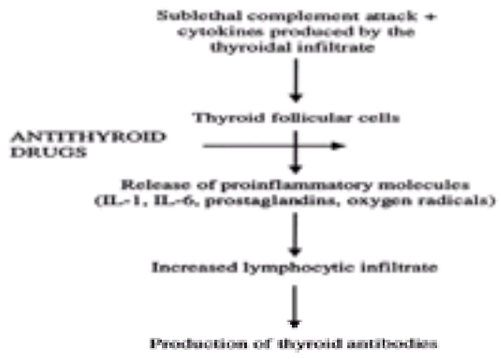

Figure 49.7. Mechanism for the thyroid-specific immunomodulatory action of antithyroid drugs in Graves disease.

IMMUNOPATHOGENESIS

It is clear that Graves disease is caused by TS Abs, which stimulate thyroid cell growth and overproduction of thyroid hormones via TSH-R. There is good evidence for a predominant Th2 response in the thyroidal lymphocytic infiltrate, a major source of TS Ab production, and a number of genetic (HLA-DR and CTLA-4 polymorphisms) and nongenetic (stress, iodide intake) factors have been identified that predispose individuals to develop Graves disease. This is not simply a disease mediated by TS Abs, however, as autoimmune responses to other thyroid autoantigens also occur in almost the same frequency as in autoimmune hypothyroidism, and occasional patients develop Graves disease after autoimmune hypothyroidism, whereas others become spontaneously hypothyroid early or late after disease onset. Moreover, autoimmune hypothyroidism and Graves disease frequently occur in different members of the same family, pointing to a shared etiology. Antithyroid drugs induce remission by modulating the intrathyroidal autoimmune response but are successful in only about one half the patients who have Graves disease. Further definition of the intrathyroidal events that perpetuate Graves disease may allow improved remission rates from medical therapy.

Animal Models of Graves Disease

Research into Graves disease has been severely handicapped by the absence of an animal model of the disease. Traditional approaches to induce Graves disease in animals have been unsuccessful, and more complicated immunologic manipulation has been necessary (reviewed in detail elsewhere: 151).

Classic immunization methods with recombinant receptor (expressed in prokaryotic or eukaryotic cells) induced TSH-R binding antibodies in mice, with some antibodies having blocking properties but no TS Ab could be produced (152,153). A minor derangement of thyroid function (both a fall and a rise in T_4) may occur in these animals, although these are inconsistent (154). Instead of recombinant receptor peptide fragments, Hidaka et al. used peptide fragments for immunization (155). Injection of DBA/1J mice with TSH-R peptides (known to stimulate T-cell proliferation *in vitro*) induced low amounts of TS Abs in some animals, but none had clinical or biochemical hyperthyroidism, and their thyroids remained histologically normal.

A novel and increasingly popular method for immunization involves the injection of animals with cDNA of the antigen of interest (rather than protein). Immunization of BALBc mice with full-length TSH-R cDNA induced antibodies that bound TSH-R in 14 of 15 animals (156). Most had TBAb activity with only one developing TS Ab. Histologically, all mice displayed severe thyroiditis with signs of epithelial hypertrophy, but none developed thyroid dysfunction. Interestingly, when the same method was applied to the NMRI outbred strain of mice, 4 of 30 female mice developed hyperthyroidism, both clinically and biochemically, with circulating TS Abs (157). This protocol was unusual in its use of outbred animals, providing a more diverse genetic background (similar to humans). Furthermore, some of these animals developed eye signs, thereby mimicking the full clinical picture of Graves disease.

Another promising approach involves the treatment of mice with fibroblasts transfected with MHC class II and the full-length TSH-R (158). The fibroblasts were MHC identical to recipient mice, and the transfected TSH-R was shown to be functional (by measuring cAMP production after TSH stimulation). Injection of these transfected cells into mice resulted in the development of TBII antibodies. Sera from one fifth of these mice showed TS Ab activity with an increase in T_4 levels. In these animals, the thyroid was enlarged, with hypertrophy in the thyroid follicles, but there was no lymphocytic infiltration, indicating that TS Abs are not necessarily produced locally in the thyroid.

Finally, T-cell transfer experiments have shown that treatment of BALBc and NOD mice with TSH-R-primed, $CD4^+$-enriched syngeneic T cells results in the induction of TSH-R antibodies (159). A Th2 response was identified in the thyroid of BALBc mice, whereas a Th1 response with thyroid destruction was evident in NOD mice. The orbit of BALBc, but not NOD, mice displayed changes consistent with TAO, suggesting that this complication of Graves disease is Th2-mediated. No convincing evidence of hyperthyroidism was found in these animals (only a minority of animals had elevated T_4), however, and no data were provided on TS Ab activity of their sera (160).

Thyroid-Associated Ophthalmyopathy and Pretibial Myxedema

The close clinical association between these conditions and Graves disease (and, less commonly, autoimmune hypothyroidism) suggests a common pathogenesis, most likely the result of an autoimmune response against an autoantigen shared between thyroid, orbit, and skin. In both TAO and pretibial myxedema (PTM), there is an infiltration of the affected site (extraocular muscle or skin) by activated T cells (Fig. 49.8) and a variety of cytokines can be detected, which can activate fibroblasts to secrete glycosaminoglycans (GAGs). The accumulation of GAGs is a cardinal feature of TAO and PTM, which in turn causes water trapping and edema. The resulting swelling accounts for most of the clinical features of these complications. Late in disease, continued fibroblast activation may lead to fibrosis, and at this stage some muscle-fiber damage may be detectable in TAO. It is noteworthy that in the early stage of the disease, muscle cells are intact; the key target is therefore most likely the fibroblasts of the extraocular muscles and the skin. Enhanced susceptibility to cytokine-mediated induction of GAG production may be a feature of fibroblasts from these particular sites, explaining the localization of the autoimmune process.

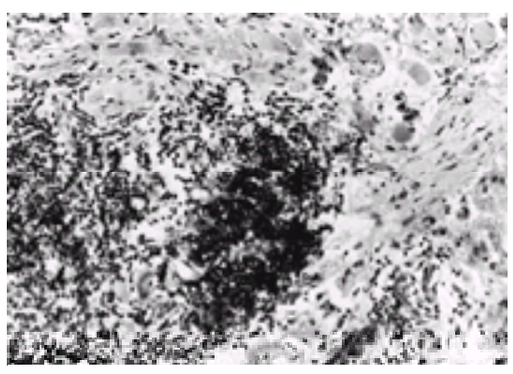

Figure 49.8. Histology of thyroid-associated ophthalmopathy. The extraocular muscles are infiltrated by a diffuse and focal lymphocytic infiltrate. The muscle fibers are intact but separated by edema secondary to glycosaminoglycan accumulation.

Treatment of mild to moderate TAO is usually supportive. In severe cases, high-dose corticosteroids, cyclosporin A, intravenous immunoglobulin, radiotherapy, and surgery can be used (161). PTM is usually left untreated, but troublesome lesions may benefit from corticosteroid ointment or the somatostatin analog octreotide.

Studies on B-cell responses in TAO have faced major difficulties, largely because the autoantigen in TAO is still unknown. The conventional thyroid antigens TG and TPO do not seem to have a role in TAO, whereas the role of TSH-R is controversial. The search for orbital antibodies has generally used nonhuman and human crude orbital tissue homogenate or extraocular muscle (EOM) membranes as a source of autoantigen. By immunoblotting, antibodies against eye-muscle (55-, 64-, and 95-kd antigens) and fibroblast (23- and 66-kd antigens) membranes have been detected more frequently in patients with TAO than in controls (162). The 64-kd reactivity created particular interest because it is shared between eye muscle and thyroid and now is known to comprise a number of different molecules, including a so-called

D1 protein, calsequestrin, and succinate dehydrogenase (163). Kromminga et al. (164) demonstrated that 82% of patients with TAO have antibodies that react with nondenatured D1 protein compared with 5% of controls, indicating a high specificity and sensitivity. Immunoreactivity against denatured protein was not detected, indicating that epitopes are conformational. Calsequestrin (63 kd) was recognized by sera from 40% of patients with TAO and only 5% of controls (165). Succinate dehydrogenase (67 kd) reacted with 67% of sera from active TAO patients, 30% of chronic disease, 30% of Graves disease without associated TAO, and 7% of controls, suggesting that antibodies to this molecule may correlate with the severity of eye disease (166). Other nonspecific candidate autoantigens in TAO include acetylcholinesterase, actin, tubulin, and acetylcholine receptor, but none has been confirmed as a key autoantigen (162).

Attention has focused on TSH-R as a potential autoantigen in TAO. Full-length TSH-R transcripts have been detected in retrobulbar tissue but not EOM or fibroblasts, suggesting that TSH-R mRNA is present in orbital fat (167). Fragments of TSH-R ECD have been detected in fibroblasts from retrobulbar muscle and connective tissue (168), but most studies used RT-PCR for TSH-R mRNA detection and applied more than 30 cycles for amplification, making the physiologic importance of TSH-R in the orbit questionable (168). Burch et al. (169) demonstrated that rabbit anti-TSH-R polyclonal antiserum reacted with retrobulbar fibroblasts, but a drawback of this study is the absence of an appropriate negative control. Other studies also detected TSH-R in orbital tissue and PTM lesions by immunostaining (170,171), thereby confirming the translation of detected mRNA into protein. This occurs particularly in the preadipocyte subpopulation of fibroblasts (161), but how this minor population of cells participates in the autoimmune process is unknown. The recent development of an animal model of Graves disease and TAO using TSH-R immunization emphasizes the possible role of TSH-R as a major autoantigen in TAO (see preceding).

Analysis of TCR gene use by the infiltrating T cells in the retrobulbar tissues revealed a strikingly limited heterogeneity in eight patients with recent-onset TAO (172). By contrast, four patients with long-standing, clinically inactive TAO had a lesser degree or an absence of restriction. Comparison of TCR use in orbital connective tissue and extraocular muscle tissue from the same patient did not show major differences, suggesting similar antigenic recognition in both compartments. Similar results were obtained by analyzing TCR restriction in seven patients with early and late stages of PTM (172). Moreover, the same group found similarities in the intrathyroidal, pretibial, and retrobulbar TCR repertoire use in two patients (141), indicating that T-cell reactivity is restricted in the early phases of TAO and PTM, whereas in the later stages recruitment of a more diverse spectrum of T cells occurs (spreading of the immune response), and these T cells can react to a variety of tissue-specific and tissue-nonspecific antigens. It remains possible that the restriction described in such studies is an artifactual finding related to the small size of samples analyzed (in particular, samples from orbital tissue), which may harbor only a limited number of lymphocytes resulting in “pseudorestriction.”

Orbital-derived T cells from patients with TAO recognized autologous orbital fibroblasts in one study but not crude eye-muscle extracts or autologous peripheral blood lymphocytes (PBLs) (173). These T cells were mainly $CD8^+$, $CD45RO^+$, and they secreted a mixture of cytokines but had little cytotoxic activity, ruling out the possibility of direct tissue destruction by these cells and favoring an indirect role in disease pathogenesis mediated by cytokine production. More recently, it was shown that orbital-derived TAO lymphocytes are mainly of the $CD4^+$ phenotype and can proliferate in response to thyroid and EOM extracts and membrane preparations (174). In addition, TAO-derived lymphocytes, but not PBLs, were shown to proliferate in response to TSH-R extracellular domain (ECD) in one patient, whereas both TAO-derived lymphocytes and PBL proliferated to TSH-R ECD in another patient, further indicating that TSH-R is an autoantigen involved in TAO.

Future Directions

Several lines of evidence indicate that autoimmune hypothyroidism and Graves disease have similar immunopathogenesis and probably represent two clinical presentations of the same broad disease process. The most important distinguishing factor is the presence of TS Abs in Graves disease; these are infrequently detected in autoimmune hypothyroidism.

In contrast to autoimmune hypothyroidism, treatment of Graves disease is problematic because of the side effects of medications used, complications of surgery, or the development of permanent hypothyroidism. Furthermore, adequate control of thyroid function is not always achievable, and treatment of extrathyroidal complications can be notoriously difficult.

The identification of genetic markers of the disease is of utmost importance. Linkage analysis studies should allow the identification of susceptibility genes involved in Graves disease, and these can be compared with genetic markers in autoimmune hypothyroidism to establish whether a real difference exists between these two clinical presentations of what seems to be a spectrum of disease. In particular, immunoglobulin V gene use by TS Abs is a major focus of study because it is possible that germline V gene differences could explain why some patients develop Graves disease and others develop autoimmmune hypothyroidism. The study of T cells early in the disease may identify restricted T-cell clones, potentially offering curative treatment by immunologic manipulation. A major breakthrough was the development of animal models of Graves disease, which have eluded researchers for the past four decades. These should help to shed some light on the initiation and progression of the disease and may allow identification of immunologic interventions that can halt the disease process.

More than 90% of Graves disease patients have TAO, with clinically obvious disease apparent in 50%. Treatment strategies for TAO are unsatisfactory at present, and almost certainly the only curative treatment of TAO will be immunologically directed. Therefore, the identification of the pathogenic mechanisms and the major autoantigens involved in TAO is a pressing task. Although several studies suggested that TSH-R is a major autoantigen in TAO, the data are not conclusive at present. The recent development of animal models of Graves disease with associated ophthalmopathy is of great importance in helping to establish the exact role of TSH-R in TAO and it is hoped will help to understand the complex pathogenesis of this disease.

ADDISON DISEASE

When Thomas Addison first described primary adrenocortical failure in 1855, the main cause was tuberculosis, and yet two of the 11 original cases were probably autoimmune in origin. In developed countries, the most common cause of Addison disease is now autoimmunity, accounting for around 80% of cases. The prevalence is between 30 and 60 per million population, but this may underestimate the current frequency as a result of either a true increase in prevalence or improved diagnosis (175). In about half of the autoimmune cases, the disease occurs in isolation, but in the remainder there is an associated autoimmune disorder, often as part of one of the two autoimmune polyglandular syndromes (APS) (Table 49.6 and Table 49.7). These syndromes are discussed in detail in the next section; the present section focuses on autoimmune Addison disease, but it considers, where appropriate, the different autoimmune features associated with APS.

Features	Frequency (%)
Major components	
Chronic mucocutaneous candidiasis	80–100
Hypoparathyroidism	80
Addison disease	70
Other autoimmune features	
Gonadal failure	10 men, 60 women
Vitiligo	30
Alopecia	30
Malabsorption	20
Insulin-dependent diabetes mellitus	10
Hypothyroidism	10
Pernicious anemia	10
Chronic active hepatitis	10
Ectodermal features	
Nail dystrophy	50
Keratopathy	40
Tympanic membrane calcification	30

TABLE 49.6. Clinical Features of Autoimmune Polyglandular Syndrome Type 1

Major endocrinopathies
Autoimmune thyroid disease (Graves disease, primary myxedema, Hashimoto thyroiditis, postpartum thyroiditis)
Type 1 diabetes mellitus
Addison's disease
Other endocrinopathies
Premature ovarian failure
Lymphocytic hypophysitis
Lymphocytic infundibuloneurohypophysitis
Isolated ACTH deficiency
Other autoimmune features
Vitiligo
Alopecia or leucotrichia
Pernicious anemia
Celiac disease/dermatitis herpetiformis
Myasthenia gravis
Serositis
Chronic autoimmune hepatitis/primary biliary cirrhosis

ACTH: adrenocorticotrophic hormone.

TABLE 49.7. Clinical Features of Autoimmune Polyglandular Syndrome Type 2

Epidemiology

The average age of onset is 30 to 35 years, and there is a female excess of twofold to threefold, although this sex difference is absent in the first two decades of life. The association of Addison disease with other autoimmune disorders in families suggests genetic susceptibility but also would be compatible with shared environmental factors; however, to date, no environmental factors have been identified that confer susceptibility. The major genetic association is with the HLA-DR3 specificity, both in the spontaneous form and that in APS type 2 (the genetic basis of APS type 1 is considered subsequently), with a relative risk of about 3.5 (176). Some studies found an association between HLA-DR4 and Addison disease, but this association may be a distortion produced by a linked susceptibility to type 1 diabetes mellitus; subtypes DRB1*0401 and DRB1*0402 are associated with limited progression to adrenal failure in predisposed subjects compared with DRB1*0404, which confers a high risk (177).

Certain polymorphisms in the CTLA-4 gene also are associated with Addison disease in some populations, implying a relatively modest effect on susceptibility akin to that found in autoimmune thyroid disease and type 1 diabetes mellitus (178). It is unknown whether these associations reflect differences in CTLA-4 expression or function.

Clinical Presentation

SIGNS AND SYMPTOMS

Addison disease has a range of presentations that depend on the degree of adrenal failure (Table 49.8). The most dramatic symptoms and signs occur in adrenal crisis, with dehydration, severe hypotension, vomiting, diarrhea, coma, and, if untreated, death. Such crises are usually precipitated by an acute illness, increasing the demand for glucocorticoids, against the background of chronic adrenal impairment. More commonly, there is an insidious onset over months or even years; the autoimmune process generally destroys the adrenal cortex, leading to impaired glucocorticoid and mineralocorticoid production (179). In women, the failure of androgen secretion may result in loss of body hair and impaired libido, but in men the testicular contribution to androgen production ensures that these effects are not seen. The main presenting features with chronic destruction of the adrenal cortex are lethargy, fatigue, weakness, postural hypotension (sometimes with syncope), and gastrointestinal disturbance. Salt craving may be prominent. Subclinical Addison disease sometimes is detected when adrenal antibody testing reveals the presence of an autoimmune process and further investigation (see later) reveals mild impairment of adrenal reserve (180).

Symptoms and Signs	Frequency (%)
Symptoms	
Weakness, fatigue	95
Anorexia	95
Nausea	90
Vomiting	70
Abdominal pain	30
Diarrhea	15
Postural symptoms	10
Myalgia, arthralgia	10
Signs	
Weight loss	95
Increased pigmentation	95
Hypotension	90
Associated autoimmune disease	25

TABLE 49.8. Main Signs and Symptoms in Addison Disease

PHYSICAL FINDINGS

Increased pigmentation is distinctive and is due to the rise in pituitary secretion of adrenocorticotrophic hormone (ACTH) as a result of impaired negative feedback from low cortisol levels. It is seen particularly in sun-exposed skin or areas subject to mild trauma, such as the elbows and knuckles. It also can occur in the mouth as a result of trauma from the teeth. The blood pressure is usually low, with a postural drop. Evidence of an associated autoimmune disorder, particularly vitiligo, occurs in 10% to 25% of cases.

LABORATORY TESTS

The diagnosis may be suggested by the presence of hyponatremia and hyperkalemia, the typical electrolyte disturbances of mineralocorticoid deficiency (hypoaldosteronism), which are present in up to 90% of patients. Hypercalcemia, normochronic, normocytic anemia, and eosinophilia also can occur. Random serum cortisol measurements are insufficient to make the diagnosis because there is a pronounced diurnal variation and an overlap with values in healthy individuals. Nonetheless, if a cortisol value lower than 100 nmol/L is obtained, this finding is virtually diagnostic, as is a value within the reference range in a stressed individual, such as a patient who has features of adrenal crisis.

In most cases, the diagnosis is confirmed by demonstrating a failure of serum cortisol to rise adequately (normal response, >550 nmol/L) 30 to 60 minutes after intramuscular or intravenous synacthen (synthetic ACTH). Because this test simply confirms adrenocortical failure, which could be primary or secondary to a hypothalamic or pituitary problem, the next step is to demonstrate that there is intrinsic adrenal disease, either by measuring ACTH and finding an elevated level or by performing a prolonged synacthen test. After continuous adrenal stimulation with ACTH, usually over 5 days, cortisol production is initiated in secondary adrenal failure but not in Addison disease.

Once the diagnosis of Addison disease is made, the cause must be established. An autoimmune cause is suggested by the presence of other autoimmune disorders and is confirmed by detecting adrenal antibodies (see later). Depending on the test used, 70% to 90% of patients with autoimmune Addison disease will be identified (181,182). Adrenal antibodies may disappear over an extended period.

PATHOLOGY

The adrenal glands in end-stage Addison disease are atrophic, and the cortex is replaced by fibrous tissue. When the disease is evolving, there is a variable but widespread mononuclear infiltrate of lymphocytes, plasma cells, and macrophages in much greater number than in the normal adrenal gland: lymphocytic infiltration of healthy adrenals increases with age, and there may be expression of MHC class II molecules on 10% to 20% of adrenocortical cells under normal circumstances. The distinctive layers of the adrenal cortex (the zona glomerulosa, zona fasciculata, and zona reticularis) disappear in Addison disease as the steroidogenic tissue is destroyed. Further pathologic analysis, including immunohistochemical characterization of the infiltrating lymphocytes, has not been undertaken because access to adrenal tissue in the active phase of disease is impossible during life, and mortality rates have declined markedly with improved recognition and treatment.

Treatment

Immunologic intervention is not indicated because properly monitored hormone replacement restores normal health and life span with little or no adverse effect (179). Hydrocortisone is given in doses of 10 mg first thing in the morning and then 5 to 10 mg at lunchtime and late afternoon. Mineralocorticoid replacement is provided by fludrocortisone, 50 to 200 µg daily. Women may benefit from dehydroepiandrosterone, which improves well-being and sexuality, although long-term studies have not yet been performed (183). Adrenal crisis is an emergency that requires intravenous saline and hydrocortisone and supportive measures; treatment must commence without delay on clinical suspicion of the diagnosis, biochemical confirmation being retrospective.

Immunopathology

HUMORAL RESPONSES

Autoantibodies to the adrenal cortex in Addison disease were first identified by complement fixation and immunofluorescence; with these techniques, about 60% of

patients were positive (184). About 25% of women and 5% of men with autoimmune Addison disease have antibodies that react not only with adrenocortical cells by immunofluorescence but also with steroidogenic cells in testis, ovary, or placental trophoblast, and this subset of antibodies was identified as being against “steroid cells.” In women with Addison disease, a strong correlation exists between the presence of steroid cell antibodies and premature ovarian failure, defined as menopause below the age of 40. The obvious implication is that autoreactivity against shared antigen(s) in the adrenal and ovary leads to both conditions, although it remains unexplained why so few men with steroid cell antibodies develop testicular failure.

Molecular approaches have clarified the nature of the adrenal and steroid cell antibody reactivities in Addison disease. Initially, the cytochrome P450 enzyme, 17a-hydroxylase (P450c17), was identified as an autoantigen when a fetal adrenal library was screened with sera from a patient with type 1 APS (185), but another adrenal autoantigen, 21-hydroxylase (P450c21), was quickly recognized thereafter (186). Antibodies to side-chain clearing enzyme (P450scc) were found in another subset of patients (187). Although there was initial confusion over this plethora of autoantigens, it is now clear that the key autoantigen in Addison disease is P450c21, which is specific to the adrenal, whereas antibodies to P450c17 and P450scc correspond to the steroid cell antibodies previously identified by immunofluorescence (181,188,189). Because steroid cell antibodies are more frequent in Addison disease associated with type 1 APS than in isolated or APS type 2-associated disease, P450c17 and P450scc are most frequent in APS type 1 (Table 49.9).

	Antibody reactivity (%)		
	P450c21	P450c17	P450scc
Isolated Addison disease or with APS type 2	80–100	<10	<10
Addison disease in APS type 1	60–70	40–50	40–50
APS type 1 without Addison disease	5–10	5–10	5–10
Other endocrinopathies	1–2	<1	<1

APS, autoimmune polyglandular syndrome; P450c17, cytochrome P450 enzyme 17a-hydroxylase; P450c21, adrenal autoantigen 21-hydroxylase; P450scc, side-chain-cleaving enzyme.

TABLE 49.9. Distribution of Autoantibodies against P450 Enzymes in Addison Disease

Other steroidogenic enzymes (11b-hydroxylase, 3b-hydroxysteroid dehydrogenase, aromatase, and adrenodoxin) have been tested for autoreactivity in Addison disease with negative results (189), and the high frequency of P450c21 antibodies in some series (182) indicates that the major autoantigens have been found. An alternative explanation for Addison disease was suggested by the finding, in bioassays, of blocking antibodies to the ACTH receptor in a high proportion of patients (190), but the most probable explanation for these results is the use of only partially purified immunoglobulin preparations. Pure IgGs from Addison patients do not block the ACTH receptor (191).

Epitope mapping studies suggest that P450c21 antibodies bind to at least three different epitopes in the C-terminal part of the enzyme, most likely part of more complex, conformational epitopes (192,193). The most important remaining question is whether antibodies to P450c21 and the other enzymes have a pathogenic role or are simply markers of cell-mediated adrenocortical destruction. The steroidogenic enzymes are intracytoplasmic, and it is difficult to see how antibodies could gain access to their targets *in vivo*. There is certainly no evidence that the inhibitory effects of P450c21 antibodies on enzyme activity and steroid synthesis *in vitro* are manifested *in vivo*, supporting the notion that the antibodies cannot react with the enzymes in living cells (194). Complement-mediated cytotoxicity has been demonstrated using steroid cell antibodies and granulosa cells *in vitro* (195), but much further work is needed using adrenal cells and carefully defined antibodies before a role for these antibodies in pathogenesis can be accepted. It should be noted that pregnancy is uneventful in women with Addison disease and that there is no evidence of adrenal insufficiency in neonates, arguing strongly against a role for adrenal antibodies alone in pathogenesis.

CELLULAR RESPONSES

In common with many other autoimmune disorders, an increased proportion of circulating T cells are activated in Addison disease, as judged by their surface expression of HLA-DR (196). The circulating population of T cells is obviously the only one that is accessible for the purposes of analyzing functional responses in this condition, although it is likely that autoantigen-specific lymphocytes accumulate within the diseased adrenal. T cells from one half of a group of patients with autoimmune Addison disease reacted to a crude adrenal antigen in a migration inhibition assay, such reactivity being absent when controls or patients with tuberculous Addison disease were examined (197).

T-cell proliferation to adrenal antigens also has been demonstrated, but the nature of the autoantigen(s) has not been defined (198). We used P450c21 in proliferation assays but found consistent positive responses only 3 of 18 patients; two additional patients had T cells that proliferated in response to P450c17 (unpublished observations). This low frequency of T-cell reactivity to what is believed to be the key adrenal antigen may be due to patients being studied at a late stage of disease and there being a low frequency of reactive T cells in the circulation. These observations and the analogy provided by autoimmune hypothyroidism strongly suggest that T-cell-mediated responses are involved in Addison disease, but it must be said that final, conclusive proof is not available and that the exact mechanism of adrenocortical cell destruction is unknown.

IMMUNOPATHOGENESIS OF DISEASE

A major breakthrough in the understanding of any autoimmune disease is the delineation of the autoantigens, and it is now clear that P450c21 is a major autoantigen in isolated Addison disease and APS type 2. The same autoantigen is implicated in APS type 1, but in this form of Addison disease, some cases appear to be the result of autoimmunity against P450c17 and P450scc. The latter two enzymes are the targets of steroid cell antibodies and, because of their tissue distribution, steroid cell autoimmunity is associated with premature ovarian failure. It is likely that the occasional occurrence of P450c17 and P450scc antibodies in isolated and APS type 2-associated Addison disease reflects a widening of the autoimmune responses following P450c21 autoreactivity.

Good but indirect evidence of T-cell involvement exists, and, by analogy with other autoimmune endocrinopathies, it seems most likely that adrenocortical destruction is cell-mediated. Whether this is mediated by perforin/granzyme, Fas-induced apoptosis or cytokines is unknown. Direct effects of P450c21 antibodies are unlikely. Previous reports of antibodies against adrenal cell-surface antigens (199) are unconfirmed, but if separate cell-surface autoantigens do exist, these would clearly be targets for complement-mediated or antibody-dependent NK cell-mediated cytotoxicity.

Animal Models

Immunization of monkeys, rabbits, guinea pigs, rats, and mice with adrenal gland extracts and adjuvant induces lymphocytic infiltration of the adrenal gland and adrenal cell antibodies, which may cross-react with ovary (200,201). The disease is presumably T cell-dependent because it is transferable with lymph node-derived cells (202). Evidence of adrenal failure, however, is poorly documented and indirect. Lowering of blood pressure has been reported in immunized rats (203), and hypoglycemia, salt wasting, and reduced plasma corticosterone have been observed in another set of experiments using rats (204). Because it is difficult to produce P450c21 in sufficient quantities, no reports have yet appeared of immunization with this antigen. The approach of cDNA immunization may be one way to circumvent this problem and to establish an animal model of Addison disease that can be investigated using modern biochemical and immunologic techniques.

The only other animal model that has been reported consists of neonatal thymectomy in mice, combined with administration of cyclosporin A (205); thymectomy alone has no effect, although it can induce autoimmune oophoritis, thyroiditis, and gastritis. This model has not been studied in detail, but adrenocortical antibodies and adrenalitis result. Certainly, the results support the involvement of regulatory T cells in preventing adrenal autoimmunity in normal circumstances.

Future Directions

Despite its rarity and the relative ease of hormone replacement, autoimmune Addison disease is important as a serious, and at times life-threatening, disorder that requires lifelong management. Recent observations, which demonstrate that many patients are overtreated with conventional doses of glucocorticoids, point to the inadequacy of current methods to determine individual hormone requirements (206). The short-term benefits of dehydroepiandrosterone replacement in women (183) also warrant more detailed study. Immunologic treatment seems most unlikely to offer any benefits because adrenal destruction is probably too great by the time Addison disease is recognized, but conceivably it may have a role in subclinical disease. The question then is whether screening is justified. The low frequency (~ 1%) of adrenal cell antibodies in patients with another autoimmune endocrinopathy suggests that this will not be cost-effective in the near future, but combined approaches

with screening for genetic susceptibility may identify particularly high-risk patients (177).

Any environmental factors leading to Addison disease remain unidentified, although an effect is suggested by the possible rise in disease frequency (175). Developments in our understanding of the immunogenetic contribution to Addison disease are most likely to come from the characterization of candidate genes from studies in the associated endocrinopathies, but this approach may leave untouched the question of why the adrenal cortex (rather than, say, thyroid or beta cell) is targeted. The development of new animal models is also a pressing need because this approach will produce fundamental insights into disease pathogenesis, particularly with regard to the involvement of antibodies and the mechanisms behind the production of cross-reactive autoimmunity to the ovary.

AUTOIMMUNE POLYGLANDULAR SYNDROMES

The main clinical features of APS types 1 and 2 are listed in Table 49.6 and Table 49.7, and these syndromes are discussed in more detail in this section. APS type 2 is also known as *Schmidt syndrome,* but many patients have only one of the three major components (autoimmune thyroid disease, type 1 diabetes mellitus, Addison disease) originally described in this syndrome and have either another presumed autoimmune endocrinopathy (premature ovarian failure, lymphocytic hypophysitis, isolated ACTH deficiency) or another autoimmune disorder (Table 49.7). Sometimes patients with autoimmune thyroid disease plus another endocrinopathy are described as having type 3 APS, but this term has not become established. The mechanism behind these nonclassic associations is probably the same as that underlying APS type 2, namely, shared environmental or genetic susceptibility factors, although there have been attempts to implicate shared sequence homologies in the different target antigens as a cause (207). This latter mechanism has no experimental support. The nonendocrine components of APS type 2 are detailed elsewhere in this book, and this chapter concludes with a brief review of the autoimmune basis for premature ovarian failure and autoimmune hypophysitis.

Type 1

This rare autosomal recessive condition is also known as *Blizzard syndrome* and *autoimmune polyendocrinopathy-candidiasis-ectodermal dysplasia* (APECED). There are clusters of APS type 1 in Finland and Sardinia. The syndrome is caused by one of at least nine identified mutations in the autoimmune regulator (AIRE) gene on chromosome 21 (208,209). This gene encodes a nuclear protein with two zinc finger domains that is expressed in thymus, lymph nodes, and fetal liver. Mutations presumably affect T-cell development, but the exact basis for the disease will become apparent only from further studies, including knockout mice, currently being developed. The phenotype varies greatly, and so far there is no clear correlation with genotype.

Clinically, the disease pattern is usually the appearance of chronic mucocutaneous candidiasis in early life, followed by hypoparathyroidism in infancy or childhood, with Addison disease occurring 5 to 10 years later (210). If unrecognized, these endocrinopathies can be fatal. Patients may be more prone to infection in childhood, and fulminant hepatic failure is an important cause of death later in life. Malabsorption is another clinical feature that can cause difficulties in management because of erratic absorption of drugs.

The pattern of autoantibodies against the adrenal cortex in APS type 1 with Addison disease is wider than in other, more common forms of the disease (Table 49.8). The frequent occurrence of P450c17 and P450scc autoreactivity is thought to underlie the gonadal failure that is often found in both sexes. The pathogenesis of the hypoparathyroidism is unclear. Antibodies against the calcium-sensing receptor have been identified in 6 of 17 APS type 1 patients with hypoparathyroidism, but these had no functional effect on receptor function (211). So far, these observations have not been repeated in another group of patients. The cytochrome enzyme P450 1A2 is a hepatic autoantigen for antibodies in APS type 1 and is associated with hepatitis (212). Autoantibodies to glutamic acid decarboxylase (GAD) occur in type 1 APS patients with diabetes mellitus as they do in the far more common sporadic disorder, but in some APS type 1 diabetic patients, these antibodies are absent, and, instead, antibodies to aromatic L-amino acid decarboxylase occur (213). It is unclear whether these antibodies are linked directly to the development of diabetes; their presence in APS type 1 is also associated with the presence of hepatitis and vitiligo. The malabsorption and diarrhea that affect about one fourth of patients with APS type 1 are associated with the presence of antibodies to tryptophan hydroxylase and the disappearance of enterchromaffin cells from the intestinal mucosa (214).

The exact basis for the tissue damage and for the associated ectodermal features in APS type 1 remains unclear. The wide spectrum of antibodies is striking and has led to identification of the likely target autoantigens, but a pathogenic role for these antibodies has not been established. A recent case report demonstrated some improvement in exocrine pancreatic failure, alopecia, and keratoconjunctivitis when cyclosporin A was given to a patient with APS type 1 (215), suggesting the possibility of using immunomodulation to treat this syndrome in the future.

Type 2

The prevalence of APS type 2 is not established; surveys have concentrated on taking one of the index disorders and determining the frequency of the others. For instance, about 6% of patients with type 1 diabetes mellitus have autoimmune thyroid disease and 0.1% have Addison disease (216). In a long-term survey of Addison disease, 30% had clinically evident autoimmune thyroid disease, 5% had subclinical hypothyroidism, and 6% had type 1 diabetes mellitus (217). It is therefore clear that APS type 2 is much more common than type 1, and, of course, point prevalence studies such as those quoted do not take full account of later onset of an associated disease. In turn, this implies that clinicians should be vigilant for the development of APS type 2 in any patient with an index disorder and most would offer patients with Addison disease annual screening, at least for thyroid disease. The place of regular screening in the other two index disorders is uncertain except that pregnant women with type 1 diabetes mellitus should be offered antenatal screening because of the high frequency of postpartum thyroiditis in these patients (218).

There is nothing unique clinically or immunologically in the individual disease components in a patient with APS type 2. The syndrome is inherited as an autosomal dominant disorder with incomplete penetrance and variable disease expression in different family members. Affected siblings share one or both HLA haplotypes in 95% of cases. The HLA-A1, B8, DR3 haplotype shows a stronger association with APS type 2 than with the individual disease components, and HLA-DR4 is associated with type 1 diabetes in the usual way.

OTHER ENDOCRINOPATHIES

Premature Ovarian Failure

Premature ovarian failure (POF) usually is defined as the onset of menopause before the age of 40; 0.3% to 1% of women are affected. As well as its effects on fertility, POF leads to early onset osteoporosis and an increased risk of cardiovascular disease resulting from the loss of estrogens. Occasional cases reverse spontaneously, and uncontrolled trials of glucocorticoids suggest possible benefit, but further work is needed in this area (219). For most women, hormone-replacement therapy is given.

Only a small proportion of women with POF have Addison disease; in these cases, an autoimmune basis for the ovarian disorder is now established, as discussed already, even if the exact pathogenic mechanisms are uncertain. More than 95% of women with POF, however, do not have Addison disease and, whereas other factors (smoking, cytotoxic drugs, irradiation, cytogenetic abnormalities, and metabolic disorders) can be identified in some of these, many women have so-called idiopathic POF. An autoimmune basis for idiopathic POF has been repeatedly suggested, but the evidence for this is, at best, incomplete and often circumstantial (220,221).

Between 9% and 38% of affected women have an associated autoimmune disorder, particularly autoimmune thyroid disease, suggesting that POF may be part of an APS-like syndrome, but it is also possible that the disturbed sex hormone milieu in POF is responsible for an increased frequency of autoimmunity. There is no significant HLA association with idiopathic POF, and animal models of oophoritis do not closely resemble the human counterpart (220,222). Antibodies against poorly characterized ovarian antigens have been found in about 50% of women in various studies (although there is considerable variation), but these antibodies are not all specific, being found in POF that clearly has a non-autoimmune basis. Antibodies to 3b-hydroxysteroid dehydrogenase, a steroidogenic enzyme, recently were found in 20% of patients with idiopathic POF, suggesting that this is a novel ovarian autoantigen (223), but it is difficult to see why steroid cell antibody positivity by immunofluorescence is generally rare in idiopathic POF. Moreover, 23% of patients with diabetes had antibody reactivity to this enzyme. We have been unable to confirm these results using an *in vitro* translation assay that demonstrated that the frequency of 3b-hydroxysteroid antibodies was only 2% in POF (Peterson et al., submitted for publication). Thus, a small proportion of women with idiopathic POF may have antibodies against this enzyme, but even then we have no proof that such autoreactivity is important in pathogenesis.

Autoimmune Pituitary Disease

Pituitary autoimmunity is rare and takes at least three forms (224). Lymphocytic hypophysitis usually presents as a pituitary mass with hormonal disturbance, in two thirds of cases occurring during or after pregnancy. About 25% of patients have an associated autoimmune disease, especially thyroiditis. Detailed systematic analysis of the immunologic features has not been performed because the condition is so rare, and access to the pituitary for research purposes is limited. Antibodies to the pituitary are detected by immunofluorescence infrequently, but reactivity to 49-kd and 40-kd pituitary proteins in immunoblots has been reported in 50% to 70% of patients (225). A second likely autoimmune disorder of the pituitary is the rare isolated deficiency of ACTH. Almost all these patients have evidence of thyroid

autoimmunity (226). Finally, lymphocytic infundibulo-neurohypophysitis may be a rare cause of diabetes insipidus (227).

50 IMMUNOLOGIC RENAL DISEASE

Mary H. Foster, M.D.

The kidney is a frequent target of humoral and cellular immune responses and is highly susceptible to immune-mediated damage. A heterogeneous group of human and experimental nephritides that have diverse clinical and pathologic phenotypes is characterized by immunoglobulin (Ig) deposition and mononuclear cell infiltration of the glomerulus and renal interstitium. The development and progression of many of these entities can be blocked by immunosuppressive agents, thus providing further evidence of direct immunologic involvement. This propensity for immune injury and mediator localization may be related to the specialized excretory function of the kidney. The extensive blood flow, daily filtration of an estimated 150 to 180 L of plasma across an open (nondiaphragmatic) fenestrated endothelium, and reabsorptive and endocytic functions continuously expose the glomerular capillary wall, mesangium, and downstream tubular epithelium to circulating antigens, soluble mediators, Ig, and lymphocytes. Notably, with rare exceptions, our understanding of the immunopathogenesis of human renal immune injury remains speculative, limited in part by the restricted availability of human renal tissue and patient pedigrees, uncertain correlation between peripheral blood sampling and processes in the kidney, and the complex genetic heterogeneity of human populations. Fortunately, a growing cadre of spontaneous and induced experimental models shares many clinical and histopathologic characteristics with human disease. These animal surrogates have proven highly instructive and continue to yield important insights into human nephritis (1,2).

Pioneering work in early experimental models of glomerular injury, most notably nephrotoxic serum nephritis (NSN) and acute and chronic serum sickness, implicated intrinsic glomerular epitopes as well as circulating foreign proteins as antigenic targets in nephritogenic humoral responses (3,4 and 5). These models, in conjunction with examination of human renal biopsy specimens using immunofluorescence and electron microscopic techniques introduced in the 1950s, revealed considerable morphologic heterogeneity in glomerular disease, suggesting that diverse pathogenic pathways are operative. Only after meticulous dissection of the mechanism of immune deposit (ID) formation in the rat Heymann nephritis (HN) model of membranous nephropathy (6) was *in situ* engagement of autoantigen recognized as a dominant mechanism of renal Ig deposition, accounting for granular as well as linear IF patterns. In the past two decades, it has become clear that a plethora of structurally diverse antigens distributed throughout the kidney, including both protein and nonprotein soluble antigens, basement membrane (BM) components, and cell-surface molecules, can serve as targets of renal immune injury. Appreciation of the importance of cellular immunity in initiating and mediating renal injury lagged behind these discoveries but ultimately emerged with the development of animal models of tubulointerstitial nephritis (TIN) and of immunologic techniques to characterize T-cell subsets. This field was further advanced by parallel investigations in renal transplantation and elucidation of the immunobiology of acute rejection mediated by infiltrating sensitized T cells. With this came evidence that resident renal parenchymal cells participate in antigen presentation and local amplification of immune responses and inflammation.

During the past decade, an explosion of investigation focused on basic mechanisms of tissue injury and repair. These studies led to the isolation and characterization of a broad array of downstream mediators and revealed an intricate network of soluble and cell-bound molecules derived from resident renal and infiltrating cells that facilitate cell–cell and cell–matrix communication, modulate injury, and ultimately promote disease resolution or progression to fibrosis. Local host factors (i.e., parenchymal cell expression of Fc receptors and complement (C) regulatory proteins) were demonstrated to influence profoundly the renal response to immune attack and inflammation. Elucidation of this network also provided a conceptual framework for the rational design of an array of novel therapeutic interventions. It is of note that, in contrast to the substantial insight gained regarding the nature of disease mediators, our understanding of events that initiate nephritogenic immune responses remains rudimentary and conjectural. Nonetheless, increasing availability of novel mutant mouse lineages and refined molecular and immunologic techniques are beginning to shed light on these processes, including the interplay of environmental factors and genetic susceptibility that induces nephropathic immunity.

INITIATION OF NEPHROPATHIC IMMUNE RESPONSES

Humoral or cellular immune effectors that target a wide variety of foreign or self-antigens (Table 50.1) can mediate renal injury. These nephritogenic effectors may arise in the course of a protective immune response mounted against a microbial pathogen as part of an allergic response to normally innocuous foreign antigen (e.g. antibiotic) or during an autoimmune response targeting normal or altered self-antigen (Table 50.2). Nephropathic Igs are also occasionally inadvertently produced as a by-product of unregulated monoclonal lymphocyte expansion. What is not clear in most cases, however, is the relationship between immunizing and tissue target antigen because it appears that they are distinct, at least in some situations. This issue is particularly germane to understanding the relative roles of autoimmune versus antiforeign responses in mediating renal injury and the mechanisms by which pathogenic Ig localizes to the kidney [i.e., *in situ* versus circulating immune complex (CIC) deposition].

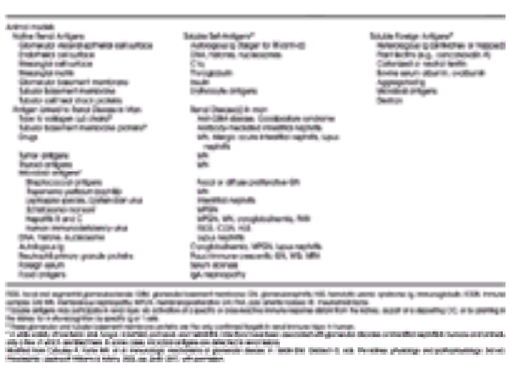

TABLE 50.1. Antigens Implicated in Immunologically Mediated Renal Diseases

TABLE 50.2. Development of Nephropathic Immune Responses

Observations over the past two decades in animal models of renal immune injury (Table 50.3) precipitated a paradigm shift that now recognizes intrinsic kidney self-antigen as a primary target of nephritogenic responses (7). Three of the most extensively studied animal models involve Ig interactions with native glomerular proteins. Pioneering studies exploited active immunization of animals with heterologous or autologous kidney extracts enriched for different renal antigens to induce nephritis marked by linear glomerular BM (GBM) Ig deposits (e.g., autoimmune anti-GBM Ig-mediated disease) or disease dominated by granular subepithelial deposits (e.g., active HN) (4,8). Subsequent investigations ultimately determined that these pathogenic Igs arose as induced autoimmune responses to GBM a3(IV) collagen and to glomerular epithelial cell membrane antigens, respectively (6,9). A third model is induced by passive administration of Ig against a rat mesangial cell phosphatidylinositol-anchored glycoprotein, termed *Thy-1 antigen* (10). Numerous additional renal or nonrenal self-antigens encompassing a diverse group with regard to molecular structure and tissue distribution have since been implicated in induced and spontaneous models of renal-restricted and systemic autoimmune nephritis (Table 50.1) and provide considerable insight into potential targets and mechanisms in humans.

TABLE 50.3. Particularly Instructive Experimental Models of Renal Immune Injury

Despite the litany of self-antigens engaged in renal injury, our understanding of the events that initiate and regulate autoimmune responses remains rudimentary. Insight into human autoimmune nephritis is limited in particular by a lack of information regarding the disease-relevant antigens. This issue will remain difficult to resolve because it will require careful and detailed analysis of Ig and T cells recovered intact from affected kidneys early in the disease course (11). Models of induced nephritis that depend on passive transfer of differentiated effectors or induction of an autologous Ig response to planted foreign antigen (e.g., the heterologous and autologous phases of NSN) (Table 50.3) provide minimal insight into the more proximal events that promote autoimmunity; nonetheless, they are excellent tools with which to study downstream mediator pathways (12). Models induced by active immunization with autoantigen-in-adjuvant are instructive in elucidating genetic factors that control disease and strain susceptibility. The relevance of these last models to disease initiation in humans has yet to be determined because they are dependent on adjuvant, a potent activator of innate immunity, to overcome immunoregulatory mechanisms that normally prevent the emergence of autoreactivity. Conversely, rodent models of spontaneous autoimmune nephritis have provided important insights into the proximal events that initiate nephritogenic responses (reviewed in 13). The common murine lupus strains [e.g., MRL/lpr, New Zealand black (NZB), BXSB] and several of the recent mutant variants or novel lineages are particularly useful for dissecting complex immunologic interactions and genetic mapping of nephritis susceptibility loci. Insight into the basis of renal-restricted disease also is extrapolated in part from observations in other models of organ-restricted autoimmunity.

It is likely that distinct disturbances in immunoregulation predominate in kidney-limited (i.e., anti-GBM disease, HN) versus systemic (e.g., lupus nephritis) autoimmune diseases (Table 50.2). Renal-restricted localization of immune effectors suggests a targeted immune response requiring activation of a specific population of autoreactive lymphocytes (via specific immunization with self- or cross-reactive foreign antigen) as well as effector localization to the kidney in response to appropriate attractants and recognition of renal-restricted ligand. Lymphocyte activation may occur in distant lymphoid tissues or locally by antigen presented in an immunogenic manner by resident macrophages, dendritic, or renal parenchymal cells. The requirement for both lymphocyte activation and recognition of locally expressed antigen is demonstrated in the rat model of induced antitubular basement membrane (TBM) TIN. The target TBM antigen is polymorphic, and in rat strains in which renal antigen is either lacking or inaccessible, nephritis does not develop despite production of a vigorous peripheral anti-TBM immune response (14). Shared kidney and microbial epitopes may provide the basis for renal localization of effectors in certain infection-associated renal diseases. Alternatively, normally inaccessible antigens may be exposed or modified by local injury or inflammation induced by infection or actions of industrial chemicals or pharmaceuticals (1), as proposed for exposure of normally privileged a3(IV) collagen epitopes in Goodpasture syndrome (GPS) (15).

The T-cell repertoire against cryptic self may be particularly important in renal-restricted disease. Normally, cryptic self-peptides are not processed or presented and thus do not tolerize reactive T cells. Lymphocytes reactive to dormant antigens, in which expression is restricted to certain developmental or differentiation states, similarly may escape tolerance induction. If conditions arise to expose previously hidden kidney self-antigen and permit its presentation with appropriate costimulation, however, normally ignorant but immunologically competent kidney-reactive T cells will be activated. This latter phenomenon is perhaps most elegantly illustrated in experimental cadmium-induced TIN (16). Cadmium-induced expression of heat shock protein-70 (HSP-70, a stress-induced neoantigen) in murine renal tubular cells recruits nontolerant cytotoxic HSP-70-autoreactive T cells to the renal interstitium. Antigen-nonspecific activation of immunologically ignorant or anergic renal-specific T cells by T-cell superantigens or bystander help are also possible but have not yet been documented as a cause of nephritis. Finally, the possibility is raised that epitope spreading during disease induction may contribute to the final nephritic phenotype, based on the observation that more severe glomerular injury accompanies the production of a more diverse autoantibody (autoIg) response in experimental anti-GBM disease and rat HN (17,18 and 19).

In contrast, more global defects in immunoregulation that alter lymphocyte activation and tolerance pathways likely contribute to the onset of nephritis in systemic autoimmunity. Genetic studies in lupus-prone mice indicated that the products of multiple susceptibility genes must interact to induce full-blown nephritis and implicate generalized defects in immune regulation that unleash autoreactivity to multiple diverse self-antigens (see later). These studies also indicated that disparate immune abnormalities can lead to a similar nephritis phenotype (reviewed in 13).

Considerable experimental and epidemiologic evidence indicates that the kidney is also frequently involved in immune responses induced by foreign antigen or exposure to exogenous agents (Table 50.1 and Table 50.2). Microbial or drug antigen is identified within renal deposits or infiltrates in some affected humans and is taken as presumptive evidence of a direct role in pathogenesis. The immunogenicity of drugs, many of which are small chemicals and poorly immunogenic in isolation, may be enhanced by *in vivo* conjugation with host proteins or direct binding to major histocompatibility complex (MHC) molecules, thus promoting antigen processing and recruitment of T-cell help and, in some cases, creating neoself-antigen as target of the nephritogenic response (20). The induced T cells, and occasionally Ig, localize to the kidney, presumably by recognition of drug “trapped” in the kidney during metabolism and excretion. Direct infection of renal cells or renal trapping of microbial antigens may similarly target antimicrobial immune effectors to the kidney (21,22). It is notable, however, that many infections [e.g., hepatitis C virus (HCV), human immunodeficiency virus (HIV), malaria, staphylococcus] are accompanied by activation of autoreactive lymphocytes (23), and a variety of pharmaceutical and

chemical agents can induce systemic autoimmunity and nephritis in susceptible individuals (Table 50.2) (24). Therefore, it remains unclear to what degree renal immune injury arising in association with exogenous agents is antiforeign versus autoimmune in origin.

IMMUNOGENETICS OF RENAL IMMUNE INJURY

Familial predisposition and reproducible differences in strain susceptibility clearly point to an important contribution of heredity in the development of immune nephritis (25). This is not surprising because selective breeding experiments in animals indicated strong genetic influences on the type and magnitude of immune and inflammatory responses. Immunogenetic studies in human nephritis are difficult to perform and interpret, however, because of problems of an outbred population, racial and ethnic differences in genetic makeup, heterogeneity in disease phenotypes (pathology, stage, and severity), uncertainty regarding pathogenesis, and the rarity of many nephritides. Nonetheless, numerous studies of human leukocyte antigen (HLA) allele association have been performed (25), and a strong association of HLA class II alleles with disease susceptibility has been reported for several disorders (Table 50.4). Isolated studies report MHC associations with disease severity or prognosis or disease associations with other immune-relevant genes with functional polymorphisms [e.g., C receptors, Fcg receptors, IgGm allotypes, Ig switch regions, T-cell receptor (TCR) constant a-chain region, tumor necrosis factor (TNF) production]. Results are often difficult to interpret, inconsistent, or lack independent confirmation.

	Population	
	Caucasian	Japanese
Disease	Class II specificity	
Goodpasture syndrome	DR2(w15)	
Membranous nephropathy	DR3	DR2(w15)
IgA nephropathy	None	DR4
Minimal change nephrotic syndrome	DR7	DR8
SLE	DR3, DR2

TABLE 50.4. Major Histocompatibility Complex Associations in Human Glomerulonephritis

The most rigorous studies in humans have necessarily been performed in anti-GBM Ig-mediated disease, the only human renal disease with a relatively well-characterized pathogenesis in which the renal antigen is known. Four series from the United States, United Kingdom, Australia, and France found that more than 80% of white patients with GPS carry a DR2 haplotype bearing DRB1*1501 and DRB5*0101 alleles, which encode b-chains of HLA class II molecules DR15b and DR15a, respectively (25). Less strong positive and negative associations have been reported with additional alleles. It was determined that DR15 molecules are capable of binding to many a3(IV) noncollagenous 1 (NC1)-derived peptides; however, most of the naturally presented peptides bind to DR15 with only intermediate affinity (26). Further investigation is needed to elucidate the basis of DR15 susceptibility and to determine the relative roles of intermediate versus high-affinity peptides in the induction of self-tolerance and autoimmunity.

No consistent class II allele associations have been reported in white patients with Ig A (IgA) nephropathy (IgAN) (25), the most common glomerulonephritis worldwide. Disparate results have been reported for antineutrophil cytoplasmic antibody (ANCA)-associated vasculitides. At least six independent studies found an association in patients with Wegener granulomatosis or antiproteinase 3 Ig with the Z allele, associated with relative enzyme deficiency, at the a_1-antitrypsin locus. Most studies in human systemic lupus erythematosus (SLE) confirmed associations with DR3, DR2, C4A, and C4B null and deficiencies of components of the classical C pathway (i.e., non-MHC-linked C1q and MHC-linked C2 and C4) or regulatory proteins (C1 inhibitor, factors H or I) (27). A potential basis for the association between C deficiency and autoimmune susceptibility was suggested by observations in mice indicating a complex role for C in the initiation and regulation of humoral immune responses, including B-cell activation and tolerance induction (28). An association of SLE with FcgR allele FCgR2A is described, and a recent directed linkage analysis of sibpairs with SLE, based on a locus syntenic to murine nephritis susceptibility locus Sle1 (see later), linked human SLE to chromosome 1q41-q42 (29).

Linkage studies and more recent genomewide screening in experimental autoimmune renal diseases in rodents (Table 50.3) concur that nephritis is a complex trait and that both MHC- and non-MHC-linked genes are essential for full expression of disease (25). As noted earlier, in rat anti-TBM Ig TIN, disease susceptibility depends on genetically determined renal expression of the relevant TBM antigen and the ability to mount an anti-TBM response (14). An unknown gene inherited in an autosomal recessive fashion with complete penetrance appears to be responsible for disease in spontaneous autoimmune TIN in kd/kd mice (30) and is currently being mapped.

Extensive genomewide linkage studies in lupus-prone mouse strains (e.g., MRL, NZB F1 hybrids, and BXSB) indicated that murine lupus nephritis is inherited as a complex polygenic trait (reviewed in 27,31). Each strain carries a unique constellation of MHC- and non-MHC-linked susceptibility loci, the products of which confer additive disease risk or protection, with certain gene combinations being particularly potent disease modifiers. No single gene is necessary or sufficient for disease but may contribute to distinct phenotypes and different gene combinations produce similar phenotypes. The position of at least 12 non-MHC susceptibility loci have been mapped in the New Zealand hybrid model. Several loci link to severe nephritis and death, i.e., Sle1/nba2/Lbw7, Sle2/nba1/Lbw2, and Sle3/Nba3/Lbw5/Lrdm1 on chromosmes 1, 4, and 7, respectively. Sle1 and Sle3, loci derived from New Zealand white (NZW) mice that lack severe autoimmunity, mediate lupus nephritis on a C57BL/6 background. Four NZW modifier loci have been identified that suppress nephritis in that strain (32). B6.NZM mice rendered bicongenic for loci Sle1 and Sle3 develop a polyreactive autoIg response and highly penetrant GN not observed in the monocongenic lines (33). Nephritis susceptibility similarly links to both MHC- and non-MHC-linked loci in induced lupus models (34). Candidate susceptibility genes include those involved in various apoptosis, cell survival, immune response, and lymphocyte signaling, selection, and adhesion pathways.

It is of note that five murine SLE susceptibility genes have been identified to date: MHC class II alleles and Src-homology 2-domain phosphatase-1 (SHP-1), molecules involved in antigen presentation and lymphocyte signaling, respectively, and three spontaneously arising autoimmunity accelerator genes, *Yaa*, *lpr*, and *gld*. The function of *Yaa* is not yet determined; the *lpr* and *gld* mutations encode nonfunctional Fas antigen and Fas ligand proteins, respectively, leading to defects in apoptosis and peripheral tolerance. Notably, the congenic MRL^{++} background is responsible for autoimmune kidney disease (35); a superimposed Fas mutation accelerates disease onset and severity. The Fas mutation expressed on the non-autoimmune C3H or C57Bl/6 background does not cause autoimmune renal damage. Lupuslike autoIg and nephritis are also reported in mice with targeted disruptions of genes encoding lyn, a Src protein-tyrosine kinase, PD-1, an inhibitory membrane protein on activated lymphocytes and monocytes, or the immunosuppressive cytokine transforming growth factor (TGF)-b1, and in mice transgenic for Bcl-2 or the cytokine interferon (IFN)-g under control of the involucrin promoter (reviewed in 13). The impact of genetic susceptibility on the expression of nephritogenic autoimmunity has been examined directly using mice rendered transgenic for Ig reactive with nephritis-associated autoantigens (DNA and BM laminin). Transgene-expressing autoreactive B cells developing in a non-autoimmune background appear to be regulated, whereas at least some specificities escape regulation in autoimmune-prone MRL mice (36,37 and 38).

ENVIRONMENTAL CONTRIBUTIONS TO NEPHROPATHIC IMMUNE RESPONSES

Synergy between inherited and environmental susceptibility is suggested by reports of monozygotic twin sets discordant for disease in the various nephritides and SLE. Experimental models suggest that infectious agents, chemicals, and pharmaceuticals may induce nephritis by diverse mechanisms (Table 50.2), many of which lead to acquired defects in immune tolerance. Inducible heat shock proteins, in particular, are highly immunogenic; they are expressed in the setting of imposed stress (ionizing radiation, heavy metal toxicity, infection), epidemiologically associated with development of TIN in humans and targets of immune attack in rodent TIN (16,39). Exposure of hidden BM epitopes by environmental insults also is implicated in the anti-GBM diseases (1). Procainamide and hydralazine induce systemic autoimmunity in humans and rodents; *in vitro* they inhibit DNA methylation, upregulate T-cell lymphocyte function-associated antigen-1 (LFA-1) expression, and induce T-cell autoreactivity. Adoptive transfer of T cells overexpressing LFA-1 induces lupuslike autoreactivity and GN in recipient mice (40). Heavy metals and allogeneic responses may preferentially induce Th2-type autoreactive $CD4^+$ T cells (reviewed in 24). Mercuric chloride is reported to trigger T-cell interleukin (IL)-4 production directly (41). Notably, however, mercuric chloride induction of nephritis in IL-4-deficient but not IFN-g-deficient mice implicates an IFN-g-dependent mechanism in this model (42). Polyclonal B-cell activation induced by these agents as well as microbial mitogens may activate nontolerant (ignorant) autoreactive B cells or in appropriate concentrations reverse anergy in tolerant B cells. Superimposed specific-antigen immunization, perhaps by nucleosomes, bacterial DNA, or apoptotic cell antigens (reviewed in 43,44 and 45), is implicated in the development of full-blown lupus nephritis. Notably, exacerbation of experimental nephritis by bacterial lipopolysaccharide or adjuvant suggests that microbial products may modulate the effector as well as inductive limb of nephritogenic responses (1). In this regard, synpharyngitic exacerbations of hematuria and renal injury are characteristic of several human GN.

RENAL PARENCHYMAL CELL ANTIGEN PRESENTATION AND LOCAL IMMUNE RESPONSES

Systemic and local immune responses and a variety of nonimmune renal injuries (e.g., acute ischemia, toxins, gentamicin, mercuric chloride) can dramatically induce class II expression on renal cells *in vitro* and *in vivo* (46). Proximal tubular epithelial cells can process and present self-antigen and foreign antigen *in vitro* for recognition by $CD4^+$ T cells (reviewed in 47). In the absence of concomitant upregulation of costimulatory molecules, however, isolated class II expression likely induces tolerance in reactive $CD4^+$ T cells. Antigen-specific nonresponsiveness (*anergy*) is induced in T cells exposed to murine tubular cells transfected with class II antigens alone, and transplantation of kidneys from transgenic mice bearing high levels of class II molecules fails to initiate autoimmune injury (47). Although less readily induced, immune accessory molecules, including intercellular adhesion molecule-1 (ICAM-1), vascular adhesion molecule-1 (VCAM-1), CD40, or B7-1 are expressed on renal tubular cells exposed to IFN-g or other cytokines and in some settings support *in vitro* T-cell proliferation and IL-2 production (47,48). Mesangial cells (49), glomerular visceral epithelial cells (50), and vascular endothelium (51) have inducible antigen-presenting functions, as do resident renal fibroblasts, interstitial dendritic cells, and macrophages. Activated resident renal cells also express a broad array of proinflammatory cytokines, chemokines, and adhesion molecules (52). The relative role of renal parenchymal cells in initiating versus amplifying local immune responses remains unclear.

MECHANISMS OF IMMUNOGLOBULIN LOCALIZATION TO THE KIDNEY

In Situ Binding to Renal Self-Antigen

Elucidation of mechanisms leading to renal Ig deposition, a major feature of glomerular immune disorders, has provided considerable insight into disease pathogenesis (1,2). Observations in two classic animal models, experimental anti-GBM disease and HN (Table 50.3), as well as in human anti-GBM disease/GPS were instrumental in documenting direct binding of autoIg to intrinsic renal antigens as a dominant mechanism of Ig deposition. These models also revealed that the location and nature of the Ig–antigen interaction is an important determinant of disease phenotype because *in situ* deposition can lead to diverse histopathologic manifestations that mimic a variety of human glomerulopathies (12). Most subepithelial deposits are thought to arise by *in situ* mechanisms. The site of IC formation also may be a determinant of the inflammatory response because subepithelial deposits generally do not cause inflammation (7,53).

Experimental anti-GBM disease is induced in susceptible mammals by active immunization with heterologous or autologous GBM-in-adjuvant (Table 50.3) as well as with a variety of other antigenic preparations [alveolar BM, choroid plexus, a3(IV) NC1 dimers, and recombinant a3(IV) collagen] (1,54). Hosts develop characteristic linear GBM IgG and C deposits and severe proliferative GN. Passive transfer of disease using anti-GBM serum or renal eluate Ig from diseased animals or patients confirmed a direct pathogenic role for induced anti-GBM Ig (55,56). A passive form of anti-GBM disease, NSN, also can be induced by administration of heterologous anti-GBM Ig, leading to both an immediate heterologous and a subsequent autologous (anti-heterologous Ig) disease phase. The major pathogenic epitope targeted by renal eluate Ig in both experimental and human anti-GBM disease has been identified as a3(IV)NC1 collagen (9,57), a highly tissue-restricted epitope found predominantly in GBM and alveolar BM. Notably, lung binding by heterologous anti-GBM usually occurs only after lung injury is experimentally induced (oxygen toxicity, gasoline exposure, cytokine administration) (1), suggesting that lung epitopes are less accessible than GBM epitopes to circulating Ig.

Whereas *in situ* binding readily accounts for linear Ig staining of the GBM, most human Ig-mediated glomerular diseases are characterized by discontinuous granular deposition of Ig. Dissection of pathogenesis in the rat HN model of membranous nephropathy revealed that *in situ* mechanisms also can induce this pattern of injury (6). In active HN (8), rats immunized with a suspension of their own kidney in Freund adjuvant develop nephrotic syndrome with a histopathologic picture similar to human membranous nephropathy. The lesion is noninflammatory and is characterized by granular Ig deposits in the glomerular subepithelial region. Disease induction by antigen preparations (termed fraction 1A, or Fx1a) enriched for tubular proteins initially prompted investigators to attribute pathogenesis to deposition of CICs composed of autoIg and tubular antigen. In now classic experiments, however, it was demonstrated that the early histopathologic findings, including granular capillary wall deposits found exclusively in the subepithelial space, could be reproduced by perfusion of isolated rat kidneys with anti-Fx1A Ig (58). It was subsequently shown that Ig eluted from kidneys with active disease binds to glomerular antigens in tissue sections and when infused into isolated kidneys, confirming *in situ* binding to an antigen expressed in the glomerulus.

The major antigen target in HN was subsequently determined to be the HN antigenic complex (HNAC) (59,60) expressed in renal proximal tubular epithelial microvilli and clathrin-coated pits on the glomerular epithelial cell. This multiple ligand endocytic receptor is composed of the 516-kd membrane glycoprotein megalin (initially gp 330), a member of the low-density lipoprotein receptor gene family, and the 44-kd receptor-associated protein, RAP (6). Several non-overlapping pathogenic epitopes were mapped on megalin and RAP using renal eluate Ig. Immunization with intact megalin, RAP, or peptides or administration of heterologous Ig to any component can induce subepithelial IDs in rats (61). IDs are thought to form by circulating anti-HNAC Igs that penetrate the GBM and bind HNAC at the base of the foot processes. ICs are then fairly rapidly shed from the cell surface and attach to the GBM. RAP has a heparin-binding site, which has been proposed as one mechanism by which the ICs bind to the GBM.

It is noteworthy that anti-HNAC Igs, although responsible for immune deposition in HN, are inefficient in inducing proteinuria, the major clinical manifestation in this disease. The crude anti-Fx1A antisera also contains additional autoIgs that recognize unrelated podocyte antigens, including a3b1 integrin receptors and glycolipid, which appear to be responsible for proteinuria and in situ C activation (18). Anti-glycolipid IgG does not form IDs independently but may associate with anti-HNAC deposits. Additional specificities have been reported (1,62), including two, dipeptidylpeptidase IV (DPPIV) and laminin, that also have been reported in experimental lupus nephritis. Although megalin/gp330 is not detected in human glomeruli, human homologs of both megalin and RAP are reported as well as an undefined glomerular epithelial antigen that is cross-reactive with nephritogenic Ig in spontaneous membranous-like GN in rabbits (63). It is not yet clear whether these human proteins are targets for autoIg. Nonetheless, similarities between the experimental and human disease suggest common pathogenic mechanisms.

When directed at a variety of additional intrinsic renal antigens, autoIgs are capable of inducing renal injury or proteinuria in experimental models (Table 50.3). An extensively studied rat model of immune mesangial injury is induced by passive administration of polyclonal antisera or monoclonal antibodies (Mabs) against the Thy-1 antigen expressed on rat (but not other species) mesangial cells (1,10). Administration to rabbits of heterologous Ig reactive with rabbit endothelial angiotensin converting enzyme (ACE) induces granular deposition of IgG on glomerular and arterial endothelium and renal injury. Notably, over several days, repeated injections lead to subepithelial IDs, interpreted as dissociation of subendothelial ICs *in vivo* with redistribution and local reassociation in the subepithelial space (64). Renal artery perfusion with antiendothelial Ig induces thrombotic microangiopathy (reviewed in 65). Injections of Ig specific for collagen IV, laminin, or heparan sulfate proteoglycan induce renal morphologic and functional abnormalities in rodents, and Ig with these specificities are isolated from rodents with spontaneous or mercuric chloride-induced lupuslike nephritis (66,67,68 and 69). Serum reactivity with a variety of renal antigens (glomerular epithelial, mesangial, and endothelial cells) has been reported in selected patients with a variety of nephritides, but their role in disease pathogenesis in humans and specificities of renal-bound Ig remain unknown. The only confirmed autoIg targets in human nephritis are a3(IV) collagen and two TBM glycoproteins, in anti-GBM diseases and certain forms of TIN, respectively (9,70,71).

In Situ *Binding to Planted Antigen*

Glomerular deposition or “trapping” of foreign antigen followed by *in situ* binding by specific Ig has been validated as a mechanism of renal immune injury in numerous experimental models (1,2). Susceptible animals immunized with foreign protein bearing affinity for the glomerulus mount a humoral immune response against the foreign protein; antigen that localizes to the kidney serves as “planted” target for induced circulating Ig. The renal disease phenotype is dependent on multiple factors, including location of the planted antigen, affinity and isotype of the autologous response, engagement of C or Fc receptors, and donor and recipient species and strain. An unambiguous example of planted antigen GN is the autologous phase of NSN. Heterologous (i.e., foreign) anti-GBM Igs induce an initial (heterologous) disease phase mediated by the injected antiserum binding to the GBM and a subsequent autologous phase mediated by induced host anti-Ig binding to deposited (planted) heterologous Ig (72). In a classic variant of this model, rodents injected with a subnephritogenic dose of polyclonal sheep anti-GBM antiserum develop a high-affinity anti-sheep Ig response and florid nephritis. A variety of plant or microbial lectins [concanavalin A (Con-A), hemagglutinin] and cationized antigens [ferritin, IgG, bovine serum antigen (BSA), avidin, myeloperoxidase], including intact ICs, bind to glomerular endothelial cells, polyanionic GBM components or podocytes to deposit in the subendothelial or subepithelial space and serve as planted antigen in experimental models (73,74).

Circulating Immune Complex Deposition

Soluble antigens combine with specific Igs to form CICs that can lodge in the kidney. The prototype CIC nephritis is acute serum sickness induced in rabbits by injection with a single large bolus of BSA. In this model, free BSA does not accumulate in glomeruli; rather, glomerular deposition and GN develop only after a substantial Ig response is established and coincides with the appearance of large cross-linked ICs between days 9 and 10 after BSA injection (5,12). It is difficult to reproduce the severe histopathologic lesions of serum sickness using passive transfer of preformed ICs. Glomerular trapping of ICs in the mesangium and subendothelial space is common, but clinical and morphologic changes are typically mild (75). Systemic or oral immunization with a variety of foreign antigens (dextran, dinitrophenol (DNP)-conjugated BSA, gluten) has met with similarly limited success in inducing florid GN. These observations have lessened enthusiasm for passive entrapment of CIC as the dominant mechanism of renal immune deposition in humans. Chronic serum sickness is induced by daily injection, often for weeks, with native BSA (5,12). The delayed onset of renal lesions (several weeks) has raised the possibility that additional mechanisms (e.g., neoantigen exposure, epitope spreading, auto-antiidiotypic Ig, autoIg) are recruited in disease induction. In both models, lesion morphology is dependent on the magnitude and nature of the immune response, including antigen dose, isotype, and epitope specificity; physicochemical properties (antigen:Ig ratio and Ig avidity, which in turn determine IC size, charge, and solubility); as well as nonimmunologic factors, such as IC clearance and renal hemodynamic parameters. CIC deposition based on a particular physicochemical

affinity of the CIC for glomerular structures also has been proposed (e.g., binding of IgA fibronectin complexes to collagen) (76).

Mechanisms of Immunoglobulin Deposition in SLE Nephritis

Lupus nephritis develops as part of a spontaneous multisystem autoimmune syndrome with a remarkably heterogeneous phenotype. As with other disease manifestations, the initial renal manifestations and course are highly variable. Although considerable controversy exists, current thinking favors the notion that nephritogenic Igs of diverse specificities, isotype, avidity, and charge arise in the course of disease and localize to the kidney by a variety of mechanisms (reviewed in 77,78 and 79). Anti-DNA IgGs are present in nephritic kidneys in both murine and human SLE and clearly implicate anti-DNA in nephritis pathogenesis. A select subset of murine and patient monoclonal anti-dsDNA IgG are capable of forming IDs and induce a variety of renal histopathologic lesions in naive animals (80,81). Nonetheless, the relative importance of reactivity with DNA versus other antigens and the mechanism by which anti-DNA localize to the kidney are the subject of much debate (82) because it appears that anti-DNA activity is neither necessary nor sufficient to induce SLE nephritis. Anti-dsDNA titers and affinity can be dissociated from the presence and severity of renal disease in both patients and experimental models, and many Igs eluted from SLE kidneys do not bind to DNA.

In situ IC formation may be a dominant mechanism of renal Ig deposition in SLE (reviewed in 77,78 and 79). Both direct binding to intrinsic renal components and Ig reactivity with planted self-antigen are implicated. Anti-DNA cross-reactivity with non-DNA antigens may be involved. Anti-DNA eluted from nephritic kidneys as well as serum and monoclonal SLE Ig cross-react with polynucleotides, phospholipids, cytoskeletal proteins, and nonnuclear glomerular antigens. Subsets of SLE Ig bind *in vitro* to isolated glomeruli, crude renal extracts, cultured endothelial and mesangial cells, and purified glomerular antigens. *Ex vivo* renal perfusion with polyclonal human SLE IgG and both human and murine SLE monoclonal Ig result in glomerular Ig deposition. Some nuclear antigens (i.e., small 100–200 base pair DNA fragments) and soluble proteins have an intrinsic affinity for glomerular cell or BM surfaces. Collagen, laminin, and fibronectin possess binding sites for DNA, and some cells express DNA-binding receptors. Cationic ICs and nuclear histones (pI ~10–11) and nucleosomes (DNA–histone) can bind polyanions in the GBM or negatively charged glycosaminoglycans in cell membranes and serve as binding sites for anionic DNA, DNA-anti-DNA ICs, antihistone or antinucleosome Ig. These autoIgs and corresponding antigens have been recovered from human and murine lupus renal lesions. Rheumatoid factors, certain Ig idiotypes, and anti-C1q Ig are reported in high frequency in SLE serum and glomerular deposits, suggesting Ig binding to previously deposited Ig or C1q.

Antigen Nonspecific Mechanisms of Immunoglobulin Deposition

Mechanisms independent of antigen specificity may underlie Ig deposition in certain renal disorders. Abnormalities in hinge region O-glycosylation, possibly related to a defect in B-cell b-1,3 galactosyltransferase activity, are reported in circulating IgA_1 of patients with IgA nephropathy (83). It is postulated that the presence of abnormal carbohydrate moieties may alter IgA_1 interactions with matrix and mesangial cell IgA FcRs or interfere with normal degradation and contribute to ID and injury; however, a similar O-glycan defect in mesangial deposited IgA_1 has not yet been proven. A role for mesangial cell IgA FcR- or FcgR-mediated trapping of IgA or IgG is also postulated.

Physicochemical properties (e.g., amyloidogenicity, self-aggregability, tissue affinity, tubular toxicity) determined by particular Ig variable region sequences or chains, are presumed to underlie renal deposition of Ig or Ig fragments in the dysgammaglobulinemias (see later). Nephritogenicity of IgG_3 in MRL/lpr murine lupus is attributed in part to the unique capacity of murine IgG_3 constant regions to self-associate through nonimmunologic Fc–Fc interactions that contribute to decreased solubility and cryoglobulin formation (84).

T CELLS IN NEPHRITOGENIC IMMUNE RESPONSES

Cellular and humoral immune responses collaborate in the pathogenesis of most immunologically mediated renal disease (85). Cellular immunity is dominant in most forms of TIN (reviewed in 39). T cells (variably $CD4^+$ dominant) and monocytes/macrophages often dominate the mononuclear interstitial infiltrate, accompanied by B cells, plasma cells, eosinophils, and natural killer (NK) cells; ICs and anti-TBM Igs are uncommon. TIN also frequently accompanies primary glomerular disorders and nonimmunologic renal lesions, such as urinary tract obstruction. Although glomerular immune injury is often dominated by Ig deposition, numerous studies indicated direct cellular contributions (reviewed in 86,87). In experimental models, the relative contributions vary by species, strain, and disease.

T-cell involvement in the pathogenesis of renal disease can occur at several levels: (a) through provision of T-cell help for B-cell production of nephritogenic Ig; (b) indirectly via release of cytokines or permeability factors that affect renal function (88); (c) indirectly through immunoregulatory functions (89); and (d) directly as activated renal-infiltrating and renal-specific effectors causing injury by direct cytotoxicity or recruitment to the kidney of activated macrophages or NK cells via a delayed-type hypersensitivity (DTH)-like response. A role for T-cell priming in inducing experimental anti-GBM Ig responses is suggested by T-cell transfer and depletion studies (90) and the ability of costimulatory blockade via interference with CD28/B7, CD40/CD40L, or ICAM-1/LFA-1 interactions to ameliorate T-dependent Ig responses and disease (91,92). Direct T-cell involvement in mediating injury is suggested by the presence of activated T cells in renal lesions (39,86), experimental transfer of disease by renal antigen-reactive T cells in the absence of Ig (93,94), and amelioration of disease by T-cell depletion in the absence of effects on the Ig response (95,96).

Most of what is known about T-cell pathogenesis in renal disease has derived from experimental models. Early work focused predominantly on spontaneous and induced models of TIN mediated by sensitized T cells reactive with TBM proteins (reviewed in 39,97,98). In the induced antigen-in-adjuvant anti-TBM TIN model in SJL mice, renal anti-TBM Ig deposition precedes a mononuclear cell infiltration, but renal injury appears to arise primarily from cellular immunity. Pharmacologic interventions can ameliorate disease without diminishing the anti-TBM Ig response or renal Ig deposition. $CD4^+$ and $CD8^+$ antigen-reactive T cells can be isolated from lymph nodes of immunized mice. The TBM-reactive $CD4^+$ T cells do not directly mediate nephritis, but they are required for induction of effector TBM-reactive MHC class I restricted $CD8^+$ T cells that mediate antigen-specific DTH responses and renal tubular cell cytotoxicity (99). $CD8^+$ effectors induce TIN after adoptive renal subcapsular transfer to naive recipient mice. Notably, nonpathogenic TBM-reactive $CD4^+$ T cells from nonsusceptible mice can induce TIN on adoptive transfer to host with cytokine-upregulated renal class II MHC expression.

Spontaneous autoimmune TIN develops in kdkd mice mutated from the non-autoimmune CBA/Ca strain (30). Analogous to the anti-TBM model, class I-restricted $CD8^+$ effector T cells mediate TBM-specific DTH and induce TIN on adoptive transfer. Antigen-reactive $CD8^+$ T cells can be demonstrated in peripheral lymphoid organs of both kdkd and CBA/Ca strains. In experimental cadmium-induced TIN, $CD4^+$ HSP-70-autoreactive a/b T cells cytotoxic for heat-shocked or cadmium-treated renal tubular cells can transfer TIN in mice expressing tubular epithelial HSP-70 (16). Cytotoxic $CD4^+$ effectors capable of transferring disease can be isolated from renal lesions in murine chronic graft-versus-host disease (GVHD) glomerulopathy (100).

A major role for sensitized T cells in mediating glomerular injury only recently became widely appreciated (101,102). Macrophages and, to a lessor extent, activated $CD4^+$ and $CD8^+$ T cells are present in glomerular lesions in most experimental GN and in human proliferative and crescentic GN traditionally attributed to humoral immunity as well as in noninflammatory lesions (e.g., rat HN) (102,103). Severe anti-GBM disease can be induced in bursectomized chickens, which lack humoral immunity, and adoptive transfer of antigen-reactive T cells, in some cases derived from diseased kidneys, induces glomerular lesions in naive recipients in the absence of Ig (93). Depletion of $CD8^+$ or $CD4^+$ T cells inhibits proteinuria, macrophage infiltration, and skin DTH responses in rat NSN and HN without modifying Ig titers or C deposition (95,96,104). In the rat active HN model of membranous nephropathy, proteinuria develops coincidentally with glomerular infiltration by Th1 $CD4^+$ and cytotoxic $CD8^+$ T cells and macrophages and is abrogated by $CD8^+$ depletion (105). Underlying strain and antigen-dependent Th1/Th2 polarization has been suggested, based on differences in glomerular and systemic cytokine, Ig isotype, and T-cell effector profiles. In experimental GN, this suggestion is based on differences in DTH responsiveness and lesion responsiveness to cytokine manipulation (i.e., administration, inhibition, or gene-targeted deletion of IL-4, IL-10, INF-g, or IL-12) (reviewed extensively in 106). Interpretation of these studies is complicated by the *in vivo* production of counterregulatory cytokines by resident renal cells as well as lymphocytes, Th1 dependence of some pathogenic Ig isotypes, and variable success using therapeutic immune deviation. Polarization to a Th1 response may be most prominent in patients and models with strong evidence of glomerular DTH (T cells and macrophages), that is, crescentic GN. A genetically determined tendency to differentiate toward a Th1 effector subset in response to heterologous Ig (the nephritogenic antigen in NSN models) is implicated in autologous anti-GBM disease induced in rabbits and certain rodent strains (Wistar Kyoto rats, C57BL/6 mice) that are particularly susceptible to crescent formation, Th1 cytokine production, and prominent glomerular mononuclear cell infiltrates (104,106,107 and 108). Susceptibility to autoimmune crescentic GN by active immunization with a3(IV)NC1 collagen also is associated with a Th1-like immune response, characterized by glomerular IL-12 and IFN-g and induction of antigen-specific IgG2a Igs that transfer disease (109).

Regulatory T-cell subsets, cytokines (TGF-b in particular), and nitric oxide (NO) play an active role in regulating the expression of cell-mediated renal injury (89,110,111). The retrieval of antigen-reactive T cells from nonsusceptible mice and humans (39,112) suggests that peripheral mechanisms are crucial in maintaining nonresponsiveness. An intricate network of suppressor and/or contrasuppressor T cells regulate autoimmunity in rodent anti-TBM TIN (reviewed in 39). TGF-b1, a potent T-cell modulator, downregulates perforin expression and T-cell proliferation and inhibits the ability of T cells to transfer TIN (110). TGF-b-resistant $CD4^+$ nephritogenic T cells induce severe interstitial lesions (113). NO also has potent T-cell antiproliferative effects (111).

Cellular and humoral responses collaborate in lupus nephritis pathogenesis. Nephritis is ameliorated in lupus mice rendered deficient in a/b $CD4^+$, a/b $CD8^+$, CD28, or B cells (114,115 and 116) or subjected to MAb interruption of CD40/CD40L or CD28/B7 costimulation (117). AutoIg production and severe GN are variably attributed to

a/b or g/d T-cell subsets in TCR gene-targeted mice (114,118). Studies using pharmacologic or genetic alteration of Th1- and Th2-type cytokines have yielded conflicting results and fail to implicate selective disease dependence on a single $CD4^+$ T-helper subset (119,120). Differential modulation of renal mononuclear infiltrates and vasculitis in MRL mice deficient in B cells or secreted Ig indicates a crucial role for antigen presentation by autoreactive B cells (121); DNA-protein conjugates (nucleosomes in particular) are proposed antigen intermediaries (43).

MECHANISMS AND MEDIATORS OF TISSUE INJURY IN IMMUNE NEPHRITIS

Classic experimental models and novel mutant mouse strains, particularly knockout (KO) mice bearing selective deficiencies in critical molecules involved in inflammatory responses, have been useful in dissecting effector mechanisms in renal immune injury (12,53). These models revealed that proteinuria in noninflammatory lesions of the glomerulus is usually due to injury to the podocyte initiated by Ig, complement, or other soluble factor. Inflammatory renal lesions are mediated by infiltrating leukocytes or proliferation of resident glomerular cells induced by Ig, activated T cells, or both, with release of numerous inflammatory mediators. Each of these cells, molecules, and signaling pathways poses a promising target for novel therapies directed at renal immune injury (122,123 and 124).

It cannot be overemphasized, however, that the responsible mediators and relative C, FcR, leukocyte, or T-cell dependence vary considerably between species, strains, and disease models, inviting considerable caution in extrapolating between models or to disease in humans. Moreover, the pathogenic potential of renal-localized Ig depends in large part on effector functions determined by Ig constant region domains, each subclass of which has a unique profile of interactions with C and FcRs, which in turn are regulated by a complex system of C regulatory proteins and cytokines. This may explain in part the observations that monospecific Igs do not reproduce the fulminant pathologic changes seen with polyclonal antisera or in native disease models and that substantial Ig deposition may occur in the absence of renal histologic or functional alterations. Finally, in addition to their effector functions, some of these intermediates are potent modulators of immune responsiveness and autoimmunity by way of their modulation of B-cell signaling (i.e., C receptors and FcgRIIB) and T-cell functions (i.e., NO, TGF-b). In some settings in which manipulation of these molecules markedly alters the nephritis phenotype, it may be difficult to determine the point of dominant effect (disease induction versus mediation) in the pathogenic response. In this regard, experimental immune complex glomerulonephritis (ICGN) induced by foreign protein immunization induces distinct humoral responses and nephritis phenotypes in wild-type, C3-, and C4-deficient mice (125). C-receptor CD21/CD35 deficiency prevents the induction of anergy in autoreactive B cells, which, when combined with Fas deficiency, leads to severe lupus nephritis (126). These complex interactions must be taken into consideration when interpreting studies involving manipulation of these molecules.

Direct Immunoglobulin-Mediated Injury

It was well documented in early models of NSN that the injection of substantial quantities of heterologous nephrotoxic serum could result in immediate massive proteinuria that was C and polymorphonuclear (PMN) independent (127). A direct effect of Ig alone was confirmed by the induction of heavy proteinuria in antiserum-perfused isolated rat kidneys (128,129). Immediate transient proteinuria also has been observed in rats injected with F(ab')2 or Fab' fragments of sheep anti-Fx1A, and heavy proteinuria is reported in active HN in C6-deficient rats unable to form the C5b-9 membrane attack complex (MAC) (130). Subsequently, it was determined that these heterologous polyclonal antisera contain pathogenic Ig reactive with glomerular podocyte surface antigens. MAbs reactive with some of these determinants are capable of inducing marked alterations in glomerular permeability, proteinuria, and ultrastructural alterations in podocyte morphology (131).

Proteinuria-inducing murine MAb 5-1-6 recognizes a 185-kd protein on rat podocyte slit diaphragms recently identified as rat nephrin, an Ig-like transmembrane protein and important regulator of glomerular permselectivity (132). Ig cross-linking induces antigen redistribution, which may contribute to proteinuria. Notably, mutations in human podocyte nephrin underlie the massive proteinuria seen in congenital nephrotic syndrome of the Finnish type (133). Injection of intact or F(ab')2 monoclonal anti-Thy-1 Ig into mice expressing human Thy-1.1 on podocytes similarly induces rapid foot process swelling and proteinuria (134). Ig reactive with podocyte a3b1-integrin alters glomerular permeability to albumin *in vitro*; active signal transduction rather than simple interference with cell–matrix adhesion is apparently necessary because glomerular permeability is not altered by non-cross-linking Fab fragments that inhibit adhesion (135). As yet, none of these target antigens has been shown to be involved in human renal disease.

Complement

Complement (C) deposition is a prominent feature of many Ig-mediated glomerular diseases (136,137). Deposited C may derive from the circulating pool or from local synthesis by intrinsic renal cells. The presence of early C components (C1q, C2, C4) indicates activation of the classical pathway (e.g., anti-GBM disease), whereas deposits are often restricted to C3 or terminal components in certain nephritides [e.g., IgA nephropathy, membranoproliferative GN (MPGN) type 2], which indicates alternative pathway activation. A critical role for C in disease pathogenesis has been established in experimental models, although the mechanism of C-induced injury varies with the model. Acute C depletion with cobra venom factor markedly diminishes disease in each of the three most well-studied models of glomerular immune injury: NSN, passive HN, and anti-Thy-1 disease (138,139). Similar results have been seen with disease induced in C-deficient mice (C3, C4, C5), rabbits, or rats (C6) or using antisera containing only non-C-fixing Ig subclasses (140,141).

The MAC-induced renal injury is best characterized in the noninflammatory passive HN model. Proteinuria is largely dependent on *in situ* C activation by podocyte-bound antiglycolipid Ig (18), followed by insertion of the MAC into the podocyte membrane (142,143). Subsequent sublytic cell injury induces the transactivation of receptor tyrosine kinases; activation of extracellular signal-regulated kinase-2 (Erk-2) and cytosolic phospholipase A_2; and local release of proteases, oxidants, and eicosanoids that induce lipid peroxidation in the GBM, alter glomerular permeability, and induce proteinuria (144). Notably, the necessary lipid environment for peroxidation is provided in part by lipoproteins that accumulate in GBM IDs in this model; the anti-HNAC Igs that contribute to immune deposition (see earlier) also block HNAC-mediated endocytic uptake of apoproteins (145), a normal route of lipoprotein clearance from the glomerular filtrate. Thus, C- and non-C-fixing autoIgs of diverse specificities collaborate to induce this disease.

The MAC also mediates inflammatory and thrombotic renal injury. In the anti-Thy-1 model, mesangial cell lysis and proliferation, platelet and macrophage accumulation, and proteinuria are C dependent but PMN independent; all forms of injury are markedly reduced in C6-deficient rats (146). MAC-mediated lytic or sublytic mesangial cell activation releases inflammatory mediators and growth factors (147). C6 deficiency ameliorates Ig-induced endothelial injury in experimental rat thrombotic microangiopathy (148), and C5 blockade ameliorates renal disease in SLE-prone NZB/WF1 mice (149). Endothelial cells from human umbilical vein that were subjected to sublytic MAC assembly secrete chemoattractants (150). A role for MAC in human nephropathy is suggested by demonstration of terminal C components in renal biopsy specimens and in the urine of patients with membranous nephropathy (151).

The binding of C1q and C activation with release of anaphylatoxins C3a and C5a are largely responsible for PMN infiltration in NSN. PMN infiltration is reduced significantly in KO mice that are deficient in either C3 or C4 (140,152). Notably, C deficiency provides only partial protection from proteinuria in this model, indicating coexisting C-independent mechanisms. C also can recruit leukocytes via CD11/CD18-dependent leukocyte adhesion, C-induced renal cell injury with release of chemoattractants, or MAC-induced mobilization of P-selectin on endothelial cells (153,154).

A role for the alternative pathway in modulating lupus nephritis is suggested by the attenuation of nephritis in MRL/lpr lupus mice deficient in factor B; serum C3 levels remained normal in KO mice (155). Non-Ig-initiated C activation has been implicated in a porcine model of MPGN type 2 associated with hereditary factor H deficiency (156). Affected piglets develop spontaneous systemic C activation and massive *in situ* GBM deposition of C3 and MAC, but no Ig, associated with mesangial proliferation and BM electron-dense deposits analogous to human MPGN type 2. Factor H inhibits C activation, whereas its deficiency leads to uncontrolled C3 activation. Notably, human MPGN type 2 and hemolytic uremic syndrome (a thrombotic lesion) occasionally are associated with factor H deficiency, but pathogenesis is not established. H_2O_2 released by activated cells can itself activate C, amplifying injury. C filtered at the glomerulus into the tubular lumen during heavy proteinuria is a postulated source of downstream tubular cell injury (157).

Renal protection from C-induced injury depends in part on circulating, soluble, and renal cell membrane-associated C regulatory proteins that limit C consumption and bystander damage (158). C-bound plasma proteins can be found in renal lesions in human GN, and depletion of plasma clusterin exacerbates proteinuria in a C-dependent isolated perfused rat kidney model of HN (159). Activated murine tubular cells also synthesize clusterin, and C-activated human mesangial cells secrete soluble decay-accelerating factor (DAF). The human cell-bound regulatory protein C3/C5 inactivators, DAF, membrane cofactor protein (MCP), complement receptor type 1 (CR1), and CD59, an inhibitor of MAC formation, are constitutively expressed in the kidney and variably modulated by immune injury *in vitro* and *in vivo*. C-regulatory proteins Crry and CD59 are expressed in virtually all types of renal parenchymal cells in rodents. The disease relevance of these molecules is demonstrated by maneuvers that modulate their *in vivo* expression or function in models of C-dependent renal injury. Soluble forms of CR1 or Crry, a rat CR1-like C regulatory protein, block C activation *in vivo* and reduce glomerular injury in experimental ICGN (19,160). Overexpression of membrane-bound Crry protects against C-mediated mesangial injury *in vitro* (161), and MAb neutralization of CD59 exacerbates injury in rat antiendothelial Ig thrombotic microangiopathy (162). Recent studies also indicated a role for these molecules in tubulointerstitial defense against autologous C attack under normal and disease conditions (163,164).

In the absence of C3 activation, C1q may play a protective role in GN through the clearance of glomerular apoptotic cells. Whereas C1q-deficient mice develop autoimmunity and GN with IgG and C3 deposits and glomerular apoptotic bodies, C1q-deficient mice that also lack C2 and factor B develop similar lesions but without glomerular C3 deposition (165). C itself has antiinflammatory effects because of its ability to solubilize and inhibit deposition by ICs that may modulate renal injury. It is noteworthy, however, that preferential renal uptake of IgG2a-containing ICs was abrogated by C depletion, suggesting that enhanced renal deposition was C

dependent (166).

C-pathway components also can serve as targets of autoIg responses. Nephritic factors (NeFs) are spontaneously arising autoIgGs that bind and stabilize alternative or classical pathway C3 convertases (C3 NeF and C4 NeF, respectively), permitting continuous C activation. NeFs are reported in association with human MPGN types 1 and 2 and occasionally in other nephritides. Their presence and serum levels do not correlate with disease activity, and it is unresolved whether they contribute to ongoing renal injury. Anti-C1q Igs are common in SLE and may contribute to nephritis by binding renal-deposited C1q. Experimental evidence suggests that neutralizing anti-Crry autoIgs develop in active HN in Fx1A-immunized rats; these autoIgs impair the C-regulatory activity of Crry, permitting unrestricted C activation and renal injury by other subsets of pathogenic Ig (167).

Fc Receptors

The FcRs constitute a complex family of constitutive and inducible polymorphic cell-surface proteins that vary in cell distribution, Ig affinity, signaling, and function. The relative balance of inhibitory (FcgRII) versus activating (FcgRI and FcgRIII) FcgRs expressed on macrophages, PMNs, and renal parenchymal cells is a major regulator of the inflammatory response to IC deposition and a major determinant of disease susceptibility (168). Mice rendered deficient in activating FcgRs by KO of the common FcRg-chain gene (FcRg-KO) are generally protected from renal immune injury, demonstrating a pivotal role for FcgRs in regulating inflammation *in vivo*. Nephritis is dramatically attenuated despite prominent glomerular IgG and C3 deposition in FcRg-KO lupus-prone NZB × NZW mice (169) and in two models of NSN induced in FcRg-KO mice (170,171); conversely, disease is accelerated in mice deficient in inhibitory FcgRII (171). Renal inflammation is similarly relieved in SLE-prone MRL/lpr mice subjected to high dose granulocyte-colony stimulating factor (G-CSF) infusions, an effect attributed to G-CSF-induced down-modulation of glomerular FcgRIII (172). Notably, however, marked proteinuria was not attenuated (170) and C-independent, angiotensin II-dependent chronic renal injury with mesangial proliferation and mononuclear cell infiltration developed in FcRg-KO mice with anti-GBM disease (171), indicating the presence of ongoing non-FcgR-dependent injury.

The IC engagement of activating FcgRs promotes leukocyte adhesion and triggers proinflammatory functions in leukocytes. An IgG-induced anti-GBM GN dependent on FcR-mediated accumulation of macrophages was described in rabbits (173), and Fc-dependent, C-independent PMN infiltration was described in a murine NSN (174). FcgR are expressed on renal parenchymal cells, and their cross-linking can induce synthesis of multiple inflammatory mediators (175,176). A novel IgA receptor distinct from CD89, the myeloid IgA receptor, is expressed on human mesangial cells (177); its engagement by IgA triggers cytokine and chemokine expression, cell proliferation, and extracellular matrix synthesis. Additonal, as yet poorly understood, renal effects of FcgR modulation are possible because novel aspects of FcgR biology continue to emerge. In some model systems, targeted deletion of FcgR dramatically increases IC deposition, presumably by an altered IC clearance. FcgRII and III on mast cells are potent regulators of IgE-mediated allergic responses and may modulate renal allergic diseases. Intracellular collaboration involving FcgRs and C-receptor MAC-1 (CDIIb/CD18) in mediating sustained PMN adhesion in acute experimental GN has been reported, suggesting complex interactions between FcgR and complement systems (178). The relative roles of FcgR and C in mediating experimental and human nephritis remain to be determined. FcR-blocking strategies have been used successfully in ameliorating experimental ICGN (179).

Additional Mechanisms of Immunoglobulin-Mediated Renal Injury

Direct Ig reactivity with PMNs and monocytes may contribute to pathogenesis in ANCA-positive vasculitides (reviewed in 180,181). ANCAs react with soluble enzymes, primarily proteinase-3 (Pr3) and myeloperoxidase (MPO), contained in PMN primary granules. Their role in the pathogenesis of vascular and renal lesions remains unclear because Ig deposition is typically absent (termed *pauciimmune*) from glomeruli and vessel walls. *In vitro* studies indicated that these enzymes become exposed on the surface of activated PMNs, monocytes, or endothelial cells, permitting antigen-specific binding of ANCA and subsequent PMN respiratory burst, degranulation, and lipid-mediator generation, endothelial damage, apoptosis, and inflammation. Binding mediated by PMN FcR engagement is also reported. ANCA stimulation of primed human PMNs in the presence of free arachidonic acid (prevalent in inflammatory microenvironments) induces strong activation of the 5-lipoxygenase pathway and release of chemoattractants and proinflammatory leukotrienes (182). Heterologous MPO induces an autoimmune anti-MPO response in rodents that contributes by an unknown mechanism to severe necrotizing crescentic GN in rats injected with a subnephritogenic dose of anti-GBM serum. Anti-MPO Igs also are expressed in several rodent models with induced or spontaneous renal vasculitis. Cationic MPO has a natural affinity for anionic GBM and can serve as a planted glomerular antigen target in MPO-immunized rats to induce an ICGN and vasculitis. A subset of cANCA (anti-Pr3) from patients with active vasculitis cross-react with a 130-kd lysosomal-associated membrane protein, h-lamp-2, expressed on renal microvascular endothelial cells and PMNs, potentially bridging PMN and endothelium (183). Direct endothelial toxicity of released proteinase 3 also has been postulated.

Recent studies suggested that SLE autoIgs may induce renal injury by a variety of mechanisms in addition to IC deposition. Disruption of cell functions by autoIgs that gain intracellular access has been postulated. Select human and murine SLE Igs are able to penetrate living cells in culture (184). Cell entry typically involves the antigen-specific binding (myosin is one putative membrane target) and may depend on the endocytosis of Ig-bound cell-surface receptors (185). Subsequent Ig localization to distinct intracellular compartments is attributable to either Ig specificity for subcellular antigens or expression of nuclear localization sequences within the Ig-variable region. A pathogenic role is suggested by the association of *in vivo* renal nuclear localization by SLE Ig with proteinuria and renal injury (184). Several mechanisms have been proposed as being involved in the pathogenesis of anti-heparan sulfate Ig, including alterations in glomerular permeability from the blockade of BM anionic sites, thrombus formation from Ig binding to endothelial cell-surface heparan sulfate, a physiologic ligand for antithrombin III, and promotion of a procoagulant state resulting from cross-reactivity with anionic phospholipids and interference with phospholipid-dependent coagulation. Selected anti-dsDNA Igs initiate C-mediated cytotoxicity of cultured kidney cells (186).

Cellular Mediators

The magnitude and relative proportion of cell types in the inflammatory infiltrate vary with the disease model and stage, species and strain, and renal expression of cytokines and adhesion molecules that attract and retain the different cell populations. Differentiated T-cell effectors (see earlier) exert their functions by interactions with other cells. Experimental models indicate that nephritogenic $CD4^+$ and $CD8^+$ T cell clones can mediate MHC-restricted cytotoxicity toward cultured renal proximal tubular cells (187). Cytotoxic clones express perforin and granzymes B and C (188), and granzyme C inhibition blocks both *in vitro* cytotoxicity and *in vivo* tubular cell destruction (188). $CD4^+$ T cells eluted from renal lesions in experimental TIN mediate DTH responses to challenge with renal antigen (39,97,98). Renal antigen-reactive T-cell clones isolated from mice with induced anti-TBM TIN or GVHD variably express a Th1, Th2, or a mixed cytokine profile (39,98,100). *In situ* studies similarly suggest a mixed cytokine profile in glomerular lesions (106). Nephropathic T cells secrete inflammatory and cytotoxic cytokines capable of upregulating renal adhesion and MHC class II molecules (IFN-g), amplifying inflammation (TNF-a, IL-1b) or promoting fibrosis (TGF-b) (189). Antigen-nonspecific T cells attracted to the inflammatory locus by chemokines may further amplify injury.

MACROPHAGES

Macrophage accumulation is prominent in TINs of all causes and in aggressive forms of GN (190). A role in renal injury has been demonstrated in experimental models in which monocyte depletion inhibits renal macrophage accumulation and abrogates disease and induction of renal lesions by passive transfer of macrophages to leukopenic rabbits during autologous anti-GBM GN (191,192). Monocytes and macrophages are recruited, retained, and activated in the kidney by a variety of Ig-, C- and T-cell-dependent mechanisms. Macrophages bind to ICs through their cell-surface Fc or C (CD11b/CD18, MAC-1) receptors and migrate in response to C5a. Activated $CD4^+$ T cells, platelets, endothelial and renal parenchymal cells release chemoattractants, upregulate adhesion molecules, and release cytokines [IFN-g, macrophage migration-inhibiting factors (MIFs)] to bind and activate macrophages (Table 50.5). Local macrophage proliferation, possibly driven by local macrophage colony-stimulating factor (M-CSF) production, contributes to macrophage accumulation in severe renal injury (193). Florid interstitial macrophage accumulation also occurs in nonimmune injury, such as obstructive nephropathy, presumably because of tubular dysfunction and chemoattractant release (194). Abnormal macrophage sensitivity to renal-expressed CSF factor 1 (CSF-1) is implicated in MRL-lpr lupus nephritis (195). Macrophages are a major source of IL-1b and release a variety of products that mediate direct cell cytotoxicity and promote mesangial cell proliferation and fibrosis (Table 50.5).

TABLE 50.5. Cell Sources of Mediators and Modulators of Renal Inflammation and Injury[a]

Macrophages are the dominant cell type in cellular crescents associated with GN. IL-1b, TNF-a, and $CD4^+$ T cells promote crescent formation, which involves macrophage migration into Bowman space, deposition of fibrin and fibronectin (a fibroblast chemoattractant), and local proliferation of macrophages and glomerular epithelial cells. Fibrin deposition depends in part on macrophage release of coagulant tissue factor-like activity; macrophage depletion prevents fibrin deposits (196). Crescent formation can be prevented in experimental GN by depletion of fibrin or $CD4^+$ T cells or blockade of ICAM-1, IL-1b macrophage MIF, or osteopontin (190,197). Rupture of Bowman capsule, mediated by infiltrating periglomerular macrophages and $CD4^+$ T cells, permits crescent infiltration by fibroblasts, leading ultimately to monocyte chemoattractant protein 1 (MCP-1)-, TGF-b- and basic fibroblast growth factor (bFGF)-mediated glomerular sclerosis.

POLYMORPHONUCLEAR NEUTROPHILS

In several models of inflammatory GN (e.g., NSN) and in exudative human GN, primarily in association with subendothelial or GBM injury, PMNs are prominent. A pathogenic role has been demonstrated by reduced injury in experimental GN by PMN depletion and reconstitution of injury with PMN repletion (198). PMNs are recruited by both C-dependent (C5a, MAC-1, C3b R adherence) and C-independent (chemoattraction, FcgR) mechanisms. Blockade or knockout of these molecules decreases glomerular PMN infiltration in experimental GN. Experimental evidence indicates that PMN-mediated renal damage occurs primarily through the release of oxidants and proteases. PMNs also have been demonstrated to collaborate with glomerular cells and platelets in transcellular biosynthesis of leukotrienes and lipoxins; lipoxins are endogenous inhibitors of PMN recruitment in GN (199).

Secondary Mediators of Renal Immune Injury

A long list of secondary mediators contributes to renal injury in immune mediated disease (Table 50.5). Insight into their actions derives from animal models; information regarding their role and importance in human disease is fragmentary, derived from *in vitro* and correlative studies. Nonetheless, they provide an abundance of potential targets for therapeutic intervention. Most are produced locally in the kidney and exert their effects at the site of synthesis in an autocrine or paracrine fashion. *In vivo* studies thus necessarily focus on changes in tissue synthesis and receptor expression, evaluation of *in vivo* pharmacologic blockade of mediator synthesis or receptor engagement, and genetic manipulation to assess the effect of overexpression or deficiency.

EICOSANOIDS

The eicosanoid family of oxygenated fatty acids derived from arachidonic acid (AA) metabolism in infiltrating leukocytes, platelets, and resident renal cells plays a major role in pathogenesis of renal immune injury (200). A long list of cytokines, hormones, physical stresses, and inflammatory mediators induce renal eicosanoid synthesis, increased production of which is described in inflammatory and noninflammatory experimental and human immune-mediated GN (201). The type and relative amounts of counterregulatory eicosanoids [i.e., proinflammatory leukotriene B4, antiinflammatory prostaglandin E_2 (PGE_2), prostaglandin I2 (PGI2), 15-S-hydroxyeicosatetraenoic acid, lipoxin A, vasodilatory PGI2, vasoconstrictive thromboxane B2, and leukotriene D4 (LTD4)] vary with the model and stage of disease. Prostaglandins, leukotrienes, and lipoxins exert a variety of often opposing effects on mesangial cell growth, contraction, and matrix formation as well as opposing effects on inflammation and renal hemodynamic function; interruption of AA metabolism pathways in experimental GN using thromboxane blockade, cyclooxygenase (COX) inhibition, LTD4 receptor blockade, or 5- or 15-lipoxygenase inhibitors has variable renoprotective or injurious outcomes (202,203; reviewed in 204). Favorable effects from PGE_1 infusion and dietary fish oil are reported in experimental and human GN in some studies; amelioration of experimental GN by 5-lipoxygenase inhibitors or transfection of rat kidney with the human 15-lipoxygenase gene confirm an *in vivo* antiinflammatory role (205).

PLATELETS

Evidence of systemic platelet activation and destruction and glomerular localization of platelet products or aggregates is observed in experimental and human glomerular injury (206). Platelets release a plethora of products that contribute to inflammation, coagulation, adhesion, cell proliferation, chemotaxis, and matrix production. Biologic relevance is suggested by disease models in which infusion of platelet-associated products alters glomerular permeability or induces glomerular cell proliferation or matrix accumulation. Platelet depletion and antiplatelet therapy are efficacious in certain experimental GN (206).

CHEMOKINES AND ADHESION MOLECULES

A diverse group of potent chemoattractants with overlapping functions can be synthesized by activated renal cells, monocytes, and T cells to regulate leukocyte trafficking (154). Renal expression of chemokines is upregulated in experimental and human renal injury; it is noteworthy, however, that the pattern of expression does not necessarily indicate the cellular composition of the infiltrate. Blockade of a variety of chemoattractants by neutralizing Ig or antagonists abrogates glomerular inflammation in experimental ICGN (207,208, reviewed in 154). KO mice revealed complex and unexpected *in vivo* roles for chemokines in renal injury. Deficiency of chemokine receptor CCR1 enhances Th1 immune responses and worsens NSN nephritis (209), and MCP-1-deficiency reduces tubular but not glomerular injury in NSN (210). The importance of chemokines to renal immune injury in humans is suggested by the correlation of urinary chemokine levels with disease activity and glomerular leukocyte infiltration.

Renal adhesion molecule expression (ICAM-1, VCAM-1, endothelial P- or E-selectin) is similarly upregulated in human and experimental proliferative GN and often correlates with inflammation (153). Numerous antiadhesion therapies have been assessed in experimental renal disease (153); results are generally positive but are ligand, species, model, and timing dependent. The role of adhesion molecules in mediation of GN is complex because they modulate not only leukocyte trafficking but also multiple other immune and inflammatory processes (e.g., antigen presentation, phagocytosis, cytotoxicity) (168). In this regard, P-selectin-deficient mice paradoxically demonstrated more severe glomerular damage in experimental anti-GBM disease; this has been attributed to disruption of production of lipoxin A4, an endogenous inhibitor of PMN recruitment, and to decreased levels of circulating soluble antiinflammatory P-selectin (168). Antiadhesion MAbs block T-cell or phagocyte-mediated cytotoxicity directed at renal cells (187) and block transcellular eicosanoid synthesis (199).

PROTEASES

Metalloproteases and serine proteases secreted by infiltrating leukocytes and activated renal cells synergize with oxidants in degradation of GBM, leading to proteinuria, and play a key role in tissue remodeling (211,212). Renal artery infusion of elastase or cathepsin G induces marked proteinuria, and proteinuria is absent in NSN induced in beige mice with PMN deficient in these enzymes (213). Cysteine proteinase inhibitors significantly reduce proteinuria in a C- and PMN-independent model of NSN. Gelatinase A directly modulates mesangial cell proliferation and differentiation *in vitro* and *in vivo*, promoting an inflammatory phenotype (214). Matrix metalloproteinase activity is regulated in part by tissue inhibitors (TIMPs).

RENAL OXIDANT STRESS

Generation of reactive oxygen species (ROS) by activated renal cells or infiltrating leukocytes is increased in noninflammatory as well as inflammatory forms of experimental glomerular injury, and administration of ROS scavengers or antioxidants in these models reduces proteinuria (reviewed in 212,215,216). Upregulation of the NADPH-oxidoreductase complex in glomerular cell membranes is reported in the HN model (216). Powerful oxidants injure the kidney by multiple mechanisms: lipid peroxidation, BM destruction in concert with proteases to alter glomerular permeability, conversion of latent proteinases to active forms, altered production of inflammatory mediators (eicosanoids, TNF-a), direct cell cytotoxicity, inhibition of glomerular cytokine-induced isoform of nitric oxide synthase (iNOS) activity, and induction of mesangial cell proliferation, activation, or apoptosis (212,215,217,218). Renal perfusion with MPO–hydrogen peroxide causes proteinuria and significant glomerular morphologic changes and platelet activation followed by marked proliferative glomerular lesions (212,219). Dysregulated renal antioxidant defenses may be an important component of severe injury (220).

NITRIC OXIDE

Intrarenal activation of iNOS in macrophages and intrinsic renal cells in experimental acute GN generates NO, which in turn mediates or modulates renal immune injury (111,221). NO executes a variety of dose-dependent proinflammatory and antiinflammatory effector functions; it mediates macrophage cytotoxicity, promotes apoptosis, promotes mesangial cell relaxation, lysis and matrix production, inhibits platelet activation and aggregation, inhibits leukocyte-endothelial adhesion, downregulates proinflammatory cytokines and chemokines, inhibits T-cell proliferation and Th1 expansion, inhibits MHC class II expression, and promotes vasodilatation. NO can neutralize or enhance superoxide toxicity, and it is variably reported to promote or inhibit intrinsic cell proliferation. Its role in pathogenesis of GN and TIN remains unclear, and is likely dependent on the particular micromilieu. Interventions in experimental GN and TIN using nonselective NO inhibition have yielded

conflicting results (221). Mixed results have been reported with selective iNOS inhibition; it had little effect on rat NSN (221), whereas disease severity increased in association with Th1-type skewing of the immune response in induced TIN in rats, suggesting a protective role for renal iNOS in the latter model (222). Knockout of iNOS did not alter the course of renal injury in induced ICGN in 129SV mice (221) or in MRL/lpr murine lupus nephritis (223); it did, however, attenuate renal vasculitis in the latter model (223).

Heme oxygenase 1 (HO-1), a cytokine- and stress-inducible heat shock protein, has antiinflammatory functions that may be renoprotective in immune injury. HO-1-catalyzed degradation of the oxidant heme generates the antioxidant bilirubin and biliverdin, the vasodilator and antiplatelet mediator carbon monoxide (CO), and iron. Bilirubin also has anticomplement activities; CO and iron are negative modulators of iNOS activity and expression. NO is reported to enhance HO-1 expression in mesangial cells (224). Administration of HO-1 inducers reduces proteinuria and glomerular macrophage and PMN infiltration in rodent models of NSN in association with downregulation of renal iNOS expression (225,226).

CYTOKINES AND GROWTH FACTORS

A wide variety of pleiotropic growth factors (GFs) and cytokines produced by activated leukocytes and renal cells can modulate biologic responses in the kidney and contribute to mediation or recovery in renal immune injury (Table 50.5) (52,106,227,228 and 229). Clear insight into their role in disease pathogenesis is lacking because of conflicting observations reported in the literature. These conflicting results reflect in part the pleomorphism, redundancy, and complex regulation of cytokines, GFs, and their receptors, their synergistic and counterregulatory actions, their involvement at multiple stages (i.e., inductive and effector limbs) of immune responses and direct actions on parenchymal as well as lymphoid cells. Various abnormalities in systemically and local cytokine production are reported in human and experimental GN and TIN (52,106,227,228). An important role in renal injury and repair has been postulated based on *in vitro* studies that assessed cytokine production and the effects on cultured renal cells, the association of immunologic renal diseases with a variety of *in vivo* abnormalities in systemic or renal cytokine, GF or receptor expression, and modulation of normal or diseased kidney by *in vivo* manipulation of GF or cytokine networks.

Cytokines involved in Th1 and Th2 differentiation (IL-12, IFN-g, IL-4, and IL-10) have received particular attention due to their proinflammatory (IFN-g, IL-12) or antiinflammatory (IL-4, IL-10) actions (Table 50.5) and potential therapeutic efficacy (see earlier) (106). *In vivo* cytokine manipulation has met with variable success in predictably modulating experimental nephritis (reviewed in 106). Recent results from KO mice are mixed and in some cases are paradoxical to those predicted by *in vivo* interventions: Crescentic GN is exaggerated in mice with gene-targeted deficiencies of IL-10 (230), IL-4 (231), or IFN-g (232), whereas IFN-g receptor-deficient autoimmune MRL/lpr and (NZB × NZW)F1 mice are protected from lupus nephritis (233,234). Data regarding the relative importance of Th1-type versus Th2-type cytokines in murine lupus nephritis are particularly inconsistent and collectively suggest that both are required for full disease expression (13,106). A pioneering approach to examine the effects of sustained local cytokine production on renal immune injury uses implantation of genetically modified cytokine-secreting tubular cells under the renal capsule (235). Using this method, autoimmune renal injury is elicited in lupus mice by local secretion of IL-12 and macrophage growth factors [as well as by the chemokine regulated on activation normal T cell expressed and secreted (RANTES)], but not by IL-6 (235).

Both IL-1b and TNF-a are broadly proinflammatory and major regulators of acute inflammatory responses. They are produced in copious amounts by activated macrophages (a major source of intrarenal IL-1b) and are inducible in intrinsic renal cells. Renal cell expression of IL-1b, TNF-a, and their receptors increases in proliferative and inflammatory lesions. IL-1b and TNF-a are implicated in the development of crescentic GN, and they have numerous effects on cultured renal cells, inducing proliferation and synthesis of eicosanoids, NO, cytokines, chemokines, enzymes, ROS, C, adhesion and MHC molecules (229,236). Administration of IL-1b or TNF-a aggravates disease and blockade of either cytokine by neutralizing Ig, soluble receptors, or IL-1b receptor antagonist diminishes injury in various experimental GN (229,236). An exception is murine lupus, because chronic administration of TNF-a inhibits nephritis in NZB/NZW mice; it is unclear whether the dominant effect is on the autoimmune or the inflammatory response. Crescent formation and PMN influx are ameliorated in NSN induced in TNF-a-deficient mice (237).

Interleukin-6 has proinflammatory and antiinflammatory properties, and it is widely overexpressed in the kidney in a variety of immunologic and nonimmunologic renal diseases. Its role in inducing mesangial cell injury has been controversial; recent results in IL-6 KO mice suggest that IL-6 plays little role in mediating glomerular injury *in vivo* (238). Unconfirmed reports indicate inducible renal tubular expression of IL-13 and IL-15; their role in renal injury awaits definition.

Transforming growth factor-b1 stimulates matrix production and decreases matrix turnover, and it is a major mediator of fibrosis in experimental immunologic and nonimmune renal injury. Renal cell production of TGF-b1 contributes to matrix expansion via autocrine pathways. TGF-b1-based therapy (neutralizing anti-TGF-b Ig or decorin) arrests matrix accumulation and fibrosis in experimental GN (239). Renal TGF-b overexpression in a spectrum of chronic human glomerulonephritides suggests a similar role in man. TGF-b also has broad immunosuppressive and antiinflammatory properties that attenuate nephritogenic responses and renal inflammation (110,240). TGF-b inhibits glomerular cell mitogenesis *in vitro*, inhibits renal cell synthesis of proinflammatory cytokines IL-1b and TNF-a, downregulates iNOS, hinders leukocyte–endothelial adhesion, and regulates the plasminogen–plasmin system. TGF-b has complex actions on macrophages that include functional suppression and potent chemoattraction; however, the physiologic role of this latter function is unclear because TGF-b1-deficient mice develop progressive multifocal inflammation (241). TGF-b suppresses nephritogenic T-cell clones *in vivo* and downregulates tubular cell MHC class II and B7 expression (110,242).

Platelet-derived growth factor (PDGF) is a mesenchymal cell mitogen and chemoattractant that plays an important role in renal injury and repair (52). Renal PDGF and PDGF receptor expression is increased in a variety of experimental and human immune renal diseases. PDGF and bFGF are potent mesangial cell autocrine growth factors; neutralization of PDGF ameliorates injury in anti-Thy-1 nephritis. Basic FGF is fibrogenic; its production is linked to progressive glomerulosclerosis and tubulointerstitial fibrosis (243,244). Basic FGF and vascular endothelial GF (VEGF) are angiogenic and linked to glomerular endothelial repair.

COAGULATION

Fibrin deposition, increased procoagulant and plasminogen activator inhibitor (PAI) activity, and decreased PA are common in human and experimental crescentic GN. Enhanced macrophage and renal cell tissue factor procoagulant activity (PCA), IL-1b, and TNF-a promote an imbalance in endothelial proinflammatory and anticoagulant activity and in the plasmin fibrinolytic system that favors intravascular thrombosis and platelet adhesion and activation (245). Anticoagulant and fibrinolytic therapies decrease fibrin deposition and crescent formation in experimental GN (reviewed in 246). Notably, thrombin has proinflammatory effects in addition to its procoagulant activity that augments injury in crescentic GN (247).

Parenchymal Cell Responses to Immune Injury

Resident renal cells are crucial modulators of the renal response to immune injury. Resident cells activated by ICs, C, autoIg, inflammatory cytokines (IL-1b, TNF-a, IFN-g), angiotensin II, thrombin, GFs, and other stimuli undergo considerable morphologic and functional alterations and express an array of *de novo* cytokines, GFs, receptors, and other molecules that act in a paracrine or autocrine fashion to modulate injury (Table 50.5). In addition to inflammatory mediators, numerous endogenous defense systems are upregulated, the balance of which ultimately determines the outcome (progression or resolution) of renal injury (220).

Mesangiolysis, matrix deposition, and proliferation induced by a vast list of leukocyte, platelet, endothelial, and podocyte-derived agents are prominent components of the mesangial cell response. Disease resolution depends on the type and duration of injury, mesangial cell apoptosis, and upregulation of antiproliferative factors; persistent imbalance in control of proliferation and matrix production leads to glomerulosclerosis (248). Pharmacologic interference with mesangial cell proliferation (i.e., blockade of PDGF, IL1-b, endothelin) proved beneficial in disease models. Endothelial cell activation leads to phenotypic changes that promote leukocyte adhesion and infiltration, intravascular thrombosis, and platelet aggregation. bFGF and VEGF play an important role in renal capillary repair in resolving GN. Injury of the highly differentiated glomerular visceral epithelial cell (podocyte) is typically noninflammatory, presumably because the podocyte is separated by GBM from the capillary lumen. Ig, MAC, or mediator-induced damage to the podocyte interferes with its endocytic functions and maintenance of glomerular permselectivity and usually is accompanied by significant proteinuria. Podocytes normally have minimal proliferative capability; however, dedifferentiation and dysregulation of podocytes may contribute to the excess extracapillary cells observed in “collapsing” variant focal segmental glomerulosclerosis (FSGS). In contrast, activated parietal epithelial cells undergo substantial proliferation and constitute a major component of cellular crescents.

Much of the progressive functional deterioration in glomerular disease is attributable to the development of tubulointerstitial injury. It has been proposed that bioactive compounds (C, iron-generated free radicals, inflammatory fatty acids, lipid mediators, cytokines, GFs, albumin) derived from the injured glomerulus reach the tubulointerstitium via abnormal ultrafiltration, postglomerular capillaries, or diffusion from the mesangium (249). These agents directly stimulate tubular cell proliferation and matrix production, modulate epithelial cell–matrix interactions, and attract mononuclear cells into the interstitium. These injurious pathways may be balanced by glomerulus-initiated tubuloprotective mechanisms (i.e., heme oxygenase expression) (250).

CLINICAL ASPECTS OF IMMUNOLOGIC RENAL DISEASE

Immune responses directed at the kidney initially may target primarily the glomerulus, tubulointerstitium, or vasculature, but, as disease progresses, other compartments inevitably become affected. Distinguishing clinical, laboratory, and histologic features of major immunologic renal diseases in humans are shown in Table 50.6; additional comments are included below. Early injury leads to well-characterized clinical manifestations (Table 50.7) or some combination of these findings. The clinical presentation depends in large part on the degree and site of underlying renal inflammation and proliferation. Glomerular pathologic entities associated with minimal cellular reaction typically present with minimal findings or proteinuria that ranges from mild to nephrotic range (arbitrarily defined as greater than 3.5 g daily).

Those glomerular entities marked by inflammation and proliferation (i.e., GN) typically are associated with an active urine sediment (hematuria, pyuria, red blood cell casts, and proteinuria) and variably with acute renal insufficiency (elevated serum creatinine), oliguria, and hypertension. GN is a manifestation of several systemic and renal-limited (primary) diseases (Table 50.6), such that correlation of clinical, serologic, and pathologic evaluation of renal biopsy are usually necessary for definitive diagnosis. Notably, hematuria and acute renal failure are also common in allergic TIN in which interstitial inflammation is the pathologic hallmark. Two common disorders, minimal change nephrotic syndrome (MCNS) and FSGS, lack significant Ig and C deposits and cellular infiltrates and thus are not regarded as classical immune-mediated diseases. Several features suggest a role for the immune system in disease pathogenesis, however.

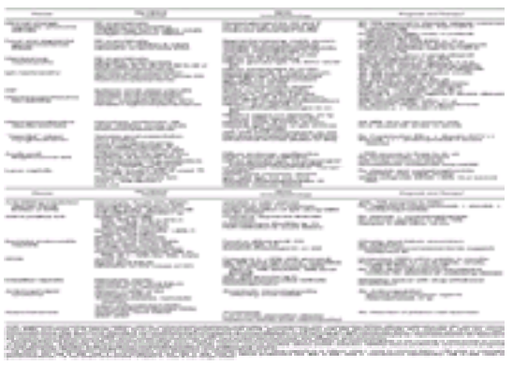

TABLE 50.6. Human Renal Diseases with a Presumed Underlying Immune Pathogenesis

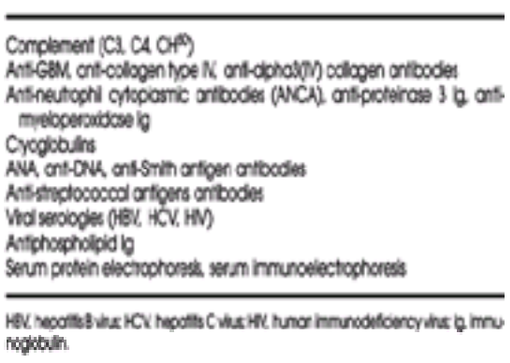
Asymptomatic urinary abnormalities (proteinuria or hematuria)
Acute nephritic syndrome
Acute glomerulonephritis
Acute allergic interstitial nephritis
Nephrotic syndrome
Rapidly progressive glomerulonephritis
Chronic interstitial nephritis
Chronic glomerulonephritis
Symptoms related to underlying systemic disease
Thrombotic microangiopathy

Nephrotic syndrome is arbitrarily defined as greater than 3.5 g per day proteinuria with its attendant edema, hypoalbuminemia, and hyperlipidemia.

TABLE 50.7. Clinical Syndromes Associated with Immune-Mediated Renal Diseases

Serologic tests are useful in differential diagnosis (Table 50.8), particularly when kidney biopsy is delayed or contraindicated and in rapidly progressive GN (RPGN) and life-threatening pulmonary or renal syndromes (SLE, GPS, ANCA+ necrotizing vasculitis). Serologies must always be interpreted in the context of the clinical features. Serum C profiles for C3, C4, and CH^{50} are particularly useful in the setting of acute GN because of the frequent association of certain disorders with low or normal C levels (251). Notably, hypocomplementemia indicates only that C consumption exceeds production; it does not necessarily reflect disease pathogenesis. Hypocomplementemia may arise due to decreased C production, through activation and depletion of C by deposited ICs, via stabilization of C3 or C4 convertase by autoIg (NeFs), and by genetic C deficiency. Glomerular C deposition can be prominent in disorders associated with either low (e.g., APSGN) or normal (e.g., membranous nephropathy) C levels. Hypocomplementemia also occurs in nonimmunologic renal injury (e.g., atheroembolism, severe sepsis).



Complement (C3, C4, CH^{50})
Anti-GBM, anti-collagen type IV, anti-alpha3(IV) collagen antibodies
Anti-neutrophil cytoplasmic antibodies (ANCA), anti-proteinase 3 Ig, anti-myeloperoxidase Ig
Cryoglobulins
ANA, anti-DNA, anti-Smith antigen antibodies
Anti-streptococcal antigens antibodies
Viral serologies (HBV, HCV, HIV)
Antiphospholipid Ig
Serum protein electrophoresis, serum immunoelectrophoresis

HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; Ig, immunoglobulin.

TABLE 50.8. Serologic Tests Commonly used in Diagnosis and Monitoring of Immune Renal Diseases

Minimal Change Nephrotic Syndrome

This disorder (lipoid nephrosis, nil disease) gains its name from the lack of abnormal histopathologic findings on light or immunofluorescent examination of the kidney. Electron microscopy reveals glomerular podocyte changes (Table 50.6) (252). In some patients, T cells, monocytes, and IgM are found in the mesangium but appear not to have a significant impact on disease course. Although no causality is proven, there is a strong association with Hodgkin lymphoma, in which the NS may remit and relapse concurrent with the tumor. Several pharmaceuticals, atopy (asthma and eczema), and allergens have been associated with MCNS; nonsteroidal antiinflammatory drugs (NSAIDs) induce a unique renal syndrome with MCNS and marked interstitial T-cell infiltrate. HLA associations are weak. Various abnormalities in humoral and cellular immunity have been reported. Collectively, these associations and the steroid and immunosuppressant responsiveness of MCNS support an underlying immunologic basis. Humoral factors derived from stimulated lymphocytes, tumors, or serum of patients are capable of enhancing capillary permeability, but none has yet been convincingly linked to pathogenesis (252).

Focal Sclerosing Glomerulosclerosis

Focal sclerosing glomerulosclerosis derives its name from the observation that early pathologic involvement is restricted to only some tufts (segmental) of some glomeruli (focal). Biopsy sampling error may lead to a diagnosis of MCNS. A “collapsing” variant of FSGS is seen with HIV infection or idiopathic FSGS and is associated with more severe disease. The pathologic findings in more advanced disease are nonspecific and a frequent finding in progressive renal disease of diverse causes. Both sporadic disease and familial clustering are reported, as are racial differences in disease incidence and severity. Familial forms were reported; genome mapping suggests that at least three genes contribute to the familial FSGS phenotype (253). Mononuclear cells, including T cells, are often present in the glomerulus and interstitium. Sera from certain patients with an aggressive form of FSGS induce a marked increase in glomerular albumin permeability *in vitro*, which correlates with rapid recurrence (as early as 24 hours) in transplanted kidneys, implicating a circulating factor. This FSGS factor can be removed and proteinuria decreased by plasmapheresis in some patients (254).

Membranous Nephropathy

Membranous nephropathy (MN) is a pathologic diagnosis that depends on the demonstration of characteristic glomerular morphology with exclusive subepithelial localization of Ig deposits (Table 50.7); C3 and MAC are present, but cell proliferation and inflammation are absent (255). Increased urinary MAC excretion may reflect disease activity. MN occurs both in idiopathic form and in association with a wide variety of secondary causes, including infections [hepatitis B virus (HBV), malaria, leprosy, syphilis] and pharmaceuticals (gold, penicillamine, captopril). In 10% to 20% of patients initially diagnosed with idiopathic MN, an associated malignancy (gastrointestinal tract, lung, breast) eventually will be found. HLA associations vary by ethnic group. An autoimmune etiology of idiopathic MN is suggested by the

remarkable similarity to the rat HN model, although attempts to identify homologous human podocyte antigens so far have been unsuccessful. Other mechanisms of IC formation also may lead to subepithelial localization (see earlier). Microbial, DNA, thyroglobulin, tumor-associated, and additional nonrenal antigens have been identified in glomerular deposits; however, because of the rarity of suitable human biopsy tissue, little is known about the specificity of renal-bound Ig. MN occurs *de novo* after renal transplantation at relatively high frequency.

IgA Nephropathy

Immunoglobulin A nephropathy (Berger disease) is the most common primary GN worldwide. It occurs at all ages, although it is most common in adolescents and young adults. Renal presentations include macroscopic hematuria (40%–45%), which may be recurrent and synpharyngitic, asymptomatic hematuria, and proteinuria (35-40%) and, less commonly, acute GN, RPGN, or NS. The incidence and prevalence are highest in Asian countries and in Native Americans. Ten percent of cases have a family history. HLA associations differ considerably by geographic region. A subset of patients with DD genotype of ACE gene will progress more rapidly and may benefit particularly from ACE-inhibition therapy (256). Numerous links to bacterial or mucosal infections or food sensitivities are reported. A variety of nonspecific immunologic abnormalities involving IgA and mucosal immune responses are reported in patients and family members (257). Autoreactive IgA is identified in a minority of patients; specificities of renal-bound Ig have not been determined. Glomerular g/d T-cell infiltration, abnormalities in the gut mucosal g/dT-cell repertoires, and reduced terminal galactose on hinge region O-glycans of circulating IgA1 have been reported (see earlier).

Diagnosis relies on renal biopsy (Table 50.6); C3, properdin, and terminal C components are frequently present, consistent with IgA being an effective activator of the alternative pathway (258). The mesangial deposits are predominantly or exclusively IgA_1 polymers (J-chain positive). The cause of this subclass restriction is unknown. IgA subclass distribution normally varies with mucosa (e.g., 85% and 35%, of respiratory tract and colon mucosal plasma cells, respectively, are IgA_1); certain types of antigens (e.g., proteins) preferentially induce IgA_1. Mesangial IgA deposition is also prominent in Henoch-Shonlein purpura and SLE nephropathy as well as in a variety of systemic disorders (e.g., cirrhosis, dermatitis herpetiformis, gluten enteropathy, and ankylosing spondylitis) in the absence of renal injury. IgAN frequently recurs in renal allografts, implicating a systemic defect.

Pathogenesis and mechanisms of mesangial IgA localization remain speculative (257). Autoreactivity and antigen-independent mechanisms are postulated. The hinge region glycosylation abnormalities may contribute to abnormal IgA_1 deposition or clearance. An affinity of IgA for matrix fibronectin and of IgA-fibronectin aggregates for collagen have been reported. The expression of novel IgA Fc receptors, distinct from myeloid IgA FcRs, by human mesangial cells may facilitate mesangial IgA deposition and trigger cell activation (177). The antiinflammatory protein uteroglobin was demonstrated to play a crucial role in preventing murine IgA nephropathy (259). Uteroglobin-deficient mice develop most pathologic features of human IgA nephropathy, whereas administration of exogenous uteroglobin prevents glomerular accumulation of exogenous IgA. Heteromerization of fibronectin and uteroglobin prevented abnormal glomerular fibronectin and collagen deposition and abrogated formation and glomerular binding of IgA–fibronectin complexes (259). Numerous animal models of spontaneous or induced mesangial IgA deposition or, less commonly, IgAN exist and have contributed limited insight into pathogenesis (260).

Mesangioproliferative Glomerulonephritis

This primary glomerular disease is considerably more common in Asian than Western countries, with the exception of a relatively high incidence in Native Americans. It is a pathologic diagnosis based on characteristic mesangial disease in the absence of secondary causes (HSP, SLE, IgAN). Genetic and environmental contributions are suggested based on geographic distribution and a high incidence of prodromal infection in Chinese patients.

Anti-GBM Mediated Diseases

Anti-GBM Ig-mediated disease is defined as acute GN mediated by autoIgs that react with the GBM. When pulmonary hemorrhage resulting from Ig reactivity with alveolar BMs is present (50% of patients at presentation), the disease is referred to as Goodpasture syndrome (261). Hemoptysis is the most common presenting feature in GPS and often precedes development of overt GN by months, although laboratory evidence of GN (microscopic hematuria and proteinuria or red blood cell casts) is almost invariably present at presentation. Crescentic GN with variable endocapillary proliferation is common; tubulointerstitial infiltration is most marked in biopsies with significant TBM Ig deposition (262). This rare disease affects all age and ethnic groups. Familial clustering and associations with MHC class II genes, particularly DR2(w15) in white patients, suggest genetic predisposition. A variety of environmental triggers are suggested by clinical observations. The syndrome is preceded by upper respiratory tract infection or flulike illness in 20% to 60% of cases; seasonal clusters and association with influenza A2 outbreaks have been described. Pulmonary hemorrhage is more likely in cigarette smokers. Exposure to hydrocarbons, solvents, or chemicals have been reported anecdotally but has been documented in fewer than 5% of cases.

Diagnosis requires demonstration of serum anti-GBM Ig or characteristic linear immunostaining for Ig on kidney biopsy. Linear staining is variably demonstrable on lung biopsy. Numerous substrates are used as target antigen in available commercial assays; cruder preparations detect nonspecific, nonpathogenic Igs that bind collagen subunits (i.e., a1 or a4 chains of type IV collagen) other than pathogenic a3(IV)NC1 epitopes. These nonpathogenic anticollagen Igs are present at low titer in 15% of patients with GPS/anti-GBM disease and occasionally in patients with pulmonary disease of other causes. Conventional assays detect only IgG; there are isolated reports of anti-GBM disease due to IgA or IgM anti-GBM Ig. Anti-GBM titers do not predictably correlate with disease severity; however, serial titers within an individual are useful in monitoring disease activity. Prompt diagnosis is crucial because early therapeutic intervention (plasmapharesis, steroids, cytotoxic agents) is critical to renal survival. Because disease may recur in renal allografts, transplantation is routinely delayed until serum anti-GBM Igs are undetectable.

Anti-GBM disease is unique in fulfilling Koch's postulates that establish etiopathogenesis in human immune renal disease and its confirmation in an animal model (1). Anti-GBM Igs are present in the circulation and among Igs eluted from affected kidneys, including renal allografts with recurrent disease, and are capable of transferring GN to nonhuman primates (263). GPS patient sera and kidney eluate Igs were used to localize the major pathogenic epitopes to the noncollagenous (NC1) carboxyl globular domain of a3 chain of type IV collagen, that is, a3(IV) NC1 (9,57). Structural analysis suggested that the GPS epitope is normally sequestered in the hexameric NC1 structure and is exposed by chemical dissociation *in vitro* (264). Immunostaining demonstrates a3(IV) expression in kidney (predominantly GBM in humans), lung, eye, aorta, choroid plexus, cochlea, and neuromuscular junctions (265). The further restriction of clinical disease to kidney and lung, with rare reports of skin or eye involvement, are variably attributed to low-level expression of a3(IV) in certain organs and tissues, an “immunologically privileged location” of the epitope within the BM, and tissue-specific expression of variant a3(IV) chains due to alternative splicing (264,266,267 and 268). It is currently unclear whether potential tolerizing epitopes are sequestered from circulating anti-a3(IV) reactive B or T cells and whether exposure of the epitope is essential for disease initiation, Ig localization, or both. Notably, T cells reactive with GP antigen can be isolated from both patients and normal controls (112). Simple unmasking of the epitope by damage to the BM is highly unlikely to be sufficient for disease induction because anti-GBM disease is a rare complication of other forms of destructive glomerular injury. Nonetheless, unmasking may facilitate epitope access by previously differentiated immune effectors. It is possible that environmental toxins alter a3(IV) immunogenicity. The absence of pulmonary hemorrhage in a subset of patients has been attributed to restricted access to pathogenic Ig as a result of the absence of fenestrations in alveolar capillaries, a circumstance that may be overcome in experimental models by alveolar injury.

An anti-GBM-ANCA overlap syndrome characterized by pulmonary-renal syndrome, skin rash, arthritis, polyneuropathy, or uveitis has been described. Renal biopsy demonstrates variable amounts of necrosis, crescents, linear IgG deposition along the GBM, and renal vasculitis. The serum is positive for both anti-GBM and ANCA. As many as 10% to 30% of anti-GBM-positive sera are also positive for ANCA or anti-MPO Ig. It is unclear, however, whether the prognosis is different in these patients.

It is noteworthy that linear IgG staining of the GBM also commonly develops in patients with Alport hereditary nephritis receiving a kidney transplant. Patients with X-linked Alport disease, the most common type, have mutations in the a5-chain of type IV collagen. Development of Ig reactive with Goodpasture antigen is attributed to a requirement for a5 for normal incorporation of a3 into the GBM (269), such that lack of a5 disrupts expression of the pathogenic epitope. Transplantation of a normal kidney into a patient with Alport disease introduces these epitopes as foreign antigen and induces anti-GBM Ig; fortunately, development of severe crescentic GN is rare, perhaps as a result of immunosuppressive therapy.

Postinfectious Glomerulonephritis

Acute poststreptococcal GN (APSGN), a disease primarily of children over the age of 2 years, typically presents as an acute GN, with edema, hypertension, gross hematuria; RPGN is more common in adults (5%–10%). It occurs in epidemic and sporadic forms following skin or throat infections with certain strains of nephritogenic group A b-hemolytic streptococci (particularly type 49 in impetigo, the usual cause of epidemic APSGN, and type 12 or 4 in pharyngitis). Because of the latent period from infection (10 days with pharyngitis, more than 21 days with impetigo) and use of antibiotics, cultures are often negative. Anti-Group A streptococcal Ig may confirm a recent streptococcal infection if the patient did not receive antibiotics; however, antistreptococcal Igs are also frequently present in children with unrelated GN as a result of the normal high incidence of streptococcal infection in children and the persistence of elevated titers (3–6 months). Notably, the immune response to streptococcal extracellular antigens varies considerably, depending on the site of infection. Anti-DNAase B and anti-hyaluronidase titers are elevated in more than 80% to 90% of untreated patients with skin infection, whereas anti-streptolysin O (ASO) and anti-NADase titers are elevated in more than 90% of untreated patients with recent pharyngitis. The rapid, passive hemagglutination streptozyme test measures Ig responses to these four antigens and streptokinase. Titers do not correlate with the severity of renal disease. Most patients have a depressed C3 level in the first week, which typically normalizes within 2 to 6 weeks. Persistent

hypocomplementemia or significant depression of early C components (C1q, C4) suggests a different diagnosis (i.e., MPGN). Cryoglobulins, RF, and other autoIgs are reported. Renal biopsy is usually reserved for atypical presentations. C3 is present but early C components are usually absent on biopsy, suggesting C activation via the alternative pathway. RF activity is prominent among some renal-eluted Ig.

Although generally considered a prototype for human glomerular injury induced by glomerular trapping of circulating ICs, the pathogenesis of APSGN remains unclear (reviewed in 22). Several streptococcal antigens are found in affected kidneys but not among renal eluted Ig. Anionic endostreptosin and nephritis strain-associated protein (NSAP) have an intrinsic affinity for glomerular components. NSAP and preabsorbing antigen (PA-antigen) can activate C via the alternative pathway. Purified NSAP can induce glomerular lesions in rabbits and mice. Certain streptococcal M proteins share epitopes with glomeruli antigens, and patient sera antistreptococcal Igs and MAbs crossreactive with glomerular antigens are demonstrable. Streptococcal M protein and pyrogenic exotoxins can act as T- or B-cell superantigens.

Numerous additional infections are associated with glomerular or tubulointerstitial injury in humans (Table 50.2 and Table 50.6). GN occurs in about 20% of patients with infective endocarditis and 4% of children with infected ventriculoatrial shunts. Bacterial antigens have been found in deposits in some patients. RF, low-titer antinuclear antibodies (ANAs), and cryoglobulinemia are common. HIV is associated with a spectrum of lesions, including classic HIV nephropathy (FSGS and its collapsing variant) and a variety of ICGNs accompanied by dense interstitial infiltrates. HIV–anti-HIV Igs are eluted from affected kidneys. HBV is associated with polyarteritis nodosa (PAN) (see later); chronic HBV and HCV are associated with MN, MPGN, and cryoglobulinemia. It is postulated that chronic viremia may predispose to IC disease as a result of persistent but ineffective humoral response against an intracellular organism. AutoIgs are also common. Epstein-Barr virus (EBV) was linked to idiopathic chronic interstitial nephritis in humans (21). EBV genome was detected in renal proximal tubular cells, which express upregulated CD21, a known EBV receptor on B cells. These researchers postulated that tubular cell infection evokes or recruits a nephritogenic cellular immune response (21).

Membranoproliferative Glomerulonephritis (Mesangiocapillary Glomerulonephritis)

Idiopathic MPGN typically presents in adolescents and young adults and varies from asymptomatic urinary abnormalities to acute GN. MPGN that occurs in association with cryoglobulinemia is now known to be caused by HCV in most cases (see later). Recurrent synpharyngitic gross hematuria is common. Serum C3 levels are reduced (>70% at presentation, >85% during course) and tend to persist at low levels. The histologic findings are diagnostic. Two major variants that appear to be distinct entities are recognized (Table 50.7); the more common MPGN I is associated with depressed serum C4 and C1q levels, whereas these components are usually normal in MPGN II. C3 and C4 NeF may be present with either type of MPGN. The different C profiles are presumed to reflect differences in mode of C activation.

Pathogenesis is poorly understood. MPGN is associated with a variety of C-deficient states (partial lipodystrophy and genetic deficiency of C1q, C2, C3, C6, C7, C8, factor B, factor H, C1 esterase inhibitor). This may lead to defective C regulation of immune responses or defective IC clearance. Renal pathologic findings (Table 50.6) suggest that MPGN I is an immune deposition disease, possibly related to chronic antigen exposure (i.e., viral antigen). The BM-dense deposits in human MPGN II stain for C3; however, their complete biochemical nature remains unclear. Notably, MPGN II recurs almost invariably in renal allografts, suggesting a systemic factor is involved. Pigs genetically deficient in C factor H develop a lethal MPGN type II characterized by massive glomerular intramembranous dense deposits containing components of the alternative and terminal C pathways (see earlier) (156). It is postulated that the absence of factor H permits spontaneous C activation and *in situ* C deposition in the GBM. A role for factor H dysfunction in human MPGN type II is unclear.

Cryoglobulinemia

Membranoproliferative glomerulonephritis is also commonly seen in the syndrome known as *essential* or idiopathic mixed cryoglobulinemia (EMC), a small vessel vasculitis now recognized in many instances to be secondary to chronic infection with HCV. More than 50% of patients have evidence of GN, with a highly variable clinical presentation. Serum levels of cryoglobulins, usually type II mixed IgM–IgG with a monoclonal IgM, are extremely variable and may not correlate with disease activity. Early components of the classical C pathway, particularly C2 and C4, are often profoundly depressed, whereas C3 levels may be normal. C levels may not correlate with nephritis severity or normalize with clinical remission. Kidney biopsy confirms the diagnosis; pathology is typically MPGN type I, with associated intraluminal thrombi of precipitated cryoglobulins. The latter have a diagnostic fibrillar or crystalloid structure on EM. Skin biopsy of affected areas reveals hypersensitivity vasculitis and may contain HCV antigens. HCV antigen and anti-HCV Ig are often concentrated in the cryoprecipitate; polymerase chain reaction (PCR) testing for HCV RNA genome in serum and cryoprecipitate is indicated. HCV-associated renal disease is thought to result from deposition in the subendothelium and mesangium of circulating HCV antigen containing ICs and IgM RFs, with subsequent C activation. Infusion of human IgMk-IgG cryoglobulins into mice induces GN (270). Notably, however, diverse autoreactivity is common in chronic HCV infection (271) and raises the possibility of *in situ* autoIg deposition. In this regard, HCV interacts with cell membrane–bound coreceptors that modulate B-cell signaling and tolerance induction.

Rapidly Progressive GN

Rapidly progressive glomerulonephritis (RPGN) is a clinicopathologic syndrome characterized by acute crescentic GN and rapidly progressive renal failure (272). It may be secondary to any cause of systemic or primary acute GN or have no identifiable underlying cause (idiopathic RPGN). Clinical presentation, serologic tests, and renal biopsy confirm the diagnosis and underlying disease, if present. The findings on immunofluorescence microscopy divide RPGN into three major pathologic categories (linear, granular, or no Ig deposits), which are broadly associated with pathogenetic mechanisms and clinical syndromes (anti-GBM disease, non-GBM immune deposition, or vasculitis, respectively). The prognosis for untreated RPGN is poor regardless of the etiology, with the exception of RPGN due to APSGN, in which renal recovery is common.

Lupus Nephritis

Clinical renal involvement characterized by glomerular Ig deposition and mononuclear cell infiltration occurs in 70% to 75% of patients during the course of SLE; subclinical disease is typically evident on biopsy in the remainder. Clinically silent diffuse proliferative GN (DPGN) is described. The renal presentation is highly variable. New-onset heavy proteinuria or acute renal failure suggests transformation to a more severe form of nephritis (not an uncommon occurrence). Serum C levels (usually monitored as C3 due to the high incidence of C4 null genes in SLE) are usually depressed during active nephritis. Notably, however, neither C nor anti-dsDNA levels consistently correlate with disease severity, histopathology, clinical relapses, or response to therapy. Associations of SLE nephritis with MHC, particularly C4A and C4B null, and inherited C deficiencies are reported (see earlier). Severe nephritis is reported but rare in drug-induced SLE.

Renal biopsy defines histology and degree of activity (inflammation, proliferation) versus irreversible fibrosis and determines the need for immunosuppressive therapy. The World Health Organization (WHO) classification distinguishes major histopathologic patterns (Table 50.6, footnote); these correlate poorly with clinical or serologic parameters. IgG is the predominant isotype deposited, but IgM and IgA are also almost always present, as are C3, C4, and C1q. IgG1 and IgG3 often predominate in proliferative nephritis, whereas IgG_3 and IgG_4 are common in MN. Granular or linear Ig and C3 deposition in the TBM is common, especially in DPGN (class IV), as is a tubulointerstitial infiltrate composed of $CD4^+$ and $CD8^+$ T cells and monocytes. An occasional patient has severe TIN in the absence of glomerular disease. Patients with antiphospholipid Ig may have intraglomerular capillary thrombi; this is variably associated with poorer outcome. Patients with class V lupus nephritis (LN) have disease similar to idiopathic MN; pathologic clues to underlying SLE include staining for IgA and IgM as well as IgG, mesangial, subendothelial, and subepithelial deposits, and endothelial tubuloreticular structures (induced by IFN-a). SLE MN often runs an indolent course. Up to 50% of patients with MN may be ANA negative. Whereas therapy of SLE WHO class II and V disease remains controversial, the vast majority of clinicians use steroids and cytotoxic agents for induction therapy of class III and IV proliferative lesions, followed by indefinite maintenance suppressive therapy, because relapse frequently follows drug withdrawal even after years of quiescent disease. Experimental therapies show anecdotal benefit (intravenous Ig) or future promise (stem cell transplantation, costimulatory blockade). The factors that confer nephritogenicity on human SLE Ig remain unresolved (reviewed in 77,78 and 79). It is clear from study of humans and mice that a highly heterogeneous group of autoIg of diverse isotype, avidity, charge and specificity contribute to disease (see earlier).

Renal Vasculitis

Both small and large vessel vasculitis can affect the kidney. The subset of vasculitides associated with IC deposition (e.g., cryoglobulinemic, HSP, and SLE vasculitis) is discussed already and is shown in Table 50.6. A distinct subset of small vessel ANCA-positive vasculitides is associated with crescentic and necrotizing GN without significant immune deposition (i.e., pauciimmune) (Table 50.6); nonetheless, an immunologic etiology is suspected. Exposure to silica and pharmaceuticals (propylthiouracil, hydralazine, penicillamine) has been associated with necrotizing GN. Vasculitides associated with serum ANCA may affect the kidney either as part of a systemic vasculitis, Wegener granulomatosis (WG) and microscopic polyangiitis (MPA), or as renal limited disease with no evidence of extrarenal disease (considered by some to be renal-limited WG/MPA). Early in WG, urinalysis and renal function may be normal, but eventually most patients develop GN. Renal involvement is almost invariably present in MPA, and pulmonary hemorrhage due to alveolar capillaritis is common. Glomerular hypercellularity is minimal in contrast to IC deposition vasculitides.

The two ANCA subtypes, C-ANCA and P-ANCA, have distinct antigen specificities and disease associations (Table 50.6), although both can be found across the spectrum of ANCA-associated nephritis. Most patients with P-ANCA-positive crescentic and necrotizing GN, with or without systemic disease manifestations, have anti-MPO P-ANCA. It is noteworthy that most assays detect only IgG ANCA; a group of patients with an MPA-like illness with predominant IgM ANCA have been described. False-positive C-ANCAs are rarely observed in other systemic diseases, and additional specificities of P-ANCA are observed in other clinical settings. ANCA

testing is primarily useful in patients with pulmonary-renal syndrome or RPGN; ANCA titers do not necessarily correlate with renal disease activity. A restricted and shared idiotype among patients with ANCA has been reported.

Renal involvement also occurs in hypersensitivity vasculitis associated with drug or foreign antigen (viral, tumor) exposure, myeloproliferative, or autoimmune disorders. Nephritis is usually mild in Churg-Strauss syndrome (allergic granulomatosis) associated with anti-MPO ANCA in about 60% of patients. Henoch-Schonlein purpura (HSP) is a small vessel vasculitis typically affecting children or young adults (Table 50.6) and is characterized by palpable purpura, joint involvement, and gastrointestinal manifestations and nephritis in 40% to 60% of patients. HSP frequently is preceded by an upper respiratory infection. Biopsy of recent skin lesions or kidney reveals IgA deposits in dermal vessels and glomeruli. Although HSP and IgAN share immunologic and pathologic features, it remains unclear if they represent distinct entities or systemic and renal-limited variants of the same process.

Tubulointerstitial Nephritis

Human acute TIN generally occurs in association with drug hypersensitivity reactions, infection, or systemic autoimmune disease. Clinical features of hypersensitivity are often present in drug-induced disease, although fewer than 30% of patients have the complete triad (fever, rash, and eosinophilia). T cells and monocytes or macrophages dominate the mononuclear infiltrate. ICs and anti-TBM Ig are uncommon, with the exception of anti-GBM disease in which up to 70% of patients may have anti-TBM Ig. Several TBM antigens reactive with human anti-TBM Ig were isolated from rabbit or bovine TBM. One target antigen, a novel 58-kd proximal TBM molecule termed TIN-Ag, promotes BM adhesion via interaction with integrins on human proximal tubule epithelial cell membranes (273), fueling speculation that autoIg interactions with TIN-Ag interfere with matrix regulation of tubular cell function. Granular deposits along the TBM are also common in patients with SLE. Interstitial infiltrates also often accompany disorders classified as primary glomerular diseases and may be striking in certain glomerulopathies, such as HIV FSGS and SLE nephritis. The interstitial lesions are predictive of subsequent disease progression. Interstitial infiltrates are also seen in other renal lesions not traditionally associated with an immune etiology, such as urinary tract obstruction. The TIN seen in nonsteroidal antiinflammatory drugs (NSAID)-induced disease is unique in that it is frequently accompanied by NS due to a glomerular lesion, typically after prolonged drug exposure and in the absence of hypersensitivity features. As noted earlier, EBV infection of renal proximal tubular cells has been linked to chronic idiopathic TIN in humans (21).

Dysgammaglobulinemia/Dysproteinemias/Plasma Cell Dyscrasias

Renal deposition of Ig-derived protein can occur in the setting of abnormal production of excess monoclonal Ig or isolated Ig chains (paraprotein) due to a clonal B-lymphocyte expansion. The monoclonal Ig usually is detected by serum or urine immunoelectrophoresis. These are primarily diseases of the elderly, associated with multiple myeloma and other benign or malignant lymphoproliferative disorders. Only certain monoclonal Ig chains cause renal disease; nephrotoxicity and tissue deposition depend on physicochemical properties of the particular monoclonal Ig (charge, size, aggregability, isoelectric point). Proteinuria may be due to excreted L chains (Bence Jones proteinuria) or albuminuria in disorders with glomerular involvement. Therapy is directed at the underlying plasma cell dyscrasia.

A spectrum of renal pathology has been described. Nephrotoxic Ig chains that filter poorly tend to form nodular deposits in glomeruli, TBM, and other renal tissues (L- or H-chain deposition disease); amyloidogenic L chains capable of forming b-pleated sheets form amyloid deposits in glomeruli, vessel walls, and the tubulointerstitium. Extrarenal deposits are common in these systemic infiltrative diseases. Certain Igs form organized glomerular deposits with a unique fibrillar ultrastructure (immunotactoid glomerulopathy); extrarenal deposits are rare. Glomeruli stain for Ig (75% polyclonal) and C, but inflammation is uncommon. Pathogenesis is attributed to disruption of glomerular structure and function by deposited Ig. Certain L chains that pass the glomerular filter precipitate in the tubular lumens to form dense tubular casts (myeloma kidney or cast nephropathy); glomeruli are normal. Tubular cell reabsorption of toxic L chains and inflammatory reaction likely contributes to this pathology. Mixed cryoglobulinemia is typically associated with MPGN (see preceding discussion). Histopathologic findings have been reproduced by passive transfer of human paraproteins to animals (274).

51 MYASTHENIA GRAVIS

John W. Rose, M.D., and Dale McFarlin, M.D.

> Nevertheless, those laboring with a want of Spirits, who will exercise local motions, as well as they can, in the morning are able to walk firmly, to fling about their Arms hither and thither, or to take up any heavy things; before noon the stock of the Spirits being spent, which had flowed into the Muscles, they are scarce able to move Hand or Foot. At this time I have under my charge a prudent and an honest Woman, who for many years hath been obnoxious to this sort of spurious Palsie, not only in her Members, but also in her tongue; she for some time can speak freely and readily enough, but after she has spoke long, or hastily, or eagerly, she is not able to speak a word, but becomes as mute as a Fish, nor can she recover the use of her voice under an hour or two (264,265).

Since Thomas Willis described “this sort of spurious Palsie” in 1672, the condition we now know as myasthenia gravis (MG) has provided many challenging, intriguing, and at times frustrating problems for clinicians, pathologists, and basic scientists. Associated thymic morbidity has been known for 90 years (38), and for the last five decades, the physiologic defect has been localized to the neuromuscular junction (NMJ) (94,151). Approximately 40 years ago, an autoimmune hypothesis for MG was proposed (229,230). Experimental autoimmune myasthenia gravis (EAMG) produced by immunization with acetylcholine receptor (AChR) protein was a landmark contribution (194). Evidence of an immune reaction against components of the NMJ (8,22) was subsequently demonstrated in the human disease, and in the vast majority of patients with MG, the disease has an autoimmune pathogenesis. Although the mechanisms leading to this autoimmune state remain to be fully elucidated, it is clear that the nicotinic AChR is the target antigen of this autoimmune disease. This chapter summarizes the clinical, physiologic, and pharmacologic aspects of MG and presents biochemical, pathologic, and immunologic findings that may lead to a better understanding of the pathogenic mechanisms in MG and related diseases of the neuromuscular junction.

THE NORMAL NEUROMUSCULAR UNIT

Advances in basic knowledge of the NMJ have contributed to the understanding and investigation of MG. A brief review of the normal anatomy, physiology, and pharmacology of this special interaction between nerve and muscle cells is necessary for an understanding of MG, in which transmission through the neuromuscular unit is impaired. As the axon passes distally from the motor neuron, it branches and gives rise to terminal nerve endings, which lie in a shallow primary groove in the muscle membranes. The ultrastructure of this region is shown in Fig. 51.1. The terminal axon is separated from the muscle cell membrane by an intersynaptic cleft 600 Å wide (75,105). Postsynaptically there are invaginations of the sarcolemmal membrane, forming secondary folds (75).

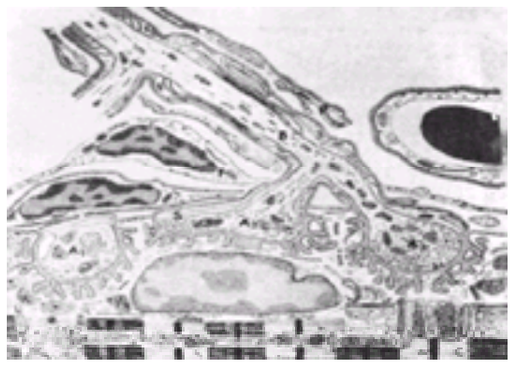

Figure 51.1. Normal neuromuscular junction. *B*, axon; A_1, A_2, A_3, axon terminals; *S*, Schwann cells; *P*, perineural cells; *F*, fibrocyte. (From Hubbard JI. Microphysiology of vertebrate neuromuscular transmission. *Physiol Rev* 1973;53:674, with permission.)

Acetylcholine (ACh) is synthesized by an enzyme, choline acetylase, in the cytoplasm of the terminal nerves and is packaged into vesicles, which tend to line up against an electron-dense area, known as the active zone, in the nerve terminal just opposite the secondary clefts in the sarcolemmal membrane. After exocytosis of the vesicles, some molecules of ACh are hydrolyzed by acetylcholinesterase; other ACh molecules traverse the intersynaptic cleft to the sarcolemmal membrane and act with the AChR. The electric organs of certain fish contain a high concentration of these AChR protein(s) and are used for many types of investigations (105,158). ACh is released from the terminal nerve both spontaneously and in response to a nerve impulse. The spontaneous release of ACh occurs constantly and gives rise to

miniature end-plate potentials (MEPPs), a phenomenon that has been shown to be quantal in nature (105). Each MEPP results from the release of ACh in a single vesicle; thus the frequency of MEPP is due to the frequency of spontaneous ACh release, whereas the amplitude of each MEPP reflects the amount of ACh released per vesicle. A nerve impulse triggers the release of larger amounts of ACh, approximately 100 to 200 quanta, which produce depolarization and subsequent contraction of the muscle fiber.

A variety of pharmacologic agents affect the NMJ (51). Three groups of agents deserve emphasis here: (a) the cholinesterase inhibitors, which decrease the breakdown of ACh and are used in the diagnosis and treatment of MG; (b) curare, which forms a competitive block of the AChR and can markedly potentiate the symptoms of MG; and (c) a-bungarotoxin (a-BTx), a protein that binds the AChR with extremely high affinity and has become a valuable tool for investigation of the NMJ (83). a-BTx is easily isolated from the venom of the elapid snake *Bungarus multicinctus* (41) and has been used to identify the presence of AChR biochemically and morphologically. The venom from another species (135), *Naja naja siamiensis*, forms a reversible reaction with AChR and is used to isolate AChR.

Biochemistry of the Acetylcholine Receptor

AChR has been purified from the electric organ of *Torpedo californica* in sufficient quantities to allow biochemical characterization. The monomeric form of *Torpedo* AChR is composed of five subunits: two a, one b, one g, and one d, with a combined molecular weight of 250,000 (117,238). The ACh-binding sites are on the a subunits (267). Recent investigations have suggested that the most likely arrangement of the subunits is abagd (238). The native receptor consists of a dimer with a disulfide bridge between the d subunits of each monomer (238). Electron microscopy in the plane normal to the membrane reveals that the subunits of each monomer form a disc with a central pit (238,267). The primary amino acid sequences of the a, b, g, and d subunit precursors of the *T. californica* AChR have been elucidated by cloning and sequencing complementary DNAs (cDNAs) for these polypeptides (47,48,180,181). Each subunit contains four putative transmembrane segments that are probably involved in forming the ionic channel (57,181).

The mammalian a subunits contain the four transmembrane segments and the regions proposed for ACh binding and major antibody-binding epitope(s), termed the *main immunogenic region* (MIR; (Fig. 51.2) (192). The AChR is a pentamer consisting of two a subunits, a single b and a single d subunit, and either a g or an e subunit. In humans, the g subunit is fetal and is replaced in infancy by an e subunit. The e subunit is necessary for normal development (178,219,269). The region on the a subunits near amino acids 192 and 193 has been proposed as the ACh-binding site (12,59,155) and is in close association with or overlapped by the a-BTx–binding site (59,87,161,179,249). ACh-binding is influenced by the d, g, or e subunits adjacent to the a subunits, resulting in different affinities of the two sites in each assembled AChR pentamer (3,172,231,238). The MIR is separate from the ACh-binding site and appears to be located in the region 67 to 76 of the polypeptide (130,238,249). The region 125 to 147 of the a subunit is exposed at the NMJ, and the synthetic peptide (125 to 147) is capable of inducing EAMG (127). The intracellular portions of the a subunits are important for binding to rapsyn, which is essential for the clustering of AChR on the postsynaptic folds of the NMJ (85,145,210). Neural factors including agrin and ACh also are required to facilitate clustering of AChR (196). Denervation results in dispersal of the clusters and increased turnover of the AChR (7).

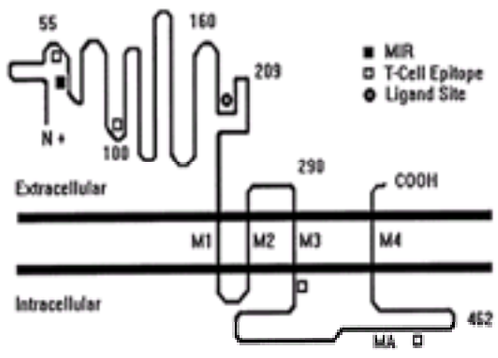

Figure 51.2. Schematic of the acetylcholine receptor (AChR) a subunit demonstrates extracellular and intracellular regions. The main immunogenic region (MIR) and ligand-binding sites are on the extracellular portion of the subunit. T-cell epitopes are more widely distributed (*open squares*). Four membrane-spanning domains are designated *M1, M2, M3*, and *M4*. The M2 domain is most critical for the ion channel formed by combination of the AChR subunits. MA is a potential fifth helix domain (58,88a,216,250).

The nucleotide sequence analysis of cloned DNAs has revealed the primary structure of the a subunit from both calf and human AChR. The mammalian a subunits show marked sequence homology with the *Torpedo* a subunits (179,180). Recent experiments using the translated products of AChR subunit–specific messenger RNAs (mRNAs) demonstrated that all four subunits are required to elicit a normal nicotinic response to ACh and confirmed that only the a subunit is necessary for a-BTx binding (161). The genes for the AChR subunits are located on three chromosomes in the mouse (a subunit on chromosome 17, b subunit on chromosome 11, and g and d subunit genes on chromosome 1) (98). In humans the a and d subunits are localized to chromosome 2, and the b subunit is on chromosome 17 (18,19). Our increased understanding of the structure and function of the AChR and the availability of pure mammalian AChR subunits are greatly enhancing knowledge of the pathogenesis and immunology of MG.

CLINICAL ASPECTS OF MYASTHENIA GRAVIS

Typical Features

MG is characterized by excessive fatigability and weakness that can be severe enough to produce total paralysis of the involved muscles (101,139,187). These symptoms usually affect muscle groups, but any individual skeletal muscle can be involved. This results in a variety of manifestations, including diplopia; ptosis; facial weakness; dysphonia; difficulty with chewing and swallowing; difficulty in breathing; inability to maintain support of the trunk, neck, or head; and weakness of the muscles of the extremities. The latter is more commonly proximal than distal. Symptoms are accentuated with the continued use of the involved muscle and improve after rest. Consequently many patients are least symptomatic in the morning and note increased severity of symptoms as the day progresses. Muscle wasting occurs in about 20% of patients, particularly in those with long-standing disease. The tendon reflexes and sensory responses are normal.

Fatigability also can be demonstrated electrophysiologically in many patients. Repetitive stimulation at low frequencies reduces the amplitude of the evoked potential and the amount of tension in the contracting muscles (Fig. 51.3) (118,199,203). The symptoms of MG lessen after the administration of cholinesterase inhibitors, and it is common practice to use either an intramuscular neostigmine (Prostigmin) or an intravenous edrophonium test (203,220) as an aid to the diagnosis. These tests are not without risk of bradycardia and syncope. Although uncommon, cardiac arrest can occur after the intravenous administration of edrophonium. In contrast, competitive neuromuscular blocking agents such as curare provoke and potentiate the weakness in this condition. Minute amounts of such agents can lead to life-threatening weakness (50).

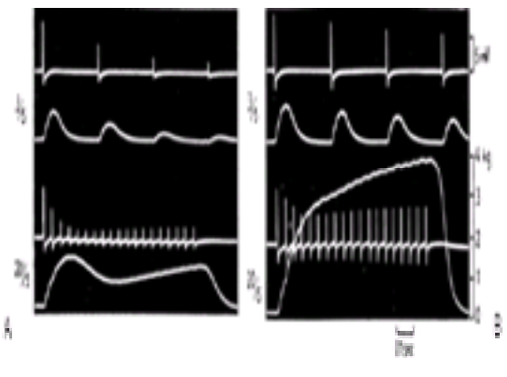

Figure 51.3. Decremental response to repetitive stimulation. **A:** Stimulation of a motor nerve first at 3 cps and later at 20 cps. **B:** Ten minutes after administration of neostigmine. (From Desmedt JE. The physiopathology of neuromuscular transmission and the trophic influence of motor innervation. *Am J Phys Med* 1959;38:248, with permission.)

Clinical Course

The peak ages of onset of MG are in the third and seventh decades. Female individuals predominate in the first group, and male individuals in the second; overall the incidence is higher in female individuals. Characteristically there is variability in both the distribution and the magnitude of involvement. Some patients have only mild involvement of a few muscles for a period of years; in others, the condition appears abruptly and in a period of weeks produces total incapacity. On the basis of clinical variants in the disease, Osserman (187) developed a classification that is a useful guide to prognosis and management. It is based on age and rapidity of onset, distribution of symptoms, and degree of involvement. The course may feature both exacerbations and remissions; however, the disease commonly progresses to severe weakness if the condition is left untreated. Since the discovery of anticholinesterase therapy and the improvement in life-support systems, the prognosis has been strikingly altered for MG patients (116,203). In general, the prognosis is best for those patients with disease restricted to the ocular muscles (29). Patients with disease involving bulbar and/or respiratory muscles have the poorest prognosis, because respiratory failure, pneumonia, or upper respiratory tract infections may develop.

Association with Autoimmune Diseases and Diseases with Immunologic Features

MG is documented in patients with systemic lupus erythematosus (SLE), thyroiditis, rheumatoid arthritis (RA), Sjögren syndrome, thyrotoxicosis, pernicious anemia, ulcerative colitis, and pemphigus (203,216). Rare cases of MG associated with multiple sclerosis are reported (140). The simultaneous occurrence of MG and any of these conditions may present extremely difficult management problems.

Ocular Myasthenia Gravis

MG may be restricted to the ocular muscles and not generalize (29). Although the patient may have major problems with diplopia, the disease has an excellent prognosis compared with that of generalized MG. Although this disorder is restricted to the ocular muscles, it can be resistant to standard treatments for MG. Only about two thirds of these patients have anti-AChR antibodies. Studies of extraocular muscles demonstrate the presence of both fetal and adult forms of mRNA for the AChR (143).

Neonatal Myasthenia Gravis

One of the pediatric forms of the disease, neonatal myasthenia, deserves special attention because it has a bearing on the pathogenic considerations discussed later. Approximately 15% of infants born of myasthenic mothers have a transitory form of the disease (160). Signs are usually present at birth but may appear at any time during the first 72 hours. Weakness of the extremities is usually symmetric and can be seen as limpness, reduced power, and absence of the Moro reflex. Weakness of the bulbar muscles can be recognized by feeble cry, inability to suck, expressionless face, and difficulty in swallowing. In severe cases, death due to respiratory failure has occurred (242). These abnormalities, which can last from only a few hours to as long as 7 weeks, respond to cholinesterase inhibitors. Recovery is complete, and the condition does not recur (242). Because of the transitory nature of neonatal MG, a circulating factor capable of crossing the placenta was implicated (159). It has now been demonstrated that in neonatal MG, there is a good correlation between decreasing anti-AChR antibody titer and improving clinical status (171).

Myasthenia Gravis Induced by Penicillamine

Autoimmune MG may develop in patients treated with penicillamine (13,244). A side effect of the drug is the induction of autoimmune diseases including not only MG, but also SLE, pemphigus vulgaris, Goodpasture syndrome, and polymyositis. MG induced by penicillamine is associated with anti-AChR antibody and, in some patients, antistriational antibody or antimuscle factor (AMF). This penicillamine-induced autoimmune MG is observed most frequently in patients with RA, and to a lesser extent in patients with progressive systemic sclerosis or Wilson disease. Clinically, the condition does respond to anticholinesterase medication and remits with discontinuation of the drug (268). Clinical improvement is associated with a marked decrease in anti-AChR antibody concentration.

SERONEGATIVE MYASTHENIA GRAVIS

Patients with clinical symptoms and signs but without detectable anti-AChR antibodies may account for 10% to 15% of individuals with MG. These patients have been described as having seronegative MG. They share characteristics of the other patients including increased sensitivity to curare and reduced AchRs at the NMJ, and their immunoglobulin can transfer disease to animals (36). The passive-transfer experiments suggest that immunoglobulin G (IgG) is more involved than is IgM. Studies by Burges et al. (36) showed that MEPPs are reduced, nerve-evoked ACh release is variable, and reduction in quantal ACh packaging can be observed (36). It is therorized that immunoglobulin may interfere with ACh packaging or release. Other studies have suggested a postsynaptic effect of the immunoglobulins (37,106). Seronegative MG may respond to plasma exchange and immunosuppressive therapy.

AUTOIMMUNE MYASTHENIC SYNDROME: LAMBERT-EATON MYASTHENIC SYNDROME

The Lambert-Eaton myasthenic syndrome (LEMS) was initially described as a paraneoplastic disorder in association with small cell carcinoma of the lung (122), but it also occurs with other neoplasms and in some patients with no tumor (65). Characteristic clinical and electrophysiologic features allow clear differentiation from typical MG (121). Weakness of ocular and bulbar musculature is rare, and is mild when present. Careful muscle testing may reveal a gradual improvement in strength on repetitive voluntary contraction. Correspondingly, repetitive electrical stimulation at frequencies greater than 10 cps increases the amplitude of the evoked potentials, whereas stimulation at 3 cps may result in a decreased response.

Electrophysiologic data indicate that the defect is due to reduced ACh released by the motor nerve (65). Freeze/fracture studies showed evidence of disruption and decreased numbers of active zones on the presynaptic membrane (80,174). Recent studies suggested that there are circulating immunoglobulins directed at the presynaptic membrane (80,81). These autoantibodies are often directed against the voltage-gated Ca^{++} channels (VGCCs) and prevent Ca^{++} entry into the nerve terminals (123,200,256). Recent evidence demonstrated depletion of presynaptic VGCCs in LEMS and the expression of neuronal class Ca^{++} channels on small-cell carcinoma cell lines (225). IgG from patients with LEMS can passively transfer the disease to the mouse and deplete the presynaptic membrane of active zones (80). Immunization of rats with cholinergic synaptosomes produces an animal model with features of LEMS (42). These findings are consistent with an autoimmune pathogenesis for LEMS (239). Treatment specific for the tumor consisting of chemotherapy and radiation therapy combined with pharmacologic and immunologic treatment may result in improved neurologic status (40).

MYASTHENIC SYNDROMES WITHOUT AN AUTOIMMUNE PATHOGENESIS

Drug-induced Myasthenic Syndromes

In certain patients, myasthenic symptoms develop after the administration of a variety of drugs including neomycin, streptomycin, kanamycin, colistin, polymycin, bacitracin, diphenylhydantoin, gentamicin, and trimethadione (268). Weakness and fatigue in such patients improve after treatment with cholinesterase inhibitors and usually resolve after discontinuation of the drug. This type of drug-induced MG is thought to be due to a direct effect of the drug agent on NMJ function (268).

Congenital Myasthenic Syndromes

Many forms of congenital myasthenia have thus far been identified and characterized (66,67,68,255). Four examples include (a) end-plate ACh esterase deficiency, (b) putative abnormality of the ACh-induced ion channel, (c) putative defect of ACh resynthesis or mobilization, and (d) congenital end-plate AChR deficiency (66,166). These diseases do not have features of autoimmune disease, are not associated with anti-AChR antibody, and generally do not respond to steroids or plasmapheresis.

Myasthenic Syndromes Associated with Denervating Diseases

A myasthenic syndrome has been described in a few patients with amyotrophic lateral sclerosis (ALS) and with the residua of poliomyelitis. In these individuals the involved muscles tire clinically and after repetitive nerve stimulation. Weakness and fatigue improve after the administration of cholinesterase inhibitors and are accentuated by curare. A potential autoimmune pathogenesis is under reconsideration as the cause of motor neuron disease in a subpopulation of patients (9). Rarely, patients appear to have features of both motor neuron disease and MG.

PATHOLOGIC CHARACTERISTICS

Thymus

About 80% of patients with MG have thymic hyperplasia, characterized by the presence of germinal centers in the medulla (Fig. 51.4) (39). In the past this was thought to represent a specific proliferation or lack of involution of thymic germinal centers, as no evidence of systemic lymphoid hyperplasia was observed. It is now believed that germinal center formation results from an intrathymic immunologic reaction (142,148).

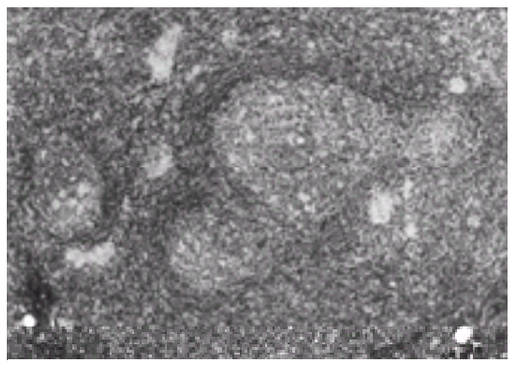

Figure 51.4. Thymic hyperplasia (×65).

Approximately 15% of myasthenic patients have a true tumor of the thymus. The thymoma associated with MG is usually well encapsulated and may show cyst formation and calcification. Microscopically, two cell types, lymphocytes and epithelial cells, are seen (Fig. 51.5). Either cell type may predominate in an individual tumor in different areas of the same tumor. Germinal centers also are seen in various areas of the thymoma. Spindle cell thymomas are virtually never seen in MG, with the possible exception of tumors that have been irradiated (216). Not all patients with MG have a hyperplastic thymus or thymoma. In a series of 35 myasthenics undergoing thymectomy, two were found to have normal thymuses histologically. In addition, involuted or atrophic thymuses without germinal centers were present in two patients (221). Germinal centers are associated with B cells that are activated (91).

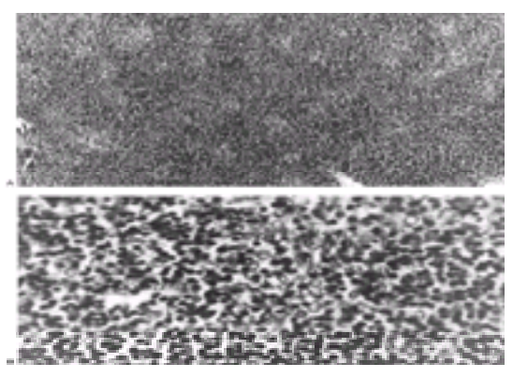

Figure 51.5. Thymoma [(A), ×50; (B), ×1,000].

Nerves

Microscopic examination of the terminal twigs of peripheral nerves, vitally stained with methylene blue, reveals two types of changes: (a) a dysplastic abnormality, characterized by marked elongation of the terminal nerve endings and by denervating processes; and (b) a dystrophic abnormality, with striking ramifications of the subterminal nerve fibers and disorganization of the terminal innervation pattern (216).

Neuromuscular Junction

Ultrastructural studies have shown that the density of synaptic vesicles in the nerve endings and the width of the synaptic cleft are normal. The major abnormality is a quantitative reduction in the subneural membrane area; the secondary folds of sarcolemmal membrane are reduced in number, and those that are present are shallow and widened (69,75,211,247). Radioiodinated a-BTx, in an autoradiographic study, showed less receptor binding in MG than in normal controls (74). In advanced cases associated with muscle wasting, the nerve endings are shrunken, and Schwann cell cytoplasm frequently extends into the cleft (75). Lymphocytes infiltrating the human NJM can be observed (150).

Muscle

The pathologic changes in skeletal muscle include focal abnormalities of the internal muscle structure (myopathic changes), which can occur with and without an inflammatory cell reaction. In some preparations, the cellular response may obscure a nearby necrotic fiber and thus appear as an isolated collection of inflammatory cells (38). Focal collections of lymphocytes in the absence of myopathic changes have been called *lymphorrhages* (38); however, serial-section studies have shown that such cellular accumulations usually lie in close proximity to a necrotic fiber (72). Reduction of fiber size (atrophy) is seen in myasthenic skeletal muscle, in one of two forms: (a) denervation atrophy, indistinguishable from that seen in diseases affecting the motor nerve; and (b) type II fiber atrophy, which is restricted to one histochemical type of muscle fiber and can accompany a variety of diseases having immunologic abnormalities as well as cachexia and disuse (72).

THE IMMUNOLOGY OF HUMAN MYASTHENIA GRAVIS

Antibody against Acetylcholine Receptor

Early attempts to demonstrate direct activity between myasthenic sera and the NMJ by immunofluorescence were unsuccessful (152). Subsequently, Almon et al. (8) reported that serum from five of 15 patients partially but significantly inhibited the binding between a-BTx and AChR from denervated muscle. An ultrastructural immunohistochemical technique that demonstrated a-BTx binding to the AChR was subsequently developed by Ringel et al. (214). Serum from 64 of 89 patients with MG blocked the binding of a-BTx to human extrajunctional receptor (137). Subsequently, radioimmunoassays were developed for detection of anti-AChR antibodies (137,162). Currently, antibodies specific for AChR are found in 90% of MG patients (185,253).

CURRENT STATUS OF THE ANTI-ACHR ANTIBODY ASSAY

Radioimmunoassay, immunoprecipitation, and enzyme-linked immunosorbent assay (ELISA) are used for the detection of anti-AChR antibodies. An internationally standardized procedure is not yet available, and methods as well as results differ in various laboratories. Therefore careful attention to laboratory standards and controls is necessary in interpreting results from these assays. A new and sensitive assay may demonstrate antibodies not detected by conventional methods in some patients thought to be seronegative by standard techniques (46,78,271). Other individuals who are seronegative for anti-AChR antibodies may have a distinct disease with an immune response directed at antigens other than the AChR and respond to immunologic therapies similar to those effective in MG (30,168).

RELATIONSHIP OF ANTI-ACHR ANTIBODY TO CLINICAL DISEASE

The majority of patients with a prolonged improvement have at least a 50% decrease in anti-AChR antibody concentration, regardless of the type of therapy (185). A decline in anti-AChR titer has been documented after thymectomy or steroid treatment (253,254). Disease severity and titer of anti-AChR antibody do not closely

correlate, but the antibody concentration is frequently high in MG patients with thymoma and relatively low in patients with localized ocular MG (183). Factors such as age, sex, and disease duration do not appear to influence the concentration of anti-AChR antibodies in MG patients when they are compared in groups.

Significant titers of anti-AChR antibody have been found in nonmyasthenic patients with SLE, Graves disease, or thymoma (84). Subsequently clinical MG develops in some of these patients, which suggests that a latent or subclinical form of the disease can exist. Significant titers of anti-AChR antibodies have been demonstrated in some patients with ALS and particularly in those treated with cobra venom (216).

Characteristics

The anti-AChR antibodies in MG patients are clearly polyclonal. IgM antibodies are produced early in the disease, and later there is a switch to IgG. Antibody to AChR is most prominent in the IgG1 and IgG3 subclasses, but can occur in all four subclasses (177,253). These antibodies are capable of passively transferring the disease to mice (245). Antibodies can be directed at epitopes on any of the AChR subunits, and some may cross-react with different subunits because there are shared epitopes (181). Although considerable diversity of antibody specificity exists, there is a predominant epitope on the a chain of AChR, referred to as the MIR (248,250). Monoclonal antibodies specific for this region can passively transfer the disease (199,234).

MECHANISM OF ACTION

Anti-AChR antibodies could change the function of AChR and/or structure of the NMJ, specifically the postsynaptic junctional folds, by at least three mechanisms: (a) blockade of the AChR, (b) modulation of the AChR, and (c) complement-mediated lysis of the postsynaptic folds.

Pharmacologic blockade of the AChR by specific antibody is the simplest explanation for the physiologic defect. Immunoglobulins capable of blocking the binding of a-BTx to mammalian NMJ were detected in the serum of 68% of MG patients (11), and Drachman (60), by using a rat muscle culture system, demonstrated that 90% of MG patients have serum immunoglobulins that produce significant blockade of a-BTx binding. Antibody that inhibits a-BTx binding to the receptor presumably also blocks ACh binding. This could result from binding to the ACh-combining site (163), steric hindrance of the ACh-combining site, or an allosteric shift of the AChR protein. Antibodies to the cholinergic binding site of AChR have been demonstrated in a large percentage of MG patients, but reactivity to other regions of the AChR is present in most individuals. The concept that anti-AChR antibodies directed at the a-BTxC binding site are the most direct and potent form for inducing disease is supported by experimental work with monoclonal antibodies. The transfer of monoclonal antibodies with this specificity against the a-BTxC binding site causes acute paralysis, but antibody directed at other epitopes does not (88). Anti-AChR antibodies from MG patients also can block the channel function of the AChR (266).

The second possible mechanism for anti-AChR action is modulation of the AChR after cross-linking by antibodies. Immunoglobulins from MG patients accelerate the rate of AChR degradation (*in vitro*). This effect was dependent on temperature and required energy, but was independent of complement (216). The accelerated degradation was produced by whole antibody and $F(ab')_2$ fragments but not Fab fragments, which implies that cross-linking of the AChR was required. The aggregates of AChR more readily undergo endocytosis after the cross-linkage (207). Although this series of studies demonstrated that antibody can modulate AChR, experimental data indicate that modulation by itself is insufficient to account for the development of EAMG in receptor-immunized mice (25).

The third mechanism for the action of anti-AChR antibody is activation of the complement pathway and damage to the postsynaptic folds (129). This is supported by a number of observations. Severe structural damage to the postsynaptic membrane, especially the junctional folds (69,211,212,247), has been demonstrated electron microscopically, and IgG, as well as C3 and C9, have been localized histochemically on the junctional folds in MG patients (Fig. 51.6) (69,211,247). Large intramembrane complexes in the junctional folds of MG patients, which are compatible with the presence of complement components (211), have been demonstrated by freeze/fractures. Interestingly, complement-mediated injury results in downregulation of muscle protein mRNAs, including those for AChR (124).

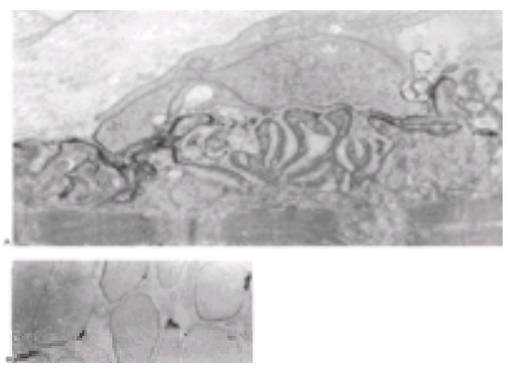

Figure 51.6. A: Localization of immunoglobulin G (IgG) at an end-plate by using peroxidase-labeled staphylococcal A protein. IgG deposits are dark and have a patchy distribution, occurring on some junctional folds but not on others and on debris in the synaptic space (×33,900) (Courtesy of A.G. Engel). **B:** Localization of C9 at the motor end plates by indirect immunoperoxidase method (×270) (Courtesy of A.G. Engel).

IN VITRO *PRODUCTION*

Peripheral blood lymphocytes (PBLs) from approximately 25% of MG patients produce anti-AChR when cultured *in vitro*. The production of AChR antibody is enhanced by culturing PBLs with mitogen or autologous irradiated thymus cell suspensions (93,176). This observation suggested that thymus from MG patients contains cell-associated antigen or helper T cells that facilitate specific antibody production. In addition, the percentage of B cells in sections of hyperplastic thymus from MG patients (2,202) was increased, and suspensions of thymus cells from MG patients contain increased numbers of B cells that spontaneously secrete immunoglobulins and anti-AChR antibody (132,139,263). In a study of cultured thymic tissue, 19 of 35 patients with MG spontaneously produced anti-AChR antibody. Antibody production correlates with each of the following factors: thymic hyperplasia, long duration of disease, and high serum anti-AChR antibody titer. *In vitro* antibody production was not detected in cultures from seven MG patients with thymoma. These findings suggest that in MG, the thymus is a site of accentuated B-cell activity (91,132).

Antimuscle Antibodies and Other Autoantibodies

Autoantibodies directed against human skeletal muscle were described by Strauss et al. (236). Subsequently, van der Geld et al. (251) found that g globulin from MG patients also reacted with a component of thymus. Immunofluorescence studies localized this reactivity to large epithelioid cells in fetal tissues. These thymic cells were shown to contain myofilamentous elements and sarcoplasmic features indistinguishable from skeletal muscle (237) and consequently became known as *myoid cells*. Antibodies from MG patients with thymoma may bind to titin (1,170) and or ryanodine receptor (232). These antimuscle protein antibodies are found in 30% of all MG patients and in up to 95% of MG patients with thymoma and can be detected by immunofluorescence or enzyme immunoassay (203). Antibodies to rapsyn, an intracellular muscle protein important in anchoring the AChRs in clusters can be found in some MG patients (5). The physiologic significance of these antibodies directed at muscle proteins is not known.

Antibodies to other tissues as well as to nuclei and nucleic acids are present in the serum of a significant proportion of MG patients. These include antithyroid and antiparietal cell antibodies, RF, antinuclear antibodies (ANAs), anti–single-stranded DNA antibodies, anti–double-stranded DNA antibodies, antithymocyte antibodies, and cold-reactive lymphocytotoxic antibodies (35,104). Antibodies directed against b-adrenergic receptors are found in MG patients (270). In some patients the presence of such autoantibodies is associated with another clinical disease, for example, RA or SLE; however, this is often not the case. Anti-presynaptic membrane receptor antibodies have been demonstrated in patients with MG (141).

HLA Association and Other Genetic Factors

Numerous studies demonstrated the association of human leukocyte antigen (HLA)-A1 and -B8 with MG in patients younger than 40 years (20,76,201,217). The highest association is with HLA-B8, which is characteristically found in young female patients with thymic hyperplasia and a high anti-AChR antibody titer (76,201). HLA-DRw3 also has been linked to MG (55). Recent study of Norwegian MG patients confirmed an increased frequency of HLA-B8, -DR3, and *DQA1*0501* (235). In a study of an Italian population, MG was associated with the DQB*502 antigen (14). In the Japanese population, in which there is an extremely low presence of HLA-B8, MG is associated with HLA-B12 and HLA-Bw35 (54). Japanese women with early-onset MG have an association with HLA-DRw53 and DQB (167). In Chinese patients the HLA-DRw9 and HLA-Bw46 antigens are associated with MG (97). Interestingly, HLA-B8 is not associated with penicillamine-induced MG. In this drug-induced MG,

the HLA-Bw35, -DR1 haplotype is the locus for susceptibility (55). The association of MG with particular HLA types and other autoimmune disease suggests that altered immunoregulatory mechanisms contribute to the pathogenesis of MG. This is confirmed by studies demonstrating altered disease severity in transgenic mice expressing different human class II molecules (240).

Other factors involved in the susceptibility to MG have included immunologic and nonimmunologic traits. Most of these associations are the results of a study in particular populations of MG patients. A number of investigators have found that polymorphisms in the region of tumor necrosis factor (TNF)-a genes are associated with MG (103). A study of markers in the CTLA-4 gene region has shown an association with MG (102).

T-Cell Studies

The numbers of blood lymphocytes and lymphocyte subpopulations have varied among reports. Although alterations in total PBLs and T cells were described by several groups, a number of investigators did not find such changes (31,104,216). Modest shifts in T-cell subsets identified by phenotype markers have been described (26,27,197). A more contemporary investigation of peripheral T-cell subsets revealed that MG patients have an increased percentage of $4B4^{+}$ T cells (helper/inducer subset), which could potentiate antibody production (165).

Cellular Immunity to Acetylcholine Receptor

Early studies of cell-mediated immunity to AChR were hampered by a number of factors. AChR is relatively insoluble, and detergents required for isolation are present in most preparations. Further, the crude extracts used for assay of antibodies largely consist of other components. Consequently, studies to date have largely used AChR isolated from fish. Lymphoproliferative responses to AChR have been studied by several investigators by using electric-organ AChR. Relatively low but significant stimulation indices (SIs) have been demonstrated in myasthenic patients as compared with controls (28,49,213). Recently, T-cell lines reactive to human AChR have been derived from the blood of MG patients (100,156,206). T-cell antigenic sites on the a chain of the AChR include amino acid sequences 48 to 67, 101 to 120, 304 to 322, and 419 to 437, which have been proposed as immunodominant epitopes (205). It is currently not known if these particular epitopes play a crucial role in the pathogenesis of MG. Abnormal and normal T-cell expansion and V gene utilization have been reported in MG lymphocytes and thymocytes (90). Dramatic results demonstrating loss of AChR from the NMJ and anti-AChR antibody production were recently obtained by injecting thymocytes from $DRW3^{+}$ MG patients into severe combined immunodeficiency syndrome (SCIDS) mice. Administration of anti-Vb5.1 antibody inhibited disease in these mice. The study implicates $CD4^{+}$ $Vb5.1^{+}$ T cells in the pathogenesis of MG in $DRW3^{+}$ individuals and suggests the potential for specific therapeutic interventions for this patient population (6).

However, many investigations strongly suggest immunologic heterogeneity of autoreactive T cells specific for the AChR in human MG (146,147,156,186,274). Transfer studies in the SCID mouse have established that CD4 cells are required and that CD8 cells may not be required for disease (259,260). Therefore, CD4 anti-AchR specificity is thought to be important for human MG (209). Establishing human T-cell lines and clones specific for AChR peptides and recombinant subunits is difficult and may limit our knowledge of the T-cell repertoire in MG. Clinical trials examining the efficacy of T cell–specific therapies will be of considerable interest but could potentially be limited by immunologic heterogeneity and epitope spreading (257).

TREATMENT

Myasthenic Crisis

Recent reviews provide useful guidelines for therapy; however, MG remains a challenging disease to manage (116,203). From time to time, an extensive muscle weakness develops in many patients with MG, including life-threatening paralysis of the respiratory muscles, which is referred to as a *crisis*. Frequently patients who are in this state are not undertreated but either are refractory to the cholinesterase inhibitors or are in cholinergic crisis. It cannot be overemphasized that in crisis, the proper management is maintenance of respiration by mechanical means, whether the weakness is due to undermedication (myasthenic crisis), a refractory state, or overmedication (cholinergic crisis) (187,203). Maintaining an airway is essential to the support of respiration. Early intubation and/or tracheostomy can be life saving. With intensive pulmonary care, it has become possible to carry virtually all patients through the crisis state. Some patients with respiratory failure can be managed for short periods with a nasotracheal tube. However, for patients with prolonged pulmonary complications, tracheostomy deserves consideration. It is easier to administer effective pulmonary care through a tracheostomy than through a nasotracheal tube (92).

Cholinesterase Inhibitors

Pyridostigmine bromide (Mestinon), neostigmine bromide (Prostigmin), and ambenonium chloride (Mytelase Chloride) are used. The degree of response to and side effects from these agents differs considerably among patients. The dose and time schedule for the administration of anticholinesterase medication must be adjusted in each individual. Potassium and ephedrine, alone or together, are commonly used as adjuncts to anticholinesterase therapy (216). Even with an optimal regimen, relief of 90% of symptoms is rarely obtained, and most patients receive far less benefit.

Excessive amounts of anticholinesterase drugs produce depolarization, which can superimpose weakness that in many cases is impossible to distinguish from that of the disease. On occasion the administration of a given dose of anticholinesterase can result in the improvement of one group of muscles and the simultaneous weakening of another group because of cholinergic side effects. Therefore an order of priority among functional muscle groups should be established. At highest priority are, obviously, the respiratory muscles, and second are the muscles used for swallowing.

Thymectomy

In 1939 the report by Blalock et al. (32) of dramatic improvement after thymectomy provided hope for an alleviative form of therapy. Recent evaluations of thymectomy reaffirmed its therapeutic potential in MG (45,62,169). Thymectomy by the transsternal approach allows the best visualization of gland and any ectopic thymic tissue. A combined cervicothoracic approach that produces lower postoperative morbidity and comparable clinical efficacy to transsternal thymectomy has been advocated by some thoracic surgeons (262).

In general, the indications for thymectomy (125,188) are (a) an operable mediastinal mass (presumably a thymoma), (b) poor medical control of the disease in patients with no contraindication to surgery, and (c) generalized MG in patients of either sex younger than 40 years who have had the disease for less than 5 years. The last group can be expected to receive the most benefit. Implicit in the use of thymectomy for the treatment of MG is commitment to highly individualized, meticulous management during the postoperative period. Some physicians have advocated the use of steroids before thymectomy for two reasons: to improve the clinical status of the patient preoperatively and to decrease the size of the thymus gland at the time of operation. The mechanisms by which thymectomy improves the clinical course of MG are not definitely known. Three factors that may alter the pathogenesis in MG after thymectomy are (a) removal of antigenic stimulus (73,110,173), (b) decline in thymic hormones or lymphokines (51), and (c) change in subsets of regulatory or autoreactive lymphocytes (31,48,82).

Corticosteroids

The use of corticosteroids in the treatment of MG was briefly investigated three decades ago and judged to exacerbate the disease (228). Von Reis and Matell (258) emphasized that after corticotropin is discontinued, the weakness is sometimes followed by a dramatic remission. Long-term treatment with high doses of prednisone is established as beneficial (108,203,261) but not without side effects (33,111,203).

When prednisone is started, it is preferable to have the patient off cholinesterase inhibitors. This is easily accomplished with patients in crises who are maintained on assisted respiration, or with patients with mild disease. Such patients may be started on approximately 1 mg/kg of prednisone, once every other day (104,261).

Patients taking cholinesterase inhibitors who are switched to corticosteroids present special and difficult problems of management. Some physicians gradually increase steroids (223). Others (71) first reduce the dose of cholinesterase inhibitors to the lowest amount that maintains respiration and swallowing, and then add corticosteroids in gradually increased amounts while reducing cholinesterase inhibitors. Other regimens including high-dose methylprednisolone have been effective (134). The simultaneous administration of steroids and cholinesterase inhibitors may result in unpredictable and life-threatening weakness and hence should be initiated on an inpatient basis.

Plasmapheresis

Plasmapheresis, either alone or in combination with immunosuppressive drugs, has been reported to be of therapeutic value in patients with MG (53,198,227). Similarly, exchange transfusion has been beneficial in the treatment of neonatal MG (58,193). The presumed mechanism is by reduction of the circulating antibodies against the AChR. Whereas plasmapheresis has proved to be a useful adjunct to therapy of acute, severe disease, it has not been effective as a long-term treatment. A favorable response to plasmapheresis suggests that the institution of immunosuppressive therapy will be beneficial (215); however, continued plasmapheresis does

not appear to act synergistically with immunosuppressive therapy such as azathioprine. Currently, plasmapheresis should be used for short-term treatment for relief of acute severe weakness unresponsive to anticholinesterase medication, thus benefiting the patient during the period before immunosuppressive therapy has become effective (96,227). Plasmapheresis also has been used preoperatively in patients undergoing thymectomy to improve postoperative respiratory function. One case report suggested that acquired antibody-negative MG may respond to plasmapheresis (159). Plasmapheresis must be administered with care in patients treated with anticholinesterase medication to avoid acute weakness precipitated by a rapid fluctuation in drug level. More selective forms of apheresis that remove IgG or anti-AChR antibodies alone are under development and will have to be compared with conventional plasmapheretic techniques (23,77,182,271).

Intravenous Immune Globulin Therapy

A recent review of intravenous immune globulin (IVIG) treatment compiled the results of the therapy in MG. Treatment of more than 60 patients is documented in the literature, with a 73% improvement rate. A significant decline in anti-AChR titer is documented after IVIG therapy (11). IVIG therapy is still under investigation. The immune globulin may be recommended as an adjunctive therapy that is beneficial in (a) reducing symptoms while other immunosuppressive treatments are initiated and (b) patients who are unable to undergo or are not responsive to plasmapheresis (11,52,115,149,275). Although it is generally well tolerated, there is the risk of anaphylaxis, leukopenia, and stroke with IVIG therapy.

Azathioprine and Cyclosporine

Results of therapy with azathioprine alone or in combination with steroid and/or thymectomy support the efficacy of this cytostatic drug. A long-term dosage in the range of 150 to 200 mg/day appears to be required for the maintenance of clinical improvement (157). Severe side effects including bone marrow suppression and systemic infection may be life threatening; therefore careful monitoring is required. Because the drug is teratogenic, it necessitates reliable birth control when administered to patients of childbearing age. Long-term therapy may be very effective, resulting in (a) decreased dosage of pyridostigmine and prednisone, (b) decreased number of hospitalizations, and (c) fewer instances of respiratory failure. The side effects of long-term therapy are not established. The possibility of oncogenesis exists with azathioprine therapy (147).

A double-blind, randomized, placebo-controlled trial of cyclosporine in MG documented that the drug is an effective treatment (243). Cyclosporine is not thought to be superior to prednisone and is limited by renal toxicity.

ANIMAL MODELS

Experimental Autoimmune Myasthenia Gravis

The major emphasis of this chapter is on MG as a human disease; however, significant contributions to the understanding of MG have emerged from studies in experimental animals, and considerable effort is still being devoted to this approach. The production of EAMG in rabbits by Patrick and Lindstrom (194) was a landmark contribution. This was accomplished by the administration of AChR from *Electrophorus electricus* in Freund's complete adjuvant. The animals developed weakness and electromyographic abnormalities consistent with neuromuscular dysfunction. Both of these parameters improved after the administration of ACh esterase inhibitors. EAMG was subsequently produced in rats (131,138), guinea pigs (136), monkeys (241), and mice (24,25,44). A variety of questions have been addressed and resolved. The sequential evaluation of physiologic and ultrastructural changes in the NMJ of rats documented that the postsynaptic region is the primary target of the autoimmune reaction. Massive destruction of this region occurs during the acute disease, and in chronic forms of the disease, the ultrastructural morphometric and electrophysiologic changes of the NMJ resemble the finding in human MG (70). Passive transfer of anti-AChR antibodies from rats with EAMG-induced signs of acute disease included invasion of the NMJ by mononuclear cells within 24 hours (70,138,204).

Animal investigations provide an approach for dissecting the immune response to AChR (191). Although some progress has been made, the results have not been as clear-cut as might have been anticipated. The presence of detergents in AChR preparations has complicated biologic experiments, and the presence of an immune response, either humoral or cellular, is not always associated with clinical disease; the latter is particularly true in mice. Lymphocyte proliferation and *in vitro* antibody production by lymphoid cells from Lewis rats immunized with *Torpedo* AChR were shown to be dependent on macrophages and T cells (56). B cells are not required as antigen-presenting cells (134). The proliferation of helper T (Th) cells was required for antibody production. The magnitude of the *in vitro* responses in this set of experiments was proportional to the total amount of circulating antibody *in vivo* and also to disease severity. Interestingly Th1 or Th2 help may generate EAMG (218). Obviously B cells are required, and the $CD5^+$ B cells associated with antibody secretion are increased (126). The demonstration that recombinant human AChR can induce EAMG in animals is a significant advance that may be particularly useful for evaluating immunotherapies (128).

The immune system of mice has been extensively characterized, and it would be expected that this would be an ideal species in which to study EAMG; however, the expression of disease varies considerably among different strains of mice and even among individual mice of a given strain (79,190,191). Variation in disease manifestation does not correlate with the immune response to AChR. Most studies of murine EAMG used *Torpedo* AChR, which shares some antigenic properties with mouse AChR; however, the shared epitopes may be less important in disease expression than the unshared ones. In addition, it was previously emphasized that many mice that appeared clinically normal after challenge with AChR clearly have NMJ dysfunction by electromyography (190). A small peptide of the AChR can stimulate T cells to provide help for a heterogeneous antibody response that results in impaired muscle function (246). Induction of EAMG in interleukin (IL)-4–deficient mice results in increased disease severity (112). IL-4 is not required for induction or progression of EAMG (17). Interferon-g (IFN-g) is important for EAMG (272). Deficiency of IFN-g reduces the incidence and severity of EAMG (273). Recent evidence implicates IL-12 in the induction of EAMG (164). Of particular interest are the investigations demonstrating that CD28–/– mice are less susceptible and CD40 ligand –/– mice are completely resistant to induction of EAMG (226).

The association between MG and major histocompatibility complex (MHC) gene products has stimulated the assessment of genetic factors that could account for variations of EAMG in mice (43). The data indicate that disease susceptibility and lymphocyte proliferation to AChR are influenced by genes within the MHC. Studies of lymphocyte proliferation in congenic and recombinant mice have mapped the response to a gene in the IA subregion. Further, experiments with allelic mutant animals indicate that the IA b chain is responsible for immune responsiveness (21,44). Obviously, extension of these studies using murine AChR and electrophysiologic techniques for evaluation would be of considerable interest.

The availability of the EAMG model has led to a better understanding of the nature of antibody responses and interactions with AChR (89), as well as regulation of the humoral responses (43). Recent studies demonstrated the therapeutic potential of a variety of treatments *in vitro* or *in vivo*, including (a) immunosuppressive drugs and IVIGs (61), (b) isogenic monoclonal anti-idiotype antibody (4), (c) Fab and Fv fragments of monoclonal anti-AChR antibody specific for the main immunogenic region (192,234,248), (d) suppressor-cell induction (153), (e) T-cell vaccination (109), (f) immunotoxins (16,119,154,184), (g) CTLA-4-Ig (154), (h) AchR and anti-AchR antibody feeding (15,99), and (i) immunizations with recombinant AchR or T-cell epitopes (113). Representative examples of the recent experimental immunotherapies are listed in Table 51.1, and of note several are effective during ongoing disease, which makes them potentially useful in human disease. A number of recent investigations have shown promise for peptide therapies in the EAMG model (10). These include cyclic peptide–blocking antibody specificity, AchR peptide sequences, and tandem peptides of T-cell epitopes (114,252).

Therapy	Effect
IVgG	Inhibits ongoing disease
IVgM (human)	Inhibits ongoing disease
CTLA-Ig	Inhibits ongoing disease
MIR specific Fv fragments	Inhibits ongoing disease
Recombinant AchR fragments	Inhibits ongoing disease and disease initiation
IL-2 Toxin	Inhibits ongoing disease
TCR specific epitope sequences	Augments ongoing disease but inhibits disease initiation
Oral anti-AchR	Inhibits disease initiation

IVgG, intravenous immunoglobulin G; MIR, main immunogenic region; AChR, acetylcholinase receptor; IL, interleukin; TCR, T-cell receptor.

TABLE 51.1. Experimental Treatments in the EAMG Model

FUTURE DIRECTIONS

MG represents a prototype of autoimmune disease in which antibodies against AChR lead to clinical manifestations. Recent discoveries reflect the value of basic and

clinical research. Nevertheless, important questions regarding the pathogenesis and treatment of the disease remain.

How Is the Autoimmune State Initiated and Perpetuated in MG?

Although the answer to this question is unknown, data from studies of the thymus demonstrate that AChR is expressed on the surface of certain thymus cell populations (73,110,173,195); these epithelial cells also are the source of immunoregulatory peptides (51). These cells in the thymus bearing AChR may be the primary targets of the autoimmune disease. Once initiated, autoimmunity to AChR in muscle could be secondary but responsible for the symptoms. The potential of MG being initiated by the molecular mimicry of AChR by antigens from specific pathogens is under investigation (222).

MG has two immunologically distinct forms, which are the early-onset disease and the late-onset disease. In the early-onset MG, thymic hyperplasia with prominent germinal centers harbors B cells secreting anti-AchR antibodies (91,132). Evidence also suggests that pathogenic T cells reside in the thymus (6). This form of MG, like many autoimmune disorders, is predominant in women and has a distinct HLA association. Other factors that may be common to autoimmune disease favoring expression in women remain to be found. In late-onset MG, there is an association with thymoma and a different HLA association. The tumor may be the source of muscle antigens. This form of MG is characterized by antibodies not only to AchR but also to titin (1,170). There is not a gender bias in the late-onset disease. Perhaps this form of the disease should be considered a paraneoplastic disorder.

Can the Immune Response Be Regulated?

It is now believed that an immune network regulates the immune response (107). Anti-idiotype antibodies interact with the antigen-specific, idiotype-bearing antibodies (120,189). Some antiidiotypes have an “internal image” of the antigen and, in some situations, are capable of initiating an immune response in the absence of antigen. MG provides an opportunity to evaluate and apply the concepts of the network hypothesis in a spontaneously occurring human disorder. Recently, in human MG, autoanti-idiotype antibodies have been described in some individuals (63,64). The interaction between idiotype and anti-idiotype does not appear to be restricted to immunoglobulin, and it now appears that the antiidiotypes may bind T-cell receptors as well. Both anti-idiotypic B and T lymphocytes have been found in MG (208). Anti-idiotype antibodies have been shown to interfere with antigen recognition by T cells (236) and, in some instances, may generate antigen-specific suppressor cells (88). Whether such mechanisms are operative in MG remains to be elucidated. Understanding of the immune response to AChR may provide new specific therapeutic approaches to the disease (34,175).

Can Therapy for MG Be Advanced?

At present we are fortunate to have effective therapies for MG, but they are not without substantial risks. Thymectomy in the early-onset patient may be curative or at least induce a remission of the disease in many patients. Administration of IVIG or plasmapheresis is particularly useful in acute crisis by respectively interfering with immunoglobulin reactivity or removing immunoglobulin with complement. Nonselective immunotherapies, particularly corticosteroids and azathioprine, help many other patients. Careful study of immunotherapies developed in the EAMG model is indicated, with the goal of finding safe and highly effective treatments. The design and conduct of clinical trials are not trivial. Special attention to patient population, treatment regimen, and outcome measures is required. Many therapies appear to be promising, based on efficacy in the EAMG model. It is our hope that over the next decade, we will have new and effective therapy for MG.

Finally, the reader of this chapter is encouraged to review the primary literature related to the AChR, the NMJ as well as MG, and the diseases of the NMJ. Only a few of the many excellent articles in these fields can be presented in this chapter.

Dedicated to the Memory of Dale McFarlin, M.D.

52 AUTOIMMUNE BLISTERING MUCOCUTANEOUS DISEASES

Hossein C. Nousari, M.D., and Grant J. Anhalt, M.D.

The autoimmune blistering mucocutaneous diseases are an interesting group of disorders for multidisciplinary investigation for several reasons. For clinicians, they are dramatic and potentially lethal dermatologic diseases that are therapeutically challenging. For clinical investigators, they provide unique opportunities to study organ-specific autoimmunity with a target tissue that is visually accessible and from which tissue can be easily sampled (1). For cell biologists, these diseases are defined by specific autoantibodies that have been used to identify structural proteins of the dermis and epidermis that are critical to the normal physiology of these tissues (2).

It is important to distinguish between pemphigus and pemphigoid (3). Historically, adult patients with acquired blistering diseases were all thought to have pemphigus. However, clinicians subsequently observed that a subset of elderly patients with “pemphigus” survived their disease, whereas middle-aged patients with skin and mucosal involvement inevitably died. The histopathologic studies of Lever revealed that patients with true pemphigus had intraepithelial blister formation, due to cell-to-cell detachment. Those elderly patients with a better prognosis had subepidermal blisters, which resulted from detachment of epidermis from the dermis (cell-to-substrate adhesion), and their disease was subsequently called *pemphigoid*. The similarity of the terms *pemphigus* and *pemphigoid* has caused confusion among physicians not thoroughly familiar with immunodermatology. This matter has been further complicated by the recent identification of a dermolytic blistering disease with autoantibodies against a collagen molecule that can mimic pemphigoid but was named *epidermolysis bullosa acquisita.* This chapter discusses diseases affecting epithelial cell-to-cell adhesion; disorders affecting epithelial cell-to-substrate adhesion; and vesiculobullous diseases, some of which are characterized by lysis within the dermis.

AUTOIMMUNE DISEASES AFFECTING THE DISORDERS OF CELL-TO-CELL ADHESION

The term pemphigus refers to three autoimmune syndromes that have in common the following characteristics: (a) loss of epidermal cell/cell adhesion, manifested clinically by blistering and erosions of epithelial surfaces; (b) autoantibodies of the immunoglobulin G (IgG) isotype bound *in vivo* around the plasma membranes of affected epithelium and detected in the serum (each form of pemphigus is characterized by specific autoantibodies directed against normal epithelial structural proteins); and (c) circulating autoantibodies that are pathogenic and reproduce the clinical features of the disease with precision *in vivo* (4). These three major forms of pemphigus, termed *pemphigus vulgaris, pemphigus foliaceus,* and *paraneoplastic pemphigus* (PNP), have distinguishing clinical, histologic, and immunologic features. Pemphigus foliaceus can be further subdivided into four subsets that have identical immunopathologic features but arise in unique circumstances (see later).

Pemphigus Vulgaris

CLINICAL FEATURES

Lesions of pemphigus vulgaris typically first develop in the oropharynx and subsequently affect the cornified epithelium of the upper trunk, head and neck, and intertriginous areas such as the axillae and groin. Lesions are restricted to stratified squamous epithelia, and internal organs other than the esophagus are not affected. The upper airway can be affected only to the level of the true vocal cords; below this, the airway is surfaced by respiratory epithelium, which is not affected. Small, flaccid bullae that break give rise to large painful denuded areas that do not heal without specific therapeutic intervention. Before the introduction of oral corticosteroids in the 1950s, the disease had a 50% mortality at 2 years and a 100% mortality by 5 years after onset. Death resulted from debilitation, electrolyte and protein loss through the skin, poor oral intake, and sepsis. Now mortality is estimated at about 5% and almost invariably results from complications of immunosuppressive therapy and not from the disease itself.

Cell dysadhesion affects all layers of the epidermis, and the blister forms just above the least differentiated, lowest layer of epidermal cells, the basal cells. Microscopic examination of an early lesion reveals loss of adhesion of the apposed plasma membranes of epidermal cells between the focal adhesion organelles, the desmosomes (also called *macula adherens*). Subsequently, the desmosomes also detach, and the detached cells assume a rounded morphology, called *acantholysis*. The basal epithelial cells remain tightly attached to the basement membrane of the dermis, for cell/substrate adhesion is not affected (32). Infiltration of blisters with inflammatory cells is highly variable.

EPIDEMIOLOGY AND IMMUNOGENETICS

Pemphigus vulgaris is the most common form of pemphigus in North America and Europe. It has been long suspected that a genetic predisposition exists, based on observations that this disease occurs more frequently in Ashkenazi Jews (5). In Jews of eastern European origin, the allele associated with predisposition to the disease is a rare human leukocyte antigen (HLA)-DR4 haplotype termed DRB1*0402 (6). It is interesting that this allele varies in only one amino acid from the gene associated with risk for development of rheumatoid arthritis, DRB1*0401. In other populations, a different DR allele is associated with risk for development of pemphigus vulgaris, DQB1*0503 (7). These data suggest that specific alterations in the hypervariable region of the b1 chain of HLA class II genes may confer susceptibility to pemphigus vulgaris. Given the immunogenetic predisposition, there surely must be a “second hit” that induces autoantibody production, the nature of which is unknown.

PATHOBIOLOGY

The antigen specificities of the three variants of pemphigus are summarized in Table 52.1. Pemphigus vulgaris sera immunoprecipitate and immunoblot a 130-kd glycoprotein that is complexed to an 85-kd protein called *plakoglobin*, a common cytoplasmic plaque protein. Amagai et al. cloned the gene, and sequence analysis showed the antigen to be a member of a family of adhesion glycoproteins called cadherins (calcium-dependent adhesion molecules) that play a critical role in homophilic cell/cell adhesion. The pemphigus vulgaris antigen is a newly defined cadherin, desmoglein 3 (8), with about 65% homology to desmoglein I, which is the pemphigus foliaceus antigen (9).

Disease	Antigen
Pemphigus vulgaris	Desmoflein 3
Pemphigus foliaceus	Desmoglein 1
Paraneoplastic pemphigus	Plakins, desmoglein 3, 1
Bullous pemphigoid	230-kd bullous pemphigoid antigen, 180-kd bullous pemphigoid antigen
Herpes gestationis	180- and 230-kd bullous pemphigoid antigen
Cicatricial pemphigoid	Bullous pemphigoid antigens, laminins 5, 6, others
Epidermolysis bullosa acquisita	Type VII collagen
Linear IgA bullous disease	Ectodomain of 180 kd, bullous pemphigoid antigen
Dermatitis herpetiformis	Tissue transglutaminase?

TABLE 52.1. Autoantigens in Bullous Diseases

There is convincing proof that the autoantibodies are pathogenic in all forms of pemphigus. *In vitro*, the addition of pemphigus serum or purified IgG fractions to skin organ cultures induces acantholytic changes that closely mimic pemphigus lesions. When neonatal mice are injected parenterally with human pemphigus autoantibodies, they develop cutaneous lesions of pemphigus in 18 to 72 hours (10). Therefore pemphigus is one of the handful of autoimmune diseases whose pathophysiology can be reproduced *in vivo* by passive transfer of human autoantibody alone.

Historically, there has been considerable debate about the importance of inflammatory events that occur after autoantibody binding to the epithelial cell surface. For example, the role of complement in the development of pemphigus lesions has been controversial. The data indicate that complement activation does occur *in vivo* after binding of pemphigus IgG to the epithelial cell surface and that this might augment acantholysis (11); but if enough autoantibody attaches to the cell surface, the cells will lose their adhesion in the absence of any activation of the complement system.

Early experiments suggested that pemphigus autoantibody might activate a cell-surface proteinase, such as plasminogen activator (PA) (12). The hypothesis suggests that localized increases in the activity of PA would generate plasmin and lead to the cleavage of cell-adhesion molecules in addition to the desmogleins and produce a fragile and disrupted epidermis. Enhanced proteolytic enzyme activity was observed in the conditioned medium of normal human explant cultures incubated with pemphigus IgG; the conditioned medium induced acantholysis in fresh explants, even those depleted of all immunoglobulin. Pepstatin A, an inhibitor of carboxyl-type proteinases, or high concentrations of soybean trypsin inhibitor, an inhibitor of serine-type proteinases, prevented pemphigus IgG induced acantholysis in organ culture. However, *in vivo* studies have solidly refuted this concept and showed that acantholysis can occur in the absence of increased PA activity. In mice that were pretreated with high-dose corticosteroids that effectively blocked PA activation, passively transferred pemphigus antibodies still produced blistering lesions. In PA-type I knock-out mice, the ability of pemphigus IgG to induce skin blistering also was undiminished.

In pemphigus vulgaris, antibodies impair the adhesive function of desmoglein 3 and cause acantholysis in the oral cavity, where this molecule seems to be of primary importance in maintaining cell attachment. This simple model for acantholysis was initially greeted with some skepticism, for there is considerable redundancy in epidermal cellular adhesion molecules, and it seemed unlikely that by impairing the function of just a single molecule (desmoglein 3), the integrity of the epithelium could be disrupted. This hypothesis that desmoglein 3 has such unique contributions to adhesion primarily in oral epithelium is supported by new data. Recently, a desmoglein 3 “knock-out” mouse was produced (13). These mice lacked desmoglein 3 expression in skin and mucous membranes, but acantholysis occurred only in the mouth, and in a limited fashion in areas of trauma such as the snout and paws. The skin was not affected, although hair abnormalities occurred later in life. As pemphigus vulgaris progresses, many but not all patients will develop cutaneous disease. That skin involvement occurs only in some pemphigus vulgaris patients is explained by the “desmoglein compensation hypothesis.” The key to this hypothesis is the desmogleins (pemphigus antigens) are key adhesion molecules that keep cells attached to each other. In some areas of the body, both desmogleins 1 and 3 are present, and both must be impaired by autoantibody to cause cell detachment. In some areas, only one desmoglein may be present at some level in the skin or mucous membrane, and there only one desmoglein must be damaged to cause cell detachment. The appearance of skin involvement in pemphigus seems to be caused by a “spread” of the autoantibody response and development of antibodies against both desmoglein 3 and desmoglein 1 (14). If both these desmogleins are inhibited by autoantibody, not just oral but also cutaneous blistering occurs (15). This may represent an example of “epitope spreading,” a phenomenon seen in autoimmunity, in which early in the disease course, patients make antibodies against one protein, but as the disease evolves, they then make additional antibodies against molecules that are similar in structure, or even unlike each other in structure, but are physically closely associated in a tissue.

In contrast, as explained later, in pemphigus foliaceus, blistering occurs only in the most superficial layer of the epidermis. These patients have antibodies that are directed against desmoglein 1. This desmoglein is expressed mostly in the upper levels of the epidermis, and antibodies binding to it cause cell detachment (blistering) only where it is primarily expressed. Desmoglein 1 is present in oral epithelium, but oral lesions “never” occur because there is coexpression of desmoglein 3 in the superficial oral epithelium, and the desmoglein 3 is able to keep the cells from detaching, even if desmoglein 1 is knocked out by the antibody (16). In skin, desmoglein 3 also is expressed in lower levels of the epidermis, so that knocking out desmoglein 1 does not cause blistering there, but just in the upper levels of the skin where desmoglein 1 is the only key adhesion molecule present.

THERAPY

The primary target for therapeutic intervention is the Ig-producing hematopoietic system, not the affected end organ, the skin. Topical corticosteroid therapy alone does not control this autoimmune disease because of its systemic nature; as long as there is sufficient autoantibody binding in the epidermis, lesions will be induced. Patients with pemphigus vulgaris should first be treated with oral corticosteroids (17). The disease will be controlled with reasonable doses in approximately half of such cases. As one would anticipate, based on the known pathophysiology, drugs that are effective at reducing autoantibody synthesis are useful clinically in controlling the disease. Immunosuppressive drugs used in the treatment of pemphigus, in order of their effectiveness, are cyclophosphamide (Cytoxan), azathioprine (Imuran), mycophenolate mofetil (CellCept) (18), high-dose intravenous immunoglobulin (IVIG), and cyclosporine (19). A coordinated regimen of short-term plasmapheresis combined with long-term cyclophosphamide therapy can produce dramatic improvement in even the most refractory or aggressive cases of pemphigus.

Pemphigus Foliaceus

CLINICAL FEATURES

In contrast to pemphigus vulgaris, mucosal lesions in pemphigus foliaceus are extraordinarily rare, and acantholysis occurs high in the epidermis, through the granular cell layer. Intact, flaccid blister formation is unusual, but widespread scaling and superficial denuding of the skin are common. Pemphigus foliaceus is a chronic, debilitating disease that only rarely results in death, possibly because of the superficial nature of the lesions and lack of mucosal involvement.

EPIDEMIOLOGY AND IMMUNOGENETICS

Several variants of pemphigus foliaceus are recognized. In pemphigus erythematosus, the features of pemphigus foliaceus coexist with clinical and immunologic features of lupus erythematosus.

Brazilian pemphigus (endemic pemphigus foliaceus/fogo selvagem) is immunologically identical to pemphigus foliaceus and is differentiated by its unique epidemiology (20). Its endemic occurrence in rural areas of South America suggests that an arthropod vector may play a role in the transmission of the disease, but direct proof of this is lacking. One study of Brazilian pemphigus involved 485 cases in 201 families. In 187 (93%) of the 201 families, the fogo selvagem occurred in genetically related members, whereas in 14 (6.9%) families, the disease occurred in genetically unrelated household members. There are increased frequencies of HLA-D1, DQ1, and DR4, and decreased frequencies of HLA-DR3, DQ2, and DR7 (21). Other data suggest that the HLA-DR7, DQw2 haplotype may confer resistance to the development of pemphigus foliaceus (22).

Drugs also can induce pemphigus, with most cases being identical to pemphigus foliaceus, whereas a few resemble pemphigus vulgaris (23). The agents that induce pemphigus are most often drugs with highly reactive sulfhydryl groups such as d-penicillamine and captopril (24). These drugs can directly induce acantholysis *in vitro* in the absence of autoantibody or, more commonly, may initiate autoantibody-mediated disease *in vivo* that persists even after withdrawal of the implicated drug.

PATHOBIOLOGY

Pemphigus foliaceus sera recognize a 165-kd transmembrane glycoprotein, desmoglein I (25). Desmoglein I is a cadherin and differs from “e” cadherins (epithelial cadherins found in simple epithelia) primarily by the presence of a very long cytoplasmic domain (26). This domain may mediate its interaction with plakoglobin and other intracellular proteins that link the cell surface with the keratin cytoskeleton of the cell. When IgG from patients with pemphigus foliaceus is injected parenterally into mice, the characteristic lesions of pemphigus foliaceus are reproduced precisely. In contrast to the results with IgG from humans with pemphigus vulgaris, intraepidermal blistering developed in the superficial granular cell layer, precisely replicating the distinctive changes of human pemphigus foliaceus (27). In endemic pemphigus foliaceus, the major autoantibody activity is found in the IgG4 subclass, which is thought to be functionally monovalent and incapable of activating complement (28). When the IgG4 fraction of serum from patients with pemphigus foliaceus was separated from other immunoglobulin subclasses and passively transferred into neonatal mice, characteristic lesions were induced (99). Monovalent $F(ab')_2$ fragments of the IgG4 autoantibodies also induced lesions *in vivo*. There was no detectable complement activation in the lesions of animals treated with intact IgG4 or the monovalent $F(ab')_2$ fragments. This finding is remarkable, for it is further evidence that antibodies binding to the cadherin protein, desmoglein I, can downregulate its function to the point of inducing blister formation *in vivo*, with lesions

confined to the precise layer in the epidermis where desmoglein 3 is not coexpressed.

TREATMENT

The treatment of pemphigus foliaceus is similar to that of pemphigus vulgaris, but in most patients, less aggressive therapy is required for control. In contrast to pemphigus vulgaris, drugs such as oral gold and antimalarial agents may be more useful than in pemphigus vulgaris.

Paraneoplastic Pemphigus

Paraneoplastic pemphigus is a newly described variant (29). To date, all patients have a known or occult neoplasm, most commonly, non-Hodgkin lymphomas, thymomas, and hematologic malignancies, especially chronic lymphocytic leukemia and giant follicular hyperplasia (Castleman tumor) (30). Patients have painful oral erosions that prove refractory to standard therapies and develop a polymorphous cutaneous eruption with episodes of blistering and healing. The mucosal and cutaneous blisters show a characteristic combination of suprabasilar acantholysis similar to those of pemphigus vulgaris, and keratinocyte necrosis that may resemble erythema multiforme or a lichenoid inflammatory eruption. All patients have tissue-bound and circulating autoantibodies that bind to all epithelia *in vitro* and have a common and unique immunologic specificity.

PATHOBIOLOGY

In PNP, the complex humoral immune response is still in the process of being completely defined. Current data indicate that a complex of epithelial antigens is recognized by autoantibodies in PNP. Almost all patients have antibodies against desmoglein 3, and a majority also have antibodies against desmoglein 1. Passive transfer of these autoantibodies into mice reproduces lesions only in skin and esophagus, and it has been shown that the desmoglein antibodies are specifically responsible for the induction of blistering by passive transfer (31). The concomitant presence of antibodies against plaque proteins of the desmosome distinguishes PNP from other forms of pemphigus. The antigen complex of targeted desmosomal plaque proteins consists of desmoplakin I and desmoplakin II (intracellular plaque proteins of desmosomes) (32); the 230-kd bullous pemphigoid antigen and plectin (plaque proteins of the hemidesmosomes); two other desmosomal plaque proteins, envoplakin (33) and periplakin (34); and an as-yet-uncharacterized 170-kd antigen. The autoantibodies of paraneoplastic pemphigus are most distinctive because they bind to the cell surface of all epithelia, not just stratified squamous epithelia. This is due to the wide distribution of desmoplakins in all epithelia and some nondesmosomal structures. The implications of autoantibodies with such a broad specificity are not clear; however, there is good evidence that these autoantibodies may be responsible for the induction of pulmonary epithelial lesions in patients. In about one third of patients with PNP, late onset of hypoxia and shortness of breath heralds the onset of a progressive disease of respiratory epithelium, eventuating in the syndrome of bronchiolitis obliterans, with death due to respiratory failure. Bronchoscopy of patients with PNP who have dyspnea and hypoxia reveals laryngeal, tracheal, and bronchial erosions with histologic signs of cell/cell dysadhesion and deposition of autoantibodies in the respiratory epithelium. These findings suggest that the pemphigus autoantibodies were the cause of the respiratory tract erosions (35). The multiorgan effects of these unique autoantibodies are being studied. It appears that PNP is a devastating illness, with autoantibody-induced damage to numerous epithelia.

THERAPY

No known effective therapy for this syndrome exists. In those individuals who have an associated benign neoplasm (thymoma, Castleman tumor), complete excision of the tumor results in slow improvement and often complete resolution of the syndrome. In most patients with malignant tumors, the disease becomes worse despite therapy with corticosteroids, immunosuppressives, and plasmapheresis. Death often results from debilitation, sepsis, respiratory failure, or gastrointestinal hemorrhage. Treatment of the underlying malignant neoplasm, or reduction of tumor burden alone, does not reduce the activity of the autoimmune disease, once it is initiated.

AUTOIMMUNE DISEASES AFFECTING THE DERMAL/EPIDERMAL JUNCTION: DISORDERS OF EPITHELIAL CELL/SUBSTRATE ADHESION

The term pemphigoid applies to mucocutaneous diseases that are characterized clinically by the presence of large, tense blisters, by subepidermal blister formation, and by the deposition of IgG and complement components along the basement membrane zone (BMZ) of affected skin or mucous membrane (36). Three major forms exist: (a) bullous pemphigoid, (b) gestational pemphigoid (herpes gestationis), and (c) mucous membrane pemphigoid. These diseases have clinical, histologic, and immunopathologic similarities, but the exact relationship of one to another is not fully defined.

Bullous Pemphigoid

The incidence of bullous pemphigoid is not certain but is estimated to be 1 per 100,000 per year, making the disease much more common than pemphigus vulgaris. Bullous pemphigoid occurs most frequently after age 60 years, but it may rarely occur in infancy or childhood. Blistering lesions in bullous pemphigoid are most often generalized, but in 15% to 30% of patients, the bullae may be localized, often on the pretibial area. Mucosal lesions are usually transient, trivial, and heal without scarring; when they are present, they are usually restricted to the mouth. The lack of mucosal involvement is the major criterion for distinguishing bullous pemphigoid from mucous membrane pemphigoid. In the latter, mucosal epithelia are primarily affected, scarring is prominent, and cutaneous lesions are transient and trivial. No racial or geographic predilection is recognized in bullous pemphigoid. In contrast to pemphigus, there is no increased incidence in the Jewish population, and there is no known immunogenetic association.

PATHOBIOLOGY

In bullous pemphigoid, autoantibodies are found along the dermal/epidermal junction in a fine linear distribution. The most frequently detected autoantibody is of the IgG4 subclass, and there is significant and sometimes more intense deposition of complement components that colocalize with IgG deposition (37). Occasionally IgE anti-BMZ antibodies are detected. The histology of a blister shows the accumulation of eosinophils and a few neutrophils along the dermal-epidermal junction. Blistering occurs between the epidermis and the dermis, and the roof of the blisters is formed by full-thickness epidermis. There is also a variable dermal infiltrate consisting primarily of eosinophils. Therefore the diagnosis of the pemphigoid is established by the clinical finding of tense blisters, subepidermal blister formation by light microscopy, and direct and indirect immunofluorescence that shows *in vivo* bound and circulating autoantibodies against the BMZ. Serum antibodies are detectable in 50% to 70% of patients with the disease. By indirect immunofluorescence, these antibodies bind to the BMZ of stratified squamous epithelia from numerous species.

Two unrelated proteins are recognized autoantibodies in bullous pemphigoid. Patients produce an immune response to (a) a 230-kd antigen (BP 230 antigen or BP Ag 1), which is a plaque protein of the epidermal basal cell hemidesmosome and has approximately 30% structural homology to desmoplakin 1; and (b) to a 180-kd protein (BP 180 antigen or BP Ag 2) (38), which spans the plasma membrane of the basal cell. It is a transmembrane protein with type II orientation, with its carboxyl-terminus in the extracellular environment. The extracellular domains of the antigen have several collagen-like repeats that probably interact with matrix proteins of the underlying dermal surface, and for this reason, it is also referred to as collagen type XVII. The intracellular portion is embedded in the hemidesmosomal plaque, and almost certainly mediates adhesion between extracellular proteins and the cytoskeleton of the basal domain of the epithelial cell. Patients with bullous pemphigoid often produce antibodies against both the BP 230 and the BP 180 antigens (69), even though there is no significant homology between these two molecules.

It is now established that the autoantibodies in patients with bullous pemphigoid are pathogenic. Curiously, antibodies against the BPAG1 (39) have not been shown to be pathogenic in any *in vivo* system tested, but antibodies against the BPAG2 were capable of inducing blistering *in vivo*. Passive transfer of human BP autoantibodies into neonatal mice, using techniques so successful in the study of pemphigus, failed to cause disease. The cause of this failure was that human anti-BPAG2 (BP 180) autoantibodies preferentially recognize an epitope of the ectodomain of the BP 180 antigen, and that in this key region, the murine BP 180 was not homologous to the human antigen. To overcome this problem, Liu et al. modified the traditional neonatal mouse model by first producing antibodies against the key epitope of the murine BP 180 domain by immunization of rabbits with a fusion protein. Then they infused polyclonal rabbit antimurine BPAG2 antibodies. The injected mice developed subepidermal blistering disease that closely mimicked bullous pemphigoid. Histologic examination of the skin of these mice revealed findings typical of pemphigoid, with subepidermal blistering, and a polymorphonuclear cell infiltration along the BMZ and blister cavity. Direct immunofluorescence examination of these mice revealed linear deposition of rabbit IgG and murine C3 along the epidermal BMZ. This study clearly demonstrated that anti–BP 180 antibodies bind the extracellular domain of the BP 180 antigen and initiate a cascade of events, including the activation of complement, attraction of polymorphonuclear cells to the BMZ, release of proteolytic enzymes, and finally subepidermal blistering. The complex cascade of inflammatory events (40) that occurs subsequent to autoantibody binding has been dissected, and the requisite participation of mast cells, eosinophils, neutrophils (41), complement activation, and potentially other proinflammatory events is apparently required for the formation of blisters *in vivo*. In contrast to pemphigus, in which antibody binding alone to the relevant antigen(s) can cause the characteristic tissue injury (acantholysis), in pemphigoid, lesions do not occur in the absence of a sequential series of inflammatory events.

TREATMENT

Pemphigoid has a very low mortality rate, so treatment can be less aggressive than that for other autoimmune blistering disorders such as pemphigus. Some mildly

affected individuals respond to high-potency topical steroids, but often the disease progresses to the point at which disfiguring or debilitating blisters arise on a large portion of the body. Oral corticosteroids are the drug of choice (such as prednisone at a starting dose of 0.5 mg/kg/day), and this frequently produces complete clearing of the lesions. The corticosteroids can then be slowly tapered over the next 6 months. Approximately half of the patients treated in this manner either go into remission or require a very low dose of alternate-day steroids to control the disease. Severely affected individuals can be treated with one of the following agents, listed in order of effectiveness: azathioprine (2 to 3 mg/kg/day), cyclophosphamide (1 to 2 mg/kg/day), dapsone (2 to 3 mg/kg/day), a combination of tetracycline and niacinamide (1,500 2,000 mg of each/day), and other agents such as methotrexate and cyclosporine. Mortality from bullous pemphigoid is rare; sepsis from cutaneous lesions is similarly rare; and the prognosis is good.

Gestational Pemphigoid (Herpes Gestationis)

Herpes gestationis is a disease of pregnancy. Most commonly, women in the late second or third trimester develop lesions that are clinically and histologically typical of bullous pemphigoid (42). These lesions begin in the periumbilical area and then spread peripherally. The disorder is usually intensely pruritic. Most commonly, the disease worsens until the child is delivered, and then resolves. It may flare for a short time in the postpartum period but then remits spontaneously in most affected individuals. The disease can be reactivated by subsequent pregnancies, and in general, in subsequent pregnancies, the disease starts earlier, and the eruption is more severe. The disease can be reproduced by stimulation with oral estrogen. It also has been associated with choriocarcinoma and hydatidiform molar pregnancies.

PATHOBIOLOGY

All patients with herpes gestationis have intense complement deposition along the BMZ of perilesional skin There is very weak IgG deposition, and circulating in the serum is a very low titer of avidly complement-fixing anti-BMZ antibody. Before this antibody was recognized as an IgG autoantibody, it was named the *herpes gestationis factor*. This antibody is specific for the BP 180 hemidesmosomal protein (43). Approximately 90% of individuals have reactivity solely with the BP 180 antigen, and about 10% of patients react with both the BP 180 and BP 230 antigens, similar to patients with bullous pemphigoid.

Although there is significant evidence that herpes gestationis is a form of bullous pemphigoid that occurs during pregnancy, there appears to exist a genetically determined predisposition for the development of this disease. In contrast to bullous pemphigoid, 60% to 85% of patients with herpes gestationis are HLA-DR3 positive, but more strikingly, approximately 45% have the combination of HLA-DR3 and DR4, which is present in only 3% of unaffected women.

What is curious about this disorder is the very specific induction of the autoimmune phenomenon by estrogens, either endogenous from the fetal tissues or exogenous from oral contraceptives. How this autoimmune disease is invoked in a genetically susceptible individual by these steroids is a subject of much speculation, but scarce hard data.

Mucous Membrane Pemphigoid

Mucous membrane pemphigoid is predominantly a disease of the elderly, with a peak incidence between the ages of 60 and 80 years. Juvenile cases are exceedingly rare. Lesions can arise on any mucosal surface covered by stratified squamous epithelium, including the nasopharynx and oropharynx, conjunctiva, esophagus, larynx, urethra, and anus. Morbidity and mortality are due to the scarring produced by recurrent lesions. Scarring is a major criterion for distinguishing mucous membrane pemphigoid from bullous pemphigoid. Moreover, in bullous pemphigoid, cornified epithelium of skin is the primary tissue involved, whereas in mucous membrane pemphigoid, mucosal epithelium is primarily affected. Therefore the two diseases are distinguished primarily by clinical criteria.

Clinically, lesions are smooth-bordered erosions with distinct margins, and only rarely are intact blisters observed. The gingivae are commonly involved, and mucous membrane pemphigoid is one cause of “desquamative gingivitis.” Other causes of desquamative gingivitis include erosive oral lichen planus and pemphigus vulgaris. About 10% to 15% of patients with either epidermolysis bullosa acquisita or linear IgA dermatitis may have scarring mucosal lesions that closely mimic the clinical phenotype of mucous membrane pemphigoid.

The conjunctival epithelium is affected in about 80% of patients with mucous membrane pemphigoid and is cause for considerable concern. Signs of active disease include a violaceous inflammatory infiltrate, superficial fine fibrotic bands, shrinkage of the conjunctival fornices, and entropion. Lesions of the larynx, esophagus, and genital mucosae consist of smooth-bordered erosions, with eventual stricture formation. Skin lesions occur in fewer than 20% of patients and are usually transient. When present, they consist of small intact blisters or erosions, usually in the head and neck area.

The diagnosis is established by three criteria: (a) scarring blisters and/or erosions, (b) subepithelial blistering as seen on histologic examination, and (c) direct immunofluorescence of perilesional epithelium showing IgG and complement components along the BMZ. In mucosal pemphigoid, indirect immunofluorescence for circulating antibodies is highly unreliable, and the findings are negative in the majority of cases. (This is a sharp contrast to the reliability of indirect immunofluorescence in pemphigus vulgaris and the presence of circulating antibodies in 50% to 70% of patients with bullous pemphigoid.)

PATHOBIOLOGY

It is presumed but not proved that mucous membrane pemphigoid is an autoimmune disease. This presumption is based on the invariable presence of immunoglobulins and complement components at the basement membrane of affected mucosae. There are no clear indications of what may precipitate the autoimmune disease, although, as in pemphigus, there are some reports of d-penicillamine producing the autoimmune phenomenon. There is a reported immunogenetic predisposition to the development of ocular pemphigoid associated with the HLA-B12 haplotype, but this has not been confirmed.

Studies to define the antigen that is identified by mucous membrane pemphigoid autoantibodies have been hampered somewhat by the absence of high-titer circulating autoantibody. Although some investigators showed that the sera from most patients with mucous membrane pemphigoid recognize the BP 230 or the BP 180 antigen or both, others found other antigens to be bound by circulating autoantibodies. It is now becoming apparent that the clinical disease is caused by multiple autoantibody-antigen interactions. The common link is that all of the implicated antigens are part of the keratinocyte's anchoring filament complex. This is a series of linked proteins that extend from the hemidesmosomal plaque, through the lamina lucida, and into the upper dermis. Proteins in this complex that have been targets of autoantibodies in individual cases of mucous membrane pemphigoid include the bullous pemphigoid antigens 1 and 2 (BP 230 and BP 180) (44), laminins 5 (45) and 6 (46,47), type VII collagen, and others. It has been found that different antigens were recognized by IgA antibodies as opposed to those of the IgG isotype from the same patient.

Indirect immunoelectron microscopic studies of mucous membrane pemphigoid suggest that the autoantibodies preferentially deposit in the lower lamina lucida, in contrast to the distribution in bullous pemphigoid, in which they are found in the upper lamina lucida. This suggests that the autoantibodies of some patients with mucous membrane pemphigoid have different antigenic specificities from those of the autoantibodies of patients with bullous pemphigoid (48).

THERAPY

Treatment is dictated by the organs involved and the anticipated morbidity. Once the disease develops, it is progressive, and spontaneous remission is rare. This disease is not highly responsive to steroids. Therefore, for example, if only the oropharynx or nasopharynx is affected, the anticipated morbidity is minimal, and treatment should be limited to topical steroids, intralesional steroid injections, or occasional short bursts of oral corticosteroids. These maneuvers provide palliation but do not halt progression of the disease. If only the gingivae are involved, topical therapy can be delivered by the construction of a flexible dental tray in which a topical steroid is applied with occlusion.

If the eyes, esophagus, or larynx is involved, the anticipated morbidity includes blindness and asphyxiation, and aggressive systemic therapy is warranted. Systemic steroids alone do not adequately control progression, and only an occasional patient responds well to dapsone therapy. Of the various immunosuppressive agents available, cyclophosphamide is the most effective. It is administered for a period of 18 to 24 months (at a dose of 2 mg/kg/day, until the white blood cell count is depressed to 3,000 4,000/µL). About three fourths of those treated with this regimen tolerate the drug, and at the end of the treatment period, most of those patients have complete clinical remissions that persist after all drugs are discontinued. To date, this cyclophosphamide regimen is the only treatment that provides the potential for a “cure” of this disease. Azathioprine is an alternative for patients who cannot tolerate cyclophosphamide, but it is not as effective.

DERMOLYTIC AUTOIMMUNE DISEASES

Epidermolysis Bullosa Acquisita

Epidermolysis bullosa acquisita is a disease of adult onset, originally described as trauma-induced blisters, predominantly on extensor surfaces, and healing with milia and scars. The fact that epidermolysis bullosa acquisita can mimic other vesiculobullous diseases, especially bullous pemphigoid, leads to diagnostic difficulties. It has

been found that a bullous pemphigoid like clinical presentation may occur in up to 50% of patients with epidermolysis bullosa acquisita. Neither histopathology nor routine direct immunofluorescence studies necessarily differentiate epidermolysis bullosa acquisita from bullous pemphigoid, because similar linear deposition of IgG occurs in both diseases, and histologic differentiation is not always reliable. Definitive diagnostic differentiation can be accomplished by direct or indirect immunoelectron microscopy, by indirect immunofluorescence on split skin, and by immunoprecipitation or immunoblotting. In epidermolysis bullosa acquisita, the immune deposits are in the lamina densa and in the sublamina densa area, whereas in bullous pemphigoid, they reside in the lamina lucida and the hemidesmosome complex. The antigen recognized by epidermolysis bullosa acquisita antibodies is type VII procollagen (49), a major component of the anchoring fibrils of the dermis. This antigen specificity can be established by immunoblotting or immunoprecipitation when circulating antibodies are detectable (50).

Dermatitis Herpetiformis

Dermatitis herpetiformis is most often seen in young adults with intensely pruritic, burning papules and vesicles distributed in a highly characteristic symmetric pattern over extensor surfaces of the elbows and knees, as well as the sacrum and scalp. Intact blisters are rarely observed, for the patients excoriate them vigorously in the earliest stages of formation. Small, 2- to 5-mm excoriations in a characteristic distribution are the most consistent clinical feature of the disease. Before the discovery of diaminodiphenylsulfone (dapsone) as an effective therapy for this disease, the most common cause of mortality in dermatitis herpetiformis was suicide prompted by intractable pruritus and complicated by skeptical physician reaction, for the pruritus is wildly out of proportion to the apparent severity of the lesions. Essentially all patients with dermatitis herpetiformis have an associated gluten-sensitive enteropathy, which is asymptomatic in most of them, and also have a distinctive genetic predisposition, with almost constant presence of the HLA-AI and B8 (75% to 90%), and DR3, DQw2 haplotype (95% to 100% of patients) (51). Also associated with dermatitis herpetiformis is an increased risk of intestinal lymphoma. Dermatitis herpetiformis may be confused with vesicular pemphigoid in the rare instances in which large blisters are present, but lesions in the latter disease usually lack the characteristic extensor symmetry of dermatitis herpetiformis. The two diseases can easily be distinguished by direct immunofluorescence, which in dermatitis herpetiformis uniformly shows granular deposits of IgA along the BMZ and in the upper papillary dermis (52), with accentuation within the dermal papillary tips, and circulating autoantibodies against the BMZ are usually not detectable.

There has been much speculation regarding the antigenic specificity of the dermal deposited IgA autoantibody and the role of gluten-sensitive enteropathy in this disease, but little is really known. Speculations include cross-reactivity between IgA antigluten antibodies and some dermal structure and trapping of intestine-derived IgA immune complexes in the skin, but no convincing pathogenetic mechanism has yet been proven. The tissue transglutaminase has been recently found to be the autoantigen for T lymphocytes and also the antigen for the antiendomysial antibodies (53) in patients with celiac disease and dermatitis herpetiformis (54).

THERAPY

Diaminodiphenylsulfone, in a usual oral dose of 50 to 150 milligrams per day, is a highly specific and effective therapy for dermatitis herpetiformis. Dapsone provides dramatic relief from pruritus in 24 to 48 hours. If dapsone cannot be tolerated by an individual because of congenital glucose-6-phosphate dehydrogenase (G6PD) deficiency (devastating hemolysis could result) or sulfone allergy, sulfapyridine can be obtained on a compassionate basis and will provide adequate symptomatic relief.

The complete and long-term elimination of gluten in any form from the diet allows affected patients to reduce or eliminate their dependence on dapsone (55). Compliance with such a regimen in our culture is usually impossible.

Linear IgA Bullous Dermatosis

The term *linear IgA bullous dermatosis* is applied to a clinically heterogeneous group of disorders that have in common the linear deposition of IgA, with or without complement components, along the dermal/epidermal junction. Patients with linear IgA deposits include those with clinical features of chronic bullous dermatosis of childhood, those with mixed clinical features of dermatitis herpetiformis and bullous pemphigoid, those with disorders resembling classic dermatitis herpetiformis, and a small number (~10% to 15%) who have the clinical features of mucous membrane pemphigoid. Patients with linear IgA bullous dermatosis differ from those with classic dermatitis herpetiformis by the absence of jejunal enteropathy; a less predictable therapeutic response to sulfones; and a different immunogenetic background, with no increase in the incidence of the HLA-B8, DR3, DQw2 histocompatibility antigens. Most patients with linear IgA bullous dermatosis are younger than those affected with other bullous diseases. Immunoelectron microscopy has confirmed that IgA dermatosis is heterogeneous. Deposition of IgA *in situ* has been observed in many different locations, including the hemidesmosome and upper lamina lucida, the lower lamina lucida, and beneath the lamina densa.

These findings suggest that individual cases of linear IgA dermatosis may represent unique syndromes or variants of other known syndromes such as epidermolysis bullosa acquisita and bullous pemphigoid, mediated by IgA rather than IgG isotypes. For example, in patients with linear IgA disease in whom epidermal deposition is found, many of these cases will recognize a 97-kd lamina lucida. Recent studies have shown that this antigen is homologous with a portion of the BP 180 antigen (56), but whether this is a processed form of the antigen or a product of alternate splicing is not known (57). In drug-induced linear IgA dermatosis, vancomycin is the leading implicated drug, but those patients have exclusively dermal deposition of autoantibody (58,59), suggesting that type VII collagen may be the target antigen. There is uncertainty about the nature of this syndrome, as the diagnosis is based on a single morphologic criterion (linear IgA deposition) rather than on a specific clinical presentation or a single antigenic specificity.

53 IMMUNE FUNCTION IN OCULAR INFLAMMATORY DISEASE

Thomas A. Ferguson, Ph.D., and Russell N. Van Gelder, M.D., Ph.D.

OCULAR IMMUNE DISEASE

Studies designed to understand the immunologic basis of ocular inflammatory disorders have been largely unsuccessful. This shortfall may be due to the inherent complexity of the disease processes. However, the failure to make significant advances in the understanding of ocular inflammatory disease may rest on the lack of clinically relevant model systems. The literature is replete with hundreds of references to an “alphabet soup” of uveitis models [experimental autoimmune uveitis (EAU), endotoxin-induced uveitis (EIU), experimental autoimmune anterior uveitis (EAAU), anterior chamber–associated immune deviation (ACAID), EIEIO, etc.] produced mostly in rodents. Although it is not clear how these models relate to human disease, this has not suppressed enthusiasm to explore even their most arcane features. This has led to a somewhat confusing literature in which paradigms are established based on perceptions and review articles rather than on experimental evidence. In this chapter, we attempt to make sense of the available experimental knowledge in the context of clinical eye disease.

INFLAMMATION LEADS TO DYSFUNCTION

The host response to pathogens involves complex inflammatory responses and immune reactions. Although these are central to host defense and vital to clearing infections, they are often associated with nonspecific injury to nearby tissue. These localized reactions do successfully contain pathogens before they spread to other areas, but they are often accompanied by nonspecific injury to surrounding tissue. Most organ systems can tolerate these responses without permanent consequences; however, there are sites that limit the spread of inflammation because it can threaten organ function. The most prominent examples of these are the eye, brain, and reproductive organs (testis, ovary), where even minor bouts of inflammation can have long-term consequences for the survival of the organism. In these organs, immune responses either do not proceed, or proceed in a manner different from those in other areas; thus they are called “immunologically privileged.” Here a functioning immune response can be the culprit that leads to disease.

Although the concept of immune privilege has been around for more than 125 years (1), only recently have we begun to understand its molecular basis. Defined as places where allogeneic or xenogeneic (1,2 and 3) tissue grafts have prolonged survival, it was originally suggested that these sites were ignored by the immune system. The prototype organ for the study of immune privilege is the eye, and most information accumulated concerning immune privilege pertains to this organ. Because even relatively minor inflammation can cause damage, dampening immune reaction protects the visual axis (i.e., vision).

HOW DO WE KNOW THE EYE IS “PRIVILEGED”?

The eye's unique relationship with the immune response was discovered serendipitously during studies with allogeneic tumor cell transplants (1,2 and 3). These investigations were designed to study tissue rejection, and the investigators chose the eye as a model for ease of observation. It was found that allogeneic tumors transplanted to the eye actually survived longer compared with those in other sites. Clinically, this finding led to the development orthotopic allogeneic cornea grafts. The vast majority of these grafts are accepted without rejection and without the use of immunosuppressive medications that are typically prescribed for all other allogeneic tissue transplants (e.g., heart and lung). These clinical and experimental observations served to define the unique nature of the eye and led to the concept of immune privilege. Because of the initial observations with grafts to the eye, many studies have demonstrated that the eye goes to great lengths to prevent the expression of immunity. Two general models could explain these findings: either the eye does not generate an immune response (passive model), or the eye actively suppresses immune reactions (active model). The blood/ocular barrier serves as a passive suppressor by limiting access of immune-response effector cells. However, were this the only mechanism of ocular immune privilege, the eye would be abnormally susceptible to damage from infectious pathogens (which is not the case). Recent studies have identified active mechanisms that prevent the expression of the immune response. Present in the eye are molecules that kill inflammatory cells (FasL), suppress the immune response [transforming growth factor (TGF)-b], inhibit complement, suppress natural killer (NK)-cell activation, and prevent the expression of systemic immunity (immune deviation). These mechanisms (active and passive) work together to dampen immune responses and protect vision.

THE MECHANISMS OF IMMUNE PRIVILEGE

Blood–Ocular Barrier

The anterior chamber (AC) and the retina possess a barrier to the movement of cells, as well as to the transport of macromolecules. Local alterations in the barrier are likely pivotal events in the development of inflammatory disease in the eye. It has been suggested that the blood–ocular barrier allows selected migration of leukocytes into the eye. Although there is currently no evidence that leukocytes normally traffic through the organ, the presence of resident macrophages, mast cells, and dendritic cells in the uveal tract suggests that they must be permitted in by some mechanism. Whether there are eye-specific homing molecules similar to those found in the skin and lymph nodes is unknown. Under normal circumstances, the entry of leukocytes into the retina is restricted. Migration of mononuclear cells through the retinal vessels is an early sign of inflammation and may signal the breakdown of immune privilege.

The transport of macromolecules into the eye is regulated differently depending on the compartment of the eye. In the retina, the blood–ocular barrier exists in tight junctions formed between adjacent endothelial cells. This excludes plasma-derived proteins such as antibody and albumin. Tight junctions in the retinal pigment epithelium also limit diffusion of these molecules into the retina. In contrast, the vessels of the uveal tract are permeable to macromolecules. In the AC of the eye, the blood–aqueous barrier normally limits protein in aqueous humor to less than 1% of the plasma concentration. Thus levels of Ig are quite low in the eye.

If the blood–aqueous and blood–retinal barriers serve to limit access of immune effector cells to the eye, the lack of a robust lymphatic drainage system likewise limits

access of antigen to the immune system. The eye has minimal, if any, lymphatic drainage. Although antigen is thought to exit the eye via the “uveoscleral” outflow pathway, the anatomic basis of this route is unknown. After AC injection of virus or protein antigen, antigens do arrive in the cervical lymph nodes (4), but this is likely due to leakage from the injection site. More important, there is currently no evidence to show that this pathway has any relationship to immune privilege. Materials in the AC do escape via the trabecular meshwork and Schlemm's canal. Schlemm's canal empties directly into the venous circulation to deliver antigen to the spleen and liver. This pathway contributes to immune privilege, partially through the induction of immune tolerance [i.e., the anterior chamber–associated immune deviation (ACAID) response, later].

Sequestration of antigens by the blood–ocular barrier has been postulated to prevent access of ocular protein to the immune system. More important, these barriers are thought to prevent deletion of self-reactive lymphocytes, such that later exposure can result in autoimmune disease. Induction of ocular disease by immunization with retinal proteins (5) has argued for this; however, observations of drainage of antigens and apoptotic cells (6,7 and 8) from the eye to the vascular system and spleen suggest a conundrum. To confuse the issue further, it was recently observed that the immune system was not made tolerant to a foreign protein expressed in the retina of transgenic mice (9). This suggests that, under certain conditions, sequestration may indeed play a role. It is safe to conclude that the role of organ antigen sequestration in the development of tolerance and autoimmunity awaits further study.

Fas/FasL

Recent studies have revealed that the parenchymal cells of the eye constitutively express FasL. FasL is a protein belonging to the tumor necrosis factor (TNF)/nerve growth factor (NGF) family (10). FasL was initially thought to be expressed on activated T cells, but recent studies have demonstrated that it is expressed constitutively in the eye (11), the testis (12), and a number of other places during neonatal and adult life (13). FasL induces apoptotic cell death in cells expressing the Fas receptor. Fas is a protein of the TNF/NGF-receptor family (10) expressed on cells of the lymphoid system, as well as at other sites in the body such as liver and heart.

Figure 53.1 shows areas of FasL expression in the eye, and demonstrates how it is strategically placed wherever there is an opportunity for interaction between the eye and the outside world. It is a sentinel at the connections of the blood–ocular barrier (11). In the cornea, FasL is expressed on the endothelium and epithelium, where it can control inflammatory cells entering from the conjunctiva or the AC. It is a major reason for the success of corneal transplant in mouse models, and possibly humans (see disease mechanisms, later) (14). FasL is expressed on the retinal pigment epithelial (RPE) cells that compose the outer most layer of the retina, and it is prominently expressed on the photoreceptors (rods and cones), where it may play a vital protective role to vision. Interestingly, FasL expression on the RPE cells also controls neovascularization associated with age-related macular degeneration (15). FasL on the iris and ciliary body can contact and kill cells entering from the vessels prominent in this tissue.

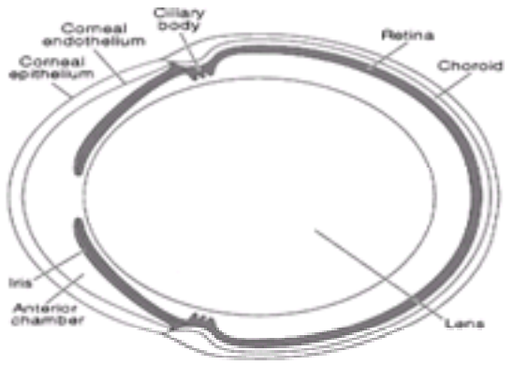

Figure 53.1. Fas ligand (FasL) expression. Schematic drawing of a mouse eye showing localization of FasL (FasL tissues in red). FasL is expressed on the corneal endothelium and epithelium, iris, ciliary body, and throughout the retina, forming a protective barrier (From Griffith TS, Brunner T, Fletcher SM, et al. Fas ligand-induced apoptosis as a mechanism of immune privilege. *Science* 1995;270:1189–1192, with permission.) (See Color Figure 53.1.)

Little is known about the modulation of FasL function during inflammation or eye disease, but it is clearly important in controlling the spread of inflammation throughout the eye. This is demonstrated in Figure 53.2, in which HSV-1 infection of the AC of normal mice results in minimal damage to ocular structure. In sharp contrast, infection of FasL-defective mice (*gld*) results in significant pathology and destruction of ocular structures. This observation suggests the centrality of FasL to immune privilege. Interestingly, experimental animals defective in Fas and/or FasL do not seem to develop spontaneous inflammation. However, challenge of these mice with an infectious agent leads to massive inflammation (Figure 53.2 and ref. 11). Thus it appears that homeostasis for the eye is exclusion of inflammatory cells (blood–ocular barrier), the presence of suppressive cytokines (TGF-b, see later), and sentinel FasL to control induced inflammation. FasL is the only mediator of immune privilege for which reduced functional expression has been shown to increase inflammation.

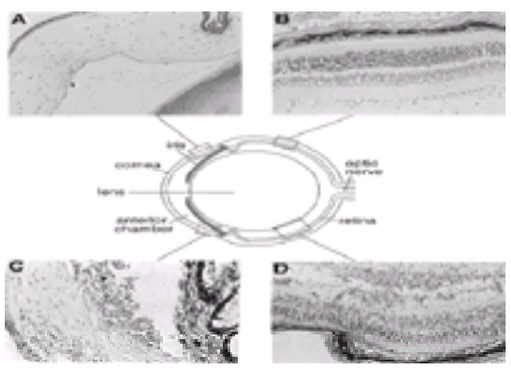

Figure 53.2. The consequences of not expressing functional FasL in the eye. B6 (**A, B**), B6-*gld* (**C, D**) mice were injected in the anterior chamber of the eye with 2.5 × 10^4 herpes simplex virus (HSV)-1 (KOS) as described (From Griffith TS, Brunner T, Fletcher SM, et al. Fas ligand-induced apoptosis as a mechanism of immune privilege. *Science* 1995;270:1189–1192, with permission.) Eyes were removed 10 days after infection, processed for paraffin sections, and stained with hematoxylin and eosin (H&E). *Boxes* on the schematic drawing of the eye (**center**) denote the area of detail for the H&E stain (× 200). (See Color Figure 53.2.)

Immunosuppressive Cytokines and Neuropeptides

Several soluble factors have been implicated in the maintenance of immune privilege (6). These include TGF-b, neuropeptides, and glucocorticoids that are made by resident ocular cells or by the innervating nervous system. Each compound has a unique immunosuppressive function that can prevent certain aspects of the immune response. TGF-b seems to be the most abundant cytokine (6) in aqueous fluids. It is derived from the ciliary epithelium, although most is latent, with only a certain level active in this constitutive pool. Because TGF-b is converted from latent to active form by low pH and/or protease activity, it must be presumed that this conversion takes place during an inflammatory response. TGF-b has well-known antiproliferative qualities, prevents macrophage activation, and is a potent inhibitor of T-cell and B-cell activation. It most likely functions in this capacity in the eye. There are three homologues of TGF-b (TGF-b1, -b2, and -b3). TGF-b2 is the family member in aqueous humor. Antigen handling by adherent cells (macrophages/dendritic cells) *in vitro* is altered in the presence of TGF-b (or ocular fluids containing TGF-b), such that injection of these cells into mice induces immune deviation by direct antigen presentation to T cells (7). Whether this actually takes place *in vivo* is not known, but has been inferred (16). Other evidence suggests that TGF-b–treated adherent cells must undergo Fas-mediated apoptosis after transfer to induce ACAID (17).

Vasoactive intestinal peptide (VIP), a-melanocyte stimulating hormone (a-MSH), calcitonin gene–related peptide (CGRP), and glucocorticoids also are present in the eye. These are most likely derived from the nerves. Constitutive concentrations of these molecules (picomolar to nanomolar range) have been shown to inhibit immune responses *in vitro*. Although their function in the eye is not well defined, the well-known antiinflammatory properties of these molecules suggest that they may play a role in the maintenance of immune privilege.

Limited Expression of Major Histocompatibility Complex Molecules

Immune responses involving T cells require recognition of foreign antigen in the context of major histocompatibility complex (MHC) molecules. This is called MHC restriction and applies to the interaction between the T cells and the antigen-presenting cells. Sites that display abundant MHC molecules, such as the spleen, lymph nodes, and skin, are very effective at inducing immune responses. Thus, organs such as the eye can maintain their “privilege” by limiting the availability of these molecules. Restricted expression of class II in the eye limits the induction of local T-cell responses such as delayed-type hypersensitivity (DTH). Cells that express MHC class II molecules occupy the tissue plane between the epithelial layers of the iris and ciliary body, and they line the uveal tract (18). These cells are bone marrow derived, dendritic, and bear the surface phenotype of splenic, skin, and airway dendritic cells (18,19). They are very efficient antigen-presenting cells when removed from the ocular environment and function to remove molecules or pathogens during aqueous outflow. They have been reported to capture foreign antigens and migrate to the spleen, where they induce immune deviation (ACAID) (7). Activation of effector T cells that enter the eye during inflammatory responses may involve these cells, and this may explain why the uvea is the frequent target of immunogenic inflammation.

The eye has been reported to be devoid of MHC classic class I (Ia) molecules (HLA-A, B, C) (9). The absence of class I would restrict the activity of cytotoxic T cells, which are responsible for antiviral and antitumor immunity. Recently, however, transcripts for these molecules have been identified (20). In addition, cultured ocular cells and fresh human donor corneal buttons have been reported to express class I (21). Nonclassic class I (Ib) molecules (e.g., Qa-2) have been reported to be present in the eye (22), but their function is not established. Further experimental evidence is needed to demonstrate the role of MHC class I (or lack of it) in the eye.

Complement Regulatory Proteins

Several complement regulatory proteins are associated with ocular tissue (23). These include MCP (membrane cofactor protein, CD46), DAF (decay-accelerating factor), and CD59, which regulate the function of complement. Their differential distribution in ocular tissue suggests that they may protect cells in the eye from destruction by complement-activating events. However, further studies will be required to determine a specific role for these molecules in the immune privilege.

Natural Killer Cell Inhibitors

A recently identified NK-cell inhibitory factor also may contribute to immune privilege (24). According to current theories, NK cells recognize and lyse cells that are deficient in MHC class I molecules (25). If the eye does not express MHC class I molecules (or expresses them minimally), the presence of this NK-inhibitory factor might be required to limit spontaneous intraocular inflammation resulting from NK-cell activity. It has yet to be shown that ocular tissue is damaged by NK cells when the NK inhibitory factor is missing.

Immune Regulation

ACAID describes the pattern of systemic responses when certain antigens are introduced to the immune system through the AC of the eye. It is a prototype immune-deviation response that may be an adaptation of the immune system to prevent destruction of the visual axis in the face of vigorous systemic cell-mediated immunity. The pattern of responses seen after AC antigen injection is distinctive. It involves activated antibody responses, and inhibited DTH responses. Recent studies (7,8) have revealed that this state of DTH “tolerance” is not simply the failure to prime an immune response, but the inhibition of T-helper 1 (Th1) cells by the preferential activation of Th2 cells. What sets this it apart from some other types of immune deviation is that there is also a $CD8^+$ cell response that actively downregulates DTH (26,27); however, these cells are not well characterized. ACAID has been induced to a variety of antigens (7,8,28) and has been associated with corneal graft survival (29), although this is not absolute (30).

Apoptosis of lymphoid cells induced by FasL is a prerequisite for the induction of ACAID to all antigens tested thus far (8). A second prerequisite is that the dying cells must be capable of producing interleukin (IL)-10 (31). Although it is not clear why this happens, the induction of the cell-death pathways in these cells initiates production of IL-10, which may lead to the DNA damage as observed after UV irradiation of some cells (32). Dying and dead apoptotic cells are washed from the eye, enter the blood, and are taken up by phagocytic cells (macrophages/dendritic cells) in the spleen. Because the dead cells contain IL-10 and are associated with antigen acquired in the eye, when they present to the immune system, there is a preferential activation of Th2-type $CD4^+$ cells (antibody production). These Th2 cells then regulate Th1 function (DTH) through cytokines such as IL-10. Apoptosis of T cells in the eye also has another effect. After cell death, T-cell proteins (most notably TCR a-chains) are released into the serum (33) and are presented in the class I pathway to $CD8^+$ cells in the spleen. The $CD8^+$ cells regulate by acting as either killer cells deletion of $CD4^+$ cells involved in DTH, or as TGF-b secreting regulatory cells.

Anterior Chamber–Associated Immune Deviation and Visible Light

An interesting twist to the ACAID model involves the capacity of the eye to trap light. It was observed that ACAID was regulated by visible light (28). Whereas mice reared under normal conditions (12 hours light/12 hours dark) develop ACAID when antigen is presented via the anterior chamber, mice dark reared or dark adapted for a short time are immune. This effect of light is an ocular event not dependent on circadian rhythms, but linked to the length of time the eye is exposed to light or dark. Incident light of 500 to 510 nm at a minimal lux of 2 was found to be responsible. Subsequent studies (34) revealed that light controlled the level of substance P–induced and FasL-induced apoptosis. Thus dark-adapted animals have high levels of substance P (which is proinflammatory), which leads to reduced levels of FasL-induced death. Because apoptosis of the lymphoid cells is a requirement for ACAID, the lack of cell death leads to the absence of ACAID. In addition, dark-adaptation also prevents the contralateral spread via the central nervous system of herpes simplex virus (HSV)-1 from the AC of one eye to the retina of the other (26). Whether the mechanism has a practical application to clinical disease is still an open question.

FasL and Tranforming Growth Factor-b

Besides the noted apoptotic (hence antiinflammatory) functions of FasL, it also has a proinflammatory function (35). This was observed after expression of FasL on pancreatic islet cells in transgenic mice (36). It was observed that these mice had a granulocytic response that accelerated rejection of this tissue. Thus FasL expression did not confer immune privilege on a nonprivileged tissue, but augmented the immune response. The proinflammatory effect was mediated by engagement of Fas on neutrophils by FasL. Interestingly, in the presence of TGF-b, FasL loses its proinflammatory function; thus ocular FasL effectively kills infiltrating lymphocytes, and TGF-b inhibits neutrophil activation, showing for the first time that two components of immune privilege can work together to prohibit inflammation.

IMMUNE DEFENSE MECHANISMS

Although the eye is known for its ability to resist immune and inflammatory responses, it also has the capacity to resist infection. Like other surface tissues, the eye is constantly exposed to microorganisms and is very capable of thwarting most of these. Much of the eyes' natural resistance relies on the properties of the lids, tears, conjunctiva, and cornea. These physiologic and anatomic mechanisms lie outside the immune-privileged environment attributed to the internal milieu. Once an invader has passed these external defenses, the eye is not very effective at preventing destructive effects of infectious agents because of immune privilege, which inhibits inflammatory responses.

Nonimmunologic

The eyelids protect the eye from trauma and screen out particulate substances by the blink reflex. Additionally, the tear film washes away debris from the ocular surface. The tear film coats and lubricates the eye surface and physically prevents the attachment of microbes.

Immunologic

The tear film contains lysozyme, b-lysin, lactoferrin, and antibody. Lysozyme is a cationic, low-molecular-weight enzyme that attacks the mucopeptide in bacteria cell walls. It is thought that tear lysozyme is produced by the lacrimal gland and is in much higher concentration in tears than it is in serum. Although all Ig classes have been detected in tears, the major type in tears is IgA. Tears contain the secretory dimeric form of the molecule. Tear Ig is produced by plasma cells of the lacrimal gland. During inflammatory conditions, there is a proportional increase in tear Ig that mimics the appearance of these proteins in serum. This is likely due to transport of antibodies into the tears.

Lactoferrin and b-lysin are synthesized by the lacrimal gland and are present in human tears. b-Lysin causes lysis of bacterial cell walls. Lactoferrin was believed to function in a nonspecific manner through its iron-binding capacity, but it may directly affect certain bacterial strains. Lactoferrin can inhibit complement activation by blocking C3 convertase. This suggests that it might play a dual role as an agent of defenses and a mediator of immune privilege.

Conjunctiva

The conjunctiva forms a natural barrier to the invasion of the ocular surface by foreign material. It contains a very high number of mast cells and leukocytes, which seem to increase with age. This suggests that exposure to inflammatory substances throughout life affects the populations of cells present. The conjunctival epithelium with its underlying blood vessels and lymphatics is similar to the epidermal/dermal junction of skin. Thus there is drainage of these areas for exposure to the immune system in regional lymph nodes. Additionally, the vascularity of the area may contribute to the passage of antimicrobial substances from the blood.

Other, less-defined mechanisms present in the conjunctiva contribute to immune protection. Epithelial cell turnover and cool temperature may serve a protective function. Additionally the conjunctiva is resistant to certain viruses, but susceptible to bacterial infection (e.g., gonococcus). This is mediated by unknown “nonspecific factors” present in this area. Thus anatomic considerations, secretions, and normal flora may all contribute to the protection of the eye from invasion. Interestingly, these all lie outside the blood–ocular barrier and the immune-privileged environment.

Cornea

The cornea is a unique tissue forming a barrier between the outside world and the inner structures of the eye. The corneal epithelium lies outside the immune-privileged area, but the endothelium is an important component. The avascularity of the cornea likely contributes to immune privilege rather than to immune protection. The central cornea is usually devoid of cells that would participate in immune responses, although the limbus (the tissue at the junction of the cornea and the conjunctiva) contains numerous MHC class II–positive dendritic cells. These cells can be attracted to the central cornea to inflammatory stimuli. They likely enter in response to infection by phagocytose invaders. They then exit to the draining lymph nodes to initiate immune responses.

The cornea also contains uncharacterized “nonspecific” inhibitors of bacterial and viral replication. There also is a natural resistance of the cornea to the adherence of bacteria and viruses to the surface. This serves to prevent invasion and colonization of the ocular surface. Infection of the cornea can result in the outpouring of inflammatory cells from the conjunctival vessels to counter the pathogen.

THE SPECTRUM OF OCULAR INFLAMMATORY DISEASE

Ocular inflammatory disease is quite prevalent. In the last major survey (37), approximately 1.2 million Americans carried the diagnosis of uveitis (the major category of ocular inflammatory disease), and about 45,000 new cases were reported that year. Ocular inflammatory disease has a high morbidity. When infectious causes such as *Oncocerca volvulus* (river blindness endemic in portions of Africa) and trachoma are included, ocular inflammatory disease ranks with cataract and glaucoma as one of the three major causes of vision loss worldwide.

There is no single, encompassing scheme for classifying ocular inflammatory disease. Individual anatomic structures can be subject to inflammatory disease through multiple mechanisms (i.e., infection, autoimmunity, or a mixture of the two), so a simple anatomic classification is incomplete. Classification by appearance also is problematic, because we know that some identical-appearing diseases have very different mechanisms. Conversely, incomplete knowledge of the pathogenesis of even the most common forms of ocular inflammatory disease makes classification by disease mechanism applicable to only a small fraction of diseases. Therefore because no classification scheme is ideal, we present an outline of each to highlight the full range of ocular inflammatory disease.

ANATOMIC CLASSIFICATION

Conjunctival and Scleral

Most conjunctival inflammatory diseases are infectious. Common “pink eye” is due to viral conjunctivitis and is frequently caused by one of several strains of adenovirus. Other infectious causes of conjunctivitis include herpes viruses, *Chlamydia trachomatis,* and *Neisseria gonorrheae.* Ocular cicatricial pemphigoid (also called mucous membrane pemphigoid) is an immune-mediated conjunctival disease. Conjunctival biopsies reveal C3, IgG, IgM, and IgA localized to the basement membrane zone, which has led to the suggestion that this disease is caused by cytotoxic hypersensitivity. There is a weak association of HLA-DR4 with this condition (38). Inflammation of the sclera, or scleritis, is a frequent feature of collagen/vascular diseases such as rheumatoid arthritis and systemic lupus erythematosus. This inflammation can be necrotizing, with spontaneous rupture of the globe. The pathobiology of scleritis is unknown.

Anterior Uveitis

Anterior uveitis also is known as iritis or iridocyclitis. Patients usually have a red eye (because of dilation of the ciliary vessels serving the iris), photophobia, and pain. Anterior uveitis is characterized by a visible inflammatory infiltrate in the AC. Normally, the aqueous humor filling this space is completely acellular, with low protein content. In anterior uveitis, the observed inflammatory reaction ranges from a few cells in the AC to frank layering of white blood cells. Increased protein concentration in the AC (due to compromise of the blood–aqueous barrier) is manifest as *flare*, or a scattering of oblique light observed with the slit lamp. When inflammation is severe enough to cause layering of white blood cells, the term *hypopyon* is used. The clinical sequelae of chronic anterior uveitis include inflammation of the cornea as well as scarring of the iris to the cornea (anterior synechiae) and lens capsule (posterior synechiae). Changes in eye pressure (either high pressures associated with glaucoma, or low pressures associated with hypotony) and cataract also are observed. Even nearly asymptomatic levels of chronic inflammation can lead to these vision-threatening sequelae. Leakage of as-yet-unidentified mediators also can cause a focal swelling of the retina [cystoid macular edema (CME)] that can significantly reduce vision.

Among the diseases that cause anterior uveitis are the HLA-B27–linked diseases, such as ankylosing spondylitis and Reiter disease. Approximately one third of all anterior uveitis patients are HLA-B27 positive, and about one third of HLA-B27–positive patients will have anterior uveitis. In children, juvenile rheumatoid arthritis (JRA) is a common cause of anterior uveitis. Upwards of 30% of patients in the pauciarticular (fewer than five joints), antinuclear antibody (ANA) positive, rheumatoid factor (RF)-negative subgroup of JRA patients will show a chronic anterior uveitis. Other diseases frequently associated with anterior uveitis are Behçet's disease, sarcoidosis, herpetic uveitis, and several idiopathic conditions (such as Fuch's heterochromic iridocyclitis, and granulomatocyclitic crisis).

Intermediate Uveitis

Intermediate uveitis refers to inflammation of the vitreous cavity. Isolated intermediate uveitis is the least common form of uveitis. Patients typically have complaints of “floaters” and blurred vision. The floaters are shadows cast by the white blood cells, whereas the blurred vision is frequently due to accompanying CME. Late sequelae of intermediate uveitis include retinal detachments from traction exerted by the vitreous on the retina, neovascularization of the peripheral retina, and chronic CME. The most common intermediate uveitis is pars planitis, a bilateral condition of unknown cause, affecting mostly younger patients. About 5% of intermediate uveitis is thought to be due to multiple sclerosis; however, the pathogenic link between the two conditions is unknown.

Posterior Uveitis

Posterior uveitis encompasses inflammation of both the neurosensory retina and the underlying choroid. Posterior uveitis is usually accompanied by some degree of vitritis. Patients have complaints of distorted or blurred vision, or loss of visual field. Although some diseases represent a pure retinitis [i.e., the cytomegalovirus (CMV) retinitis seen in immunocompromised patients], most posterior uveitis represents a chorioretinitis, with continuous inflammation noted in both the retina and the underlying choroid. The most common forms of posterior uveitis are infectious, including reactivation toxoplasmosis, CMV retinitis, acute retinal necrosis syndrome caused by herpesviruses, and a focal chorioretinitis called presumed ocular histoplasmosis disease. Other diseases significantly associated with posterior uveitis are sarcoidosis and Behçet's disease. Sequelae of posterior uveitis include retinal detachments, chronic CME, loss of choroid and retina leading to scotoma, retinal vasculitis, and subretinal neovascularization.

Panuveitis

Panuveitis refers to simultaneous inflammation of the anterior, intermediate, and posterior compartments. When caused by a bacterial infection, this is referred to as bacterial endophthalmitis. Although many agents can cause panuveitis, this is seen most commonly with sarcoidosis, syphilis, toxoplasmosis, and Behçet's disease.

OCULAR DISEASE CAN BE CLASSIFIED BY CLINICAL APPEARANCE

Our brief excursion into the anatomic variants of uveitis makes it clear that many diseases can have similar presentations, and one disease can have protean manifestations. Certain groups of diseases, however, have very similar presentations. The most common distinction applied by clinicians is granulomatous versus nongranulomatous disease. Although precise identification of a granuloma can be made only histologically, granulomas can be observed clinically as aggregations of cells visible on the corneal endothelium, iris, and conjunctiva (Fig. 53.3). Granulomatous causes of uveitis include sarcoidosis, syphilis, tuberculosis, toxoplasmosis, as

well as some idiopathic eye diseases such as sympathetic ophthalmia and Vogt-Koyanagi-Harada disease. Most other uveitides are considered nongranulomatous, including the HLA-B27 anterior uveitides, Behçet's disease, and most of the herpesvirus-caused diseases.

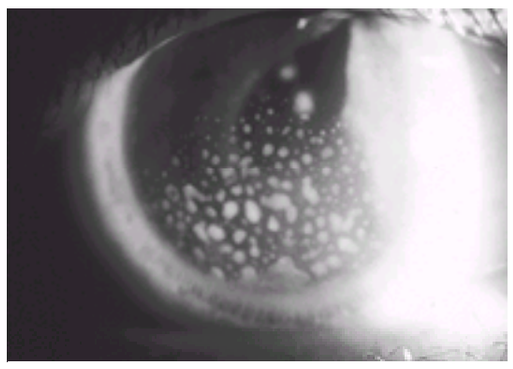

Figure 53.3. Typical appearance of granulomatous anterior uveitis on the cornea of a 46-year-old African-American woman with sarcoidosis. The corneal endothelium is covered in dense keratic precipitates, composed of epithelioid cells in small noncaseating granulomas. (See Color Figure 53.3.)

OCULAR DISEASE CAN BE CLASSIFIED BY MECHANISM

The causes of many forms of uveitis, including Behçet's disease, sarcoidosis, and idiopathic anterior uveitis, are unknown. Of the known mechanisms, some are clearly infectious, a few are primarily immune-mediated, and many appear to be mixed.

Infectious Disease

CMV retinitis is an example of an infectious uveitis. This virus is nearly ubiquitous in the American population, and generally does not cause significant primary ocular disease. However, in an immunocompromised host (particularly with $CD4^+$ cell count less than 50), this virus will reactivate and cause an aggressive, necrotizing retinitis, with a very characteristic clinical appearance. Evidence that CMV is causative of this condition includes histologic identification of CMV inclusions in postmortem specimens, recovery of viral DNA by polymerase chain reaction (PCR) from actively infected patients, and successful treatment with antiviral therapy effective against CMV (ganciclovir and foscarnate). Another form of infectious uveitis is acute retinal necrosis syndrome. This is a fulminant retinochoroiditis caused by reactivation of herpes simplex or varicella zoster virus. Herpetic keratopathy is frequently associated with an anterior uveitis, and herpes simplex virus can be recovered from the anterior chamber in these cases. This suggests that this condition is infectious. The most common form of posterior uveitis in the United States is ocular toxoplasmosis, caused by the intracellular parasite *Toxoplasma gondii.* Reactivation of latent cysts in the retina leads to local necrosis, whereas the accompanying inflammatory reaction leads to a severe vitritis and vasculitis. Other uveitides may be infectious, with unknown pathogens. Whipple's disease, for example, can cause an aggressive panuveitis; only in the last several years has the pathogenic organism for this condition been identified as *Tropheryma whippelii* (39).

Autoimmune Disease

The extent to which uveitis is autoimmune is unknown. A few conditions clearly have an autoimmune basis. Ocular cicatricial pemphigoid, for example, is a chronic inflammatory disease of the conjunctiva that leads to scarring and foreshortening of the conjunctiva. Its pathogenesis includes the deposition of antigen/antibody complexes in the conjunctiva. Lens-induced uveitis occurs after trauma that leads to lens proteins being released from the lens capsule into the aqueous and vitreous. Because lens proteins are sequestered in the privileged space of the eye during development, these proteins are highly immunogenic. The combination of a compromised blood–ocular barrier and large antigen load overcomes active immune privilege, and leads to a fulminant inflammatory reaction to these proteins, causing a severe uveitis. Surgical removal of the lens fragments is curative, allowing a return to baseline immunologic privilege.

Direct evidence of autoimmunity is suspected, but not proven, for many other diseases. Sympathetic ophthalmia is a rare chronic granulomatous inflammation caused by injury. It follows injury with loss of uvea to the fellow eye. It is hypothesized that priming with previously sequestered uveal antigens causes autoimmune disease in the uninjured eye. Removal of the injured eye early in the disease limits the extent of damage to the fellow eye. Cancer-associated retinopathy is a rare paraneoplastic condition associated with certain tumors, particularly small-cell lung cancer. Autoantibodies to retina-specific proteins, particularly recoverin, are found in most patients with this disorder. It has been hypothesized that these antibodies are pathogenic, although definitive demonstration is difficult. Other diseases, such as ankylosing spondylitis, have a very strong HLA association, frequently taken as a hallmark of autoimmune disease. The relative risk of ankylosing spondylitis, given an HLA-B27 haplotype, is ~100. Birdshot chorioretinopathy, an uncommon posterior uveitis, has one of the highest known HLA associations, with a relative risk of disease of greater than 150 for the HLA A-29 haplotype in some populations (40). A list of uveitic diseases with significant HLA associations is shown in Table 53.1.

Disease	Antigen	Relative Ris
Acute anterior uveitis	HLA-B27	10
	HLA-B8	5
Ankylosing spondylitis	HLA-B27	100
Behçet's disease[a]	HLA-B51	4–6
Birdshot choroidopathy	HLA-A29	50–200
Mucous membrane pemphigoid	HLA-B12	3–4
Reiter syndrome	HLA-B27	40
Rheumatoid arthritis	HLA-DR4	11
Sympathetic ophthalmia	HLA-A11	4
Vogt-Koyanagi-Harada disease	HLA-DR4	15

HLA, human leukocyte antigen.

TABLE 53.1. HLA Associations of Uveitic Disease

Indirect supporting evidence for an autoimmune cause for uveitis comes from animal models of uveitic disease. Because the eye is a privileged site, immune tolerance to native eye proteins frequently fails to develop. One can generate uveitis by immunizing animals (in adjuvant) to a number of eye-specific proteins. These include arrestin [retinal S antigen causing experimental autoimmune uveitis, or EAU (41)], interphotoreceptor retinoid-binding protein (IRBP) (5), recoverin, rhodopsin, or melanin-associated proteins [causing experimental autoimmune anterior uveitis, or EAAU (42)]. In these models, adoptive transfer of $CD4^+$ T cells can transfer disease, suggesting that these cells are sufficient to cause uveitis. Antibodies to these same retinal proteins have been detected in a variety of uveitic conditions. Although strong priming with proteins in adjuvant is sufficient to cause autoimmune uveitis in rodent models, it is unclear that this level of priming occurs in human disease. For example, panretinal photocoagulation is routinely carried out in the treatment of diabetic retinopathy. Despite abrogation of the blood–retinal barrier (by laser-induced anastomosis of the retina and RPE), and release of retina-specific proteins from damaged cells, neither ipsilateral nor contralateral uveitis is commonly observed. Retinal damage secondary to uveitis also will expose these proteins to the immune system. This results in detectable antibody titers but no known disease pathology directed to the retina. Thus it is unclear if the detected self-reactive antibodies represent a primary disease-inducing agent, or are merely indicators of ongoing ocular damage from other causes. These models do demonstrate, however, that autoimmune targeting of previously sequestered antigens is sufficient to induce uveitis. Unfortunately, the clinical appearance of the rodent “diseases” does not resemble most of the human ocular diseases d escribed earlier.

Unknown Disease Mechanisms

Many of the more common causes of uveitis have unknown mechanisms. There are no models at present to account for the most common form of uveitis: non–HLA-B27 idiopathic anterior uveitis. Although injection of endotoxin into the AC of rodents produces a transient anterior uveitis mimicking clinical disease [endotoxin-induced uveitis, or EIU (43)], an infectious trigger for idiopathic anterior uveitis has not been identified. Sarcoidosis is a very common form of uveitis, particularly among African-American patients. Although patients with sarcoidosis demonstrate widespread granulomas and cutaneous anergy, it is not clear that this

disease is primarily immune mediated rather than infectious. Some of the epidemiology of sarcoidosis suggests the latter (44).

FINDING THE LINK: OCULAR IMMUNOLOGY AND CLINICAL UVEITIS

From the preceding sections, it should be clear that (a) much is understood about the unique nature of the eye with respect to immune privilege, and (b) much is understood about the natural history and differential diagnoses of uveitis. Unfortunately, very little is understood about the connection between these, and useful answers to questions such as, “Why does uveitis appear and behave clinically the way it does?” do not exist. Fortunately, from a clinical perspective, the ability to create substantial systemic immunosuppression with agents ranging from prednisone to cyclophosphamide has allowed treatment of many of these conditions without precise knowledge of their pathogenesis.

Plausible molecular mechanisms have been elucidated for a handful of clinical conditions. In this section, we discuss animal models of two conditions for which good molecular models exist for the pathogenic mechanisms.

Corneal Transplantation and Fas/Fas Ligand

One clinical consequence of ocular immune privilege is the ready acceptance of corneal allografts. Approximately 40,000 corneal transplants [or penetrating keratoplasties (PKPs)] are performed in the United States annually. Donor corneas are routinely screened for viral disease, but are not HLA matched, as a large prospective study showed no increased risk of rejection in non–HLA-matched donors (45). Postoperative systemic immunosuppression is generally not given, and topical therapy is often limited to prednisolone eye drops. When it occurs, graft rejection is usually seen several weeks to several months after surgery. It is readily observed clinically by an encroaching line (called the Khodadoust line) of immune complex deposition (Fig. 53.4). The overall rejection rate of corneal grafts is only about 10%. This remarkable success has been linked to ocular immune privilege.

Figure 53.4. Allotypic corneal graft rejection. The *white line* in the graft represents an infiltrate of host lymphocytes. Very subtle rejection can be readily seen because of the transparency of the cornea. Despite routine use of non–human leukocyte antigen (HLA) matched donors and minimal immunosuppressive medication, corneal allografts are rejected in fewer than 10% of cases. (See Color Figure 53.4.)

As described in the first section of this chapter, the eye is protected from invading inflammatory cells by the activity of the Fas/FasL proteins (11). In this model, invading lymphocytes (which are Fas^{+}) are killed by FasL expressed on the corneal endothelium. This model makes the strong prediction that corneas lacking FasL should be rejected at higher rates than are wild type. Similarly, lymphocytes lacking Fas should cause increased rates of rejection of wild-type corneas. Mouse mutants exist for both Fas (the *lpr* mutation) and FasL (the *gld* mutation). Corneal grafts of *gld* or *lpr* corneas onto wild-type hosts are rejected with much higher frequency (nearly 100%) than are wild-type corneas. Conversely, *lpr* and *gld* host mice reject wild-type corneas that are accepted by wild-type hosts. The dependence of ACAID on Fas/FasL-induced apoptosis (8) and the association ACAID with graft acceptance also lends support for the role of Fas/FasL in corneal graft success. Experiments demonstrating the identical expression of FasL on human corneas suggest that the same mechanisms may be operative in humans (14).

Herpetic Stromal Keratitis

Much uveitic disease appears to have both infectious and immune-mediated features. A mechanistic link between the two has now been identified for one ocular inflammatory disease. Herpetic stromal keratitis (HSK) is a T-cell–mediated disease causing clouding of the corneal stroma after HSV-1 infection (Fig. 53.5). Although disease only occurs in patients with a history of epithelial herpes infection, attempts to culture the virus from the inflamed stroma have been unsuccessful. The disease can be adoptively via T cells from an affected animal, but is not clear that these cells are specific for the virus. Similarly, viral antigens are rarely recovered from diseased eyes. The question then is “How does the herpesvirus trigger this autoimmune condition?”

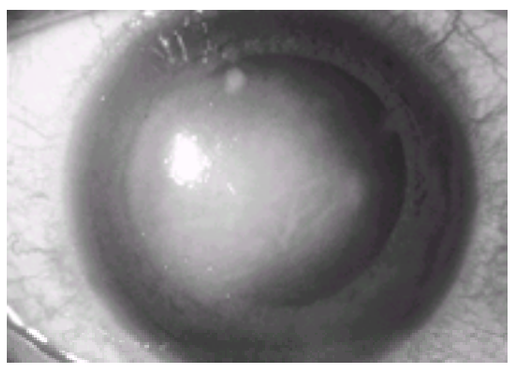

Figure 53.5. Herpetic stromal keratitis. After corneal infection with herpes simplex type 1 (HSV-1), a subset of patients subsequently develops a chronic, autoimmune keratitis. Herpesvirus is not recovered from these lesions. Murine models of this condition suggest that molecular mimicry between a corneal antigen and an HSV-1 coat protein causes the autoimmune keratitis. HSV-1 mutants lacking this antigen cannot trigger stromal keratitis, and mice made tolerant to this antigen are likewise protected from this disease. (See Color Figure 53.5.)

Recently Avery et al. (46) used a fortuitous observation to demonstrate that autoreactive T cells directed against a molecular mimic likely underlie HSK. The group noted that allotypic variation in IgH genes (Ig heavy-chain genes) determines susceptibility to experimental HSK. Mouse strains carrying the IgH^{d} or IgH^{e} alleles are susceptible to stromal keratitis after HSV-1 infection, whereas congenic strains carrying IgH^{b} allele are not. A peptide sequence within the IgH^{b} protein is stimulatory to T cells from mice with HSK (i.e., mice carrying IgH^{d} or IgH^{e}) (46). This suggested that IgH^{b} mice are protected from HSK because of tolerance to a peptide shared between IgH^{b} and the cornea. Autoreactive T-cell clones to this peptide are eliminated in IgH^{b} mice, but not in IgH^{d} or IgH^{e} mice. Remarkably, there is a nearly identical peptide on a coat protein of the HSV-1 virus. Mutant HSV-1 lacking this peptide is unable to produce HSK (47). The proposed mechanism of HSK is as follows: (a) Immune privilege in the eye prevents tolerance to intrinsic corneal antigens by limiting exposure to these antigens during thymic selection; (b) Infection with HSV-1 induces T-cell clones that also recognize the intrinsic corneal antigens; because of the broken immune privilege created by the infection, these cells can then attack the cornea; (c) IgH^{b} mice are protected from HSK because of the fortuitous presence of the immunogenic peptide in the IgH allele. This allows developmental deletion of the autoreactive T-cell clones.

This mechanism may be much more general for antigens whose identity is hidden from thymic selection because of immune privilege. Identification of uveitic conditions with this mechanism awaits identification of the stimulatory peptides underlying their pathogenesis. However, diseases such as presumed ocular histoplasmosis syndrome, serpiginous choroidopathy, and others are certainly candidates.

54 AUTOIMMUNE HEPATOBILIARY DISEASES

Stephen P. James, M.D.

The liver has the largest mass of any internal organ of the body, and it carries out a wide variety of critical and complex metabolic functions. In addition, the liver plays several roles in the normal function of the immune system. First, it synthesizes most complement components (see Chapter 26). Second, the liver synthesizes most coagulation factors, which may interact with certain components of the immune system and thereby play a role in immunologic reactions. In addition to these metabolic functions, the liver is a major organ of the reticuloendothelial system in the body, and thus plays an important role in removal of particulate materials and antigen/antibody complexes, particularly those originating in the gastrointestinal tract. Last, in some species, the hepatobiliary system plays a major role in immunoglobulin (Ig)A responses in the gut. In rodents, biliary excretion via a specific secretory component–mediated pathway is a major route for transporting secretory IgA into the intestinal lumen, and probably for clearance of IgA immune complexes. However, in humans, biliary excretion of IgA is only a minor pathway for secretion of secretory IgA.

The following sections review the clinical, laboratory, and immunologic aspects of hepatobiliary diseases that are thought to have primarily an immunologic basis. Immune-mediated injury also is a critical component of other important liver diseases such as viral hepatitis, but these are not reviewed here. As might be guessed from the discussion of the role of the liver in normal immune responses, severe liver disease may secondarily alter immune function. Particularly for the diseases of unknown cause, such as primary biliary cirrhosis (PBC) and sclerosing cholangitis, it is important to try to distinguish the immunologic features of the disease that are important in pathogenesis from those that are secondary effects of liver disease. Two other interesting aspects of liver disease, graft-versus-host disease and liver transplantation, are included in Chapter 83 and Chapter 84.

AUTOIMMUNE CHRONIC ACTIVE HEPATITIS

Introduction

HISTORICAL FEATURES

Autoimmune hepatitis is an uncommon form of chronic hepatitis of unknown etiology, predominantly affecting women. The features of the disease were first clearly described by Waldenström in 1950 (1) in young women with cirrhosis, plasma cell infiltration of the liver, and marked hypergammaglobulinemia. In 1955 the lupus erythematosus (LE) cell phenomenon was demonstrated in patients with this disease (2), and because of the finding of frequent multisystem disease in these patients (3,4), the term *lupoid hepatitis* was subsequently applied to the disorder (5). However, it is now clear that autoimmune hepatitis is distinctly different from systemic lupus erythematosus, and this term should not be used.

Since the original descriptions of the syndrome, the current understanding of the disease has been repeatedly modified by the discovery of hepatitis viruses and the advent of specific diagnostic tests for viral hepatitis. Earlier descriptions of the syndrome are complicated by the inclusion of patients with viral hepatitis. Further clarification of the clinical syndrome has occurred with the realization that many drugs may produce a syndrome resembling autoimmune hepatitis. Of particular importance was the demonstration that untreated patients with severe symptomatic disease had a high likelihood of progression to cirrhosis and death, and that this poor course can be significantly altered by immunosuppressive treatment. A discussion of autoimmune hepatitis must be now tempered with the realization that there may be forms of hepatitis for which there are as-yet-undiscovered viral or environmental etiologies.

IMMUNOLOGIC HIGHLIGHTS

The characteristic immunologic features of autoimmune hepatitis include chronic liver disease with infiltration of the liver by lymphoid cells associated with hepatocyte necrosis, the presence of serum autoantibodies, and absence of known viral or toxic etiologies. Type I autoimmune hepatitis is characterized by high titers of antinuclear antibodies (ANAs) and/or smooth muscle antibodies (SMAs). Type II is characterized by absence of ANA and presence of anti–liver-kidney microsomal (anti-LKM-1) antibodies. The disease is associated with specific human leukocyte antigen (HLA) serotypes and has a favorable response to therapy with corticosteroids with or without azathioprine.

Epidemiology

GENETICS

A number of features of autoimmune chronic active hepatitis suggest the importance of genetic factors (6). Autoimmune hepatitis typically is diagnosed in women, with a sex ratio of about 8:1, and has two peaks of incidence: in young women aged 10 to 30 years, and in women aged 50 to 70 years. There is a definite preponderance of cases in individuals of northern European descent. The disease is rare in southern Europeans, Africans, and Asians. Familial occurrence is distinctly unusual (7), but there are reports of multiple cases in siblings, parents, and grandparents. There is an increased incidence in family members of circulating autoantibodies, hypergammaglobulinemia, and occult liver disease (8,9). Multiple studies have confirmed that there is a significantly increased frequency of HLA-B8 in autoimmune hepatitis (10,11), and also an increase in other alleles in linkage disequilibrium with HLA-B8, including HLA-A1 and -Cw7 (12), and HLA-DR3 (13). More recently it was found that these HLA antigen associations occur in young women with the “classic” form of autoimmune hepatitis with a high frequency of autoimmune phenomena, whereas older women diagnosed as having autoimmune hepatitis have a lower frequency of these HLA types. These earlier serologic studies have been validated at the allelic level with significant associations of HLA DRB1*0301 and DRB1*0401 with autoimmune hepatitis (14). Further studies have examined the possible associations with other HLA region genes, such as association of type 1 autoimmune hepatitis with a variant allele of tumor necrosis factor (TNF)-a (15).

Mackay (6) and others (16) described a significant association of the Gm allotype ax with autoimmune hepatitis; in particular, the increased risk of this allotype was confined to patients with HLA-B8. These findings led to the suggestion (6) that the association of autoimmune hepatitis with these genetic factors may represent a multifactorial process at the molecular level: an increased tendency for certain antigens to be recognized in the context of particular major histocompatibility complex (MHC) genes, a particular tendency of certain immunoglobulin genes to code for antibodies reactive with antigens important in the disease, and finally, the importance of female sex in conferring a higher tendency to autoimmune phenomena.

ENVIRONMENTAL

Compared with other liver diseases, autoimmune hepatitis is rare. The prevalence in northern European and North American white populations is estimated to be between 50 and 200 cases per million. The disease is infrequent in Africa and Asia; however, the high prevalence of viral hepatitis in these locations may obscure the diagnosis. The search for specific environmental triggers has provided no conclusive associations. Reported associations with measles, Epstein-Barr virus (EBV), and various drugs has not been reproducible.

Clinical Presentation

The clinical presentation is very heterogeneous, and none of the manifestations is pathognomonic for autoimmune hepatitis (Table 54.1) (17). Some patients are discovered with very mild, asymptomatic disease from screening blood studies. Patients with clinically severe disease may have easy fatigability, jaundice, dark urine, abdominal pain, anorexia, myalgias, delayed menarche, and amenorrhea. Superimposed symptoms of advanced liver disease may occur late in the disease or sometimes be the presenting manifestations. Occasionally patients have an acute or subfulminant course. Abnormal physical findings include hepatomegaly, jaundice, splenomegaly, spider nevi, and cushingoid features. Likewise late in the disease, other physical abnormalities typical of advanced decompensated liver disease may be found. A significant proportion of patients have no physical abnormality.

Etiology	Unknown
Epidemiology	Predominantly young women, northern European descent; second peak of incidence in older women
Genetics	Strong HLA-B8, -DR3 -DR4 association with type I; familial cases uncommon
Symptoms	Fatigue, jaundice, abdominal pain, myalgias, delayed menarche, amenorrhea
Physical findings	Hepatomegaly, splenomegaly, spider nevi, cushingoid features
Laboratory	High transaminases, hypergammaglobulinemia Type I: high-titer ANA, anti-SMA Type II: anti-liver-kidney microsomal (LKM-1) antibodies
Associated syndromes	Thyroiditis, arthritis, Sjogren syndrome, multiple others
Liver histology	Piecemeal necrosis; may be associated with bridging necrosis fibrosis, and cirrhosis
Prognosis	Untreated severe cases have high mortality
Treatment	High response rate to corticosteroids; may be combined with azathioprine

SMA, smooth muscle antibodies; HLA, human leukocyte antigen; ANA, antinuclear antibody

TABLE 54.1. Typical Clinical Features of Autoimmune Chronic Active Hepatitis

Associated Autoimmune Syndromes

Approximately half of patients with autoimmune hepatitis have other syndromes of possible autoimmune nature (3,4,17,18). The most common of these are thyroiditis, rheumatoid arthritis, Sjögren syndrome, and other connective tissue disorders. Additional associations include thrombocytopenic purpura, pernicious anemia, myasthenia gravis, iritis, urticaria, pyoderma gangrenosum, peripheral neuropathy, Coomb-positive hemolytic anemia, membranoproliferative glomerulonephritis, cryoglobulinemia, pericarditis, and fibrosing alveolitis. The relationship of these associations to the underlying liver disease is uncertain.

Laboratory Abnormalities

Common laboratory abnormalities include elevation of serum aminotransferase levels and hypergammaglobulinemia. Hyperbilirubinemia is commonly found, but the laboratory findings of cholestasis are much less prominent than in other diseases such as PBC. Results from tests of copper metabolism are usually only slightly abnormal. Abnormal prothrombin time reflects hepatic synthetic dysfunction.

Pathologic Findings

The major histologic finding is “piecemeal necrosis,” in which hepatocytes in the periportal region undergo necrosis in association with disruption of the limiting plate of the portal tract and infiltrating lymphoid cells (Fig. 54.1). The degree of hepatocyte necrosis is highly variable, from minimal lesions to severe lesions in which necrosis may extend to central veins (bridging necrosis) or to adjacent lobules (multilobular necrosis). These pathologic changes are not pathognomonic and may be found in viral hepatitis. Cirrhosis, with or without active inflammation, may be present.

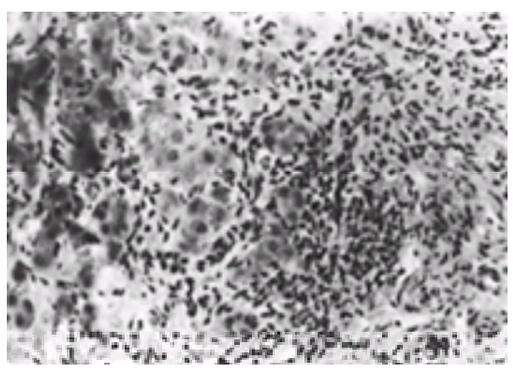

Figure 54.1. Idiopathic autoimmune chronic active hepatitis. Piecemeal necrosis with portal infiltrate and lymphocytes surrounding hepatocytes.

Treatment and Prognosis

Patients with severe autoimmune chronic active hepatitis, who served as controls in therapeutic trials, have a high probability of progressing to cirrhosis and have a high mortality (19). In patients with moderate disease activity, significant morbidity and mortality also occur. Primary hepatocellular carcinoma has been reported, but appears to be rare in autoimmune hepatitis.

Controlled clinical trials have shown that corticosteroid drugs, alone or in combination with azathioprine, significantly improve symptoms and survival in severe autoimmune chronic hepatitis (17). These beneficial effects are often achieved at the expense of significant drug-induced side effects, however. The indications for treatment of patients with mild or moderately active disease are less certain. The indications and regimens for treatment are described in detail elsewhere (17). Remission of disease is achieved in the majority of treated patients. Some patients have long-lasting remissions, whereas others have relapses requiring retreatment. Patients with end-stage autoimmune hepatitis may be candidates for liver transplantation, but the liver disease may recur after transplantation (20). It is not now certain whether underlying autoimmune phenomena, a transmissible agent, or graft rejection is the cause of the recurrent hepatitis.

Immunopathogenesis

IMMUNOPATHOLOGY

Immunohistochemical staining shows the presence of numerous plasma cells, and, in contrast to chronic viral hepatitis, a lower proportion of T cells have the CD8 phenotype (21,22,23 and 24). IgG can be demonstrated by indirect immunofluorescence on hepatocyte membranes (25). In some studies, the deposited IgG has a linear pattern, whereas other authors found both linear and granular patterns.

AUTOANTIBODIES

Type 1 Autoimmune Hepatitis (Typical or Classic Autoimmune Hepatitis)

The frequency with which specific serologic abnormalities are found in typical autoimmune hepatitis varies in the literature and depends in part on arbitrary diagnostic criteria. The typical case of classic lupoid hepatitis is associated with high titers of ANAs in serum, which is the immunologic hallmark of type 1 autoimmune hepatitis. Classic autoimmune hepatitis (CAH) does not appear to be associated with any one specific pattern of nuclear reactivity, and there are no clinical correlates with different patterns of reactivity. The frequency of antibodies to double-stranded DNA, the hallmark of active lupus, appears to be low in CAH. ANA positivity can be found in other forms of chronic liver disease.

By generally accepted criteria, typical or type I autoimmune hepatitis is by definition associated with the presence of another non–organ-specific autoantibody, anti-SMA. The antigen usually recognized by anti-SMA is actin, a major cytoskeletal component of cells. However, in many cases, it appears that antigens other than actin are the targets of the antibody, and these have yet to be identified. Although the presence of this antibody is necessary for diagnosis, its presence has no diagnostic specificity, because anti-SMA is frequently found in many forms of chronic liver injury.

Antimitochondrial antibodies (AMAs) also can be found in a minority of patients with CAH. Sometimes, patients with this antibody, which is typically found in high titers in patients with PBC, have a syndrome that truly has features that overlap CAH and PBC (13). However, one distinguishing feature is that this syndrome behaves clinically like CAH in that the response to corticosteroids is good, whereas in PBC, the evidence for good responses to corticosteroids is more controversial.

Type 2 (Anti–Liver-Kidney Microsome) Autoimmune Hepatitis

Type 2 autoimmune hepatitis is a relatively infrequent syndrome that has distinctive clinical and laboratory features. The age at onset is typically younger than 15 years, and it has been found primarily in European countries. The disease is more often associated with other autoimmune syndromes such as insulin-dependent diabetes, autoimmune thyroid disease, and vitiligo. The presentation may be acute and have a rapidly progressive course to cirrhosis. Usually, non–organ-specific autoantibodies such as ANAs and SMAs are absent, but patients characteristically have antibodies to LKMs (anti-LKM) (26). The target antigen was identified by Manns et al. (27) as cytochrome P-450 db1 (now termed P-450 IID6). Two other types of antimicrosomal antibodies have been found. In patients with tienilic acid–induced hepatitis, antibodies against cytochrome P-450-8 were found, and in patients with chronic hepatitis D virus infection, a third type of anti-LKM (anti–LKM-3) was found.

The relationship of type 2 autoimmune hepatitis to chronic hepatitis C is an interesting problem. About one third of patients with type 2 autoimmune hepatitis have anti–hepatitis C antibodies, usually in low titer, which initially raised the suspicion that these were false-positive reactions associated with autoimmunity. That the majority of such patients respond to treatment with prednisone, and that some patients with the syndrome treated with interferon (IFN)-g appear to deteriorate, tend to support this argument. However, some patients have viral RNA in their circulation, indicating that they do indeed have hepatitis C virus infection. In such patients, whether the viral infection is the trigger of the apparent autoimmune disease or whether hepatitis C virus infection is the etiology of the syndrome is unclear. It has been suggested that type 2 autoimmune hepatitis be divided into two subgroups, type 2a and type 2b, on the basis of the absence or presence of hepatitis C virus markers, respectively, because it seems likely that, at least in some patients, hepatitis C virus infection is important in the pathogenesis of the syndrome.

Soluble Liver Antigen (SLA)

A subgroup (about 10% of CAH patients) has a novel pattern of autoantibody to soluble liver antigens. Manns et al. (28) identified patients who had no history of blood exposure and clinical features of CAH but had no ANAs, SMAs, or LKM antibodies. These patients were found to have serum antibodies that reacted with cytosolic fractions of hepatocytes [soluble liver antigens (SLAs)]. Subsequent studies revealed that the antigens recognized are cytokeratins, which are not specific for liver cells but are expressed at high levels in hepatocytes. Clinically the small number of patients found to date with this syndrome is similar to that of patients with type I CAH, in that they are predominantly female and respond well to immunosuppressive treatment.

Other Autoantibodies

In early experimental studies on the pathogenesis of autoimmune hepatitis, it was found that immunization with crude extracts of liver membranes was capable of inducing hepatitis in rabbits (29). These preparations were designated *liver-specific proteins* (LSPs), although it is clear now that these preparations contained numerous components, many of which are not liver specific. These studies gained widespread attention because it was shown that patients had both antibodies directed against LSP and evidence of lymphocyte reactivity to LSP, providing evidence for autoimmune mechanisms in patients with the disease. More recently it was shown that LSP contains at least one hepatocyte-specific membrane protein, the hepatic asialoglycoprotein receptor (ASGP-R) (30). Anti-ASGP-R has been detected using human-specific recombinant proteins, and it appears that these antibodies can be found in at least some patients with a wide array of acute and chronic liver diseases (31), suggesting that the autoreactivity to this protein is a secondary consequence of liver injury. Furthermore, the prevalence of anti-ASGP-R is similar in the different subgroups of patients with CAH. Titers of anti-ASGP-R are much higher in active CAH, consistent with either a primary pathogenic role or a secondary epiphenomenon. Antineutrophil cytoplasmic antibodies (ANCAs) also are found in some patients, with the perinuclear pattern (p-ANCA) found in patients with ulcerative colitis.

Cryptogenic Autoimmune Hepatitis and Cirrhosis

Although recent sophisticated methods for diagnosis of viral hepatitis, including improved serologic and polymerase chain reaction (PCR) methods, have shown that many patients with “cryptogenic” cirrhosis have liver disease caused by viruses, there remain subgroups of patients in whom no etiology or autoantibodies can be identified. Some of these patients, although lacking autoantibodies such as ANAs, SMAs, LKM antibodies, and SLAs, have clinical features that otherwise resemble those of patients with CAH, including hypergammaglobulinemia, typical liver biopsy features, and favorable responses to corticosteroids (32). Although generally indistinguishable from patients with typical CAH, they tend to present at an older age and are more likely to have cirrhosis at the time of presentation. It has been suggested that these patients may have had autoantibodies early in the course of their disease that had been lost.

COMPLEMENT SYSTEM

Because of the possibility that antibody-mediated tissue injury might be responsible for tissue injury in autoimmune hepatitis, a number of studies have focused on the complement system in these patients. In contrast to patients with PBC and chronic hepatitis B, however, patients with autoimmune hepatitis do not have abnormal catabolism of complement or increased levels of cleavage products of C3 (33,34). C3 and C4 may be low in patients with autoimmune hepatitis, but in view of lack of other evidence of activation of the complement system, these findings may reflect decreased hepatic synthesis of complement components. Properdin and factor B levels are normal.

IMMUNE COMPLEXES

Materials reactive in different immune-complex tests have been detected in the sera of patients with autoimmune hepatitis (35). The frequency of positive results appears to be lower than that in viral hepatitis. Positive results are obtained in many other liver diseases, and to date, the nature of the materials reacting in these tests and whether there are any disease-specific components of these complexes remain undetermined.

LYMPHOCYTE SUBPOPULATIONS AND RESPONSES

The percentage of circulating lymphocytes may be diminished in autoimmune hepatitis, but this appears to be a nonspecific effect of liver disease. The proportion of T cells in the circulation may be normal or diminished (36). The CD4/CD8 ratio is variable but on the average higher than that in controls (37). The infiltrates within the liver are predominantly T cells, but in autoimmune hepatitis, there are more B cells and plasma cells than in viral hepatitis. In contrast to viral hepatitis, in autoimmune hepatitis, liver T cells demonstrate a higher CD4/CD8 ratio. Lymphocytes with the phenotypes of natural killer (NK) cells are rare in the liver. HLA-DR–positive lymphocytes have been reported to be present in the liver. By lymphocyte stimulation tests and migration inhibition tests, patients with this syndrome have been demonstrated to have sensitivity to LSP antigen preparations (38,39). These responses are not specific for autoimmune hepatitis, and whereas they suggest that certain membrane antigens may serve as common effector targets in different liver diseases, these findings also are consistent with secondary epiphenomena.

LYMPHOCYTE CYTOTOXICITY

Many studies of lymphocyte-mediated cytotoxicity have been carried out. By measuring the loss of adherent viable autologous hepatocytes from microwells, a number of studies have shown that peripheral blood lymphocytes mediate “cytotoxicity” against autologous hepatocytes in patients with autoimmune hepatitis (40).

Interestingly, this reaction was blocked by addition of LSP or aggregated IgG to the test systems, and was mediated by non-T cells (41). Thus it has been suggested that antibody-dependent cell-mediated cytotoxicity (ADCC) may play a role in hepatocyte necrosis in autoimmune hepatitis, presumably mediated through NK cells. There was much less T cell–mediated "cytotoxicity" in comparison with that in patients with viral hepatitis, as determined by this test system. As mentioned earlier, the majority of lymphocytes infiltrating the liver in autoimmune hepatitis are T cells, and so it remains to be proved that ADCC plays an effector role in liver damage in this disease.

IMMUNOREGULATORY FUNCTION

Because of the prominent role of autoimmune phenomena and marked hypergammaglobulinemia in some patients, a number of investigators examined the possibility that alterations in the function of immunoregulatory T cells are important in the pathogenesis of this syndrome. Using methods in which T cells are preactivated with concanavalin A (Con A), it was demonstrated that patients have diminished suppression of proliferative responses (39). Similarly, suppression of pokeweed mitogen–stimulated immunoglobulin synthesis *in vitro* is diminished. Suppressor function improved after treatment of patients with corticosteroid therapy (42,43 and 44). However, these *in vitro* abnormalities of polyclonally activated cells are not specific for autoimmune hepatitis, being found in other liver diseases described in this chapter and in nonliver diseases. Using production of migration inhibition factor (MIF) in response to LSP as an assay of specific lymphocyte function, it was found that patients with autoimmune chronic active hepatitis lacked cells that suppress this response, suggesting a possible mechanism whereby abnormal function of suppressor cells might contribute to specific immune damage to hepatocytes (39). However, the importance of antibodies to LSP remains to be proved in this disease. Nonetheless, alteration of the function of immunoregulatory T cells, particularly diminished suppressor function, may contribute secondarily to the development of autoimmune phenomena.

PRIMARY BILIARY CIRRHOSIS

Introduction

HISTORICAL FEATURES

The first descriptions of what was probably PBC were published in the nineteenth century (45), but the recognition of PBC as a distinct clinical entity did not occur until the appearance of reviews on the syndrome in the twentieth century (46). The most commonly used name for the syndrome is a misnomer, in that many patients do not have cirrhosis early in the course of the disease, which may have a very mild, indolent, subclinical course. Important historical developments in PBC include the introduction of cholestyramine for treatment of pruritus and hypercholesterolemia, the description of the characteristic antimitochondrial antibody (47), the discovery of high levels of hepatic copper, and the recognition that the syndrome often has an asymptomatic, indolent course. Large treatment trials studied the efficacy of azathioprine, D-penicillamine, and ursodeoxycholic acid. End-stage PBC is an important indication for hepatic allograft transplantation, which offers the hope for long-term survival to patients with severe progressive liver disease.

IMMUNOLOGIC HIGHLIGHTS

PBC is a chronic disease of unknown etiology, affecting primarily middle-aged women, and characterized pathologically by inflammation and necrosis of intrahepatic bile ducts (Table 54.2). The destruction of intrahepatic bile ducts causes chronic cholestasis, with its multiple clinical manifestations, and may progress to biliary cirrhosis and death. The immunologic hallmark of the disease is the presence of high titers of serum AMAs in most patients with the disease. Because of the histologic features of the disease, the occurrence of autoantibodies, and the frequent association with systemic autoimmune diseases, abnormal immune mechanisms may play a primary role in the pathogenesis, although this hypothesis remains to be proved.

Etiology	Unknown
Epidemiology	Predominantly middle-aged women
Genetics	No known HLA association; familial cases rare
Symptoms	Pruritus, fatigue, arthralgias, dry eyes, hyperpigmentation
Physical findings	Hepatomegaly, splenomegaly, hyperpigmentation, excoriations, xanthelasma
Laboratory	Increased alkaline phosphatase, bilirubin, cholesterol; antimitochondrial antibodies usually present in high titer
Liver biopsy	Early: nonsuppurative destructive cholangitis; late: biliary cirrhosis
Cholangiography	Normal in early disease; nonspecific changes due to cirrhosis late in disease
Prognosis	Mean survival, 11 years; asymptomatic patients may have normal survival
Treatment	Supportive; cholestyramine, fat-soluble vitamins; ursodeoxycholic acid; liver transplantation for advanced disease

HLA, human leukocyte antigen.

TABLE 54.2. Typical Features of Primary Biliary Cirrhosis

Epidemiology

GENETICS

Multiple familial occurrence of PBC is rare, having been reported in sisters (48), in mothers and daughters (49,50), in brothers (51), and in twins (52). PBC has been associated with an increased incidence of HLA DR8 (53). Family members of patients with PBC have been reported to have an increased incidence of immunoglobulin abnormalities (54) including autoantibodies, and abnormalities of suppressor cell function (55), suggesting the possibility that hereditary immunologic characteristics may predispose to the disease. To date, genomewide searches for linkage have not been conducted in PBC, in part because familial occurrence is uncommon.

ENVIRONMENTAL

The epidemiologic features of PBC have been studied best in Great Britain, where the point prevalence is estimated to be 2.3 to 14.4 per 100,000 (56,57 and 58). The variation in prevalence may be due to the more frequent diagnosis of asymptomatic patients in urban areas. Although clustering of cases was reported in one report (56), this was not confirmed by another study (58). The distribution of the disease is worldwide and occurs in all races. The diagnosis is made most commonly in the fifth and sixth decades, but the age at diagnosis varies widely from the early twenties to the ninth decade. Approximately 90% of patients are female. There is no evidence to implicate infectious or toxic factors in etiology, although it is known that certain drug reactions may cause chronic cholestasis that resembles PBC.

Clinical Presentation

The clinical features of PBC have been reviewed in detail (59,60,61 and 62). Typically, the symptoms have an insidious onset and include pruritus, fatigue, increased skin pigmentation, arthralgias, dryness of the mouth and eyes, and Raynaud phenomenon. Jaundice or gastrointestinal bleeding may be presenting complaints. Common physical findings include hepatomegaly, splenomegaly, skin hyperpigmentation due to melanin deposition, excoriations, xanthomata, xanthelasma, and spider telangiectasia. Late in the course of the disease, deep jaundice, petechiae and purpura, and signs of hepatic encephalopathy occur because of advanced liver disease. The symptoms and signs of some of the associated syndromes (see later) may be the presenting manifestations. In asymptomatic patients, it is not unusual for the physical findings to be entirely normal (60,63,64). Patients have been described with AMAs and histologic features of PBC on liver biopsy, but without symptoms of liver disease or abnormalities of liver enzymes (65). These patients appear to represent an early phase in the spectrum of the disease, because some may eventually develop more significant manifestations of PBC.

Associated Autoimmune Syndromes

PBC has been associated with a number of autoimmune syndromes (Table 54.2) (3,66 and 66a). Keratoconjunctivitis sicca is probably the most commonly associated syndrome. It is often asymptomatic or present in a very mild form and is a secondary sicca syndrome (usually anti-SSA, SSB negative) (67,68). Several forms of arthritis are frequently found. Most often patients have a seronegative nondestructive arthritis affecting small joints, and less often there is evidence of joint destruction (69,70). Rheumatoid arthritis has been associated with PBC but may not be more common than the fortuitous association of two diseases. Scleroderma, either as the complete syndrome or as the CREST (calcinosis, Raynaud phenomenon, esophageal involvement, sclerodactyly, and telangiectasia) variant, also is associated with PBC (71,72). Evidence of hypothyroidism is common, and autoimmune thyroiditis may be the presenting manifestation of PBC (73,74 and 75). Other associations have

been reported uncommonly, and may represent fortuitous associations. They include systemic lupus erythematosus (76), dermatomyositis (61), gluten-sensitive enteropathy (77), bullous pemphigoid (78), pyoderma gangrenosum, lichen planus (79,80), cutaneous vasculitis with membranous glomerulonephritis (81), polymyalgia rheumatica (82), hemolytic anemia (83), interstitial lung disease (84), and myasthenia gravis (3).

LABORATORY

Common laboratory abnormalities include elevation of the serum alkaline phosphatase and g-glutamyl transpeptidase. Total bilirubin levels are normal early in the disease, and increase progressively with advancing disease. Mild to moderate elevations of serum aminotransferases are found. Hypercholesterolemia and lipoprotein abnormalities are frequent. Urine copper excretion is increased because of reduced biliary copper excretion in cholestatic liver disease, and serum ceruloplasmin is elevated. Abnormalities found with advanced liver disease, such as hypoalbuminemia and prolonged prothrombin time, occur with hepatocellular decompensation. Cholangiography shows normal biliary ducts, except when cirrhosis is present, which may cause nonspecific irregularity and tortuosity of small intrahepatic bile ducts (85). Serum total IgM is often elevated (see later). AMAs are present, usually in high titer, in more than 90% of patients, and is the only relatively specific diagnostic test other than liver biopsy.

PATHOLOGIC FINDINGS

The liver histopathologic abnormalities in PBC are relatively specific and have been classified in four stages (86), but these may overlap (Fig. 54.2). The earliest and most specific lesions identified (stage 1) show chronic inflammation and necrosis of intrahepatic bile ducts, which are infiltrated with lymphocytes and may be surrounded with granulomas. In stage 2, bile ductules proliferate, mononuclear infiltration of portal areas is prominent, and some portal fibrosis may be evident. In stage 3, there is a reduction in the portal inflammatory infiltrate, bile ducts are absent from portal triads, and there is an increase in portal fibrosis. Stage 4 is characterized by biliary cirrhosis with a paucity of bile ducts and increased hepatic copper. Thus the histopathologic features of PBC consist of a chronic inflammatory process that leads to destruction and disappearance of intrahepatic bile ducts and progressive portal fibrosis, leading to biliary cirrhosis. Hepatocellular necrosis is not a prominent feature, although in occasional cases piecemeal necrosis surrounding portal tracts may resemble autoimmune chronic active hepatitis; in some cases, there is a clinical syndrome with features of both chronic active hepatitis and PBC (autoimmune cholangiopathy).

TREATMENT AND PROGNOSIS

The treatment of PBC includes supportive care, such as cholestyramine for pruritus and fat-soluble vitamins for nutritional deficiencies, and antiinflammatory and immunosuppressive drugs directed at the underlying medical disorder. Corticosteroids have been shown to cause improvement in biochemical abnormalities in some patients, but these drugs are generally regarded as contraindicated for long-term treatment of PBC because they greatly exacerbate the metabolic bone disease to which these patients are prone (87). Although previous studies found no benefit of treatment with azathioprine (88,89), more recently, treatment with this drug was shown to prolong survival; however, this beneficial effect of the drug appears to be marginal (90). Although initially treatment with D-penicillamine appeared to increase survival (91), long periods of follow-up indicate that it causes no significant increase in survival, and it is associated with many potentially serious side effects (92,93 and 94).

A small study of chlorambucil indicated that treatment with this drug is associated with decreased intrahepatic inflammation and improvement in some biochemical abnormalities, but the long-term usefulness of this drug is unknown (95). Cyclosporine has been used in a small number of patients (96), and its use also is associated with improvement in some clinical measurements of disease activity; however, significant renal toxicity developed in patients, possibly because the drug is metabolized in the liver, and its biologic half-life may be significantly prolonged in liver disease. Levamisole was studied in a small preliminary trial, but was without benefit (97). A controlled trial suggested a beneficial effect of treatment with colchicine, but the benefit appears to be marginal (98). The single most effective therapy is ursodeoxycholic acid, which has been shown in multiple trials to improve symptoms, serum biochemical abnormalities, and, in one study, prolong survival (99). The mechanism of improvement caused by this drug is unknown.

For patients with advanced and deteriorating liver disease, the best available treatment is hepatic transplantation. The survival rate for patients with PBC receiving hepatic allografts is excellent. Recurrence of PBC in hepatic allografts has been reported in approximately 10% of patients, and may be difficult to distinguish from chronic allograft rejection (100). However, the recurrent disease appears to be indolent, possibly as a consequence of immunosuppression.

The prognosis for PBC is highly variable. Overall mean survival time is about 12 years (60), in contrast to earlier studies of primarily symptomatic patients in whom the average survival time is only about 6 years (59). Survival in patients who are asymptomatic at the time of diagnosis is very much better (59,64). The presence of granulomas, which are found in early disease and correlate inversely with fibrosis, is a good prognostic sign (101), whereas increasing serum bilirubin and onset of symptoms and signs of portal hypertension are poor prognostic signs (102). The complications of PBC are many, including symptoms and signs associated with chronic cholestasis such as pruritus, steatorrhea, hyperlipidemia, metabolic bone disease, and those complications related to cirrhosis and portal hypertension. These are reviewed in detail elsewhere (62).

Immunopathogenesis

IMMUNOPATHOLOGY

Immunofluorescence studies have shown that plasma cells in the portal infiltrates stain predominantly for IgM (103). Deposition of IgM and complement has been observed in portal areas (104). There is increased expression of HLA-DR antigens (53) and intracellular adhesion molecule-1 (ICAM-1) on bile duct epithelial cells (105). The portal infiltrates are composed primarily of T cells, which have a higher proportion of $CD4^+$ cells than in viral hepatitis, but $CD8^+$ T cells may be found in close proximity to some bile ducts (106,107,108 and 109). The differential diagnosis of the hepatic histologic lesions includes secondary biliary obstruction, sclerosing cholangitis, drug-induced cholestasis, pericholangitis associated with bowel disease, sarcoidosis, chronic active hepatitis, graft-versus-host disease (110), and allograft rejection (111,112).

SERUM IMMUNOGLOBULINS

Polyclonal elevation of serum immunoglobulins is found in most patients with PBC as the disease progresses (61,113), although immunoglobulin levels may be normal early in the disease. There is frequently a disproportionate elevation of IgM (114), a feature that distinguishes PBC from other chronic hepatic diseases. One explanation of the striking IgM elevation found in some PBC patients is that low-molecular-weight (monomeric) IgM may give a falsely elevated IgM level, as determined by radial immunodiffusion (114,115). The presence of monomeric IgM is not, however, specific for PBC. Elevation of serum total and secretory IgA also is found in PBC (116,117), but this finding also is common in other liver diseases such as alcoholic liver disease. A case has been reported with PBC and selective IgA deficiency, indicating that IgA is not required as an immune effector mechanism for the pathogenesis of PBC (118).

The elevated immunoglobulin levels in PBC are usually due to polyclonal increases in immunoglobulins, but production of oligoclonal antibodies is occasionally found,

and in some cases, these monoclonal antibodies have been shown to have specificity for mitochondrial antigens.

AUTOANTIBODIES

The discovery of AMAs in the serum of patients with PBC (47) was one of the first observations that suggested that altered immunity may play a role in the pathogenesis of the disease, and it also provided an important diagnostic test. As detected by the standard indirect immunofluorescence method using whole cells rich in mitochondria, the antibodies are found in more than 90% of patients with PBC. When performed this way, reactivity with mitochondria is found in other liver diseases and in rheumatologic diseases (119), although usually in lower titers than those in PBC patients. AMAs are not species or organ specific. Although predominantly of the IgG class, they also may be IgM or IgA. A number of the mitochondrial antigens have been cloned and identified. The dominant antigen is the E2 subunit of pyruvate dehydrogenase, and the other antigens are related component mitochondrial 2-oxo-acid dehydrogenase enzymes (120). Interestingly, AMAs inhibit the function of pyruvate dehydrogenase, but the significance of this abnormality is uncertain. The cloning of the AMA antigens has led to more sensitive and specific enzyme-linked immunosorbent assay (ELISA) for PBC. Interestingly, antigens cross-reactive with the E2 subunit of pyruvate dehydrogenase are expressed on the apical surface of biliary epithelial cells of patients with PBC, even in AMA-negative patients.

Many other autoantibodies have been described in PBC, but these are not specific for this disease. SMAs are found in the serum of 20% to 50% of patients (121,122), but titers are usually lower than those in patients with diseases characterized by prominent hepatocellular necrosis, such as CAH. Antibodies to cytoskeleton components, which contain actin to which SMAs bind, also are found in PBC (123). In one study, the majority of patients with PBC had serum antibodies that reacted with bile ducts (103); however, this reactivity is not specific for PBC and may be due to the presence of SMAs. Antiasialoglycoprotein antibodies are found in patients with PBC, in common with other chronic liver diseases. ANAs are found in about one third to one half of patients. The presence of the multiple nuclear dot pattern correlated with the presence of sicca syndrome (124), and the presence of anticentromere antibodies correlated with the presence of sclerodactyly (125). The pattern of autoantibody reactivity in PBC differs from that of primary Sjögren syndrome in that the latter, but not the former, have reactivity to small ribonucleoproteins by radioimmunoassay (RIA) (126). Other autoantibodies commonly found in PBC include rheumatoid factor (about two thirds of patients) (127), antithyroid antibodies (75), and anti–native DNA (128), and antiribosomal antibodies (129).

Whatever the significance of autoantibodies in PBC, it is unlikely that such antibodies play a primary role in the pathogenesis of the bile duct lesions. First, the titer of the autoantibodies does not correlate with activity of disease, and patients with otherwise typical PBC may not have detectable AMAs. Second, none of the autoantibodies described to date is entirely disease specific, each having been found in a variety of other hepatic and nonliver diseases. Third, immunization of animals with purified autoantigens, such as mitochondrial antigens, does not produce liver disease, although it does lead to production of AMAs (130). Fourth, patients with AMA-negative PBC have similar clinical and pathologic abnormalities as do AMA-positive patients. It is possible nonetheless that such antibodies may play a secondary role in tissue injury. The pathogenic mechanism by which autoantibodies are formed in PBC is no better understood in this disease than it is in other autoimmune states. It is possible that their occurrence relates to a fundamental abnormality in immune regulation.

IMMUNE COMPLEXES

The discovery of the important role of circulating immune complexes in other human diseases led to a search for such complexes in liver diseases. Circulating immune complex–like materials have been reported in PBC in several studies. Patients have serum substances reactive in the Raji cell (RIA) for immune complexes (131,132 and 133). A correlation was found between the presence of immune complex–like material and the severity of portal inflammation and the presence of autoimmune syndromes. In addition, materials reactive in the iodine 125–Clq binding assay for immune complexes (134) have been found. Many patients with PBC have been shown to have cryoprecipitable material in serum, which, although not containing complement components, is able to activate complement, suggesting the presence of antigen-antibody complexes in the cryoprecipitates (135). One report found evidence of antigens derived from bile in circulating immune complexes (136), and another report found evidence that they contained AMAs (137). Patients with PBC have a defect in Kupffer cell–mediated clearance of C3b-coated immune complexes (137) in the liver. The cause of this abnormality is unknown, but it may account for the accumulation in serum of immune complex–like materials that are normally cleared by the liver. In contrast to these findings, in another carefully conducted study, using several well-defined methods, little evidence for circulating immune complexes was found in patients with PBC (138) when fresh serum specimens were used.

Part of the difficulty in defining the presence of circulating immune complexes in PBC may be the abnormal properties of the IgM, which has been shown to have the capacity to fix complement in the apparent absence of antigen binding, and to be more readily cryoprecipitable (139). Other arguments against an immune complex–mediated pathogenesis of PBC are the absence of typical histopathologic features of immune complex deposition in the liver, and the low frequency of associated immune complex–mediated syndromes such as vasculitis and glomerulonephritis.

COMPLEMENT ABNORMALITIES

Because antibody-mediated tissue injury may play a primary or secondary role in tissue injury in PBC, a number of studies have focused on the function of the complement system in this disease. The investigation of serum complement in liver disease is complicated by the fact that a number of complement components are synthesized in the liver, and therefore altered levels of complement components may be secondary to the liver disease itself. Studies of complement turnover using ^{125}I-labeled purified C3 showed that patients with PBC have an increased fractional catabolic rate of C3, as well as evidence of an increased extravascular to intravascular pool (140). Similarly, the fractional catabolic rate of C1q is increased in patients with PBC. These findings are not simply due to the presence of liver disease, because patients with hepatitis B surface antigen (HbsAg)-negative chronic active hepatitis do not have these abnormalities. Patient sera have been shown to contain elevated levels of C3, decreased levels of C4, and circulating conversion products of C3 (141). More recently, activation of the classic complement pathway was demonstrated by the finding of C1r, C1s, and C1 inactivator complexes in serum of patients, but no evidence of activation of the alternative pathway was found (142). The mechanisms by which the classic complement pathway are activated in PBC are unknown; these findings are compatible with the presence of antigen-antibody complexes that might be formed in the disease, but might also be due to abnormal properties of serum proteins, such as that referred to earlier for serum IgM.

LYMPHOCYTE POPULATIONS IN PERIPHERAL BLOOD

Patients with PBC often have a decrease in the absolute number of total circulating lymphocytes, which is a nonspecific feature of liver disease. The proportion of T cells, determined by rosetting or with the monoclonal antibody anti-CD3, is either normal or decreased. The proportion of B cells is normal. Subpopulations of T cells defined with the monoclonal antibodies CD4 and CD8 are highly variable. In some studies, no differences were found compared with controls, whereas in others, the proportion of $CD4^+$ cells is diminished (143,144). In one study, the proportion of $CD4^+$ cells was diminished in patients with less advanced disease, whereas the proportion of $CD8^+$ cells was diminished in patients with more advanced disease (143). Because these monoclonal antibodies define heterogeneous populations of cells, it is not clear what implications these findings have for the pathogenesis of PBC; they may in part represent secondary changes due to liver disease.

STUDIES OF LYMPHOCYTE FUNCTION

More than half of patients with PBC have diminished or absent delayed-type skin-test reactions to a variety of antigens, including purified protein derivative (PPD), keyhole limpet hemocyanin (KLH), and dinitrochlorobenzene (DNCB) (145). The mechanism of skin-test anergy is unknown, but is probably a secondary effect of liver disease, because anergy correlates with stage of disease and is found in other liver diseases. Many patients have diminished *in vitro* lymphocyte proliferative responses to mitogens (145). The diminished response may at least in part be due to serum inhibitory factors, because extensively washed lymphocytes have normal responses, and patient sera inhibit the responses of normal lymphocytes. The nature of this inhibitory factor is unknown. It is of interest that inhibitory substances have been isolated from normal liver, and it is possible that inhibitory substances are released secondary to liver injury. High concentrations of bile acids, cholesterol, and lipoproteins, which are found in liver disease, might also contribute to diminished lymphocyte responses.

Antigen-specific lymphocyte responses have also been examined. Lymphocytes from patients have been shown to produce MIF in response to the liver membrane preparation LSP (38), and in response to protein preparations from human bile (146). These responses, however, are not specific for PBC. Again, this type of reactivity might represent secondary sensitization due to liver damage.

It is worthwhile to note that pathologic lesions closely resembling those of PBC are found in patients with chronic graft-versus-host disease (110,147,148) and in chronic liver allograft rejection (111,112). Furthermore, in a mouse model of chronic graft-versus-host disease, similar biliary lesions also are noted (149). These findings suggest that immunologic mechanisms similar to those in graft rejection may play a role in PBC. Attempts have been made to determine whether patients have cell-mediated cytotoxicity against liver target cells. In a number of different experimental systems, patients' cells showed increased cytotoxicity against xenogeneic liver target cells, but normal cytotoxicity against LSP-coated red cells (150) and against the PLC/PRF/5 hepatoma cell line. Because of the design of these studies, it is likely that, in each instance, the cytotoxic reaction observed was not mediated by specific T-cell mechanisms, but by non–antigen-specific (NK) cytotoxic mechanisms. Nevertheless, PBC patients' cells have diminished NK cytotoxicity against typical NK target cells. This decrease in function does not appear to be due to a decrease in the number of circulating cells having phenotypic markers of NK cells, but rather to a decrease in their functional activity. Interestingly, in studies of ADCC, it was found

that patients' cells have normal activity, indicating that this activity is not affected by the disease process.

Because of the autoimmune associations of this disease, a number of studies have examined the question of whether immunoregulatory cell function is abnormal in PBC (151). Although the proportion of $CD8^+$ lymphocytes is usually normal (143), T cells from patients have a diminished ability to suppress pokeweed mitogen–stimulated immunoglobulin synthesis (152). In addition, Con A–activated lymphocytes from patients have a diminished capacity to mediate suppression of proliferative responses or pokeweed mitogen–stimulated immunoglobulin synthesis. Interestingly, healthy relatives of patients with PBC have a similar abnormality of suppressor cell function (55), suggesting that this may be a genetic marker of disease predisposition. This abnormality, which has been identified in other diseases, may play a role in hypergammaglobulinemia and the production of autoantibodies, as well as in autoreactive T cell–mediated cytotoxicity.

Patients with PBC have a diminished autologous mixed lymphocyte reaction (153), which also has been found in a variety of other autoimmune diseases. Autoreactive cells have the ability not only to provide help for, but also to suppress immunoglobulin synthesis *in vitro* (154). Thus autoreactive cells may have important immunoregulatory functions. Whether this defect is intrinsic, or secondary to liver disease, has not yet been determined, but it may play a role in the altered immunoregulatory function mentioned earlier.

To summarize the immunologic abnormalities of PBC (Table 54.3), the disease is characterized by the presence of non–organ-specific autoantibodies in serum, evidence of activation of the classic complement pathway, and alteration of the function of immunoregulatory T cells. As yet there is no definitive evidence of immunologically mediated damage to the primary tissue site of injury: the intrahepatic bile ducts. It remains an important unanswered question as to whether the damage to bile ducts is a primary autoimmune event, or whether the inflammatory response is secondary to damage to bile ducts that occurs by some other mechanism. It is likely that there is an underlying genetic predisposition, as well as important hormonal effects, which interact with the immune system by mechanisms that are not yet understood.

Humoral immune abnormalities
1. Hypergammaglobulinemia, particularly IgM
2. Autoantibodies
a. AMA
b. Nonspecific: SMA, LMA, anti-LSP, ANA, RF, antithyroid antibodies
3. Immune complex–like materials in serum
4. Increased complement catabolism
5. Decreased Kupffer cell–mediated clearance of C3b-containing immune complexes
Cellular immune abnormalities
1. Skin test anergy (nonspecific)
2. Diminished T-cell proliferative responses
3. Diminished NK-cell activity
4. Abnormal function of immunoregulatory T cells
a. Diminished autologous MLR
b. Decreased suppressor T-cell function
5. Morphologic: infiltration of liver with $CD4^+$ cells, plasma cells, and $CD8^+$ T cells in close proximity to damaged bile ducts

IgM, immunoglobulin M; SMA, smooth muscle antibody; ANA, antinuclear antibody; RF, rheumatoid factor; NK, natural killer; AMA, antimitochondrial antibody; LMA, liver membrane autoantibody; LSP, liver-specific protein; MLR, mixed lymphocyte reaction.

TABLE 54.3. Immunologic Abnormalities in Primary Biliary Cirrhosis

PRIMARY SCLEROSING CHOLANGITIS

Introduction

HISTORICAL FEATURES

Primary sclerosing cholangitis (PSC) is a disease of unknown etiology that is characterized by inflammation and fibrosis of both intrahepatic and extrahepatic bile ducts and the common association with inflammatory bowel disease (IBD). PSC apparently was not recognized prior to the twentieth century. The term seems to have originated with Castleman and Towne (155), and was used later by Schwartz and Dale (156). The first large review by Warren et al. (157) suggested diagnostic criteria that excluded other causes of biliary strictures. The most important historic aspect of this disease was the advent of endoscopic retrograde cholangiography in the 1970s, which led to a marked improvement in the ability to diagnose the disease, which in turn led to the realization that what was thought to be a rare disease is relatively common. More recently, clinical trials for the medical treatment of sclerosing cholangitis have resulted in a clearer definition of the clinical features and natural history of the disease (158,159 and 160). Finally, the other important historic development was the recognition that hepatic transplantation could salvage patients from inexorable progression of this form of liver disease, which frequently leads to biliary cirrhosis and death from hepatic complications or cholangiocarcinoma (161,162).

IMMUNOLOGIC HIGHLIGHTS

The pathognomonic feature of PSC is the characteristic inflammatory destruction of intrahepatic and extrahepatic bile ducts, which leads to progressive fibrosis, strictures, and cirrhosis. The strong association with IBD (50% to 75% of patients), particularly ulcerative colitis, suggests that overlapping immunologic mechanisms are important, including both genetic and environmental factors. No specific immunologic features of the disease can be distinguished from those of IBD, other than the presence of concurrent liver disease. Thus the immune features are similar to those of ulcerative colitis, with a high prevalence of autoantibodies, such as pANCA.

Epidemiology

GENETICS

Genetic factors have been suggested to be important. Multiple studies have shown a strong association between PSC and HLA haplotypes. Associations have been found with HLA-B8 (162a), -DR3, -DR2, and HLA-A1. A striking association with HLA-DRw52a was reported in one study (163) but has not been confirmed by others. Associations with $DRB1^*1301$, $DQA1^*0103$, and $DQB1^*0603$ also have been found. Some haplotypes, such as HLA-DR4, have been associated with aggressive disease. There have been rare reports of familial sclerosing cholangitis and ulcerative colitis (164). This seems surprising because the familial nature of associated ulcerative colitis seems more clear cut.

ENVIRONMENTAL

The prevalence of PSC has not been accurately assessed in the United States. Based on estimates of the prevalence of ulcerative colitis and of PSC associated with ulcerative colitis, the prevalence of PSC has been estimated to be between two and seven cases per 100,000 population. This estimate is similar to the estimated prevalence of PSC in Sweden of 6.3 per 100,000 population. It is widely believed that these figures underestimate the true prevalence. Some cases are not associated with IBD, and clearly some patients are asymptomatic and may have normal serum biochemical laboratory tests early in the course of the disease. It is thought that IBD has important environmental components, possibly represented in the normal bacterial flora of the gastrointestinal tract and reinforced by animal models in which disease is minimal in the germ-free state. However, no specific environmental factor has specifically been associated with PSC. Furthermore, PSC and IBD in individual patients often seem to run independent courses, suggesting that the diseases may have separate but overlapping pathophysiologic mechanisms and environmental triggers.

Clinical Features

The symptoms of sclerosing cholangitis are similar to those of other cholestatic liver diseases (Table 54.4) and include fatigue, pruritus, hyperpigmentation, xanthelasma, and jaundice (164a). Patients also may have symptoms of cholangitis with fever and abdominal pain. Symptoms of underlying IBD may be prominent, but often are mild or absent. Unlike PBC, patients are often young men. Serum AMAs are nearly always absent, and extrahepatic syndromes such as keratoconjunctivitis sicca, arthritis, and thyroid disease are rare. The disease has been found in young children with ulcerative colitis (165,166 and 167).

Etiology	Unknown
Epidemiology	Predominantly young men; most have ulcerative colitis
Genetics	Familial cases rare
Symptoms	Pruritus, fatigue
Physical findings	Often normal early; late: hepatomegaly, jaundice
Laboratory	High alkaline phosphatase and bilirubin; antimitochondrial antibodies absent; p-ANCA in association with IBD
Histologic features	Liver: fibrous obliteration of intrahepatic and extrahepatic bile ducts; rectum, colon: features of ulcerative colitis, minimal to advanced
Cholangiography	Irregular, tortuous, beaded appearance of intrahepatic or extrahepatic bile ducts
Prognosis	Highly variable; may progress to biliary cirrhosis and death
Treatment	No medical treatment proved to arrest disease; supportive: cholestyramine; antibiotics for acute cholangitis; endoscopic procedures or surgery for isolated high-grade obstruction; liver transplantation

p-ANCA, anti-neutrophil cytoplasmic antibody; IBD, inflammatory bowel disease.

TABLE 54.4. Typical Features of Idiopathic Sclerosing Cholangitis

Laboratory Abnormalities

The routine laboratory features of sclerosing cholangitis are similar to those of PBC (329), described in detail earlier. Elevation of serum IgM is not so striking as in PBC, and serum AMAs are nearly always absent. As in other cholestatic liver disease, copper accumulation may be striking in the liver, and results of laboratory tests of copper metabolism are abnormal (168). The most important laboratory test is cholangiography. Cholangiograms demonstrate variable degrees of narrowing of intrahepatic or extrahepatic bile ducts with tortuosity and areas of dilatation, leading to a beaded appearance. This is in contrast to PBC, in which the ducts appear normal until cirrhosis is prominent, in which case, there may be narrowing and irregularity of intrahepatic bile ducts.

Pathologic Findings

The liver biopsy specimen usually appears abnormal, but pathognomonic changes are often not seen. The portal tracts show expansion with edema and fibrosis and relatively modest cellular infiltration. Later, fibrous septa and finally biliary cirrhosis appear. The typical changes in the intrahepatic bile ducts are a fibrous-obliterative process in which segments of bile ducts are replaced by solid cords of connective tissue, leading to an “onion skin” appearance (Fig. 54.3). When the course is associated with bacterial cholangitis, numerous polymorphonuclear cells may be present within and around bile ducts. When extrahepatic ducts are involved, the histologic appearance shows no unique pathognomonic features, revealing only fibrosis with a relatively modest inflammatory component. It has been suggested that the nonspecific hepatobiliary lesions identified in association with IBD, previously alluded to as *pericholangitis*, are in fact part of the spectrum of sclerosing cholangitis. The finding of portal inflammation and fibrosis in association with ulcerative colitis should indicate the need for careful examination of the biliary tree by cholangiography for evidence of sclerosing cholangitis.

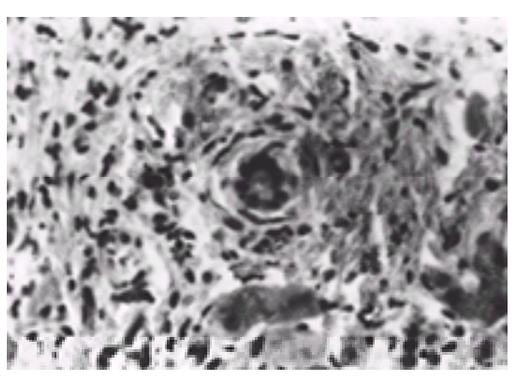

Figure 54.3. Idiopathic sclerosing cholangitis. Bile duct surrounded by lymphocytes and increased collagen.

Treatment and Prognosis

No form of medical treatment has been proved useful at retarding the progressive damage to bile ducts (169). Medical management currently is limited to alleviation of complications of the disease, such as with cholestyramine, fat-soluble vitamins, and antibiotics for episodes of acute cholangitis. Antiinflammatory drugs have not been proved to have any predictable beneficial effect, and as alluded to earlier, colectomy in patients with ulcerative colitis has not been predictably associated with a beneficial effect on the liver disease. For patients with localized areas of high-grade obstruction and symptomatic cholestasis or recurrent cholangitis, a variety of palliative surgical measures directed at the dominant area of obstruction may be useful. The only treatment now for patients with advanced liver damage due to sclerosing cholangitis is liver transplantation.

Immunopathogenesis

The etiology of sclerosing cholangitis is completely unknown. Because of the association with IBD, it has been suggested that absorption of bacteria or toxic materials from the intestine might be important in the etiology. However, sclerosing cholangitis appears to be a rare complication of IBD, and there is no obvious correlation with the extent or severity of bowel disease. Sclerosing cholangitis occurs in patients with minimal IBD, and indeed, from 25% to 50% of patients have no underlying IBD that can be identified. Furthermore, the course of the liver disease appears to be independent of the bowel disease. Patients having undergone colectomy for ulcerative colitis may have relentless progression of the liver disease. This disease may be related to an underlying disorder of fibrogenesis, because other unusual forms of fibrosis have been associated with the disease, including mediastinal fibrosis, Riedel thyroiditis, orbital pseudotumor, and retroperitoneal fibrosis (170,171 and 172).

Because the disease is rare, relatively little is known concerning the immunologic aspects. Antiasialoglycoprotein antibodies are found in some patients, but are not specific for this disease. ANCAs are found in many patients with sclerosing cholangitis and ulcerative colitis, adding further evidence that these diseases share a common pathophysiologic basis (173). Patients with PSC and ulcerative colitis may have anticolon antibodies, and there is evidence of shared cross-reactive epitopes in these two different epithelial cell lineages that could be targets of these antibodies (174). Tests for circulating immune complexes have been reported to be positive in about 70% of patients, but the nature of these circulating immune complex–like materials is unknown, and their relationship to the pathogenesis of the disease is uncertain (175). Peripheral blood lymphocytes show a higher than normal CD4/CD8 ratio in patients with sclerosing cholangitis. Phenotypes of T lymphocytes have been examined in hepatic tissues; whereas $CD8^+$ lymphocytes appear to infiltrate bile duct epithelium, CD4 lymphocytes tend to accumulate around other bile ducts (176). Using a leukocyte migration–inhibition test, it was shown that some patients with sclerosing cholangitis may have leukocyte sensitivity to protein antigen preparations derived from human bile, suggesting that cellular reactivity to biliary epithelial cell–derived antigens might play a role in the disease (177).

The occurrence of biliary cholangiocarcinoma in patients with sclerosing cholangitis suggests that the mechanisms that cause damage to bile ducts might also cause premalignant changes in the biliary epithelium, raising the possibility that the pathogenesis of sclerosing cholangitis may be related to ulcerative colitis, but with a different target epithelial cell, because ulcerative colitis is clearly associated with inflammation and dysplasia of colonic epithelial cells. Further progress in understanding the pathogenesis of ulcerative colitis might provide some future insights into the pathogenesis of sclerosing cholangitis.

55 IMMUNOLOGIC DISEASES OF THE GASTROINTESTINAL TRACT

William F. Stenson, M.D., Rodney D. Newberry, M.D. and Robin G. Lorenz, M.D., Ph.D.

MUCOSAL IMMUNITY

To understand the immunologic changes seen in inflammatory bowel disease (IBD), celiac disease, or other diseases of the gastrointestinal tract that have immune components, it is first necessary to understand normal mucosal immunity (1,2 and 3). Systemic immunity and mucosal immunity are distinct but partially overlapping systems; the two systems are interactive but in a limited way. One distinction is that the induction of peripheral immune responses by peripheral antigen does not result in significant mucosal immunity; however, induction of a mucosal immune response often results in cell-mediated and antibody responses in the systemic immune system.

The mucosal immune system is the major interface of the organism with the outside world. Both the quantity and the diversity of antigens faced by the mucosal immune system are much greater than those faced by the systemic immune system. Moreover, the mucosal immune system must adjust its response to fit the specific antigen. Most of the foreign antigens faced by the systemic immune system are pathogens, which require a vigorous immune response. In contrast, most of the antigens faced by the mucosal immune system are either from the diet or from commensal bacteria. The response of the mucosal immune system to these benign dietary and microbial antigens is to downregulate or suppress the immune response. However, the mucosal immune system is also exposed to bacterial pathogens such as *Salmonella* and *Shigella.* The mechanism by which the mucosal immune system distinguishes between bacterial pathogens, which require a vigorous immune response, and commensal bacteria, which require a suppressed immune response, is not clear. Although the response of the mucosal immune system to normal dietary and commensal bacterial antigens is suppressed, an immune response is generated to these agents nonetheless. In comparison with animals colonized with normal commensal bacteria, histologic evaluation of the small intestine in animals raised in a bacteria-free environment reveals a diminished number of macrophages and lymphocytes, shortening of the epithelial crypts, and elongation of the villi. Thus, one of the characteristics of the normal mucosal immune system is the presence of a chronic low-grade tightly controlled inflammatory response generated against dietary antigens and commensal bacteria. Moreover, this limited inflammatory response affects the turnover of epithelial cells and the architecture of the mucosa.

Parenteral exposure to an antigen results in a much less vigorous systemic immune response if the animal has first been exposed to the same antigen by the oral route (4). This process, termed *oral tolerance,* is related to the suppressed intestinal immune response to elements of the diet and commensal bacteria. The mechanism of oral tolerance is not well understood, but it appears to be T-cell mediated. Clonal deletion of T cells capable of responding to a specific antigen and the generation of regulatory T cells producing downregulatory cytokines such as interleukin-10 (IL-10) and transforming growth factor-b (TGF-b) have been invoked as mechanisms for oral tolerance. Feeding autoantigens has been effective in diminishing the systemic immune response in animal models of autoimmune diseases; whether similar manipulation of oral tolerance will be effective in treating autoimmune diseases in human patients is not known.

The mucosal immune system has a distinct architecture (Fig. 55.1) (1,2). One component of this architecture is the epithelial layer, which stands as an effective barrier to luminal antigens and separates them from macrophages and lymphocytes in the lamina propria just below the epithelium. The lamina propria contains immunoglobulin A (IgA) plasma cells along with large numbers of T cells, B cells, and macrophages. The cell-surface antigens expressed on the lymphocytes of the lamina propria suggest that they are activated. Another component of the mucosal immune system is the Peyer's patch; this structure includes a layer of specialized epithelial cells, M cells, situated immediately above a lymphoid follicle containing T cells, B cells, and macrophages. The immune cells of the Peyer's patch are activated, but less so than those in the lamina propria. The lymphoid follicles have germinal centers with follicular-dendritic cell clusters that are involved in B-cell maturation. M cells take up and transport luminal antigens including proteins, viruses, and bacteria. Some luminal pathogens such as *Salmonella typhimurium* and reoviruses use M cells as a portal of entry. Antigens that pass through the M cell intact are taken up by macrophages and are carried into the underlying lymphoid follicle, where an active immune response can be generated. A third architectural component of the mucosal immune system is the intraepithelial lymphocytes located between the epithelial cells in the small intestine and colon. These are predominately $CD8aa^+$, $TCR\text{-}gd^+$ lymphocytes that express a variety of activation antigens and are $CD45RO^+$ (memory cells). The adherence of intraepithelial lymphocytes to epithelial cells is mediated by an integrin expressed on intraepithelial lymphocytes, $a_E b_7$, whose ligand, E-cadhedrin, is expressed on epithelial cells (5). The function of intraepithelial lymphocytes is not well understood.

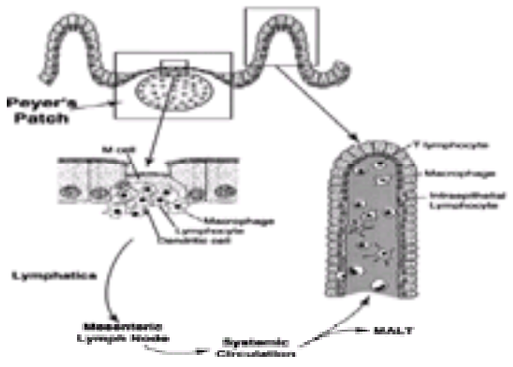

Figure 55.1. The architecture of the mucosal immune system. In Peyer patches, antigens cross the M cells, are taken up by macrophages and dendritic cells, and are presented to lymphocytes. Activated lymphocytes leave Peyer's patches through lymphatics and travel to mesenteric lymph nodes and then through the thoracic duct to enter the systemic circulation. Activated lymphocytes are distributed back to the intestine, where they establish themselves in the lamina propria; they are also distributed to other components of mucosa-associated lymphoid tissue including the respiratory tract, the genitourinary tract, the lactating breast, the lacrimal glands, and the salivary glands. (Adapted from Dean PA, Elson CD. Immunology. In: Nichols RJ, Dozois RR, eds. *Surgery of the colon and rectum.* New York: Churchill Livingstone, 1997:57, with permission.)

An important distinction between the mucosal immune system and the systemic immune system is the prominence of IgA in the mucosal immune system (6). IgG is the most abundant Ig in the serum, whereas the IgA is the most abundant in the intestinal mucosa. IgA is produced by plasma cells in the lamina propria. IgA dimers are

taken up on the basolateral surface of enterocytes and are coated with a glycol protein, secretory component, and are excreted out the apical surface of the enterocyte into the lumen. In the intestinal lumen, IgA binds bacterial and viral surface molecules and mediates their binding to the epithelium. IgA also agglutinates bacteria and viruses, trapping the complexes in the mucus barrier and allowing them to be passed out in the stool.

Lymphocytes in the mucosal immune system have a distinctive trafficking pattern that relates closely to the function of the system (7). Lymphocytes activated in Peyer's patches leave these structures through lymphatics that drain by mesenteric lymph nodes and from there travel through the thoracic duct and enter the systemic circulation (Fig. 55.1). These activated lymphocytes circulate widely through the body, but they “home” back to the intestine and other organs of the mucosa-associated lymphoid tissue (MALT), including the respiratory tract, the genitourinary tract, the salivary glands, the lacrimal glands, and the lactating breast. Homing is the result of interactions of adhesion molecules on the circulating lymphocytes and the endothelial cells of these organs. In the intestine, homing is a product of the interaction between the a_4b_7 integrin expressed on lymphocytes and mucosal addressin-cell adhesion molecule-1 (MAdCAM-1) on endothelial cells. This pattern of lymphocyte trafficking allows activation of the immune response to an antigen in one mucosal organ to result in an immune response to the same antigen in other mucosal organs.

The intestinal immune system was designed to combat infections with enteric pathogens (3). Activation of the intestinal immune system by exposure to enteric pathogens increases intestinal motility and salt and water secretion. In turn, increased motility and secretion cause the intestine to flush the offending pathogens out of the organism. Increased motility and secretion are mediated by inflammatory mediators, including prostaglandin E_2 (PGE_2), produced by activated macrophages and neutrophils. The evolutionary pressure of enteric infections results in the intestinal responses of increased motility and secretion. These responses have become the stereotyped responses of the intestine to any immune-mediated injury. As a consequence, patients with IBD or celiac disease develop increased motility and secretion and, as a result, diarrhea in response to intestinal immune activation, even though they have no pathogens to eliminate.

GASTRITIS

The stomach has three regions: the fundus and body, both of which contain acid-secreting gastric parietal cells and pepsinogen-secreting zymogenic cells; and the antrum, which contains gastrin-producing cells. In contrast to the small and large intestine, B cells, plasma cells, and granulocytes are absent from the normal stomach, and there is only a small population of T cells (CD8>CD4), macrophages, and Langerhans cells. Immune infiltration into the stomach results in two different types of *chronic atrophic gastritis,* based on whether the lesion affects the gastric antrum (8). *Autoimmune atrophic gastritis* (previously known as type A gastritis) is a severe, progressive, atrophic gastritis that shows sparing of the antral mucosa, hyperplasia of gastrin-secreting cells, and autoantibodies to parietal cells and intrinsic factor. Autoimmune atrophic gastritis is the antecedent to pernicious anemia, which is characterized by decreased vitamin B_{12} absorption. *Multifocal atrophic gastritis* (previously known as type B or AB) can present as superficial or atrophic gastritis and is associated with antral involvement, moderate impairment of gastrin secretion, and colonization with *Helicobacter pylori. H. pylori* infection-related gastritis has a strong link with duodenal ulcers and gastric tumors, both carcinomas and lymphomas (9,10,11 and 12). Gastric biopsies from patients with either type of chronic gastritis show a mononuclear cellular infiltrate in the submucosa, which extends into the lamina propria between gastric glands. This infiltrate includes plasma cells, T cells, and B cells and is accompanied by replacement of parietal and zymogenic cells with cells resembling intestinal cells (intestinal metaplasia). Gastritis associated with *H. pylori* infection also has an “active” component with polymorphonuclear leukocytes seen in the infiltrate (13).

Pernicious Anemia

Pernicious anemia is the most common cause of vitamin B_{12} deficiency. About 2% of people who are more than 60 years old have undiagnosed pernicious anemia, which is the end stage of 20 to 30 years of chronic autoimmune atrophic gastritis. The first successful treatment of this anemia was by eating 1 lb of cooked liver daily, and this suggested the lack of an “extrinsic factor” (later identified as vitamin B_{12}) and the discovery of an “intrinsic factor” in gastric secretions. The “discoveries concerning liver therapy in causes of anemia” resulted in the Nobel Prize in Physiology or Medicine in 1934 for George Whipple, George Minot, and William Murphy (14).

This disease is characterized by the presence of autoantibodies to intrinsic factor and parietal cells (15). The major molecular target of these antibodies in human disease is gastric hydrogen, potassium adenosine triphosphate (H^+, K^+-ATPase), the enzyme responsible for acidification of the gastric lumen. Data from small rodent models suggest that these autoantibodies are not pathogenic. Mouse models using either neonatal thymectomy or immunization with mouse H^+, K^+-ATPase demonstrate that gastritis is mediated by CD4 T cells that react with a peptide of the b subunit of H^+, K^+-ATPase (16,17 and 18). The autoreactive T cells are thought to be controlled under normal conditions by a $CD4^+$ $CD25^+$ immunoregulatory cell (19).

The cellular infiltrate in murine autoimmune gastritis results in increased major histocompatibility complex class II (MHC II), Fas, and intercellular adhesion molecule-1 (ICAM-1) expression on gastric epithelial cells and increased expression of IL-2, IL-3, IL-5, IL-6, and IL-10, interferon-g (IFN-g), tumor necrosis factor-a (TNF-a), and granulocyte-macrophage colony-stimulating factor, but not IL-4 (20). Additionally, gastric epithelial cell hyperplasia is seen (21). Neutralizing antibodies to IFN-g reduce disease incidence in murine autoimmune gastritis (22). Based on these findings, the steps leading to the histologic lesion of autoimmune gastritis are thought to be: (a) interaction between parietal cells and $CD4^+$ effector cells; (b) increased expression of MHC II molecules, ICAM-1 adhesion molecules, and Fas antigen on gastric epithelial cells; (c) target cell lysis of parietal cells through Fas-FasL interactions resulting in a loss of parietal cells; and (d) disruption of the normal gastric epithelial cell developmental pathway, resulting in loss of zymogenic cells and amplification of immature epithelial cell types.

Helicobacter pylori Infection

In 1985, *H. pylori* was conclusively shown to be involved in acute gastritis (23). All patients infected with *H. pylori* develop a chronic inflammatory infiltrate, which primarily affects the antral region of the stomach; however, most infected patients are asymptomatic. *H. pylori* is a major factor in the pathogenesis of duodenal and gastric ulcer disease, gastric adenocarcinoma, and MALT lymphoma, with 10% to 20% of infections progressing to serious clinical disease (24). Regardless of disease outcome, all patients mount a vigorous, but ineffective systemic immune response. Therefore, it is important to understand the local immune response and its involvement in disease (24,25). Indeed, studies in mouse models of infection have shown that the cellular immune response is essential for the gastric disease that develops after *Helicobacter* infection (26).

Bacterial virulence factors play a major role in adaptation to the hostile gastric milieu and in the development of gastric disease (9,10,27). Three groups of factors have now been identified: colonization factors, disease-inducing factors, and factors promoting *H. pylori* persistence (13). As the complete genomic sequences of several *H. pylori* strains have become available, rapid progress should ensue on the precise identification of many bacterial virulence factors (28,29 and 30). On infection, *Helicobacter* places itself on or near gastric epithelial cells. Epidemiologic studies have shown an increased incidence of ulcer disease in persons with blood group O. This blood group is associated with $Lewis^b$ blood group antigens (Le^b), which are receptors on gastric mucous cells for *H. pylori.* The ability of bacteria to attach to the gastric epithelium results in a more severe inflammatory response and increased gastric destruction in a mouse model of infection (31).

Innate Immunity

Once the *Helicobacter* has established colonization, it elaborates additional gene products, which interact with the host and induce inflammation. Products of the urease gene and the *cag* pathogenicity island (PAI) are important in direct epithelial destruction and in triggering the host immune response (Fig. 55.2, step 1) (32,33). Strains of *H. pylori* with the *cag* PAI are associated with more severe ulcer disease and preferentially upregulate the expression of IL-8 by gastric epithelial cells 32. The *picB* gene, which is upstream of the *cagA* gene, is essential for induction of IL-8 from gastric epithelial cells *in vitro* (34). This induction of IL-8 is mediated by nuclear factor-kB (NF-kB) in gastric epithelial cells (35). The finding that *H. pylori* is a potent activator of NF-kB has important implications, because other genes important in the immune response (TNF-a, IL-1, IL-6, and ICAM-1) also respond to NF-kB (36). IL-8, in addition to other chemotactic factors released by the bacteria, initiates an influx of neutrophils and activated macrophages (Fig. 55.2, steps 1 and 2) (37). The importance of factors such as lipopolysaccharide (LPS) of *H. pylori* in the modulation of gastritis has been demonstrated in animal models (38).

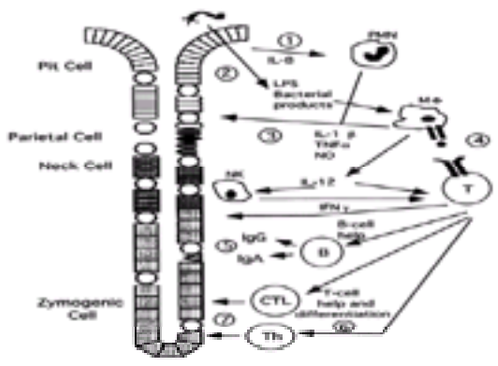

Figure 55.2. Immune-mediated damage in gastric disease. After colonization, *Helicobacter* signals gastric epithelial cells to produce interleukin-8, which, in addition to other chemotactic factors released by the bacteria, initiates an influx of neutrophils and activated macrophages (steps 1 and 2). These recruited mononuclear cells secrete the proinflammatory cytokines and immunomodulatory messenger molecules (step 3). These mediators can directly damage the gastric epithelium, as well as enhance the cytotoxic activity of natural killer cells, support cytotoxic T-lymphocyte generation, and promote the development of T-helper cell (Th1) responses (step 4). The subsequent T-cell activation can lead to production of cytokines, which result in increased T- and B-cell help and differentiation and direct damage to the gastric epithelium (steps 5 to 7).

The recruited mononuclear cells secrete the proinflammatory cytokines TNF-a and IL-1b, and the immunomodulatory messenger molecule nitric oxide (NO) (Fig. 55.2, step 3) (39,40 and 41). These factors not only are important mediators of the subsequent inflammation, but also may play a role in direct epithelial damage because TNF-a and NO are associated with tissue injury. In addition, TNF-a and IL-1b upregulate gastric mucosal Fas antigen expression, which could prime gastric mucosal cells to undergo apoptosis (42). Polymorphisms in both IL-1b and TNF-a predispose to more severe clinical disease after *H. pylori* infection (43,44). One potential explanation is that IL-1b stimulates gastric cell proliferation and directly inhibits gastrin-stimulated histamine secretion, leading to decreased gastric acid secretion (45). IL-12, a cytokine produced by activated macrophages, induces the expression of IFN-g and other cytokines in T and natural killer (NK) cells. In addition, IL-12 enhances the cytotoxic activity of NK cells, supports cytotoxic T lymphocyte (CTL) generation, and promotes the development of naive T cells into T-helper (Th)-1 cells (in conjunction with IFN-g).

Adaptive Immunity

In chronic immune responses, $CD4^+$ Th cells can be divided into two major subsets, termed Th1 and Th2, based on their patterns of cytokine production. Th1 cells predominantly produce IFN-g and IL-2 and elicit delayed-type hypersensitivity. Th2 cells produce IL-4, IL-5, and IL-10 and provide help for some B-cell responses. Differentiation into the Th1 or Th2 phenotype is directed by the cytokines present at the time of specific antigen activation, so IL-12 promotes Th1 development and IL-4 promotes Th2 development. The polarized development of these subsets determines the clinical outcome of many pathologic immune responses, including autoimmune and infectious diseases (46,47). Growing evidence indicates that clinically evident human infection by *H. pylori* induces a predominant $CD4^+$ Th1 response, with the proinflammatory cytokines IFN-g and IL-12 seen, but not the regulatory cytokine IL-4 (Fig. 55.2, step 4) (41,48,49 and 50). These data are consistent with the demonstration of a selective expansion of $CD4^+$ T cells in the gastric lamina propria of patients with *Helicobacter*-associated gastritis (51). This propensity toward a Th1, cell-mediated hypersensitivity type of response, instead of a Th2, humoral-mediated mucosal protection type of response, could combine with other host factors to contribute to epithelial damage and disease.

This theory is supported by results from mouse models of infection, which demonstrate that C57BL/6 mice (which produce a predominant Th1 response) have severe chronic active gastritis, whereas BALB/c mice (predominant Th2 response in other infectious models) exhibit only mild gastritis (52,53). The role of Th1 cells in infected and immunized C57BL/6 mice was addressed by *in vivo* neutralization of IFN-g (54). These studies implicated IFN-g in both protection from *H. pylori* infection and the inflammation induced by this infection (55). In contrast, immunization or infection of IL-4 (Th2 cytokine)–deficient mice (C57BL/6 x 129/Sv) resulted in the inability to protect against *H. felis* infection and a higher load of infectious organisms (56).

The presence of $CD4^+$ Th1 cells that produce or induce the destructive cytokines IFN-g and TNF-a has clearly been shown (41,49). These cytokines could directly contribute to epithelial cell death (Fig. 55.2, steps 3 and 4). In addition, Th1 cells could mediate apoptosis of epithelial cells through Fas-Fas Ligand (FasL) interactions or indirectly through T-cell help to epithelial cell-reactive $CD8^+$ CTLs (Fig. 55.2, step 7). The possibility has been raised that the antigen specificity of $CD4^+$ Th1 clones isolated from patients may play a role in the pathogenesis of the disease. The antigen-recognition repertoire of T-cell clones isolated from a group of six patients with peptic ulcer disease was studied (49,57). The major known *H. pylori* antigens recognized were cagA, vacA, and urease. Because two of these proteins (vacA and urease) have significant homology to subunits of the gastric H^+, K^+-ATPase (58), investigators have postulated that this T-cell response results in autoreactive T-cell clones. In addition, several other *H. pylori*–specific proteins have considerable sequence homology to gastric-specific proteins (59). Consequently, at least some components of the pathogenesis of *Helicobacter* infection must now be considered to result from antigenic or molecular mimicry, which results in an autoimmune attack against specific gastric components. This hypothesis is supported by studies in the *H. felis* mouse model, because the main site of disease (body of the stomach) is away from the area of colonization (antral region) (26,38).

For many years, the classification of human gastritis into two separate groups (autoimmune and multifocal atrophic) has provided a useful framework for investigation into the etiology and pathogenesis of human gastric diseases (8). One of the major differences between these two types of gastritis is the presence or absence of clinically measurable serum autoantibodies. This distinction has been challenged by multiple reports of the presence of autoantibodies in patients with *H. pylori*–induced gastritis (60,61,62 and 63). The first reports of the presence of autoantibodies in *H. pylori*–induced chronic active gastritis were of antibodies that recognized gastrin-producing cells in the gastric antrum (61). This observation was not followed-up for more than 10 years; however, it has become clear that infection with *H. pylori* can lead to the production of anti-*H. pylori* antibodies that cross-react with human gastric mucosa (60,63). That these autoantibodies have the potential to play a crucial role in the pathogenesis of gastric diseases was clearly shown by the experiment of Negrini et al., in which a hybridoma secreting a *H. pylori*–reactive monoclonal antibody caused gastric abnormalities similar to gastritis (Fig. 55.2, step 5) (60). One component of this antigenic mimicry is epitopes contained in the Lewis blood group antigen (64), which are important for adherence of *H. pylori* to surface epithelial cells in the gastric epithelium (31). In addition, Lewis epitopes are present in the b chain of gastric H^+, K^+-ATPase and the LPSs of *H. pylori* (64).

Mucosa-Associated Lymphoid Tissue Lymphomas

H. pylori infection is associated with the development of gastric lymphoid follicles (12). These structures are similar to intestinal Peyer patches, with B cells making up the majority of the lymphoid follicle. Primary non-Hodgkin lymphoma of the stomach accounts for 10% of lymphomas and is the most common extranodal form of non-Hodgkin lymphoma (65). Most of these tumors are diffuse, large-cell lymphomas of the B-cell lineage. Low-grade primary gastric lymphomas recapitulate the structure of Peyer patches (MALT), rather than that of lymph nodes (66). These low-grade MALT lymphomas can evolve into high-grade primary gastric lymphomas, which have classic associations with *p53* inactivation and deletions of *p16* (66). However, some low-grade MALT lymphomas have an additional unique genetic profile, as compared with nodal lymphomas, in that there is a marked increase in the frequency of trisomy 3.

MALT lymphomas have a favorable prognosis and present at an early clinical stage: stage IE or IIE using the Ann Arbor staging system (12). Low-grade MALT lymphomas respond to therapy and have approximately a 78% to 90% survival rate at 10 years (66). This favorable behavior is thought to result from the influence of antigen on tumor growth. Lymphoid tissue accumulates in the gastric mucosa almost exclusively as the consequence of *H. pylori* infection (66); this finding has led to the suggestion that *H. pylori* provides the antigenic stimulus for the growth of gastric MALT lymphoma. Clinical experience demonstrating that 50% to 70% of low-grade gastric MALT lymphomas can be eradicated by antibiotic treatment strengthens this hypothesis (67). However, as tumors evolve into late-stage high-grade lymphomas, the effect of antibiotic treatment is lost. A second line of experimentation has also implicated *Helicobacter* antigens in driving the tumor formation. These experiments have shown that MALT lymphoma B-cell proliferation depends on *H. pylori*–specific T cells and their products, rather than on the bacteria themselves (48,68).

Vaccination

Eradication of chronic *H. pylori* infection with antibiotics markedly alters the natural history of gastroduodenal diseases and reduces clinical symptoms. However, eradication is currently clinically recommended only for patients with peptic ulcer (69,70). Because of the rapid emergence of resistant strains of *H. pylori,* there has been a significant interest in developing a prophylactic or therapeutic vaccine (71). In animal models, a vaccine of crude or purified *H. pylori* antigens can induce a protective immune response against infection with *Helicobacter* species (71). Unfortunately, immunized animals develop severe gastritis when challenged with *Helicobacter* (postimmunization gastritis) (72,73). This gastritis appears to be a prerequisite for protection and underlines the necessity of understanding immune and inflammatory responses in the gastric mucosa. This knowledge will be required for defining immunization regimens or antigens able to elicit the appropriate protective immune response without inducing inflammation.

CELIAC DISEASE

Celiac disease, also known as gluten-sensitive enteropathy, celiac sprue, or idiopathic sprue, is an antigen-driven enteropathy of the small intestine, resulting from an inappropriate immune response to dietary gliadin, a component of wheat proteins. The clinical manifestations of celiac disease are varied in character and severity, with most symptoms attributable to malabsorption resulting from the loss of absorptive capacity of the small intestinal mucosa. As a result of advances in elucidating its pathogenesis, celiac disease is one of the best understood immunologically mediated enteropathies, and it could be considered a model for understanding other T-cell mediated enteropathies driven by luminal antigens.

Clinical Features

The incidence of celiac disease varies dramatically throughout the world, ranging from absence in persons of African and Asian descent to a peak incidence of approximately 0.3% in persons of northern European descent (74). This variance is explained predominantly by the strong genetic linkage of celiac disease with specific MHC II complexes that are not distributed uniformly across all ethnic backgrounds. The clinical manifestations of celiac disease are also variable, with many, if not most, affected persons having mild or no symptoms, thus giving rise to the impression that the true incidence of celiac disease may be much higher than currently appreciated. This impression is supported by studies documenting an increased incidence of antiendomysial antibodies in asymptomatic blood donors from Europe and the United States (75,76 and 77).

The predominant symptoms of celiac disease, when present, are attributable to malabsorption, and they include diarrhea, flatulence, abdominal cramping, abdominal bloating, and weight loss. Patients with extensive involvement of the small intestine may have symptoms attributable to deficiencies in folate, iron, calcium, and vitamins A, D, E, K, and B_{12}, resulting from malabsorption. These deficiencies may lead to myriad extraintestinal manifestations of celiac disease, as outlined in a Table 55.1.

Affected Organ System	Manifestation	Cause
Skeletal	Osteopenia	Malabsorption of calcium and vitamin D
	Pathologic fractures	Osteopenia
	Osteoarthropathy	Unknown
Hematopoietic	Anemia	Iron, folate, vitamin B_{12}, or pyridoxine deficiency
	Hemorrhage	Hypoprothrombinemia, thrombocytopenia, folate deficiency
Nervous	Peripheral neuropathy	Thiamine and vitamin B_{12} deficiency
	Demyelinating central nervous system lesions	Unknown
	Seizures	Unknown
Endocrine	Secondary hyperparathyroidism	Calcium and vitamin D deficiency
	Amenorrhea, infertility, impotence	Malnutrition, ? hypothalamic-pituitary dysfunction
Muscular	Atrophy	Malnutrition
	Tetany	Calcium, vitamin D, and magnesium malabsorption
	Weakness	Atrophy and hypokalemia
Integument	Follicular hyperkeratosis and dermatitis	Vitamin A and vitamin B complex deficiency
	Petechiae and ecchymoses	Hypoprothrombinemia, thrombocytopenia
	Edema	Hypoproteinemia
	Dermatitis herpetiformis	Unknown

TABLE 55.1. Extraintestinal Manifestations of Celiac Disease

Of particular note is the association of celiac disease with dermatitis herpetiformis, IgA deficiency, autoimmune disorders, and malignant disease. Dermatitis herpetiformis is a characteristic pruritic, vesicular skin lesion involving the extensor surfaces of the extremities, trunk, buttocks, scalp, and neck. The skin lesion of dermatitis herpetiformis associated with celiac disease is composed of a subepidermal collection of acute inflammatory cells and fluid with characteristic granular IgA and complement deposits at the dermal-epidermal junction. This skin lesion, like the small intestinal lesion of celiac disease, responds to the withdrawal of gluten from the diet. IgA deficiency and autoimmune disorders including type 1 diabetes and autoimmune thyroid disease are found with increased frequency in patients with celiac disease. The relevance of these associations to the pathogenesis of these diseases is not known. However, the increased occurrence of diabetes and celiac disease could be explained by the increased frequency of persons with human leukocyte antigen (HLA) haplotypes resulting in a susceptibility for diabetes in patients with celiac disease, rather than a common disease pathogenesis. Perhaps most concerning for affected patients is the association of celiac disease with an increased incidence of malignant disease, and in particular malignant diseases involving the gastrointestinal tract. Patients with celiac disease are estimated to be at a tenfold increased risk for the development of any gastrointestinal tract malignant disease and at a many-fold increased risk for developing an enteropathy-associated T-cell lymphoma (78,79,80 and 81). This risk may be decreased by lifelong adherence to a gluten-free diet and thus forms the basis for this recommendation. The complications of celiac disease are mainly limited to the development of malignant disease, as described earlier, and the development of symptoms refractory to withdrawal of gluten from the diet.

Diagnosis

The laboratory abnormalities associated with celiac disease vary with the severity of the small intestinal mucosal lesion and are generally attributable to malabsorption. These findings can be seen in many malabsorptive processes and are not specific to celiac disease. A potential exception to this observation is the presence of antigliadin and antiendomysial antibodies in the serum of patients with celiac disease. Serum IgA antigliadin antibodies have a sensitivity of 80% to 90% for the diagnosis of celiac disease; however, the utility of this test is limited by its low specificity for this diagnosis. Conversely, the presence of IgA antiendomysial antibodies in patients with presentations consistent with celiac disease has a specificity and sensitivity of approximately 90% for this diagnosis (82,83 and 84). The utility of antiendomysial antibody titers is limited by the expense of the test and the difficulty of standardization of testing among laboratories. The discovery that most, if not all, antiendomysial antibodies are directed against tissue transglutaminase (tTG) allowed for the development of a relatively inexpensive, quantitative assay to measure anti-tTG antibody titers (85). This assay is expected to share the relatively high sensitivity and specificity of the more traditional antiendomysial antibody titers. At present, establishing the diagnosis of celiac disease relies on small intestinal biopsy; however, anti-tTG antibody titers may have a role in screening susceptible populations and in following patient responses.

The diagnosis of celiac disease is established by demonstration of the characteristic histopathologic lesion on examination of small intestinal biopsies in patients with the appropriate clinical presentation, in concert with resolution of symptoms on a gluten-free diet. The histopathologic lesion seen in celiac disease, villous atrophy, is characterized by blunting of the small intestinal villi in association with crypt hyperplasia and expansion of the lamina propria mononuclear cells (Fig. 55.3). This lesion is characteristically located in the distal duodenum and proximal jejunum and is believed to decrease absorptive surface area in the small intestine and to result in malabsorption, as described earlier. The lesion does not affect the submucosa, muscularis, or serosa, and it is not associated with ulcers or granulomas. These histologic changes can be patchy, with intervening areas of normal mucosa, thus necessitating multiple small intestinal biopsies to rule out the diagnosis of celiac disease with confidence (86).

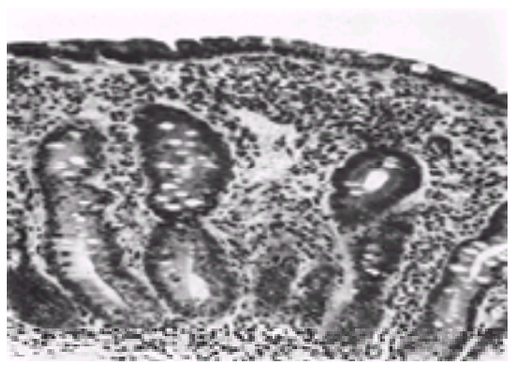

Figure 55.3. Light photomicrograph of a small intestinal biopsy from a patient with celiac disease. The biopsy shows the characteristic lesion of celiac disease: blunted villi, epithelial cell crypt hyperplasia, and expansion of the lamina propria with mononuclear cells. These changes result in a loss of absorptive surface area in the small intestine and give rise to malabsorption.

Therapy

Therapy for celiac disease, although conceptually simple, represents a difficult task with significant social and financial burdens. Within a few weeks of adherence to a gluten-free diet, the patient affected with celiac disease should note a diminution of symptoms. An exception to this rule is the rash of dermatitis herpetiformis, which resolves slowly on a gluten-free diet and is therefore treated with dapsone in appropriate patients. Patients who fail to respond as anticipated should have their dietary history reviewed meticulously, because incomplete removal of gluten is the most common cause of treatment failure. In patients who fail to respond despite strict adherence to a gluten-free diet, alternative diagnoses should be considered, as well as the possibility of associated diseases that are not responsive to a gluten-free diet such as refractory sprue, collagenous colitis, or enteropathy-associated T-cell lymphoma. Some patients with refractory sprue respond to corticosteroids or other

immunosuppressive agents; however, these should be employed only after other potential diagnoses have been investigated.

Mechanism of Disease

Celiac disease was first described in children in 1888 (87), and it was reported in adults in 1932 (88). A major advance in understanding the pathogenesis of this disease occurred in the 1950s, when it was demonstrated that dietary wheat was harmful to children and adults with celiac disease (89). Subsequently, the harmful portion of dietary wheat was shown to be the water-insoluble portion of wheat protein or gluten (90). The component of gluten playing a role in the pathogenesis of celiac disease was identified as the alcohol-soluble portion of wheat gluten, or gliadin, a complex mixture of glutamine- and proline-rich polypeptides (91). Initially, the relevant pathophysiologic mechanism of celiac disease was believed to involve the “susceptible” mucosa that was postulated to arise as a result of an intestinal enzyme deficiency or as a result of a defect in mucosal permeability. As our understanding of celiac disease has progressed, the concept of the “susceptible” mucosa has lost favor. Current evidence suggests that celiac disease is predominantly an immunologically mediated disorder involving an inappropriate T-cell mediated immune response to dietary gliadin.

The initial clues to understanding the immunologic mechanism of celiac disease arose from genetic studies documenting a concordance of celiac disease and specific HLA antigens (92,93). Follow-up to these observations revealed that approximately 95% of patients with celiac disease express the MHC II complex HLA-DQ2. In most persons, the HLA-DQ2 complex is either encoded in *cis* by alleles DQA1*0501 and DQB1*0201, in patients with the DR3-DQ2 haplotype (94), or in *trans* by alleles DQA1*0501 and DQB1*0202, in patients with the DR5-DQ7/DR7-DQ2 haplotype. Alleles DQB1*0201 and DQB1*0202 differ at one amino acid and are believed to be functionally equivalent. Most patients with celiac disease lacking the HLA-DQ2 complex express the HLA-DQ8 complex encoded by alleles DQA1*0301 and DQB1*0302 (95,96). The association of celiac disease and these MHC II complexes is so strong that most patients with celiac disease express either HLA-DQ2 or HLA-DQ8. Among the primary functions of MHC II are thymic selection of $CD4^+$ T lymphocytes and presentation of antigen to $CD4^+$ T lymphocytes in the peripheral immune system. Therefore, the strong genetic linkage of specific MHC II complexes with the requirement for the exposure to gliadin implied a role for T-lymphocyte responses specific for gliadin as a mechanism of disease.

Further advances in the understanding of celiac disease were facilitated by the development of techniques allowing *in vitro* assays of intestinal biopsies from patients with celiac disease. Using these assays, investigators showed that small intestinal biopsy tissue from patients with celiac disease that was exposed to gluten in culture produced a proinflammatory cytokine response dominated by the production of IFN-g (97). Further studies documented that inhibition of T-cell activation in this *in vitro* system could prevent the production of IFN-g and antiendomysial antibodies by small intestinal biopsies from patients with celiac disease on exposure to gliadin (98). In further support of these findings, $CD4^+$ T lymphocytes bearing T-cell receptors (TCRs) specific for a naturally occurring peptide of gliadin in association with HLA-DQ2 were cloned from the intestine of patients with celiac disease, but not from control populations (99).

The understanding of celiac disease was further advanced by the demonstration that most antiendomysial antibodies from patients with celiac disease are directed against the self-protein tTG (85). The role of antibodies directed against tTG in causing celiac disease is unclear; however, tTG may play a role in augmenting the immune response to gliadin. tTG has the capacity to deamidate neutral charged glutamines, converting them to negatively charged glutamate residues. Deamidation of gliadin peptides allows them to bind HLA DQ-2 with increased affinity and more effectively to drive an immune response mediated by small intestinal T cells in patients with celiac disease (100). In addition, tTG may generate novel antigenic epitopes by cross-linking gliadin peptides with self-proteins and may potentially initiate an autoimmune response (101). This work has been extended to identify the immunodominant tTG-modified gliadin epitopes predominantly responsible for driving the inappropriate T-cell responses in some patients with celiac disease (102,103).

Taken together, this body of work suggests the following model for the pathogenesis of celiac disease (Fig. 55.4). In persons expressing the specific MHC II complexes DQ2 and DQ8 along with other as yet undefined susceptibility factors, small amounts of dietary gliadin cross the epithelial cell layer and initiate an immune response. The gliadin peptides may undergo deamidation by tTG present in the intestinal mucosa, and cross-linking of these peptides to other nonself-proteins and self-proteins including tTG. These peptides are taken up by antigen-presenting cells and are processed and presented in association with MHC II complexes DQ2 and DQ8, notably the deamidated gliadin peptides bind DQ2 with increased affinity; the result is more efficient intestinal T-cell stimulation. $CD4^+$ T lymphocytes specific for these gliadin peptides in association with MHC II are then stimulated by TCR ligation and undergo proliferation, clonal expansion, and cytokine production. T-cell activation and cytokine production result in a cascade of yet undescribed downstream events, damaging the mucosa and resulting in the characteristic pathologic lesion of celiac disease: villous blunting, crypt hyperplasia, and lamina propria expansion. Studies have shown that most antiendomysial antibodies produced in patients with celiac disease are specific for tTG, and investigators have proposed that this occurs because of cross-linking of gliadin to tTG that eventually results in the production of antibodies directed toward tTG. The requirement for anti-tTG antibodies or T-cell responses specific for self-protein in the development of celiac disease remains to be proven.

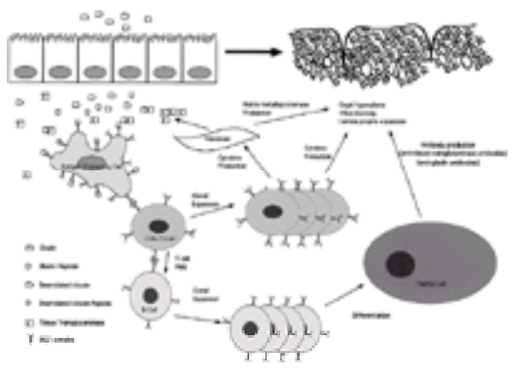

Figure 55.4. Immunologic mechanism for the pathogenesis of celiac disease. In susceptible persons expressing the HLA-DQ2 complex, small amounts of gliadin in an immunogenic form traverse the intestinal epithelium after the ingestion of dietary wheat products. Tissue transglutaminase present in the mucosa may deamidate gliadin, and/or crosslink gliadin with other proteins, including tissue transglutaminase. Gliadin, deamidated gliadin, and gliadin linked to other proteins may be taken up by professional antigen-presenting cells, processed, and presented to $CD4^+$ T cells in association with major histocompatibility complex class II (HLA-DQ2). Notably gliadin peptides bind HLA-DQ2 with increased affinity and have been shown to stimulate intestinal T cells from patients with celiac disease more efficiently. Gliadin-specific T cells proliferate, expand, and produce cytokines that can facilitate B-cell proliferation and differentiation to plasma cells. Activated T cells can further induce tissue transglutaminase production by fibroblasts; the result is further deamidation of gliadin on dietary wheat ingestion. B cells with B-cell receptors specific for gliadin cross-linked to other proteins, including self-proteins, may be preferentially expanded by presenting these antigens to T cells, and subsequently differentiate into plasma cells producing antibodies directed against self-proteins such as tissue transglutaminase. This continual immune activation results in yet undefined downstream events leading to mucosal damage and the characteristic lesion consisting of villous blunting, crypt hyperplasia, and lamina propria expansion.

Despite the major advances in our understanding of the pathogenesis of celiac disease, many questions remain, including the role of autoimmune responses in the development of celiac disease, the relevant responses downstream of T-cell activation resulting in the pathogenesis of celiac disease, and the reason most persons expressing MHC complexes DQ2 and DQ8 do not develop celiac disease. At present, celiac disease represents one of the best understood immunologically mediated enteropathies, and it may suggest a framework to understand other immunologically mediated diseases in the intestine.

INFLAMMATORY BOWEL DISEASE

IBD includes *ulcerative colitis* and *Crohn's disease,* which are chronic inflammatory diseases of the gastrointestinal tract (104). They are diagnosed by the appearance of a set of clinical, endoscopic, and histologic characteristics. The inflammatory response in ulcerative colitis is largely confined to the mucosa and submucosa, but in Crohn's disease, inflammation extends through the intestinal wall from mucosa to serosa. Ulcerative colitis is confined to the colon, whereas Crohn's disease has the potential to involve the patient's entire gastrointestinal tract, even though only a small segment is involved initially. Despite these differences in distribution, no single finding is absolutely diagnostic of one disease over the other. Moreover, there is a group of patients whose clinical picture falls between the two diseases; these patients are said to have indeterminate colitis.

Genetics and Environmental Factors

The pathogenesis of IBD involves a complex set of interactions among susceptibility genes, the environment, and the immune system (105). The most important risk factor for IBD is a family history; approximately 15% of patients with IBD have affected first-degree relatives, and the incidence among first-degree relatives is 30 to 100 times that of the general population. The best estimate of the lifetime risk of developing IBD among first-degree relatives of affected persons is 3% to 9%. Concordance among monozygotic twins is high, especially in Crohn's disease. Susceptibility to IBD does not follow any simple mendelian mode of inheritance. Although no specific

genetic abnormalities have been demonstrated to predispose to the development of IBD, the available data suggest oligogenic inheritance; that is, more than one gene may predispose to the development of IBD. Moreover, both ulcerative colitis and Crohn's disease are genetically heterogenous. Work is under way to identify predisposing genes using both the candidate gene approach and systematic genomewide scans. HLA class II genes are associated with IBD. The DR1-DQW5 complex and the DRB3*0301 allele are associated with Crohn's disease, and HLA-DR2 is associated with ulcerative colitis. Linkage analysis in multiply affected families suggests that genes outside the HLA complex are also important determinants of susceptibility in ulcerative colitis and Crohn's disease. A susceptibility locus for Crohn's disease is found on chromosome 16; localization is centered around loci D165409 and D165419 (106). Other major susceptibility loci map to chromosomes 1p, 3q, and 4q. The next step is to identify candidate genes in these regions that may be relevant to IBD.

Clear evidence indicates activation of the immune response in IBD. The lamina propria is infiltrated with lymphocytes, macrophages, and other cells of the immune system, and high levels of proinflammatory cytokines and inflammatory mediators are found in the mucosa. The earliest histologic changes in Crohn's disease are the changes of immune activation. Lymphocytes, macrophages, and plasma cells accumulate near mucosal crypts. Immune activation next to a crypt can lead to the development of a crypt abscess with destruction of the epithelium. An inflammatory process involving adjacent crypts leads to the development of an aphthous ulcer, the earliest macroscopic evidence of disease. This sequence is important in that it demonstrates that in IBD immune activation leads to epithelial injury, rather than epithelial injury leading to immune activation.

Although clear evidence indicates activation of the immune response in IBD, the specific antigen that triggers this response has not been identified, despite an intensive search over the past 40 years. In IBD, immune activation is largely confined to the gastrointestinal tract; therefore, the search for an antigenic trigger has focused on the intestinal lumen, where most of the foreign antigens are either microbial or dietary in origin. Three major hypotheses of the antigenic trigger in IBD have been postulated (104). One is that the antigenic trigger is a microbial pathogen that has not yet been identified because of fastidious culture requirements. According to this hypothesis, the immune response in IBD is an appropriate but ineffective response to a pathogen. Various viruses, bacteria, and mycobacteria have been proposed as candidate organisms, but little evidence has been found to support any of these as a causal agent in IBD.

The second hypothesis of the antigenic trigger in IBD is that it is one expressed on the patient's own cells, particularly intestinal epithelial cells. In this autoimmune hypothesis, the patient mounts an appropriate immune response against some luminal antigen, either dietary or microbial; however, because of similarities between proteins on the epithelial cell and the luminal antigen (molecular mimicry), the patient's immune response also attacks the epithelial cells. Anticolon antibodies have been identified in patients with IBD. The best characterized of these is an IgG antibody to tropomyosin; this antibody was eluted from resected, washed ulcerative colitis tissue (107). Although this antibody has been well characterized, no evidence indicates that it plays a role in the pathogenesis of ulcerative colitis.

The third, and best supported, hypothesis of the antigenic trigger in IBD is that it is some common dietary or usually nonpathogenic microbial agent against which the patient mounts an inappropriate immune response. In healthy people, a finely tuned, low-grade chronic inflammation is present in the intestinal lamina propria. This chronic inflammation is a product of exposure of immune cells in the lamina propria to luminal antigens. Failure to suppress this inflammatory response would result in an inappropriately vigorous and prolonged immune response to normal luminal antigens. The uncontrolled immune activation seen in IBD may reflect the failure of these normal suppressor mechanisms. The genetic basis of IBD may relate to an inability to mount a suppressor response to a specific luminal antigen. Perhaps patients with IBD are genetically programed to mount an intense immune response to some common luminal antigen, either dietary or microbial, to which immunologically normal persons mount a suppressor response. Whether this failure of suppression is specific to a single antigen on a single strain of bacteria or is a global failure of suppression to large groups of bacterial strains is not clear. In genetically based mouse models of colitis, defects in T-cell function or cytokine production result in uncontrolled immune responses to normal colonic bacteria. It may be that in IBD a defect in immune regulation results in an inappropriately active immune response to normal colonic bacteria.

An insight into the breakdown of suppressor mechanisms in IBD comes from an *in vitro* study of the immune response to intestinal bacteria. Peripheral blood mononuclear cells and lamina propria mononuclear cells from immunologically normal persons do not proliferate when they are incubated with bacterial sonicates from autologous intestine. However, lamina propria mononuclear cells from inflamed areas of IBD intestine proliferate when cocultured with bacteria (108). These data do not suggest that patients with IBD have a specific defect in their immune response to bacteria, but rather they suggest that the tolerance to intestinal bacteria is broken in IBD. The regulatory events that downregulate the mucosal immune response to normal luminal antigens have failed. In this sense, there is no antigenic “trigger” in IBD, but rather the inappropriate immune response is initiated by a failure of the suppressor response to luminal antigens.

Immune System

Analysis of circulating leukocytes shows only modest differences between immunologically normal persons and patients with IBD (109). The number of circulating lymphocytes and the proportions of $CD4^+$ and $CD8^+$ T cells subsets are normal. The lymphocyte proliferative response to mitogens is also normal. The most obvious difference is an increase in the number of neutrophils. Immunohistochemical analysis of the lamina propria reveals that the total number of T cells is increased in IBD, but the $CD4^+$:$CD8^+$ ratio is the same, at 2:1 (110). The number of intraepithelial lymphocytes in IBD mucosa is normal. Lamina propria T cells in IBD are more activated than in normal intestinal tissue, with increased cell-surface expression of activation markers, increased Ig secretion, and increased proliferation (111,112).

Most patients with IBD have normal serum levels of all the Ig classes (IgG, IgA, IgM, and IgE). Turnover studies demonstrate increased turnover of IgG and IgM with increases in both synthesis and catabolism. Although serum antibody levels are largely normal, Ig production in the lamina propria is markedly enhanced in IBD. Isolated lamina propria mononuclear cells from IBD surgical resections synthesize and secrete IgG, IgA, and IgM at elevated levels. Some of these antibodies are directed to luminal bacteria (113). There are marked differences in IgG subclass production in IBD, with increased IgG1 production in ulcerative colitis and increased IgG2 in Crohn's disease.

Immunoregulation

Although the antigenic trigger that activates the immune response in IBD has not been identified, the sequence of events involved in the immune activation and tissue destruction in IBD has been characterized (109,114). This sequence, presented in Fig. 55.5, is used to organize a review of normal events in mucosal immune activation and the abnormalities seen in IBD. Several genetic manipulations of the immune system have been shown to induce chronic colitis in mice. These manipulations include targeted disruption of the genes encoding IL-2, IL-10, and the TCR, alterations in T-cell subsets and reconstitution of severe combined immunodeficiency (SCID) mice with T-cell subsets (115,116,117,118,119 and 120). The sequence of events in Fig. 55.5 is used to integrate these mouse models into what is known about normal and dysregulated immune activation in the intestine.

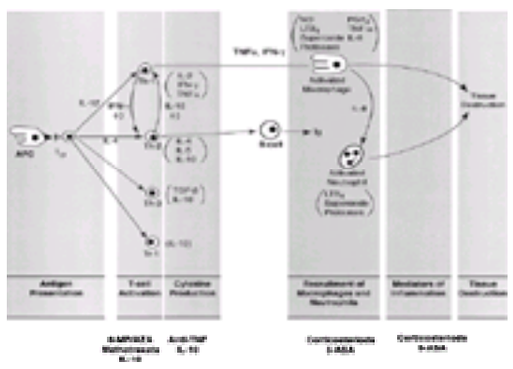

Figure 55.5. The pathogenesis of inflammatory bowel disease. The mucosal immune response develops through a series of steps (e.g., antigen presentation, lymphocyte activation, cytokine production). The drugs used to treat this disease act by affecting some of these steps. The names of the drugs are listed below the name of the step they affect. Among these drugs are azathioprine (AZA), 6-mercaptopurine (6-MP), and 5-aminosalicylic acid (5-ASA). Antigen-presenting cells (APCs) present antigen to naive $CD4^+$ T cells (T), which differentiate to four different $CD4^+$ T-cell subsets (Th1, Th2, Th3, Tr1) under the control of various cytokines (interleukin-4 (IL-4), IL-10, IL-12). These $CD4^+$ T-cells subsets, in turn, produce a variety of cytokines. Two of these cytokines, tumor necrosis factor-a (TNF-a) and interferon-g (IFN-g), activate macrophages and result in the production of nitric oxide (NO), leukotriene B_4 (LTB_4), superoxide, proteases, prostaglandin E_2 (PGE_2), TNF-a, and IL-8. Neutrophils, in turn, are activated by IL-8. Both activated macrophages and activated neutrophils contribute to tissue destruction through the production of superoxide and proteases.

The first step in the immune response to antigen in the intestine consists of the uptake and processing of antigen by professional antigen-presenting cells (primarily macrophages and dendritic cells). $CD4^+$ T cells undergo stimulation by TCR ligation by antigenic peptides presented in conjunction with HLA class II molecules on macrophages and dendritic cells. Optimal T-cell stimulation requires “costimulation” or ligation of CD28 on T cells by CD80 or CD86 on antigen-presenting cells.

Evidence also indicates that intestinal epithelial cells can express class II and may play a role in antigen presentation within the intestinal immune compartment; however, it is unclear if they can efficiently provide costimulatory signals (121). HLA class II is expressed on small intestinal epithelial cells in Crohn's disease; whether antigen presentation by epithelial cells plays any role in the pathogenesis of Crohn's disease remains to be seen. The antigen specificity of $CD4^+$ T cells is determined by their TCRs. One could imagine that a germline abnormality in the TCR could result in oral reactivity and could contribute to disease susceptibility. However, carefully performed studies have failed to demonstrate differences between patients with IBD and control subjects in their TCRs. Azathioprine, 6-mercaptopurine, and methotrexate are all used to treat IBD, particularly Crohn's disease, and all appear to act by inhibiting T-cell activation.

Activation of T cells results in cytokine production. In mice, differentiated $CD4^+$ T cells may be grouped into subsets based on the cytokines they produce after antigenic stimulation. This paradigm may have significant importance in IBD, because cytokines produced by one subset of $CD4^+$ T cells (Th1) are believed to have pathogenic roles, whereas cytokines produced by other subsets (Th2, Th3, Tr1) are believed to be immunoregulatory or beneficial. Th1 cells produce IL-2, IFN-g, and TNF-a, whereas Th2 cells produce IL-4, IL-5, IL-6, IL-10, and IL-13. Activation of Th2 cells promotes B-cell activation. Naive Th0 cells differentiate down either the Th1 or the Th2 pathway when they ligate antigen. The pattern of differentiation is determined by the cytokines that are present in the environment at the time of differentiation. IL-12 promotes differentiation down the Th1 pathway, whereas IL-4 promotes differentiation down the Th2 pathway. The development of a dysregulated Th1 response has been demonstrated in genetically engineered mouse models of colitis (114,115,116,117,118,119 and 120). T cells secreting IFN-g and TNF-a are found in intestinal lesions in these models, and therapy with anti–IFN-g or anti-TNF is effective. The importance of Th1 activation in mediating intestinal inflammation is supported by the demonstration that antibodies to IL-12 improve both the clinical and histopathologic aspects of trinitrobenzene sulfonic acid colitis in mice (122). In this model of colitis, lamina propria T cells demonstrate a Th1 pattern of cytokine production. Administration of monoclonal antibodies to IL-12 results in marked improvement in this model even if given therapy is after the inflammatory response is well established (122). The ability of IL-12 antibodies to downregulate the immune response in this model suggests that preventing lymphocytes from differentiating down the Th1 pathway blocks the development of colitis.

In all these models, colitis does not develop if the genetically manipulated animals are raised in a germ-free environment (123). Moreover, transfer of Th1 cells that react with bacterial antigens from mice with colitis to immune-deficient mice induces colitis (124). These findings demonstrate that a genetically determined defect in systemic immunity can have as its only manifestation colitis that results from an inappropriately robust immune response to normal colonic bacteria. Whether this is a global response to all colonic bacteria or a selective response to particular bacteria has not been established. These data could support the suggestion that these models result from a failure to mount a suppressor response to colonic bacteria. These findings also support the suggestion that colonic bacteria are the targets of the immune activation in IBD.

Whether the Th1/Th2 model can be applied to IBD in humans is not clear. In one study, lamina propria mononuclear cells isolated from IBD surgical resections were stimulated with anti-CD2/CD28, a stimulus that would determine their capacity to produce T-cell cytokines (125). T cells from Crohn's disease mucosa produced IFN-g, whereas those from ulcerative colitis mucosa produced IL-5, a finding supporting the suggestion of an overactive Th1 response in Crohn's disease. Cytokine production in IBD mucosa has been measured in several studies. The most striking finding is that IFN-g and IL-12 are produced at high levels in Crohn's disease mucosa but not in ulcerative colitis mucosa. Further support for the role of cytokines in the pathogenesis of Crohn's disease comes from the demonstrated therapeutic efficacy of anti-TNF antibody and from the suggestion that exogenous recombinant IL-10 is also therapeutic in Crohn's disease (126,127). IL-10 promotes the differentiation of Th0 cells to non-Th1 subsets, which, in turn, may inhibit the differentiation of Th1 subsets; therefore, one may expect that exogenous IL-10 would diminish Th1 activation in Crohn's disease. Taken together, these data suggest that the gastrointestinal immune activation in Crohn's disease is mediated by activation of Th1 cells.

In health, the intestinal inflammatory response is maintained under tight control despite exposure of lamina propria immune cells to an enormous number of luminal antigens. The tight check on the mucosal immune response is mediated by populations of regulatory T cells. Most studies of regulatory T cells in the intestine have been performed in mice, and the applicability of these studies to human IBD is not clear. One population of regulatory T cells, designated Th3, produces TGF-b, which downregulates Th1 cells (128). A second population of regulatory T cells, designated Tr1, produces large amounts of IL-10 (129). The immunomodulatory function of Tr1 cells was confirmed using the $CD45RB^{high}$ transfer model in mice. Splenic $CD4^+$ T cells can be divided on the basis of their expression of CD45RB; naive $CD4^+$ cells are $CD45RB^{high}$, whereas primed or memory $CD4^+$ cells are $CD45RB^{low}$. Transfer of $CD4^+$, $CD45RB^{high}$ splenocytes into SCID mice induces colitis, whereas transfer of $CD4^+$, $CD45RB^{low}$ splenocytes causes no disease (118,119). Transfer of the two populations together also causes no disease. $CD45RB^{high}$ $CD4^+$ splenocytes produce IFN-g, whereas $CD45RB^{low}$ $CD4^+$ splenocytes produce TGF-b and IL-10, which inhibit the production of IFN-g. The $CD45RB^{low}$ subset contains Tr1 cells, which produce IL-10. These experiments demonstrate that colitis can be induced by transfer of a population of lymphocytes that occur in normal mice; moreover, this colitis can be prevented by transfer of Tr1 T cells.

In a particularly interesting set of studies, investigators demonstrated that colitis induced in SCID mice by transfer of $CD45RB^{high}$ $CD4^+$ T cells can be prevented by cotransfer of murine Tr1 clones derived from $CD4^+$ T cells expressing a transgenic TCR for ovalbumin (129). Immune suppression of this system depends on antigen-induced activation of Tr1 cells *in vivo* because these cells inhibit colitis only when recipients are receiving ovalbumin in their drinking water. By contrast, the effect of Tr1 cells is not antigen specific because these cells can inhibit the function of T cells responding to unknown intestinal antigens. Thus, IL-10 and TGF-b produced by Tr1 cells in response to one antigen can suppress T-cell activation in response to a wide variety of other antigens. It is likely that this phenomenon, termed *antigen-driven bystander suppression,* accounts for some of the global downregulation of the immune response in the normal intestine. Failure of antigen-driven bystander suppression could account for the inappropriate immune activation seen in IBD.

Macrophages

The next step in immune activation in the intestine is the activation of lamina propria macrophages by cytokines produced by activated T cells (130). IFN-g produced by Th1 cells activates mucosal macrophages and causes them to produce TNF-a. In contrast, the activation of mucosal macrophages is downregulated by TGF-b and IL-10, which are produced by Th3 and Tr1 regulatory T cells.

Intestinal macrophages, like macrophages in other organs, are derived from monocytes in the peripheral blood. The phenotype and functional capacity of macrophages are influenced by the tissue microenvironment in which they reside. Normal intestinal macrophages have a downregulatory phenotype and cannot be easily induced to mediate acute inflammatory responses. Perhaps the cytokine environment of the intestinal mucosa induces migrating monocytes to differentiate to a down regulatory phenotype, or it may be that monocytes predisposed to differentiate toward a downregulatory phenotype selectively migrate into the intestine. One example of the downregulatory properties of normal intestinal macrophages is their failure to express CD14, which mediates the response to LPS (131). Compared with macrophages in other organs, intestinal macrophages make large amounts of IL-10 and relatively small amounts of IL-12. This pattern of cytokine production should upregulate the Th2 response and downregulate the Th1 response. Intestinal macrophages are also relatively resistant to activation by IFN-g; they fail to generate a respiratory burst when they are stimulated with IFN-g. In contrast, macrophages isolated from the intestines of patients with IBD act to promote rather than to suppress the inflammatory response. Many lamina propria macrophages in IBD express CD14 and are therefore more responsive to activation by LPS (131). In contrast to macrophages from normal intestine, many macrophages isolated from IBD mucosa can be triggered by incubation with IFN-g to undergo a respiratory burst generating reactive metabolites of oxygen including superoxide, hydrogen peroxide, and hydroxyl radical. There are also important differences in the abilities of normal and IBD lamina propria macrophages to express cytokines. Normal lamina propria macrophages do not express IL-1 or IL-18 when they are activated with LPS, whereas lamina propria macrophages from patients with IBD do express these cytokines in response to LPS.

In health, lamina propria macrophages secrete factors, including IL-10 and PGE_2, that downregulate the immune response. Lamina propria macrophages express cyclooxygenase-2 and produce large amounts of PGE_2 through cyclooxygenase-2 (132). The PGE_2 produced by lamina propria macrophages acts as an immunomodulator. In T-cell responses to antigen, PGE_2 modulates the immune response. Clinical exacerbation of IBD by nonsteroidal antiinflammatory drugs may be the result of inhibition of the synthesis of immunomodulatory prostaglandins in the intestinal mucosa.

Inflammation

The next step in immune activation in the intestinal tract is the activation of macrophages and neutrophils to produce proteases, reactive oxygen species, and inflammatory mediators (3). Macrophage activation results in the production of IL-8 and other chemotactic factors that enhance the migration of additional peripheral blood neutrophils into the inflamed mucosal. In IBD, enormous numbers of neutrophils leave the circulation and enter the inflamed mucosa and submucosa of the bowel. Some of these neutrophils migrate across the epithelium into the lumen and are passed into the stool, and others are destroyed in the inflamed tissue before they have a chance to migrate into the lumen. This constant flux of neutrophils is mediated by the expression of adhesion molecules on circulating neutrophils and vascular endothelial cells; these adhesion molecules allow the neutrophils to bind to the endothelium before migrating into the tissue. Both the expression of adhesion molecules and the migration of neutrophils are regulated by inflammatory cytokines (IL-8 and TNF-a) and by lipid mediators of inflammation including platelet-activating factor and leukotriene B_4. IL-8, TNFa, platelet-activating factor, and leukotriene B_4 are all found at elevated levels in IBD mucosa. Neutrophil activation in the inflamed gut results in the release of granule-bound proteases and the production of superoxide and other reactive oxygen species. These products of activated neutrophils play an important role in the destruction of the epithelium in IBD. Functional and macroscopic changes seen in IBD mucosa, including hyperemia and edema, are changes typical of any inflammatory state and are the products of soluble mediators released in the process of inflammation. Inflammatory mediators cause tissue edema by increasing vascular permeability to albumin and other macromolecules; hyperemia results from mediators that induce vasodilation. PGE_2 is a mediator of both enhanced vascular permeability and vasodilation in IBD. Both corticosteroids and 5-aminosalicylate have certain pharmacologic effects that could contribute to their

efficacy in IBD. All these pharmacologic effects are focused on blocking either the recruitment or activation of macrophages and neutrophils.

Immune activation in IBD also induces epithelial cells to express proteins they do not ordinarily express. Epithelial cells in areas of active inflammation in IBD express inducible NO synthase (iNOS), cyclooxygenase-2 (an enzyme involved in prostaglandin synthesis), and the neutrophil chemotactic agent epithelial neutrophil-activating peptide 78 (133,134 and 135). The expression of these proteins is regulated by IL-1 and TNF-a, and the high levels of these cytokines in IBD mucosa may account for the expression of these proteins in epithelial cells.

The last step in the pathogenesis of IBD is the destruction of the epithelium. The major mediators of epithelial destruction appear to be reactive oxygen species and proteases produced by activated neutrophils and macrophages. Proinflammatory cytokines including TNF-a and IFN-g may also contribute to the destruction. Activation of neutrophils and macrophages is mediated in part by the transcription factor NF-kB. The expression of IL-8, iNOS, and cyclooxygenase-2 is regulated by NF-kB activation. Each of these proteins plays a role in the pathogenesis of IBD. Administration of an antisense phosphorothioate oligonucleotide to a subunit of NF-kB abrogates the inflammatory response in the trinitrobenzene sulfonic acid model of colitis in the mouse (136). This raises the question whether pharmacologic manipulation of NF-kB would be useful in human IBD.

This sequence of events that occurs in the development of IBD (Fig. 55.5) is much the same as the sequence of events that occurs in response to infection with *Salmonella* or *Shigella* (3). However, in *Salmonella* or *Shigella* infection, this sequence of immune activation is followed by a downregulation of the inflammatory response and epithelial repair. In these infections, the inflammatory response is downregulated when the organisms driving the upregulation of the inflammatory response have been eliminated. In contrast, in IBD, there are no pathogenic organisms to eliminate and thus no easy mechanism for shutting down the immune response.

WHIPPLE DISEASE

G.H. Whipple first described *Whipple disease* in 1907 as lipodystrophia intestinalis (137,138). Although he described the presence of a rodlike bacillus in the lamina propria of the intestine, it was not until the early 1990s that molecular biologic techniques were used to identify the organism as a gram-positive actinomycete, which was given the name *Tropheryma whippleii* (137,138).

Although primarily thought of as a gastrointestinal disorder, Whipple disease is a chronic, systemic illness. The presentation is variable and can include many different signs and symptoms; however, the most common clinical presentation is a combination of diarrhea, weight loss, and malabsorption, which has been preceded for months to years by other symptoms such as arthralgias (139). Whipple disease has a low incidence (frequency less than 0.1%) and occurs primarily in white, 40- to 50-year old men, although all age groups (including children) can contact the disease. A genetic predisposition can be seen in the HLA-B27 positive population because 28% to 44% of patients with Whipple disease are HLA-B27 positive (versus 8% in the general population) (138,140).

Patients with Whipple disease often have laboratory evidence of malabsorption (deficiency of fat-soluble vitamins, hypoalbuminemia, hypocholesterolemia, mineral deficiency) and normocytic hypochromic anemia of chronic disease. However, small intestinal biopsy and histologic demonstration of characteristic lesions make the diagnosis of Whipple disease. Endoscopy shows areas of thickened folds with the typical granular, yellow-white shaggy covering (from thickened or blunted edematous intestinal villi). The first and second portions of the duodenum are characteristically involved, and disease extends variably throughout the distal small intestine. The histologic hallmark of Whipple disease consists of foamy macrophages, which are characteristically periodic acid-Schiff (PAS)–positive (141). The substance in macrophages that stains positive with PAS is thought to be remnants of the cell walls of phagocytosed bacilli. These PAS-positive monocytes also contain gram-positive, acid-fast bacillus–negative *T. whippleii.* These PAS-positive macrophages can be detected in almost all tissues in patients; however, the presence of PAS-positive macrophages is not pathognomonic of Whipple disease, because they have also been identified in other infections *(Mycobacterium tuberculosis, M. avium-intracellulare).* The intestinal mucosa demonstrates widened villi with numerous PAS-positive macrophages in the lamina propria and decreased numbers of lamina propria plasma cells, lymphocytes, and eosinophils. Small intestinal mucosal or submucosal lymphatic vessels are dilated and have easily visualized lipid droplets, a finding suggesting that the malabsorption is secondary to lymphatic stasis.

The suspicion of Whipple disease based on characteristic histologic lesions can be confirmed by polymerase chain reaction (PCR) based on the 16S ribosomal RNA of *T. whippleii* (142). The recommended treatment is daily intravenous streptomycin and penicillin for 14 days, followed by oral trimethoprim-sulfamethoxazole for 1 year (138). Under this treatment, the joint symptoms disappear in days, whereas intestinal symptoms take weeks to improve. Even with this extended antibiotic regimen, the rate of relapse is significant (35%), and investigators have recommended that PCR should be used to monitor response to therapy, with a negative result on PCR after 1 year predicting a low likelihood of clinical relapse (142,143).

The pathogenesis of Whipple disease is still unclear; however, it has been hypothesized that patients with the disease have an altered host response. Most patients show an impairment of delayed-type hypersensitivity and appear to have an inability to eliminate the *T. whippleii* bacilli effectively (i.e., persistence of PAS-positive macrophages) (137). One immunologic defect in this disease is the reduced ability of monocytes to produce IL-12 on activation (144). This primary defect in IL-12 production results in a secondary effect of reduced IFN-g production by Th1 cells. Because IFN-g is important for activating macrophages to kill organisms more effectively, this may explain the inability of patients with Whipple disease to control *T. whippleii* infection. This monocyte-macrophage cytokine defect is supported by an absence of the cell-surface marker CD11b on PAS-positive macrophages in the lamina propria of patients with Whipple disease (137,144).

Until recently, *T. whippleii* could not be isolated or propagated; however, investigators have reported that IL-4 deactivated macrophages and human fibroblasts are permissive to *T. whippleii* growth (145,146). This use of IL-4 to induce permissive growth conditions for *T. whippleii,* when considered in the light of the reported monocyte IL-12 production deficiency, allows an intriguing hypothesis to be proposed. These two cytokines have well-described effects on the development of differentiated Th subsets; IL-12 enhances T-cell development to IFN-g–producing Th1 cells, whereas IL-4, in the absence of IL-12, enhances the development of IL-4–producing Th2 cells. Evidence based on PCR analysis of healthy people has shown that 11% to 35% of people are colonized with *T. whippleii* (147,148). In light of this finding, the genetic predisposition to produce Th2 more than Th1 cells may allow a commensal bacillus to become pathogenic.

IMMUNOPROLIFERATIVE SMALL INTESTINAL DISEASE

Immunoproliferative small intestinal disease (IPSID) is a clinical syndrome of malabsorption, chronic diarrhea, and weight loss that is endemic in Middle Eastern and Mediterranean countries (149). This syndrome is thought to represent a spectrum of diseases, which in the past were known as a-heavy-chain disease and Mediterranean lymphoma. It is similar in clinical presentation to celiac sprue, which predominates in other parts of the world. Both syndromes involve a chronic stimulation of the intestinal MALT and are associated with an increased risk of malignant disease.

IPSID was first described in the mid-1960s in Israel in young adults with dietary malabsorption (149). The histologic appearance is characterized by plasmacytic or lymphocytic infiltrate in the lamina propria of the small intestine. The intestinal villi are broadened, and the crypts are shortened, whereas the intestinal epithelial cells appear relatively normal (150). Over time, this early lesion evolves into late-state IPSID, which is characterized by broadening of the villi to the point of complete effacement and infiltration by malignant lymphocytes. This lesion was originally known as Mediterranean lymphoma.

In some cases, plasma cells in the intestinal lamina propria secrete an IgA heavy-chain protein (a-CP) devoid of light chains (151,152). This unique a-CP is an approximately 30,000 MW protein that consists of a free a_1-heavy chain that is missing the variable (V_H) and constant (C_H1) regions because of a structural mutation. This deletion allows a-CP to be secreted in the absence of light chains. a-CP can be detected in serum by immunofixation electrophoresis or in tissue sections by immunohistologic staining of plasma cells. The less sensitive diagnostic test of serum electrophoresis often cannot detect a-CP. The presence of this monoclonal Ig, in conjunction with clinical and histologic signs of Mediterranean lymphoma, led physicians to term the disease a-heavy-chain disease.

Most patients with IPSID originate from developing countries in the Mediterranean basin, the Middle East, Africa, and the Far East. They are usually young, can be either male or female, and live in areas of poor sanitation and hygiene (149). In addition to malabsorption, patients often present with clubbing, abdominal pain, and growth retardation. The diagnosis of IPSID is made by intestinal biopsy, which reveals the characteristic histologic picture described earlier. Endoscopy variably shows a nondistensible intestine resulting from submucosal infiltrates and thickened mucosal folds or ulcers. Bacterial overgrowth and intestinal parasitosis (primarily with *Giardia*) are common, and serum a-CP may be present (20% to 87%) (153,154).

The high prevalence of intestinal microbial overgrowth in IPSID and its endemic nature in areas of poor sanitation in the Middle Eastern and Mediterranean countries have led to the proposal that IPSID represents a chronic immunoproliferative response of MALT B cells to bacteria or parasites that eventually becomes monoclonal (155,156). This is similar to the association between *H. pylori* infection and primary gastric lymphoma (MALT lymphomas) (66). This association has led to the recommended treatment for early stages of IPSID with tetracycline or other broad-spectrum antibiotics (157), which has been reported to yield a 20% to 71% response rate. Patients with late-stage disease have been treated with total abdominal radiation or multiple combination chemotherapy regimens (157). Overall, complete remission rates have averaged 64%. One report has linked the regression of refractory IPSID to the eradication of *H. pylori* (158).

GRAFT-VERSUS-HOST DISEASE

The term *graft-versus-host* describes an immunologic entity characterized by skin abnormalities and diarrhea and caused by immunologically competent cells introduced into an allogenic immunoincompetent host (159). *Graft-versus-host disease* (GVHD) is a significant cause of morbidity and mortality after allogeneic hematopoietic stem cell transplantation. Acute GVHD usually presents within the first 100 days after transplantation with a distinctive syndrome characterized by a triad of dermatitis, hepatitis, and gastroenteritis (159). The incidence of acute GVHD is increased in older patients and in patients who received marrow transplants from related, but HLA-nonidentical donors or transplants from HLA-matched unrelated donors (159). The risk of GVHD has been correlated with minor HLA antigen disparities, which act as alloantigens that can be recognized by donor lymphocytes. The diagnosis of acute GVHD involving the intestinal tract is made most accurately by upper gastrointestinal endoscopy with biopsy (160). The endoscopic appearance of the stomach and duodenum ranges from subtle mucosal erythema and edema to frank ulceration and mucosal sloughing. The histologic findings from intestinal biopsy include crypt epithelial cell apoptosis and dropout, crypt destruction, and lymphocytic infiltration (160).

GVHD is caused by an attack of donor T cells against alloantigens of the recipient (161). Depletion of T cells in the donor marrow prevents GVHD, but it results in a higher rate of graft failure and an increased incidence of leukemic relapse (i.e., loss of the graft-versus-leukemic effect) (161). Animal models of GVHD indicate that dysregulated cytokine production is responsible for many of the manifestations of acute GVHD. This dysregulation is postulated to occur in three sequential phases. The agents used to prepare the recipient for marrow transplantation initiate phase 1. This includes total body irradiation or chemotherapy, which activates host cells to secrete increased levels of inflammatory cytokines (e.g., TNF-a, IL-1, and IL-6) and injures the mucosal surface of the gastrointestinal tract such that bacterial breakdown products (e.g., endotoxin or LPS) can enter the systemic circulation (162). In phase 2, the activation of alloreactive donor T cells in the presence of inflammatory cytokines such as IL-12 results in activated donor T cells that predominantly secrete IL-2 and IFN-g (“type 1” cytokines). These cytokines control and amplify the alloantigen response in T cells and NK cells. These inflammatory mediators, along with specific antihost cytotoxicity mediated by Fas pathways, NK cell cytolysis, and NO, result in the pathophysiology of GVHD. Murine allogeneic bone marrow transplant models have demonstrated a link between excessive TNF-a production and the manifestation of acute GVHD. This knowledge has led to several novel approaches to GVHD prophylaxis. The most direct of these treatments is the use of TNF inhibitors, which directly block the effects of TNF-a (163). However, agents such as keratinocyte growth factor and IL-11, which both work upstream of the release of TNF-a, also effectively decrease acute GVHD in mouse models (164,165). The advantage of these therapies is that they reduce the incidence of GVHD while preserving the graft-versus-leukemic effect.

SMALL BOWEL TRANSPLANTATION

Small bowel transplants are performed less commonly than other solid organ transplants (heart, lung, liver, kidney), but the number performed has increased markedly over the past few years. The usual indication for small bowel transplantation is irreversible failure of the intestine's ability to support the patient's nutritional needs (166). This failure is most often the result of short bowel syndrome after extensive surgical resection of the intestine or, less commonly, absorption and motility disorders. In children, the common causes of intestinal failure resulting in transplantation are volvulus, gastroschisis, intestinal atresia, and necrotizing enterocolitis. In adults, the common causes are thrombotic disorders, Crohn's disease, desmoid tumors, and trauma. Most patients with intestinal failure are managed first with long-term total parenteral nutrition. Small bowel transplantation is usually considered only when long-term total parenteral nutrition has failed because of complications including line sepsis, thrombosis of access sites, and hepatic failure.

Grafts are obtained from ABO-matched cadaveric donors. Recipients and donors are not usually closely HLA-matched. Isolated intestinal grafts and combined liver-intestinal grafts are both common. Immunosuppression after transplantation is achieved with a combination of tacrolimus and low-dose steroids to which PGE_1 is added briefly during the early postoperative period. Rejection is managed with prednisone, OKT3, azathioprine, and adjustment of the tacrolimus dose.

The immunologic aspects of small bowel transplant are complicated. There are large numbers of lymphocytes in graft and complex interactions between activated and regulatory T cells. After transplantation, the host lymphocytes rapidly infiltrate Peyer patches and eventually replace the donor lymphocytes in the lamina propria (167). Donor intraepithelial lymphocytes are not replaced unless there is an episode of rejection (this finding supports the suggestion that intraepithelial lymphocytes are highly differentiated and turn over slowly). Successful transplantation requires the development of a chimeric state with both donor and recipient lymphocytes in the graft. Inadequate immunosuppression results in rejection, but overly aggressive immunosuppression results in failure of the host immune cells to populate the graft mucosa and, as a result, failure to develop the tightly controlled downregulated immune response that is characteristic of the normal mucosal immune system.

Events associated with organ procurement, preservation, and transplantation promote a less tightly controlled and more vigorous mucosal immune response (168). Epithelial injury secondary to ischemia and reperfusion leads to loss of epithelial integrity and stimulation of neutrophils and macrophages by products of dying epithelial cells. Exposure to bacterial products leaking through the damaged epithelium causes activation of lamina propria macrophages with production of cytokines that promote graft rejection through recruitment of additional leukocytes and increased MHC expression.

In acute rejection, the graft is infiltrated with lymphoblasts. The inflammatory reaction extends into the lamina propria and results in epithelial injury and crypt cell apoptosis. Acute histologic rejection is associated with pericryptic infiltration with $CD3^+$ $TCRab^+$ T cells containing clusters of $CD8^+$ cells, numerous $CD25^+$ cells, and $CD68^+$ macrophages (169). The presence of clusters of $CD8^+$ cells around and in necrotic crypts suggests that these are CTLs and play a role in the epithelial destruction characteristic of intestinal rejection. Rejection may be widespread, but it is typically worst in the ileum. As rejection becomes more chronic, obliterative arteriopathy develops. Episodes of rejection that start later, more than 100 days after transplantation, tend to have more crypt cell apoptosis and less mucosal injury.

Success rates with small bowel transplantation are improving but are still disappointing. The largest series reported the results of 71 transplants in 63 recipients (170). Of the 63 recipients, 32 were alive and 28 had functioning grafts; 4-year survival was a little less than 50%. Causes of graft loss included technical and management errors, cytomegalovirus infection, lymphoma, rejection, and sepsis. Predictors of graft loss included positive donor cytomegalovirus serology, inclusion of the colon in the graft, OKT3 use, steroid recycle, and high tacrolimus blood levels. Lymphomas developed in 12 of the 63 recipients and caused 8 deaths. These B-cell lymphomas, also termed lymphoproliferative disorders, are associated with Epstein-Barr virus infection.

EOSINOPHILIC GASTROENTERITIS

Eosinophilic gastroenteritis is a pathologic entity marked by idiopathic infiltration of eosinophils in the gastrointestinal mucosa (171). Eosinophilic infiltration can affect any part of the gastrointestinal tract, although the stomach and small bowel are most commonly involved. Infiltration with eosinophils can be predominately mucosal or predominately muscular. With mucosal infiltration, the primary complaints are diarrhea and crampy abdominal pain; gastric involvement results in nausea and vomiting. In a few cases, mucosal infiltration is extensive enough to result in malabsorption and weight loss. Mucosal infiltration can be diagnosed by endoscopic biopsy. With mucosal involvement, barium studies show thickened folds, reflecting eosinophilic infiltration and edema secondary to eosinophil activation. Muscular involvement presents as obstruction with nausea, vomiting, and abdominal pain. Endoscopic biopsies may not be helpful if the eosinophilic infiltrate is confined to the muscularis propria. With muscular infiltration, barium studies show irregular narrowing of the antrum or small bowel, depending on the distribution. The eosinophil count in the peripheral blood is usually modestly elevated in eosinophilic gastroenteritis. Extremely high levels of peripheral eosinophilia should suggest a different diagnosis.

The differential diagnosis of abdominal pain and diarrhea associated with eosinophilic infiltration of the gastrointestinal mucosa is limited. Certain parasitic infections, including ascariasis, strongyloidiasis, trichinosis, and trichuriasis are associated with peripheral eosinophilia, gastrointestinal eosinophil infiltration, and gastrointestinal symptoms. In contrast to worm infections, which are associated with eosinophilia, protozoan infections, such as amebiasis and giardiasis, are not associated with eosinophilia.

About half of patients with eosinophilic gastroenteritis have significant allergic histories with childhood food allergies, eczema, allergic rhinitis, asthma, or urticaria. Although an association with allergic disease exists in some patients, sequential withdrawal of food substances is not likely to yield relief of symptoms in eosinophilic gastroenteritis.

The mechanism of the eosinophilic infiltration in the intestine is not well understood. IL-3, IL-5, and granulocyte-macrophage colony-stimulating factor all promote eosinophilic infiltration and may be involved (172,173). The mechanisms of eosinophil-mediated intestinal injury are also poorly understood. In eosinophilic gastroenteritis, many of the intestinal tissue eosinophils are degranulated. Eosinophil granules contain major basic protein, eosinophil cationic protein, eosinophil-derived neurotoxin, and eosinophil peroxidase. Activated eosinophils produce cytokines including IL-1, IL-5, and TNF-a.

Treatment of eosinophilic gastroenteritis is not particularly satisfactory. Patients who have a strong indication of allergy to a specific food, such as positive radioallergosorbent tests for specific IgE antibodies for specific foods, should be given a trial of an elimination diet. Oral corticosteroids are frequently effective; however, they should be used in the lowest effective dose. The duration of the requirement for steroids is variable, and, in many patients, these drugs can be successfully withdrawn after a course of therapy.

IMMUNODEFICIENCIES

The gastrointestinal mucosa is a primary interface of an individual with the outside world. The importance of the mucosal immune system in host defense is demonstrated by the wide spectrum of mucosal opportunistic infections that affect immunocompromised individuals. However, individuals with milder or more selective immunodeficiencies are frequently asymptomatic. This observation may be explained by the presence of nonimmunologic components of host defense as well as the multiple overlapping functions of various components of the immune system, such that loss of one component results in only mild effects. Primary immunodeficiencies resulting in absence or malfunction of bone marrow–derived components can be divided into those affecting the innate immune system and those affecting the acquired immune system. The latter group can be subdivided further into disorders affecting T-cell function, B-cell function, and antibody production and those affecting both T-cell and B-cell function. Selective immunodeficiencies affecting antibody production can have varied gastrointestinal manifestations ranging from primarily asymptomatic (selective IgA deficiency) to frequent opportunistic infections resulting in diarrhea and malabsorption (common variable immunodeficiency). Patients with immunodeficiencies resulting in the loss of T-cell function or combined B-cell and T-cell function frequently have more severe manifestations of diarrhea and opportunistic infections of the gastrointestinal tract; however, in these syndromes, gastrointestinal manifestations do not form a dominant part of the presentation because of the overall severity of the clinical picture in affected patients. In addition, gastrointestinal diseases resulting in protein-losing enteropathy may give rise to immunodeficiencies. Immunodeficiencies secondary to gastrointestinal enteropathies are generally not believed to be of clinical significance, except in the case of intestinal lymphangiectasia, in which hypogammaglobulinemia is accompanied by lymphopenia. For an overview of gastrointestinal manifestations in immunodeficiencies, the reader is referred to Table 55.2. For a more in-depth discussion of primary immunodeficiencies and secondary immunodeficiencies.

56 MULTIPLE SCLEROSIS

Amit Bar-Or, M.D., Kevin C. O'Connor, Ph.D., and David A. Haffler, M.D.

Multiple sclerosis (MS) is a chronic inflammatory illness affecting central nervous system (CNS) pathways and leading to progressive neurologic dysfunction. It represents the principal adult demyelinating disease and remains the leading cause of neurologic disability in young adults in the Western Hemisphere. More than 1 million people in North America and Europe have the illness, with prevalence rates ranging from less than 30 to 150 cases per 100,000. Accumulating evidence indicates that MS is caused by the activation of myelin-reactive T cells by cross-reactive microbes in genetically susceptible hosts. Common pathologic features include CNS perivascular infiltration of inflammatory cells, plaques of demyelination, astrogliosis, and axonal injury.

Historically, support for the view that MS is an immune-mediated disease has been largely based on the pathologic appearance of the lesions, the common presence of abnormally elevated immunoglobulin (Ig) levels in the cerebrospinal fluid (CSF), the magnetic resonance imaging (MRI) demonstration of focal fluctuations in the integrity of the blood–brain barrier (BBB), the genetic linkage to immune-related molecules, and similarities to the animal model experimental autoimmune encephalomyelitis (EAE). Several contemporary observations warrant a rethinking of the mechanisms underlying the development of MS. The suggestion of treatment responders and nonresponders in therapeutic trials and descriptions of the pathologic heterogeneity that exists among individual patients raise the possibility that the spectrum of clinical MS spans several distinct pathophysiologic processes (1,2). Alternatively (or more likely in combination), the clinical and pathologic heterogeneity may reflect the diversity of unique host attributes.

Axonal damage is increasingly recognized as a prominent pathologic feature in both acute and chronic lesions as well as in normal-appearing white matter in the brains of patients with MS. Although these observations do not preclude the role of inflammatory demyelination in MS pathogenesis, modern MRI modalities demonstrate that axonal compromise may predate the inflammatory lesions, a finding that raises the possibility that an independent axonal disorder may contribute to the primary pathobiology of the disease.

Nonetheless, based on accumulating data from immunologic studies of patients with MS and a wealth of animal model data, autoimmune dysregulation has been viewed as the major contributor to tissue damage. The clinical features of relapses and spontaneous remissions seen in the classic form of MS are shared with other inflammatory diseases and implicate the immune system in the underlying pathophysiology of acute attacks. Long-standing experience with immunosuppressive treatments and the more recent development of immunomodulating therapies that affect the course of MS further support the important pathophysiologic contribution of the immune system.

This chapter focuses on MS as an autoimmune disease of the CNS. Topics to consider relate to the following: mechanisms by which tolerance to CNS components may be broken; sites and processes involved in recognition of putative antigens; cellular and humoral responses; dynamics of immune-cell infiltration across the BBB; immune-neural interactions; mechanisms of immune-mediated tissue pathology; and mechanisms of repair.

HISTORICAL PERSPECTIVE

Although the disease was first depicted in the late 1830s (3), the earliest cohesive accounts of MS are attributed to Jean Martin Charcot, a French neurologist at the Salpetrière in Paris, who coined the term *sclérose en plaques disseminés* and was first to highlight the prominent accumulation of inflammatory cells in a perivascular distribution within the brain and spinal cord white matter of patients (4,5 and 6). Early in the twentieth century, in his studies of acute and fulminant forms of MS, Otto Marburg emphasized the vascular orientation of demyelinated lesions (7), work that further contributed to the concept that MS was a primary inflammatory demyelinating disease. Marburg also described the prominent axonal disorder associated with acute lesions. Controversies soon developed regarding the pathobiology of MS, and the field was variably divided into “immunologic” and “developmental” schools of causality.

In 1916, James Dawson presented a detailed clinicopathologic correlation of the disease and provided a comprehensive summary of preexisting reports (8). His work was quoted extensively in Russell Brain's important textbook *Diseases of the Nervous System,* which proposed in its earliest edition that the disease was mediated by perivascular infiltration of lymphocytes and plasma cells with subsequent phagocytosis of myelin, glial overgrowth, and axonal damage (9). The identification of increased levels of Igs in the CSF of patients with MS (10), and the use of isoelectrofocusing (IEF) to demonstrate the typical oligoclonal pattern of Ig migration (11), further implicated responses of the adaptive immune system in the disease.

Parallel developments in the field of glial cell biology eventually identified oligodendroglia as the myelin-forming cells of the CNS (12,13,14,15,16,17 and 18), and further studies implicated oligodendrocytes, myelin components, and axons as the probable targets of immune-mediated pathologic features in MS (19,20,21,22 and 23).

The long-standing observations that MS is nonrandomly distributed across populations and geographic zones spurred a wealth of epidemiologic studies into the relative contributions of genetic predisposition and environmental factors to the pathobiology of the illness. More recently, molecular epidemiologic studies have consistently implicated the major histocompatibility complex (MHC) gene, and in particular the HLA-DR2 allele, as risk conferring. Population-based studies, as well as clinical trials in MS, have faced major challenges given the fluctuating and unpredictable course of the illness within any given individual patient as well as the great variability that exists across individual patients. Refinements in disease classification and diagnostic criteria, and the development of ancillary testing, have improved both the sensitivity and specificity of diagnosis. In particular, MRI has unveiled substantial subclinical fluctuations in disease activity attributed to local inflammation and has provided several powerful parameters to follow both the natural history of CNS involvement and the response to therapy. Since 1991, three immunomodulating treatments have been approved for the treatment of relapsing-remitting MS (RRMS) in the United States, based on a combination of clinical and MRI efficacy data. These major advances have established MS as a treatable neurologic illness. Nonetheless, the development of more effective and safer treatments that can be used at the time of diagnosis for this potentially disabling illness is paramount, and it is predicated on a more thorough understanding of the underlying immunopathology.

IMMUNOLOGIC OVERVIEW

Our current understanding of MS immunopathology is that autoreactive proinflammatory T cells are critical to the propagation of CNS tissue injury. Myelin-reactive T cells appear to be in an enhanced state of activation in the periphery of patients with MS, a finding suggesting a peripheral breach in tolerance to CNS antigen (Fig. 56.1). Selective expression of adhesion molecules, chemokines and chemokine receptors, and matrix metalloproteinases (MMPs) has also been demonstrated on inflammatory cells, endothelial cells, and glial cells in samples from patients with MS. These molecules are likely to be important in mediating the transmigration of effector cells across the BBB and into the CNS perivascular tissue. Invading autoreactive T cells can then become reactivated on encounter with their antigen in the CNS. The effector profile of such cells is likely to depend on several factors in the microenvironment, including the cytokine milieu and the costimulatory profile of local and infiltrating antigen-presenting cells (APCs). Further release of local cytokines, chemokines, and MMPs may support the recruitment of subsequent waves of infiltrating effector cells, including T cells, monocytes, and B cells. Mechanisms of myelin destruction and axonal damage are likely to be multiple and include direct effects of proinflammatory cytokines, oxygen radicals and complement fixing antibodies, antigen specific and nonspecific cytotoxicity, and apoptosis. Activation of resident CNS glial cells, such as microglia, may provide the basis for the generation or maintenance of pathologic responses, even in the absence of further infiltration of exogenous inflammatory cells. In contrast, evidence that glial elements may play a role in the repair and recovery from myelin injury may lead to the development of novel therapeutic approaches in MS and underscores the importance of elucidating the complexities of glial-immune interactions.

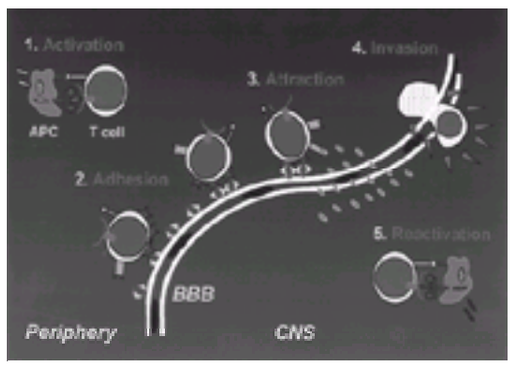

Figure 56.1. A model of multiple sclerosis (MS) immunopathogenesis. Myelin autoreactive T cells are found in an enhanced state of activation in the circulation of patients with MS. Upregulation of adhesion molecules *(1)*, chemoattraction *(2),* and elaboration of matrix proteinases *(3)* results in invasion of activated autoreactive T cells across the blood–brain barrier *(4)* (BBB). Inside the central nervous system (CNS), reactivation of T cells by local or infiltrating antigen-presenting cells (APCs) results in release of proinflammatory and cytotoxic mediators and leads to tissue injury. (See Color Figure 56.1)

Studies in EAE, the most commonly used animal model of MS, have provided important insights into mechanisms of T-cell–mediated CNS autoimmune disease. It appears likely that when a genetically susceptible host immune system encounters a common environmental antigen (e.g., an infectious organism), a process of *molecular mimicry* results in the peripheral activation of cross-reactive T cells that can migrate to the CNS and mount proinflammatory responses to myelin epitopes. Local damage results in exposure of additional myelin components that may become primary targets of subsequent waves of infiltrating cells, leading to the phenomenon of *epitope spreading.*

Studies of the mode of action of immunosuppressive and immunomodulating therapies in MS have further contributed to our understanding of the immunopathology of the disease. Putative mechanisms of action include the following: downregulation of costimulatory molecules and decreased peripheral activation of autoreactive T cells; interference with migration of inflammatory cells into the CNS by downregulation of adhesion molecules and MMPs, shifts in cellular responses from inflammatory to suppressive, or antiinflammatory effector profiles; or the generation of regulatory cells that may abrogate proinflammatory responses in the CNS by “bystander suppression.”

The successful search for safer, more effective therapies in MS will be predicated on our ability to determine the relative contributions of genetic and environmental factors, their respective impact on immune responses in health and disease, and the delicate balance between injury and repair that exists at the neural-immune interface.

EPIDEMIOLOGY

The broad clinical spectrum of MS and its fluctuating, unpredictable course make it an especially challenging illness to study from an epidemiologic perspective. In the absence of a definitive test, accurate diagnosis and reliable case ascertainment are not always possible. The long latency of expression of clinically evident disease poses a particular challenge to both retrospective and prospective studies of etiologic factors. Despite these complexities, much has been learned about MS through well-designed epidemiologic studies. Overall, the accumulating data support a model in which one or more environmental exposures in a genetically susceptible individual may result in the triggering of a CNS autoimmune disease.

The prevalence rates of MS in North America range between 30 and 150 per 100,000. Based on a weighted mean of several studies, the average annual incidence of MS in the United States is 3.2 per 100,000 per year. The median age of onset of symptoms is 23 to 24 years of age, with a peak age of onset for women in the early 20s and for men in the late 20s (24,25 and 26). As in most diseases classified as autoimmune, there is a clear female predominance in MS cases. In a summary of 30 incidence-prevalence studies, the cumulative female-to-male ratio was approximately 1.8 to 1.0 (27). The sex ratio of MS cases may have a nonrandom geographic distribution, much like the disease itself. For example, most studies conducted in Scandinavia and Canada (28) report female-to-male sex ratios that are near 1.5:1, whereas reports from Taiwan (29), Malaysia (30), and Northern Australia (31) find a ratio of 2.3:1 or greater. An exception to these is the Pharsee population in India, in which one sees a strong male predominance (32).

Environment

Global maps of MS prevalence rates, constructed based on multiple descriptive epidemiologic studies, reveal a nonrandom geographic distribution of the disease. A diminishing north-to-south gradient of MS prevalence was described in the Northern Hemisphere (33,34,35 and 36), with an opposite trend identified in the Southern Hemisphere (34,37). In general, investigators have observed that the highest prevalence rates are found in the temperate zones of both the Northern and Southern hemispheres, and the prevalence rises as one moves away from the equator. This nonrandom geographic distribution of MS likely reflects a combination of genetic and environmental influences. In both Europe and the United States, the prevalence of MS may reflect the degree of Scandinavian and northern European heritage in resident populations (38). Nonetheless, the severalfold difference in the south-north prevalence in Australia, across a genetically homogeneous population, argues for a nongenetic effect (39). The identity of such a latitude-based risk factor remains elusive. Cluster studies, in which an apparent excess of MS cases is reported within a small geographic area, have not contributed greatly to the etiologic understanding of MS (40,41). Likewise, ecologic studies, although useful in generating and providing early support for a wide range of etiologic hypotheses, are not directly amenable to inferences of causality (41,42). Hundreds of studies have attempted to explore the possible correlation between geoclimatic exposures (climate, natural radiation, geologic features, water, soil content, forestry, and rainfall) or sociocultural exposures (industry, agriculture, housing, diet, toxins, occupation, and religion) and the occurrence of MS (43). None of these putative risk factors have been substantiated.

Migration studies in MS have suggested that migrants from high-risk to low-risk areas show a decreased rate of MS (41,44,45 and 46). Furthermore, the age of emigration appears to influence whether the migrants acquire the risk of the new environment or retain the risk of their home country. Although such comparison studies are fraught with difficulties because of differences in case definition, case ascertainment, treatments, and survival, and the potential for nonrepresentative sampling (41,47,48), they do suggest that some environmental exposure during a particular window of time (likely in early adolescence) may contribute to the risk of developing MS.

These observations, together with studies of proposed “MS epidemics” (41), have contributed to the hypothesis that MS has an infectious origin. Despite multiple candidate organisms, to date, no infectious agent has been established as the cause of MS. A distinction must be made between the proposed role of an infectious agent as the specific cause of the disease and a cross-reactive interaction or even a relatively nonspecific interaction with a susceptible host immune system. Each of these may result in the onset, or exacerbation, of an immune-mediated disease. An infection may also unmask a preexisting deficit, rather than be involved in its pathophysiology. Indeed, several studies have identified an increased risk of MS exacerbation after a viral illness (41,49,50 and 51). Further discussion of the possible mechanisms underlying these observations is provided later in this chapter.

Genetics

Race has been identified as an independent factor affecting susceptibility to MS and, as noted, is likely to contribute to the nonrandom geographic distribution of the disease. European whites are at highest risk of the disease. Hispanic origin appears to confer a lower risk; in one study, persons of Hispanic origin comprised only 1% of MS cases, although they represent 8% of the total population. Likewise, African Americans comprised approximately 5% of MS cases in the United States, although they represent 12% of the general population (52). MS is also uncommon in Asia. Japanese persons and other Asians retain their relatively low susceptibility after emigration to the United States (53). Australian aborigines (39), natives of New Zealand (54), and black South Africans (55) are rarely affected, whereas MS is more common in the respective comingled white populations.

The combined results of several of the larger population-based MS twin studies (56,57,58,59 and 60) (Table 56.1, part A) demonstrate a concordance rate of approximately 27% in monozygotic twins and a 2.4% concordance in dizygotic, same-sex pairs (61). The dizygotic concordance rate is essentially the same as that found in nontwin sibships, and it exceeds the general population risk (approximately 0.2% lifetime risk). The further tenfold increase in risk observed in monozygotic twins provides clear evidence for a genetic contribution to MS risk, but it also underscores the importance of environmental factors.

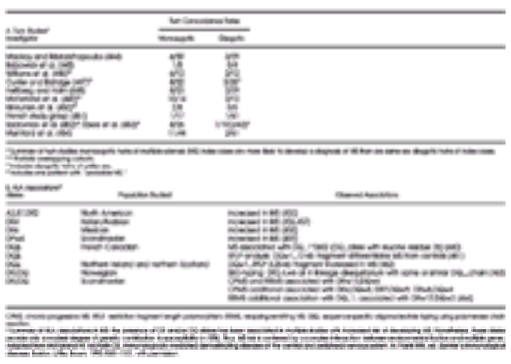

TABLE 56.1. Genetics of Multiple Sclerosis

Linkage analysis studies in MS multiplex families (with more than one affected member) have revealed an association of the MHC alleles with increased risk of developing the illness (Table 56.1, part B) (41,62). Extended MHC haplotype analysis concluded that class II DR2 conferred true susceptibility to the disease, rather than just being marker of an “at risk” population (63). More specifically, the class II MHC alleles DRB1*1501 or DRB5*0101, DQA1*0102 and DQB1*0602 (64,65) on chromosome 6p have been consistently implicated. Increased frequencies of these haplotypes are seen in northern Europeans, a finding suggesting that these genes may contribute to the geographic trends in MS prevalence. Nonetheless, these genes provide only a modest degree of genetic contribution (less than 10%) to susceptibility (66). Weaker associations have been reported, although not always replicated, for other MHC alleles, the T-cell receptor (TCR) and Ig chain encoding regions, myelin basic protein (MBP), and tumor necrosis factor (TNF) genes (67,68 and 69). There is no established evidence for a genetic marker that confers protection from the disease.

Three full genome searches, applying microsatellite polymorphism markers in large numbers of affected sibling pairs (70,71,72 and 73), identified chromosomes 2p23, 5q13, 6p21, and 19q13 as susceptibility regions, a finding supporting the existing hypothesis that genetic susceptibility to MS is conferred by multiple interacting genes, each with relatively modest individual contribution. From investigations of the EAE model, it is also likely that minor differences in protein structure identified by single nucleotide polymorphisms may have major consequence in immune function that are translated into disease susceptibility.

A general genetic predisposition to autoimmune diseases (an “autoimmune disease haplotype”), is suggested by some studies (74,75), but it would account for only a few patients with MS. Scattered reports note the concurrence of MS and systemic lupus erythematosus, scleroderma, myasthenia gravis, ankylosing spondylitis, uveitis, inflammatory bowel disease, autoimmune thyroid diseases, and diabetes (76,77,78,79,80,81,82,83,84 and 85), although none of these associations have been confirmed in rigorous population-based surveys except for thyroiditis.

CLINICAL PRESENTATION

Symptoms and Physical Findings

The hallmark of MS is the great variability in the clinical presentation and course of the illness. Inflammatory lesions may develop at any site along myelinated CNS white matter tracts, and symptoms therefore depend on the functions subserved by the pathways involved. The most common symptoms and signs involve alteration or loss of sensation resulting from involvement of spinothalamic or posterior column fibers, visual loss from optic neuritis, limb weakness and spasticity related to disruption of corticospinal tracts, tremors and incoordination of gait or limbs, largely related to cerebellar or spinocerebellar fiber involvement, and abnormalities of cranial nerve function (such as double vision from disturbance in conjugate eye movement) secondary to brainstem lesions (86). Trigeminal neuralgia and other paroxysmal sensory disturbances are not uncommon. The Lhermitte symptom is described as a sensation of electric shock radiating down the spine or into the limbs on neck flexion. It is a common symptom among patients with MS and is thought to reflect a lesion of the cervical spinal cord. Bowel, bladder, and sexual dysfunction occurs in more than two thirds of patients at some time during the course of their illness (87,88), largely because of disruption in spinal cord pathways. Fatigue is a common symptom of elusive origin that may significantly interfere with daily functioning (89). Depression in MS may occur in as many as half of patients (90,91), and it has been variably attributed to the direct effect of CNS lesions, to medications, or to affliction with a chronic, unpredictable illness. Cognitive impairment is increasingly recognized as an important problem in MS. Patients often complain of memory loss, distractibility, and difficulty in sustaining mental effort. Neuropsychologic testing reveals deficits in more than half of the patients tested, with most frequent abnormalities involving attention, recent memory, processing speed, and abstract conceptualization (92). A correlation with progressive brain atrophy on MRI has implicated axonal loss as the pathologic substrate of the cognitive deterioration in MS (93,94 and 95). Disability in MS is most often the result of fatigue, ataxia, spastic paresis, mood and cognitive changes, and gait disorders.

Most patients experience some degree of spontaneous improvement in symptoms after an acute attack. This has been attributed to the resolution of inflammation and edema at the site of the responsible lesion, rather than to the reversal of demyelination, which may persist even in the absence of symptoms (96). Patients often report transient worsening of existing symptoms, or a transient recurrence of old symptoms, when their body temperature increases. This form of heat sensitivity most likely results from a reversible deterioration in conduction in previously injured fibers and was classically described as the Uhthoff phenomenon, in which a hot bath led to transient visual deterioration in a patient with a prior history of optic neuritis. Exercise, fever, and a hot climate can similarly unmask preexisting lesions.

Clinical Course and Prognosis

MS is generally categorized as being either *RRMS* or *primary-progressive* in onset. A relapsing-remitting onset is observed in 85% to 90% of patients, and this form of the disease is characterized by a series of exacerbations that result in varying degrees of disability from which patients recover partially or completely. An exacerbation is followed by a remission period of variable duration (weeks to many years) before another attack. In keeping with the inflammatory substrate, attacks typically present subacutely. Symptoms develop over hours to several days, persist for days to several weeks, and gradually dissipate. Later in the disease, the extent of recovery from attacks is often decreased, and baseline neurologic disability accrues. The course of disease in about 40% of patients with RRMS ultimately changes to a progressive form known as *secondary-progressive* MS (SPMS). The progressive forms of disease (SPMS and primary-progressive MS) lack the acute attacks and instead typically involve a gradual clinical decline. Assessment of disability in MS has most often employed the Expanded Disability Status Scale (EDSS), ranging from 0 (no disability) through 10 (death from MS) (97). Several limitations of the EDSS scale (including its nonlinearity and underemphasis of upper extremity and cognitive functions) have led to the development of newer tools, such as the MS Composite, which is being validated in clinical trials (98).

The outcome of MS is highly variable. Untreated, approximately 50% of all patients with MS require the use of a walking aid (EDSS of 6) by 10 years after clinical onset (99), although the consequences on prognosis of newer treatment regimens are not yet clear. Men tend to have a more severe course of MS than women (100). Increased attack frequency and poor recovery from attacks in the first years of clinical disease predict a more rapid deterioration. Multiple T2-weighted and gadolinium-enhancing lesions on the presenting MRI scan also predict a more severe subsequent course. Conversely, minimal MRI T2-weighted or gadolinium-enhancing lesions on the initial scan, as well as first presentation with optic neuritis, the presence of sensory rather than motor symptoms, and good recovery from relapses, have all been associated with a more benign course (41,101). The life expectancy for patients with MS is mildly reduced compared with the general population, with important causes of MS-related mortality including depression, suicide, and severe neurologic disability (102).

Diagnosis

In the absence of a specific defining assay, the diagnosis of MS continues to be predicated on the clinical history and neurologic examination, although use of the MRI has had a major impact on early diagnosis. The old criteria for the diagnosis of *clinically definite* MS require evidence for the involvement of two or more separate CNS white matter sites as well as historical evidence of at least two episodes of neurologic dysfunction, separated in time. With the common use of MRI scanning, newer criteria for the diagnosis of MS will be required for patients presenting with monophasic symptoms. In one prospective study, patients experiencing their first episode suggestive of CNS demyelination and having corroborative MRI evidence of at least three typical lesions were followed for an average of 42 months (range, 13 to 84 months). Within the follow-up period, 83.4% of patients developed an additional relapse and thus qualified for the diagnosis of clinically definite MS. More than half of those patients developing clinically definite MS experienced the additional relapse within 1 year of their first episode (103). In another study, treatment of a similar group of patients (with a single demyelinating episode and abnormal MRI) with interferon-b1a (IFN-b1a) significantly delayed the occurrence of the disease-defining second episode (data reported at the annual American Academy of Neurology meeting, San Diego, 2000). The availability of treatments that are able to affect the course of MS favorably early on underscores the importance of timely and accurate diagnosis.

Acute disseminated encephalomyelitis is a monophasic demyelinating illness that can present with clinical, imaging, and laboratory manifestations indistinguishable from an acute MS attack. However, typical acute disseminated encephalomyelitis is seen in pediatric populations, it has a more explosive course associated with alterations in mental status, and a postviral or postvaccination history is often elicited. Although one should reasonably exclude alternate diagnoses that may also cause fluctuating neurologic dysfunction, with particular attention to treatable disorders, this is usually not a major issue. More common differential diagnostic considerations include collagen vascular diseases, sarcoidosis, vasculitides, and Lyme disease; however, patients with biopsy-proven sacoidosis, or with clear laboratory evidence of Lyme disease or systemic lupus erythematosus, may still exhibit what also clearly fits the clinical and MRI criteria of MS. Even after antibiotic treatment for Lyme disease, these patients often follow the course of typical MS, a finding that raises the possibility that two common diseases occasionally occur in the same patient. Other diseases that should be excluded include vitamin B_{12} deficiency, syphilis and human immunodeficiency virus (HIV) infection, and, rarely, mitochondrial disorders or late-onset leukodystrophies. Paraclinical tools such as visual, auditory, or somatosensory evoked responses show abnormal responses in 85%, 67%, and 77% of patients with MS, respectively (104), and these findings may support the diagnosis by providing evidence of involvement of additional CNS sites, although these additional test are often not needed with the use of the MRI. When the neurologic examination (alone or with supportive electrophysiologic evidence) demonstrates the involvement of two or more sites, but no clear history is elicited for multiplicity of events in time, the identification of certain CSF abnormalities may be used to make the diagnosis of *laboratory-supported* MS. The CSF of patients with MS typically shows normal glucose, a few lymphocytes, normal to mildly elevated total protein, and oligoclonal bands (OCBs) (Fig. 56.2 and discussion later in this chapter). Often absent early in the disease, OCBs can eventually be detected in more than 90% of patients with clinically definite MS (105), but they also occur in several other infectious, inflammatory, and lymphoproliferative disorders. Patients with human T-cell lymphotropic virus type I–associated myelopathy/tropical spastic paraparesis (HAM/TSP) exhibit high levels of intrathecally synthesized IgG (106). CSF OCBs have also been described in conditions such as subacute sclerosing panencephalomyelitis (SSPE) (107), neurosyphilis (108), varicella-zoster virus infection (109), and HIV infection (110), as well as in collagen vascular diseases, cerebrovascular accidents, and up to 5% of healthy persons. The frequencies of immunologic abnormalities in the CSF of patients with MS are shown in Table 56.2.

Cerebrospinal Fluid Abnormality (References)	Frequency (%)
Increased IgG (465,466)	50
Increased IgA, IgM (467)	25
Increased IgG index (465,468)	80–90
Increased IgG synthesis rate (466,469)	80–90
Oligoclonal bands (466,470,471)	90
Increased free κ light chains (472)	80–90

TABLE 56.2. Cerebrospinal Fluid Abnormalities in Multiple Sclerosis

Role of Magnetic Resonance Imaging

MRI has become established as the optimal imaging modality for MS. From a diagnostic standpoint, the typical appearance of multiple hyperintense lesions on T2-weighted imaging is not specific for MS. In the appropriate clinical setting, however, this appearance provides an important ancillary diagnostic tool that may establish the multifocality of CNS involvement. MRI has also been used to assess MS disease activity, disease burden, and the dynamic evolution in these parameters over time (111) (Fig. 56.3). MRI is four to ten times more sensitive than the clinical evaluation in capturing CNS lesions (112), and serial studies have unequivocally demonstrated that clinically apparent changes reflect only a minor component of disease activity. Lesions in the cerebrum are much more likely to be clinically silent, as compared with lesions in the brainstem or spinal cord.

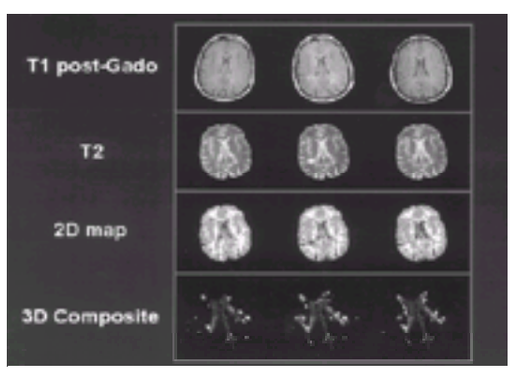

Figure 56.3. Serial magnetic resonance imaging (MRI) studies in multiple sclerosis (MS) highlight the dynamic disease pathophysiology. Serial brain MRI studies of a single patient with MS were taken at three different times **(left column:** study performed day 0; **middle column:** day 266; **right column:** day 362). **Top row:** Axial T1-weighted sequences obtained after gadolinium-contrast administration. Corresponding anatomic levels are compared at the three time points. A ring-enhancing lesion, absent in the first scan, is present on day 266 and disappears again by day 362. **Second row:** T2-weighted images at the same anatomic level demonstrate the appearance and subsequent shrinkage of this lesion, which remains visible on T2, but no longer enhances, at day 362. **Third row:** Computed algorithms enable the construction of accurate two-dimensional (2D) maps that distinguish and quantify white matter *(white),* gray matter *(gray),* ventricles *(blue),* and lesions *(yellow).* The ring-enhancing lesion is red. **Bottom row:** Three-dimensional (3D) composite model of the whole brain. The gray matter and white matter are stripped away to reveal the dynamic changes in lesional activity and burden over time (see text for further discussion). (From Weiner HL, Guttmann CR, Khoury SJ, et al. Serial magnetic resonance imaging in multiple sclerosis: correlation with attacks, disability, and disease stage. *J Neuroimmunol* 2000;104:164,165,166,167,168,169,170,171,172 and 173, with permission from Elsevier Science.) (See Color Figure 56.3)

Serial imaging studies, together with studies that correlate pathologic findings with recent MRI lesions, have been particularly informative and suggest that acute inflammation represents an early event in the development of an MS lesion (113). Newly appearing (acute) MS lesions on MRI show contrast enhancement on T1-weighted imaging after intravenous administration of gadolinium-chelate (114). This appearance reflects focal breakdown of the BBB, and correlative pathologic studies demonstrate acute inflammatory infiltrates at the same sites (115,116,117 and 118). Each contrast-enhancing lesion can also be seen as an area of hyperintense signal on T2-weighted MRI. This is thought to reflect a relatively nonspecific increase in water content at the site of the lesion. The contrast enhancement of a typical new MS lesion gradually dissipates over 4 to 12 weeks, a finding reflecting local restoration of an intact BBB that has been correlated with a decrease in the focal inflammatory profile. Concurrently, the T2-weighted hyperintense signal of the same lesion typically shrinks, leaving a smaller, often permanent T2-weighted abnormality that marks a site of previous inflammation (Fig. 56.3). Pathologically, regions corresponding to areas of increased T2 signal on MRI have a heterogeneous appearance ranging from interstitial edema without evidence of tissue damage through variable degrees and combinations of demyelination, axonal injury, axonal loss,

and astrogliosis (115,119,120 and 121). This lack of specificity may explain in part why T2-weighted lesion burden correlates poorly with disability (122,123). Newer imaging approaches, including magnetic transfer imaging (124) and MR spectroscopy (125,126), as well as measurements of T1-weighted hypointense lesions (127) and atrophy on MRI (119), have demonstrated improved correlation with disability and are likely to provide more specific quantitative measures of tissue injury. Based on these imaging studies and on pathologic observations (128,129), cumulative axonal injury is emerging as a major contributor to neurologic disability in MS.

Pathology

Gross examination of classic MS specimens reveals multiple irregular but sharply demarcated foci of discoloration and shrinkage scattered throughout the brain and spinal cord (Fig. 56.4). There is a predilection to the optic nerves and white matter tracts of the periventricular regions, brainstem, and spinal cord. Small plaques in cortical regions reflect involvement of intracortical myelinated fibers. In a single brain, lesions of variable age and size may be identified with the naked eye: fresh plaques may be pink (related to the hyperemia of active inflammation) or white to yellow (reflecting lipid breakdown products); more chronic plaques are retracted and grayish tan (from focal gliosis). Typical lesion size is 0.5 to 2.0 cm, although some lesions may be confluent whereas others remain microscopic. Global atrophy and *ex vacuo* hydrocephalus (predominantly from white matter tissue loss) correlate with disease duration.

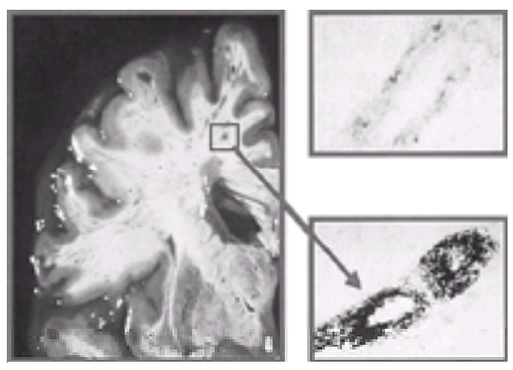

Figure 56.4. The pathology of multiple sclerosis (MS). **Left**: Coronal section of a cerebral hemisphere of a patient with MS. Multiple areas of discoloration, such as the one outlined in the **box,** are seen in the periventricular and subcortical regions and represent the classic MS plaques. **Lower right:** Microscopic view of a cryostat section from outlined subcortical plaque, stained with anti-CD4 antibody (magnification × 98). The hallmark perivascular inflammatory infiltrate is demonstrated. **Upper right:** Antikeratin control stain. See the text for a discussion of the pathologic heterogeneity of MS lesions. (From Windhagen A, Newcombe J, Dangond F, et al. Expression of costimulatory molecules B7-1 (CD80), B7-2 (CD86), and interleukin 12 cytokine in multiple sclerosis lesions. *J Exp Med* 1995;182:1985–1996, with permission of the Rockefeller University Press.) (See Color Figure 56.4)

Microscopically, MS lesions may be classified as active, chronic-active, or chronic-inactive or as “shadow plaques.” Since the earliest pathologic studies of MS in the 1830s, there has been general agreement that the hallmark of the disease is the inflammatory perivascular demyelinated plaque with reactive glial scar formation (19,130,131 and 132) (Fig. 56.4). More recent studies have elegantly demonstrated that substantial axonal injury occurs, and axonal transection is abundant throughout active MS lesions, along the hypercellular edge of chronic-active lesions and to a lesser, but significant, extent also in the hypocellular core of chronic-inactive lesions (128,129).

The inflammatory cell profile of active lesions is characterized by perivascular infiltration of predominantly T cells ($CD4^+$ a/b and g/d as well as $CD8^+$) and monocytes with occasional B cells and infrequent plasma cells (Table 56.3). Endothelial activation and perivascular edema are common. Lymphocytes may be found in normal-appearing white matter beyond the margin of active demyelination (20). Macrophages are most prominent in the center of the plaques and are seen to contain myelin debris, whereas oligodendrocyte counts are reduced. In ultrastructural studies, macrophages appear to strip myelin lamellae from axons, a feature that implicates them as important mediators of tissue injury. In the peripheral nervous system, clearance of myelin debris after nerve injury is a prerequisite to subsequent regeneration, and this raises the possibility that some macrophage functions may, in fact, be beneficial in the CNS as well (133).

Cellular
T cells, (CD4, CD8, TcRα/β and TcRγ/δ)
Macrophages, B cells and plasma cells
Reactive microglia, reactive astrocytes, reactive endothelial cells
Molecular
Immunoglobulins (variable isotypes)
Complement components (including membrane attack complex)
Proinflammatory cytokines (TNF-α, IFN-γ, IL-2, IL-12, LT, etc.)
Chemokines and matrix metalloproteinases
Adhesion molecules (on endothelia, leukocytes and glia)
Evidence of injury
Axonal damage
Myelin stripping and myelin debris
Oligodendrocyte loss (apoptosis, necrosis)

IFN, interferon; IL, interleukin; LT, leukotriene; TNF, tumor necrosis factor.
[a] The diversity of cellular and molecular elements found in MS plaques and the identification of unique patterns of plaque pathology suggest that several distinct pathogenic processes may be contributing to tissue injury in MS.
From Hickey WF. The pathology of multiple sclerosis: a historical perspective. *J Neuroimmunol* 1999;98:37–44, with permission from Elsevier Science.

TABLE 56.3. Variable Elements Identified in Multiple Sclerosis Plaques[a]

In chronic-active lesions, the inflammatory cell infiltrate is less prominent and may be largely restricted to the rim of the plaque, a finding suggesting some ongoing inflammatory activity along the lesion edge. Plasma cells may be more frequent than lymphocytes along the vessels of chronic-active lesions (134,135). In the center of a chronic plaque, astrocytic proliferation and denuded axons are found, with scattered foamy macrophages and microglia (containing lipid debris) and a paucity of oligodendroglia. Chronic-inactive plaques are generally characterized as sharply demarcated glial scars.

“Shadow plaques” are areas of thinly myelinated axons in which the myelin appears to be healthy, albeit thinner and less dense than usual. These are thought to represent regions of new myelin formation at sites of recent injury (136,137). The reason that this process is not uniformly seen in all cases of MS remains unclear.

Serial imaging studies with MRI and MR spectroscopy have provided important insights into the dynamic evolution of MS lesions and the extent of inflammatory activity, BBB compromise, and axonal injury, thus calling for a reevaluation of MS pathology (113,126,138,139). Indeed, the application of criteria defining MS lesional activity and the detailed analysis of plaques from both early and late stages of the disease with respect to the patterns of demyelination, cellular activation, and oligodendrocyte pathologic features have demonstrated that a spectrum of distinct lesion types may exist. These, in turn, may reflect divergent mechanisms of tissue injury (1,2,137,140,141). In certain plaques, T cells predominate, whereas in others, monocytes and Igs are principally involved at the site of damage. Some severely demyelinated plaques contain largely intact oligodendroglia, whereas in other plaques, demyelination is associated with significant oligodendrocyte destruction. In some lesions, the predominant mechanism of oligodendrocyte injury is necrosis, whereas in other lesions, apoptosis is much more prominent.

No correlation exists between either the extent of oligodendrocyte destruction or the predominant pattern of oligodendrocyte injury (apoptosis versus necrosis) and the stage of demyelinating activity. Furthermore, neither the extent nor the pattern of oligodendrocyte destruction correlates with the overall severity of the lesions. Thus, the distinct patterns of oligodendrocyte injury do not appear merely to reflect the temporal progression or the severity of a single pathogenic process, a finding suggesting that multiple immunopathogenic mechanisms are acting in parallel. In the comprehensive study by Luchinnetti et al. (1), however, the pattern of disease tended to be the same in multiple lesions from any single patient with MS. These observations raise the possibility that distinct immunopathogenic mechanisms may be operating in different patients with MS to produce variable patterns of tissue injury (1). MS classifications based solely on clinical criteria may fail to capture important nuances of the underlying pathophysiologic processes.

This hypothesis is supported by accumulating data from *in situ* and immunohistochemical analyses of MS plaques. Such studies reveal a broad range of cellular and molecular elements (Table 56.3) that may define a variety of immunologically distinct processes, rather than support a convergent, uniform model of MS immunopathogenesis. Both environmental exposures and polygenetic susceptibilities contribute to MS pathogenesis, and the combination and complex interactions of these factors may dictate the predominant immunopathogenetic response in a given individual. If this hypothesis is true, it could in part explain the broad heterogeneity that is seen in clinical course, disease severity, and response to therapy. Ultimately, the most effective treatment in a given MS patient may require insights into the

injurious mechanisms most prominent in that individual person at that time.

IMMUNOPATHOGENESIS

Lessons from the Animal Model

EAE is an immune-mediated disease of the CNS that is characterized by multifocal demyelinating plaques and perivascular inflammatory infiltrates, primarily comprised of T cells and monocytes, and associated with a paralytic illness. These pathologic and clinical features provide the impetus for studying EAE as a model of MS. EAE is mediated by $CD4^+$ T cells that recognize a variety of CNS autoantigens and secrete proinflammatory T-helper (Th1)-associated cytokines, such as IFN-g and TNF-a. It can be induced in several species of animals by injection of adjuvant with homogenized whole myelin or myelin components such as MBP, proteolipid protein (PLP), or myelin oligodendrocyte glycoprotein (MOG). The ability to induce EAE by passive transfer of $CD4^+$ MHC class II–restricted T cells that are reactive with these antigens (142,143 and 144), but not by serum from affected littermates, established EAE as a T-cell–mediated disease. The role of B cells is less well established. EAE has been successfully induced in B-cell–deficient animals, a finding suggesting that B cells are not critical for disease expression (145,146 and 147). In one of these studies, recovery from EAE was slower in the B-cell–deficient mice compared with wild-type littermates, a finding suggesting that B cells, in fact, may have a role in recovery (146). In other studies, however, B cells were required for the complete expression of the disease (148), with variable roles attributed to the presence of complement fixing antibodies or to the role of B cells as APCs (149). The observation that EAE can be induced in the marmoset model by injection of Igs directed against the myelin antigen MOG has rekindled interest in the humoral responses in EAE (150).

Susceptibility to EAE depends on the strain of the animal (151,152 and 153) (Table 56.4). For example, mice such as B10.Pl, SJL/J, and PL/J are susceptible , whereas BALB/c and C57BL/6 mice are relatively resistant. Disease severity and course are also influenced by the genetic background and may range broadly from a mild, uniphasic illness to aggressive relapsing-remitting and progressive disease patterns. Investigators now recognize that the development of EAE and the pattern of EAE pathology are dictated by the coordinated expression of certain genes that are involved in the activation and effector functions of inflammatory cells. The expression of these genes, in turn, is modulated by the animal's environment such that genetically identical animals with different infectious exposures may manifest distinct profiles of EAE induction and phenotype. An important component of susceptibility to EAE relates to the MHC background of the animal, which influences the T-cell repertoire, as well as which portions of the myelin proteins are encephalitogenic in any given strain (154). Genes that encode for costimulatory molecules, cytokines, chemokines, and adhesion molecules have been the focus of intense study. Molecular genetic techniques have enabled the dissection of the effects on disease phenotype of underexpression (knock-out) and overexpression (transgenic) of an ever-growing array of immune-related molecules (153,155,156,157 and 158). Table 56.5 provides a partial summary of this rapidly expanding body of work.

Mutation	Effect on Disease Susceptibility Relative to Wild Type	Reference
Knockouts		
TNF-α	Increase	473
TNF-α	Decrease	474
LT-α	Decrease	475
TNF-α + LT-α	Increase	476
LT-β	No change	475
β2-microglobulin	No change	477
CD8	Increase in relapses, decrease in mortality	478
IL-4	No change	479
IFN-γ	No change	473
IFN-γ	Increase	477
Interferon regulatory factor-1	Decrease	480
Transgenics

TABLE 56.5. Specific Molecular Mutations and Their Effects on Susceptibility to Experimental Autoimmune Encephalomyelitis[a]

The observation that IFN-g knock-out animals developed worse EAE than wild-type littermates led to a trial of IFN-g in MS that resulted in disease exacerbation (159). Likewise, anti–TNF-a receptor antibody, shown to ameliorate EAE (and rheumatoid arthritis), caused worsening disease in patients with MS (160). Another example relates to the therapeutic application of altered peptide ligands (APLs). In the animal model, a single amino acid substitution within the peptide sequence of an encephalitogenic myelin epitope resulted in an APL that induced TCR antagonism, partial agonism, and anergy when used to stimulate T-cell clones generated against the original encephalitogenic antigen. Treatment of EAE with the APL induced a myelin-reactive T-cell repertoire that was shifted with respect to its cytokine responses from an inflammatory (Th1) toward an antiinflammatory (Th2) profile and was associated with improvement (161). Based on these results, an APL of the immunodominant MBP (83,84,85,86,87,88,89,90,91,92,93,94,95,96,97,98 and 99) epitope was used in a trial of MS. Unfortunately, clinical deterioration and a dramatic increase in new gadolinium-enhancing lesion formation was seen in several patients receiving the APL (see further discussion later).

Thus, although EAE in a single inbred strain of animals may reflect single patients, the wide range of genetic diversity and the broad environmental exposure of highly outbred humans are clearly not well modeled by EAE. In spite of these limitations, studies of EAE have been used to define fundamental mechanisms underlying immune-mediated CNS demyelination and have helped to elucidate novel themes in autoimmunity, such as molecular mimicry, epitope spreading, and bystander suppression (described in detail later). The emphasis in the following section of this chapter is on data generated from human studies of MS. When appropriate, reference is made to the EAE literature to highlight general principles of immune system–nervous system interactions, elucidated in the animal model, that may have relevance to MS.

Autoreactive T Cells

The earliest demonstration that self-antigen may induce an autoimmune CNS inflammatory disease came about in the 1880s, when persons receiving the neural tissue containing Pasteur rabies virus vaccine were unfortunate enough to develop encephalomyelitis (162). The EAE model was developed in an effort to study this phenomenon, and based on the observation that $CD4^+$ T cells directed against myelin epitopes mediate EAE, there has been a long-standing effort to characterize myelin autoreactive cells in MS. In several studies (typically employing limiting dilution analysis), the calculated frequencies of T cells reactive to MBP (163,164,165,166,167,168 and 169), myelin-associated glycoprotein (MAG), and MOG (170,171 and 172) were similar or slightly higher in the circulation of patients with MS compared with normal subjects. Increased frequencies of PLP-reactive T cells in the blood and CSF of patients with MS compared with controls were also reported (172,173). Although the development of tetramer technology should permit a more comprehensive characterization of myelin antigen-specific cells, it is clear that myelin-reactive T cells can be found in the peripheral blood of both healthy persons and patients with MS (167). Thus, the mere presence of autoreactive cells in the periphery is an insufficient explanation for the development of autoimmune disease. If myelin-reactive T cells are nonetheless involved in MS immunopathogenesis, the prediction would be that these cells must differ in some way from those found in healthy persons. Indeed, Zhang et al. found that the interleukin-2 (IL-2) receptor, a hallmark of activated T cells, was expressed on MBP-reactive T cells from patients with MS but not on those obtained from healthy persons (174). Similar frequencies of MBP- and PLP-reactive $CD4^+$ T cells were obtained from peripheral blood mononuclear cells (PBMCs) of patients with RRMS and controls after primary stimulation with antigen. However, when the PBMCs were first expanded with IL-2 and then were further expanded with antigen, much higher frequencies of MBP- and PLP-reactive $CD4^+$+ T-cell activation requires two signals, one delivered through the TCR interacting with the MHC-peptide (signal 1) and the other provided by engagement of costimulatory molecules on the APC with their ligands on the T-cell surface (signal 2) (175). One important T-cell costimulatory pathway is represented

by the engagement of CD28 on T cells by the B7-1 or B7-2 molecules, typically expressed on the surface of activated APCs. Two reports have demonstrated that MBP-reactive T cells from the peripheral blood of patients with MS are less dependent on B7 costimulation for their activation, compared with MBP-reactive T cells from healthy persons. Stable cell transfectants expressing the MHC class II DR2 molecule, either alone or in combination with the human B7-1 or B7-2 costimulatory molecules, were used to present the immunodominant myelin peptide MBP (p85-99) to highly purified $CD4^+$ T cells obtained from DR2-matched patients with RRMS or controls (176). As expected, MBP-reactive T cells from healthy persons did not expand to transfectants expressing the DR2 molecule alone, but these cells readily proliferated when B7-1 or B7-2 molecules were also present. In marked contrast, transfectants expressing the DR2 molecule alone could expand MBP-reactive T cells obtained from patients with MS. In other experiments, antibodies that blocked the engagement of B7 molecules inhibited the expansion of MBP-reactive T cells from healthy persons but did not inhibit the expansion of these T cells from patients with MS (177). Together, these studies demonstrate that MBP-reactive T cells in patients with MS are in an enhanced state of activation and have less stringent stimulation requirements, a finding suggesting a breach in peripheral tolerance to this autoantigen. An important extension to these observations has been the demonstration that MBP-reactive T cells in patients with MS are more likely to belong to the memory T-cell pool than the autoreactive T cells in healthy persons (178).

Although myelin-reactive T cells in MS are less dependent on costimulation for activation, evidence suggests that upregulation of costimulatory molecules may contribute to disease pathogenesis. Immunohistochemical staining of MS plaques and inflammatory stroke lesions from the same brain reveals that whereas B7-2 is expressed in both types of lesions, the expression of B7-1 is restricted to the MS plaques (179,180). In other studies, enhanced expression of B7-1 was detected on B cells in peripheral blood and CSF of patients with MS compared with controls, whereas levels of B7-2 expression were the same. The increased expression of B7-1 appeared to correlate with disease activity, and, in one study, treatment response to IFN-b1b was associated with normalization of the levels of B7-2 expression on B cells of patients (181). In EAE, the B7:CD28/CTLA-4 costimulatory pathway is more directly implicated in disease pathogenesis and regulation (182). In an adoptive transfer model of EAE, *in vivo* treatment with CTLA-4–Ig (that prevents engagement of both B7-1 and B7-2 molecules with CD28 on T cells) during EAE induction or *in vitro* treatment of myelin autoreactive T cells before transfer of cells ameliorated the disease induced in the recipient animals. However, CTLA-4–Ig treatment of recipient mice after the transfer of autoreactive T cells did not influence either disease course or disease severity. Thus, CTLA-4–Ig was assumed to block the induction phase but not the effector phase of T cells in EAE. Local CNS delivery of CTLA-4–Ig using a nonreplicating adenoviral vector was able to ameliorate ongoing EAE (183). Members of the B7:CD28 costimulatory pathway are differentially regulated during the course of EAE (184), and the patterns of B7-1 and B7-2 expression appear to be distinct when comparing peripheral immune organs with the CNS. *In vivo* blockade of B7-1 during induction of relapsing-remitting EAE protected from the disease and skewed myelin autoreactive cells toward a Th2 (antiinflammatory) profile. In contrast, B7-2 blockade exacerbated disease and skewed autoreactive T-cell responses toward a Th1 (inflammatory) cytokine profile (185,186). Blockade of B7-1, but not of B7-2, after the first remission of relapsing-remitting EAE significantly decreased the incidence of subsequent relapses, a finding suggesting that B7-1 blockade prevented epitope spreading (187). However, it has become clear that the strength of signal delivered through the TCR influences the role of B7 molecules in the type of costimulatory signal delivered to the T cell.

Cytokines

T cells have been classified according to the cytokine profiles they produce on activation (188,189). MHC class II–restricted $CD4^+$ IL-2, lymphotoxin, and TNF-a, have been defined as Th1 (inflammatory) cells and have been clearly shown to be pathogenic in EAE. IFN-g induces APCs to secrete high levels of IL-12, which is a powerful proinflammatory cytokine by virtue of its ability to differentiate naive (Th0) cells into Th1 cells (190,191). Mice deficient for the IL-14p40 gene are resistant to EAE, and neutralizing antibodies to IL-12 inhibit the development of EAE *in vivo* (192,193). In contrast, $CD4^+$ 197). TGF-b producing cells have been termed Th3 cells and are also protective in EAE. Th2 cytokines promote humoral immune responses, and although defined as antiinflammatory cells in the context of EAE (a well-established cell-mediated disease), Th2 responses may be pathogenic in settings such as antibody mediated, immune complex, or allergic disorders (198). Multiple approaches used to manipulate *in vivo* cytokine functions, including neutralizing antibody administration and the development of cytokine transgenics and knock-out animals, have demonstrated that cytokines may have divergent, unpredictable effects on EAE (193,199,200). Such results may reflect differences in systemic versus CNS immune responses or, in the case of genetic engineering approaches, developmental redundancy or compensation (197).

The Th1/Th2 paradigm of T-cell responses appears to be less stringent in human $CD4^+$ cells as compared with mice, and defining MS as a Th1 disease has been less straightforward than in EAE. This may relate to differences in regulation of the IL-12 receptor b chain between humans and mice. Several reports have suggested that myelin-reactive T-cell lines derived from patients with RRMS have a Th1 bias (201,202 and 203), although it appears that most myelin-reactive T cells secrete both Th1 and Th2 cytokines, and cytokine secretion depends on the culture conditions (204). In other words, depending on *in vitro* conditions, MBP-specific cytokine responses can be shifted to a Th1 or Th2 phenotype in both patients and controls, an observation that may have important therapeutic implications (204). In a study of T-cell clones generated to PLP from patients with MS at different clinical stages of disease, cytokine profiles of clones were related to the stage of disease (205). During acute attacks, T-cell clones had Th1-like phenotypes with no TGF-b secretion. During remission in the same patients, however, most clones showed Th0, Th1, and Th2 cytokine profiles. However, these studies have not been replicated in other laboratories, and without MRI examinations of patients, it is not clear whether so-called “stable” patients are truly stable. In other studies, intracellular cytokine staining confirmed that PBMCs from patients with chronic-progressive MS express more IL-12 on activation than do those from healthy persons (206). Moreover, treatment of these patients with cyclophosphamide and methylprednisolone reduced the frequency of IL-12–staining monocytes to normal levels. In the same study, a greater frequency of T cells from untreated patients secreted IFN-g and TNF-a compared with T cells from normal control subjects. Frequencies of T cells expressing Th2 cytokines were comparable among patients with MS and healthy persons.

Several further lines of evidence support the hypothesis that Th1 cells may be pathogenic in MS. Th1 and Th2 cells express distinct profiles of chemokine receptors. An increased proportion of T cells from patients with MS was shown to express the characteristic Th1 chemokine receptor pattern, and MS plaques were found to express increased levels of the corresponding chemokines (207,208 and 209). Analysis of cytokine mRNA in CSF from patients with MS showed a bias toward Th1 cytokines (210). Immunohistochemical studies of MS plaques *in situ* have demonstrated the presence of the proinflammatory cytokines TNF-a and IL-12 (180,211,212). TNF-a was detected in chronic lesions from patients with MS, but it was not detected in the CNS of neurologic controls or in the spleen or PBMCs of patients with MS, a finding suggesting a specific association of TNF-a with the CNS lesions (212). Within the MS plaques, astrocytes and macrophages were found to be the source of the TNF-a (211). Thus, although direct evidence that MS is a Th1 disease is still lacking, there has been an ongoing effort to evaluate existing therapies as well as emerging therapies with respect to the profile of cytokine responses that they induce. Interventions that shift or deviate the cytokine responses away from a Th1 and toward a Th2 profile have been thought to be favorable. As discussed later, the ability to shift myelin autoreactive T-cell responses toward a Th2 cytokine profile may limit putative Th1-mediated injury. Furthermore, autoreactive T cells migrating into the CNS and elaborating Th2 cytokines at the site of inflammation may provide further benefit by suppressing local Th1 responses of other autoreactive T cells, in a process known as *bystander suppression.*

Humoral Immune Response

While accumulating studies of MS and EAE have led to the characterization of MS as a cell-mediated immune disorder and have directed the focus to the role of T cells in disease pathogenesis, an abnormal humoral immune response has also been well described in patients with MS. Indeed, a renewed interest in the possible contribution of B cells to MS immunopathology has been sparked by nonhuman primate and MS pathologic studies. Whether the abnormal humoral responses described in MS are directly involved in disease pathogenesis or whether these reflect epiphenomena of a dysregulated immune system remains to be elucidated.

Intrathecal Immunoglobulins

Intensive investigation into the role of the humoral response in the pathogenesis of MS followed the report by Kabat et al. in the 1940s that the CSF of patients with the disease contained elevated levels of Igs (10). This seminal observation has been consistently reproduced, such that detection of elevated levels of CSF Ig is still used to support the diagnosis of MS in some cases. The elevated Ig levels mostly result from increased synthesis of IgG (213), with lesser elevations also observed for the IgM (214), IgD (215), and IgA (216) isotypes. In pathologic studies, B cells identified in MS plaques are mostly surface IgG positive (217), and a population of plasma cells appears to reside in long-established plaques from patients with chronic progressive disease (134). Contrasting their common presence in the CSF of patients with MS, OCBs are only rarely found in the circulation of the same patients (218). These findings, and the observations that Ig-to-albumin ratios are higher in the CSF compared with the serum of patients (219,220), together provide evidence for the intrathecal production of the Ig. IEF separates proteins according to their isoelectric point. Thus, Igs derived from a clonal population of B cells migrate to the same position on an IEF gel. CSF Ig from most patients with MS separated by IEF reveal a distinct pattern of bands not observed in healthy persons (11). These OCBs correspond to a limited set of charged Ig proteins (Fig. 56.2). These bands are believed to represent Igs derived from an oligoclonal population of B-cell clones within the CNS. OCBs can be detected in more than 90% of patients with clinically definite MS (221,222 and 223). Additional techniques, such as immunoelectrophoresis (218), two-dimensional electrophoresis (216), and idiotype analysis (224), have supported the oligoclonal origins of the CSF Igs in MS. As noted earlier in this chapter, CSF OCBs and evidence of intrathecal Ig synthesis are found in conditions other than MS and are likely to reflect nonspecific CNS inflammation.

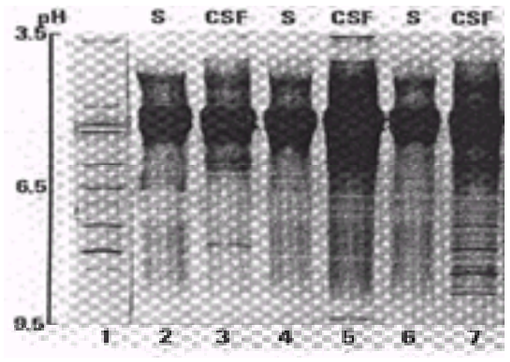

Figure 56.2. Oligoclonal bands (OCB) in multiple sclerosis (MS). Demonstration of OCB pattern of MS cerebrospinal fluid (CSF). Agarose isoelectric focusing of CSF and serum (S) from a patient with paraesthesia *(lanes 2 and 3),* myopathy of unknown cause *(lanes 4 and 5),* and multiple sclerosis *(lanes 6 and 7).* The *dark bands* in the lower part of *lane 7* are also present in immunofixation of the same isoelectrofocusing gel using antiserum against immunoglobulin chains, a finding indicating that these bands are largely composed of immunoglobulin G. *Lane 1* shows the pI reference standards. (From Link H. B-cells and autoimmunity. In: Russell WC, ed. *Molecular biology of multiple sclerosis.* New York: John Wiley, 1997:161,162,163,164,165,166,167,168,169,170,171,172,173,174,175,176,177,178,179,180,181,182,183,184,185,186,187,188,189 and 190, with permission.)

Substantial effort has been invested to elucidate the antigenic specificity of MS CSF Ig. Much of the earlier research in this field focused on exogenous antigens and on the identification of antibodies, within the elevated CSF Ig, directed against viruses and bacteria. This was fueled by early reports that measles antibodies could be detected in MS sera (225). Since then, oligoclonal IgG antibodies that react with a range of viruses, including measles, mumps, herpes simplex virus type-1 (HSV-1), varicella-zoster virus, cytomegalovirus, and rotavirus, have been reported in some patients with MS (226). Antibodies reactive toward Epstein-Barr virus antigens are present in more than 80% of CSF samples from patients with MS (227). Antibodies directed against b-hemolytic streptococcus, *Haemophilus influenzae* type B, *Escherichia coli,* and *Enterococcus* have also been reported (228). However, in all these studies, the viral and bacterial antibodies constitute only a minor fraction of the elevated MS CSF Ig (229). In contrast, in SSPE, much of the intrathecal Ig is directed against the measles virus (230), and in HSV-1 encephalitis, the elevated CSF Ig is largely accounted for by antibodies directed against the herpes virus (231). Furthermore, the antimicrobial antibodies variably identified in MS CSF have a lower antigen affinity than their counterparts in SSPE and HSV encephalomyelitis (232). These observations imply that the production of CSF Ig in SSPE and HSV-1 is antigen driven and is directed against the causative infectious agent. In MS, however, the driving mechanism behind the Ig elevation has not been successfully assigned to a single exogenous antigen.

The possibility that CSF Ig in patients with MS is generated as a response to myelin self-antigens has also been considered. Antibodies specific for MBP have been identified in the CSF (233,234), as well as in CNS tissue (235), of patients with MS. In another study, autoantibodies to MBP were detected in the CSF of more than 90% of patients with MS with active disease, whereas they were undetectable in 98% of non-MS CSF (236). Antibodies directed to PLP are also found in MS CSF; however, curiously, it seems that anti-MBP and anti-PLP antibodies are not present simultaneously in a given patient (237,238). Whether this observation reflects the gradual spread of the antigenic focus in MS (epitope spreading) remains to be established. Autoantibodies reactive with MAG (239), with the enzyme transaldolase (TAL) (240), and with oligodendrocyte-specific protein (OSP) (241) have also been detected in the CSF of some patients with MS. In one study, high-affinity autoantibodies directed against TAL were detectable in CSF of 15 of 20 patients with MS, whereas they were absent in 145 healthy persons and in patients with other autoimmune and neurologic diseases (240). TAL is expressed in oligodendrocytes and is of interest because it shares amino acid sequence homologies with core proteins of human retroviruses. The putative B-cell epitope of OSP shares sequence homology with several viral peptides. These reports suggest a role for molecular mimicry in the development of MS CSF Igs. In all these studies, however, only a minor component of the total Ig measured in MS patient CSF samples could be explained by antibodies directed against the myelin self-antigens under question. Standard approaches to the detection of antibodies in body fluids and tissues may be limited, in part, by the formation of immune complexes. This potential limitation has been addressed in studies in which CNS tissue has been subjected to acidification to effect elution of bound immune complexes. After such treatment of MS plaques, otherwise undetectable OCBs have been revealed (107,242,243).

Autoantibodies reactive with MOG were also detected is MS CSF in previous work (244). The potential role of anti-MOG antibodies came under sharper focus with the development of a marmoset EAE model. Marmosets immunized with antibodies against MOG developed EAE (150), an outcome that in other EAE models generally requires immunization with the actual antigen and adjuvant or the passive transfer of activated autoreactive T cells. No demyelination occurred when animals were similarly immunized with antibodies against MBP. Disease-inducing T cells enhanced the lesions in this model. In a follow-up to these studies, autoantibodies to MOG were found bound to disintegrating myelin segments in actual MS lesions (245). This body of work has contributed to the renewed interest in humoral responses in MS.

An intriguing, although poorly understood, humoral phenomenon in many MS CSF samples is the appearance of free light chains (218). These free k and l chains do not appear to result from degradation of whole Ig, but rather are thought to be produced by intrathecal plasma cells (246). Indeed, free light chains have been reported in MS CSF that does not contain oligoclonal IgG (247). More recently, investigators reported that the same, or similar, k light chain variable regions can be shared between CSF B cells from different patients with MS (248). Light chains were originally described as a product of multiple myeloma, in which a B-cell neoplasm produces the dimeric light chains known as Bence Jones proteins. Whether B cells within the MS CNS behave as though they have undergone a form of malignant transformation has not been established. Finally, although frequently found in MS, CSF light chains are not specific to MS and have also been reported in cases of neurosyphilis (249) and in HIV-1–infected patients (250).

Despite much effort, the bulk of the specific activity of intrathecal Ig in MS has not been definable. Nonetheless, evidence suggests that an antigen-driven response may be at work. Examination of CNS Ig in MS reveals that much of the IgG present is of the IgG1 subclass (251,252). The CNS Igs that react with various bacterial or viral antigens also have IgG subclass restrictions (252). This finding implicates, in both cases, an antigen-driven response rather than nonspecific activation. Analysis of the Ig V_H domains from MS samples reveals that these gene segments have accumulated replacement mutations in the complementary determining regions (CDR) (253). These findings have since been reproduced and strongly suggest an antigen-driven response, with associated somatic hypermutation, rather than polyclonal B-cell activation (254,255 and 256).

B Cells

Relatively little research has been performed regarding the B-lymphocyte population in MS. As noted earlier, hypersomatically mutated (presumably memory) B cells have been detected in the CSF of patients with MS (253). Several studies have examined the relative numbers of autoreactive B cells in the CNS. This was done by using ELISPOT to enumerate the autoantigen specific Ig-secreting B cells in MS plaques. Elevated numbers of CNS cells from patients with MS secreting antibodies to MBP (257), PLP (172), MAG (258), and MOG (171) have been reported. These autoreactive B cells were typically found in much lower numbers in the peripheral blood of the same patients with MS and in control subjects, a finding suggesting a preferential accumulation in the MS CNS. Several studies using fluorescence-activated cell sorter analysis have demonstrated that the relative number of peripheral B cells ($CD19^+$) in MS is not abnormally elevated (259). The subset of $CD19^+CD5^+$ lymphocytes, implicated in autoantibody production, has also been studied, and although cells with this phenotype have been detected in MS CSF, a conclusive role in autoantibody production in this compartment has not been established (260,261).

Serum Autoantibodies

The detection of autoantibodies directed against myelin antigens in the serum of patients with MS has been elusive. This may in part relate to a tendency to form immune complexes that hampers their detection (262). Serum anti-MBP antibodies have been reported (263,264), although not in all studies (257,265,266). In one study, 54% of MS sera tested was positive for MOG autoantibodies, whereas 22% of sera from healthy individuals were also positive (267). As with MBP, reports are conflicting regarding the detection of anti-MOG antibodies in MS serum (244). Investigators have reasoned that negative results reported from searches for autoantibodies may be caused by the deposition of the relevant antibodies in the CNS that may act as a sink. Certainly, low affinity and low concentration may be hampering detection. Sporadic reports have noted detecting serum autoantibodies against recombinant TAL (240), and B cells secreting autoantibodies directed against PLP have been identified in the peripheral blood of patients with MS (172). Autoantibodies to other putative MS antigens, such as myelin oligodendrocyte glycoprotein (MOBP), 2',3' cyclic nucleotide 3' phosphodiesterase (CNPase), myelin oligodendrocyte glycoprotein, ab-crystalline, and S-100b have not been analyzed in sera (268). Autoantibodies directed against nonmyelin antigens have also been detected in the sera of some patients with MS. Antinuclear antibodies (269), anticardiolipin antibodies (270), and antibodies against b_2-glycoprotein I (271) are detected in MS sera more frequently than in the sera of healthy persons. Elevated autoantibody levels toward a large panel of organ-specific and non–organ-specific antigens were measured in patients with MS relative to control subjects (272). The pathogenic relevance of these observations is not established, and a form of nonspecific systemic immune dysregulation is suspected.

Complement

Elevated levels of the membrane attack complex (C5b-9) have been reported in the CSF of patients with MS (273,274). C5b-9–enriched vesicles have also been demonstrated in the MS CSF (275). Consistent with these findings is the observation that CSF C9 concentrations are decreased in patients with MS relative to control subjects (276), a finding implying increased consumption of C9 in MS, as occurs during formation of the C5b-9 attack complex. These results suggest that complement components may participate in the tissue-damaging processes in MS. Overall, however, reports on the involvement of complement in MS have been conflicting, and a pathogenic role has not been established.

Migration of Inflammatory Cells into the Central Nervous System

Perivascular infiltration of inflammatory cells in the CNS represents one of the pathologic hallmarks of MS lesions and requires adhesion and transmigration of these cells across the BBB (277,278) (Fig. 56.1). The concept that the CNS is an immunologically privileged site has been challenged and modified over the years, and it is now accepted that small numbers of lymphocytes continuously migrate across the BBB in the normal state (196,279,280 and 281). This process appears to be unrelated to the antigenic specificity of the infiltrating cells and is thought to represent a random surveillance function of the immune system. Activated T cells, however, express upregulated levels of adhesion molecules and are able to migrate across the BBB much more efficiently than naive, resting T cells. Extravasation of cells has been characterized as a multistep and highly regulated process (282). This involves a sequence of overlapping molecular interactions between inducible ligand-receptor pairs on the surface of the migrating cell and the endothelial barrier (277,283). According to this *rolling-adhesion model,* initial tethering is achieved by selectin-carbohydrate binding that results in a reversible rolling of the leukocyte along the endothelial surface. Firm adhesion may be achieved if activated leukocyte integrins interact with Ig superfamily members, expressed on the endothelium. Locally generated chemokines promote integrin activation and contribute to cellular arrest (284). Chemokine-chemokine receptor interactions further drive the migration of cells toward the source of the chemical gradient, and elaboration of MMP effects a breakdown of the basement membrane and facilitates tissue infiltration (285). Evidence from EAE and MS studies has implicated each of these molecular interactions in disease pathogenesis and identifies potentially exciting novel therapeutic targets.

Selective Expression of Adhesion Molecules

Intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1), both members of the Ig superfamily, play important roles in endothelial-leukocyte interactions and in leukocyte extravasation (286,287). ICAM-1 binds to the integrin receptors leukocyte factor antigen-1 (LFA-1) (CD11a/CD18) and type 3 complement receptor-1 (CD11b/CD18) on the surface of leukocytes (288). VCAM-1 binds with a_4 integrins, including very late antigen-4 (VLA-4) a_4b_1 integrin, which is constitutively expressed on most mononuclear cells (289,290). Elevated levels of ICAM-1 have been identified on endothelial cells of both acute and chronic-active MS lesions, and these levels were shown to correlate with the extent of leukocyte infiltration (283,291,292 and 293). VCAM-1 was detected in chronic-active MS lesions, on both endothelial cells and on microglia, in contrast to normal brain, in which no VCAM-1 was identified (294). The ligands for ICAM-1 and VCAM-1 (LFA-1 and VLA-4, respectively) have been identified on the perivascular inflammatory cells of MS lesions (295). More direct implication in pathophysiology is derived from observations in the EAE model. Myelin autoreactive T cells fail to cross the BBB in VLA-4–deficient animals (296,297). Moreover, treatment of wild-type animals with monoclonal antibody directed against VLA-4 results in diminished infiltration of the CNS by inflammatory cells with a concomitant diminution in disease severity (298,299). The specificity of these molecular interactions is underscored by the demonstration that whereas the interaction between the a_4b_1 integrin (VLA-4) and VCAM-1 is required for the development of EAE, blockade of the interaction between the a_4b_7 integrin and VCAM-1 does not influence disease development (300).

Several studies have demonstrated adhesion molecules on the surface of CNS glial cells. ICAM-1–positive astrocytes are found both within and around active MS lesions, but not in normal brain (291,294). VCAM-1 and LFA-1 are detectable on microglial cells in chronic-active MS lesions (294). In addition to the possible role in inflammatory cell migration, investigators have proposed that glial cell expression of adhesion molecules may play roles in antigen presentation and T-cell costimulation (295,301,302), as well as in glial–extracellular matrix interactions (303). The local immune microenvironment may have important ramifications on the expression of adhesion molecules, influencing, in turn, the recruitment of further inflammatory cells. ICAM-1 expression on cultured human astrocytes is enhanced by proinflammatory cytokines (304). A similar observation is made in murine systems in which this upregulatory effect can be countered by antiinflammatory cytokines (305,306). This cytokine-mediated regulation of adhesion molecule expression on glial cells appears to be cell-type specific (306), and the molecular mechanisms underlying these effects are currently under active study (286). Elevated levels of the soluble forms of adhesion molecules including sICAM-1 and sVCAM-1 have been detected in the serum (307,308 and 309) and CSF (310,311 and 312) of patients with MS compared with control subjects. These levels appear to correlate with clinical and MRI indicators of disease activity and with the pattern of MS (308,309,313). Proteolytic cleavage of membrane-associated adhesion molecules appears to be the most likely source of sICAM-1 and sVCAM-1, and MMPs (see later) may be involved in this process (314,315). Although no consistent association has been found between levels of soluble E-selectin (sE-selectin) and disease activity (309,312,316), there appears to be a selective elevation of sE-selectin in patients with primary progressive MS that is not seen in patients with the RRMS (317,318).

During treatment with IFN-b1b (which has been shown to decrease MS activity), levels of sVCAM and sICAM were increased, and these elevations correlated with a decrease in the MRI lesion burden (319,320,321 and 322). In view of these seemingly contradicting observations, it remains difficult to assign a clear pathophysiologic role to soluble adhesion molecules. A possible explanation may stem from the additional observation that VLA-4 expression on peripheral blood lymphocytes is decreased in patients with MS during treatment with IFN-b (323). Conceivably, the elevated levels of soluble adhesion molecules (e.g., sVCAM-1) associated with IFN-b treatment may result in quenching or downregulation of their ligands (e.g., VLA-4) on the inflammatory cells and thereby may inhibit pathologic cellular infiltration of the CNS (286,323).

Selective Expression of Chemokines

Chemokines can enhance immune cell migration through direct chemoattraction and by activating leukocyte integrins to bind their adhesion receptors on endothelial cells. Certain a and b chemokines have been identified that appear to recruit T cells and monocytes selectively into the CNS and are associated with EAE disease activity (324). Karpus and colleagues directly compared the roles of macrophage inflammatory protein-1a (MIP-1a), membrane cofactor protein-1 (MCP-1), and MIP-2 in the induction of EAE (325,326). *In vivo* administration of monoclonal antibodies against MIP-1a inhibited adoptively transferred EAE, whereas antibodies directed against MCP-1 inhibited relapses. Consistent with these observations, immunohistochemical analysis of postmortem brain tissue from patients with MS has demonstrated that astrocytes, but not perivascular or parenchymal microglia, express MCP-1 in both active demyelinating and chronic active lesions (327). In another study, mRNA levels of RANTES (regulated on activation normal T cell expressed and secreted), chemotactic for lymphocytes and monocytes, were examined in brain samples of patients with MS (328). RANTES was expressed by activated perivascular T cells that were localized predominantly at the edge of active plaques. A comprehensive study by Sorensen and colleagues examined the expression levels of chemokines and chemokine receptors on cells in the CSF of patients with MS, neurologic control patients, and healthy persons, as well as the expression of chemokines and their receptors by brain tissue obtained from patients with MS (209). The authors noted an increase in RANTES levels and a threefold increase in interferon inducible protein 10 (IP-10), chemotactic for activated T cells, in the CSF of patients with MS compared with control subjects. There were no differences among the study populations in the levels of IL-8 or GRO-a, which are chemotactic for neutrophils. An increased frequency of $CD4^+$ and $CD8^+$ T cells from the CSF expressed the IP-10 receptor CXCR3. Immunohistochemical staining confirmed these results. There was an increased perivascular expression of CXCR3 in MS lesions, whereas RANTES staining was also upregulated in MS plaques but was expressed in a more diffuse manner. CCR5, the receptor for RANTES, was also detected on lymphocytes, macrophages, and microglia in actively demyelinating lesions. Thus, in addition to MIP-1a and MCP-1, the data suggest that the IP-10/CXCR3 and RANTES/CCR5 pathways have selective roles in MS pathogenesis.

Data indicate that some of the chemokines and chemokine receptors that have been implicated in both EAE and MS are preferentially chemotactic for the proinflammatory Th1 cells (208,209,328). Th1 cells preferentially migrated in response to the CC chemokines MIP-1a and RANTES, whereas neither Th1 cells nor the antiinflammatory Th2 cells responded to CXC chemokines (207). The extent to which chemokines and their receptors contribute to MS pathogenesis is unclear. For example, absence of a functional RANTES/CCR5 system alone is not sufficient to protect against the development of MS, because several patients with MS have been identified in whom a homozygous mutation prevents the expression of CCR5 (329).

Selective Expression of Matrix Metalloproteinases

MMPs comprise a family of tightly regulated proteolytic enzymes that are secreted into the extracellular matrix. Degradation of the extracellular matrix plays an important role in many normal physiologic processes, but under pathologic conditions, extracellular matrix degradation may promote tissue invasion by neoplastic or inflammatory cells (330). MMPs are expressed by activated T cells, monocytes, astrocytes, and microglial cells (331,332,333 and 334), and they are typically secreted as proenzymes, requiring proteolytic cleavage for their own activation and undergoing downregulation by tissue inhibitors of MMPs (TIMPS). Potential mechanisms of MMP contribution to MS pathophysiology include the following (335,336): (a) disruption of basement membrane of the BBB (337,338), thereby facilitating transmigration of inflammatory cells; (b) breakdown of extracellular matrix enabling infiltration into the neurophil (331,339); (c) proteolytic cleavage of membrane-bound proinflammatory cytokines such as TNF-a (340,341); and (d) direct damage to the myelin sheath (342).

In pathologic studies of MS tissue, gelatinase B (MMP-9) was expressed in white matter perivascular mononuclear cells and, together with other MMPs, was associated with both monocytes and astrocytes in demyelinating lesions (333,334). Microglia in active MS lesions express a range of inflammatory cytokines that have been shown to induce gelatinase B expression by inflammatory cells *in vitro* (293). Participation of MMPs in MS lesion development may result from aberrant

overproduction of the proteases or from failure to downregulate their actions sufficiently.

Increased activity of CSF proteolytic enzymes has been reported in patients with MS compared with healthy persons (343,344). Gelatinase B levels are increased in both serum and CSF of patients with MS during acute relapse, and the elevated levels correlate with the degree of BBB disruption as evidenced by the numbers of gadolinium-enhancing lesions on MRI (345,346). Furthermore, treatment with corticosteroids that are known to suppress MMP transcription is associated with a reduction in both CSF gelatinase levels and in the number of enhancing MRI lesions (347).

In vitro studies demonstrate that IFN-b1b inhibits T-cell expression of MMPs and subsequent T-cell migration. These observations may explain in part the ability of IFN-b1b to diminish the gadolinium-enhancing burden and to modify the progression of disease in patients with MS (348,349 and 350). In EAE, the interaction between T cells and endothelial cells, mediated by the adhesion molecule VCAM-1 (see earlier), induces T-cell secretion of the MMP gelatinase (351). MMPs, in turn, are able to participate in the release of adhesion molecules from the cell surface (315). Furthermore, MMPs have been shown to cleave surface-bound proinflammatory molecules including TNF-a, which has been shown to promote BBB breakdown and tissue injury (340). Ongoing studies in EAE allow more direct examination of the complex interactions among chemokines, adhesion molecules, MMPs, and proinflammatory cytokines and provide the opportunity to study novel therapeutics aimed at these molecular targets.

Central Nervous System Reactivation and Immune-Neural Interactions

A more complete understanding of the immune responses that take place within the unique CNS environment requires an appreciation of the complex interplay between immune and neural elements. In this context, the CNS should not be regarded merely as a passive target of immune-mediated injury. Rather, investigators now recognize that CNS elements may initiate, regulate, and sustain local immune responses (352). Immune cells percolate through the CNS at a low baseline rate as part of the normal process of immunosurveillance. Thus, a network of immune-neural interactions exists even under physiologic conditions and may serve to maintain the normal CNS microenvironment.

Autoaggressive T-cell responses directed against myelin elements require reactivation of these T cells on entry into the CNS that, in turn, is predicated on appropriate antigen presentation. This may occur at the BBB interface (by endothelial cells or by “perivascular microglia”) or within the CNS parenchyma (by resident microglia, astrocytes, or infiltrating monocytes or macrophages). BBB endothelial cells have been shown to process and effectively to present myelin antigen to T cells (353). Although the endothelial cells do not express MHC class II molecules in the resting state, they can be induced to do so on exposure to proinflammatory cytokines (e.g., IFN-g), which concurrently upregulate B7 costimulatory molecules (352,354). In studies using human brain microvascular endothelial cells (HBVECS) as APCs to autologous T cells, proliferative responses of the T cells could be either enhanced or inhibited, depending on the *in vitro* microenvironment, a finding suggesting that BBB endothelial cells may have a regulatory role in CNS inflammatory responses (354). In the context of CNS T-cell reactivation, “perivascular microglia/macrophage” may be particularly important APCs, based on their unique location at the interface between the circulation and the CNS, their apparent high basal level of expression of MHC class II molecules, and their ability to phagocytose and process antigens efficiently (355). In addition, perivascular macrophage may regulate the ability of T cells to migrate beyond the perivascular space and into the CNS parenchyma (356).

Within the CNS, parenchymal microglia, derived from hematogenous precursors during embryogenesis (357,358), also constitutively express MHC class II molecules (359) and can phagocytose and present antigen to T cells (360,361). These resident CNS microglia share several phenotypic and functional characteristics with professional antigen-presenting dendritic cells, including the constitutive expression of B7-2 costimulatory molecules and the propensity to upregulate B7-1 molecules on activation (359). Microglia studied within MS plaques *in situ* were shown to express B7-1 in addition to B7-2, whereas microglia from inflammatory stroke lesions in the same brain expressed B7-2 but not B7-1 (179,180). This selective upregulation points to a role for microglial activation and B7-1 signaling in the immunopathogenesis of MS. Activated CNS microglia are therefore poised to present myelin antigens to autoreactive T cells efficiently.

Investigators have further shown that, on contact with activated T cells, human microglia are capable of producing large amounts of IL-12, which, as noted previously, is perhaps the most potent inducer of Th1 responses (352). The IL-12 production depends on the engagement of CD40 (on microglia) by CD40-ligand (upregulated on activated T cells) and can be enhanced by IFN-g from the T cells (362) as well as by autocrine secretion of TNF-a from activated microglia or infiltrating macrophages (363,364). Microglia express several “pattern recognition” receptors (such as the lipopolysaccharide receptor, CD14) and can become rapidly activated in response to a range of CNS insults including infection, trauma, and tissue degeneration (352). The subsequent elaboration of proinflammatory cytokines (including IL-1b, IL-6, IL-12, and TNF-a) may trigger an inflammatory cascade that self-perpetuates long after the original insult is gone. These interactions place microglia at the interface between innate and adaptive immune responses and highlight the possible roles of these resident CNS cells in initiating, propagating, and maintaining MS inflammatory responses.

Astrocytes, although capable of upregulating MHC class II molecules on activation (365,366), have generally not been viewed as efficient APCs. Activated human fetal astrocytes expressing MHC tend to induce T-cell anergy, perhaps because of the absence of B7 expression (367,368 and 369). Astrocytes have also been shown to mitigate the inflammatory responses induced by microglia, and they may have a downregulatory role on T-cell inflammatory responses in the CNS (370,371). The elaborate “cross-talk” that exists among T cells, microglia, and astrocytes underscores the importance of immune-neural interactions in the disease immunopathogenesis.

Mechanisms of Tissue Injury and Recovery

The following is a summary of the major themes of immune-mediated injury in MS; a more comprehensive discussion of the multiple mechanisms of tissue damage in MS is provided elsewhere (129,372,373). Although MS can be regarded as a systemic autoimmune disease, the distribution of tissue injury is remarkably specific. Disease is largely limited to CNS myelin or its cell of origin, the oligodendrocyte, and to the underlying axons. Axonal injury may be secondary to immune responses or the loss of trophic support from myelin, and evidence suggests that a primary process of axonal injury may play an important role (129,372). The selective injury pattern is likely conferred by features of both the effector elements of the immune system and the target tissue itself. Responses of the adaptive immune system (mediated by a/b T cells, B cells, and specific Igs) provide a high degree of selectivity based on recognition of particular tissue antigens. In contrast, effector elements of the innate immune system, such as a/b T cells, natural killer (NK) cells, macrophages, and complement, are less restricted by specific antigens, and selective responses depend on properties of the target microenvironment, including interactions with elements of the adaptive immune system, such as complement fixation of bound antibodies. Table 56.3 lists the various cellular and molecular elements found in MS plaques and suggests that distinct pathologic mechanisms may be playing a role.

Initial lesion development appears to depend on infiltration of T cells and may be largely driven by autoantigen-specific responses. These may involve both MHC class II–restricted a/b $CD4^+$ T-cell responses and MHC class I–restricted cytotoxicity mediated by $CD8^+$ cells. Antibodies directed against myelin or oligodendrocytes may induce injury by both antibody-driven cytotoxic responses and by complement fixation of bound antibody. NK cells, NK T cells, and a/b T cells may damage cells by perforin-granzyme release. Oligodendrocytes are also susceptible to apoptotic cell death (mediated by both Fas and TNF pathways); the degree of susceptibility is, in part, determined by additional factors in the microenvironment as well as by the internal signaling environment of the target cells (129,372,374,375 and 376). A range of toxic proinflammatory cytokines and other soluble elements such as nitric oxide and reactive oxygen species may contribute to nonspecific injury and oxidative stress (340,372,377,378,379,380,381 and 382). Mononuclear phagocytes are the major effector cells responsible for removing myelin in MS lesions. The role of resident microglia, discussed earlier, may represent a mechanism by which damaging inflammatory processes may be maintained, long after the initiating events have dissipated. Finally, reports also note that both cellular (e.g., astrocytes) (383) and humoral (e.g., TNF-a neurotrophin receptor/NGF) (372,384,385,386,387,388,389 and 390) elements in MS lesions can exert a dual role, promoting either injurious proinflammatory or protective antiinflammatory responses in a context-dependent fashion.

Recovery in MS may involve resolution of active inflammation, remyelination of surviving oligodendrocytes, or maturation of progenitor cells. The rapid improvement typically observed in the first week or so after a relapse is likely to reflect resolution of local edema and removal of potentially toxic immune mediators that may adversely affect axonal transmission. In contrast, the more gradual recovery that some patients experience over months after an exacerbation probably reflects a limited degree of remyelination and reorganization of sodium channels on demyelinated axons (129,391). Shadow plaques, originally mentioned by Marburg (7) and Dawson (8), are described earlier and are thought to represent attempts at remyelination.

Several studies have suggested that the humoral response in MS may promote remyelination after damage. Proposed mechanisms include binding of antibodies promoting oligodendrocyte proliferation, binding of antibodies promoting oligodendrocyte clearance and replacement with viable cells, and antibody-mediated blockade of otherwise pathogenic molecule (392). The Theiler murine encephalomyelitis virus (TMEV) model of MS produces chronic, progressive, inflammatory CNS demyelination. Chronically infected SJL/J mice show limited spontaneous remyelination, which is in part due to T-cell–mediated immune responses that are shown to inhibit myelin repair. Several antibodies with specificity toward unidentified oligodendrocyte antigens promote CNS remyelination when they are passively transferred into syngenic mice (392,393 and 394). Analysis of these antibodies revealed that they shared characteristics with natural autoantibodies (393) in that they are of the IgM isotype and had few, if any, somatic mutations. Collectively, these results suggest that natural autoantibodies may have the potential to promote remyelination in animal models of MS. Natural autoantibodies have been shown to provide a beneficial effect on other autoimmune animal disease models such as myasthenia gravis (395), diabetes (396), and lupus (397). Whether remyelinating oligodendrocytes are derived from proliferation and subsequent differentiation of progenitor cells or whether they arise from dedifferentiation of mature oligodendrocytes remains unclear. A more thorough discussion of this important question is presented elsewhere (398).

Disease Initiation and Progression

One of the fundamental difficulties in studying the initiating events in MS relates to the prolonged time interval that separates the onset of the pathogenic processes from the development of clinical disease. There has been an ongoing effort to link the known genetic susceptibility conferred by the HLA-DR2 allele with the observation that myelin-reactive T cells are abnormally activated in MS. Triple-transgenic mice were developed that express the relevant human HLA-DR2 molecule, the TCR from an MBP-specific, DR2-restricted human T-cell clone, and the human CD4 coreceptor. The mice could be induced to develop EAE, but, more important, some of the animals developed spontaneous disease without introduction of exogenous antigen. This work demonstrates that a risk-conferring MHC allele can mediate both induced and spontaneous disease by presenting an MBP self-peptide to T cells (399). Elegant studies have elucidated the three-dimensional crystal structure of the complex formed by the HLA-DR2 molecule and the immunogenic MBP peptide (Fig. 56.5) (400). The primary sequence of the MBP peptide was a good predictor of its orientation within the binding groove of the HLA-DR molecule, and it was hoped that similar structural analyses would provide a reliable approach to understand and predict both normal and aberrant immune responses. Subsequent work, however, revealed that structure-function correlates are not always reliable. A possible explanation for this apparent failure may relate to the observations that T-cell responses appear to be far more degenerate than previously appreciated, and cross-reactivity may be the rule rather than the exception (401).

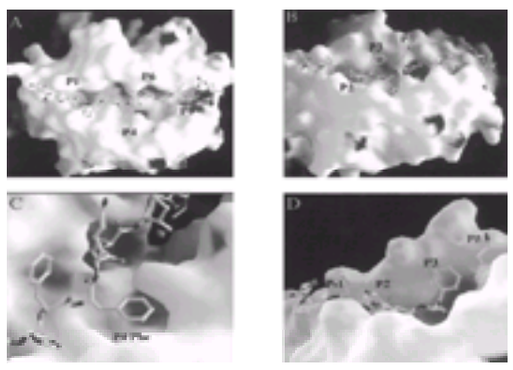

Figure 56.5. Structure of the HLA-DR2–myelin basic protein (MBP) peptide complex. **A** and **B**: Top and side views of the complex; 14 residues are included for the MBP peptide. P1 and P4 are hydrophobic pockets in the DR molecule and are occupied by the P1 Val and the P4 Phe of the MBP peptide, respectively. These interactions anchor the peptide in the groove. Peptide atoms are shown as ball-and-stick structures. **C**: Close-up view of the P4 pocket. The Gln b70 of the DR2 molecule (not labeled) is positioned over the P4 Phe of the MBP peptide. **D**: The T-cell receptor contact residues of the MBP peptide. P2 His, P3 Phe, and P5 Lys (previously shown to be important for T-cell recognition of the MBP peptide) are prominent, solvent exposed residues. (From Smith KJ, Pyrdol J, Gauthier L, et al. Crystal structure of HLA-DR2 (DRA*0101, DRB1*1501) complexed with a peptide from human myelin basic protein. *J Exp Med* 1998;188:1511–1520, with permission of the Rockefeller University Press.) (See Color Figure 56.5.)

In this context, molecular mimicry has been proposed as one mechanism that may underlie the induction of MS or the triggering of a flare. According to this hypothesis, an infectious agent may express antigenic epitopes that have sufficient functional homology with a host antigen that peripheral activation of T-cell responses to the pathogen may inadvertently induce autoreactive T cells. The latter may migrate across the BBB in their activated state where they would recognize the CNS autoantigen and mediate tissue injury. Molecular mimicry has been convincingly demonstrated in several animal models of autoimmune disease, including EAE (402,403,404 and 405), thus making it a highly attractive hypothesis of the cause of MS in a genetically susceptible individual. However, the profound limitations of human clinical immunology may preclude the possibility of providing strong evidence for this hypothesis in patients.

Another possible mechanism of MS initiation is represented by the induction of a CNS autoimmune demyelinating disease after infection with TMEV. In this model, direct CNS infection by the virus leads to an initial T-cell response directed to the TMEV-infected resident APCs, whereas the subsequent chronic T-cell–mediated disease involves the activation of myelin-reactive $CD4^+$ T cells (406,407 and 408). Superficially, the expansion of myelin-reactive T cells after viral infection may be viewed as another example of molecular mimicry. However, in an important extension to this model, investigators showed that microglia, isolated directly from the CNS of TMEV-infected animals, were able to present PLP epitopes to T-cell lines efficiently. Thus, direct viral infection of the CNS resulted in endogenous processing and presentation of myelin antigen and the subsequent expansion of previously naive myelin autoreactive T cells (408,409).

These two models of disease initiation need not be mutually exclusive. Peripheral activation of autoreactive T cells by molecular mimicry, which alone may not precipitate a CNS autoimmune disease, may result in disease if a prior insult to the CNS results in exposure of cross-reactive self-antigens that would otherwise not be accessible to immune surveillance. Indeed, these two models were shown to work in concert in EAE, in which prior expansion of T cells to myelin self-antigen was necessary for disease induction by T cells primed with a cross-reactive environmental antigen (410). In both models, CNS tissue injury would lead to exposure of additional epitopes and the subsequent development of autoreactive T cells recognizing those new targets. The clinical diagnosis of MS is often made years after the immunologic onset of the disease, by which time activated T cells recognizing multiple myelin epitopes are likely to have developed. This process of epitope spreading may explain why, to date, it has not been possible to identify a single antigenic target that drives the pathogenic immune response in MS (174,411). Not all inflammatory insults of the CNS (e.g., stroke) are followed by a progressive CNS autoimmune disease. The explanation may lie in the demonstration that blocking the interaction between B7-1 on CNS APCs and CD28 on T cells prevents epitope spreading and abrogates the development of relapses in murine EAE (412). The notion that B7-1 expression is critical for the process of epitope spreading is in keeping with the *in situ* immunohistochemical demonstrations, described previously in this chapter, that B7-1 is selectively expressed in MS plaques but not in inflammatory stroke lesions from the same brain.

TREATMENTS AND IMMUNOLOGIC MECHANISMS ACTION

Therapeutic approaches in MS may be broadly divided into treatments that are symptomatic or supportive and treatments that are directed at the underlying pathophysiology of the disorder. Effective medical management of spasticity, bladder symptoms, dysesthesias, fatigue, and depression may significantly improve daily functioning and may enhance the patient's quality of life. Ambulatory aids, patient education, appropriate use of physical and occupational therapy services, and psychological and social supports, should all be elements of the comprehensive management plan.

A new era in the treatment of MS emerged in the 1990s with the demonstration of efficacy of four immunomodulating therapies that affect the course of RRMS. These are, in order of approval in the United States, recombinant IFN-b1b (rhIFN-b1b, Betaseron/Betaferon), recombinant IFN-b1a (rhIFN-b1a, Avonex and Rebif, the latter available only in Europe and Canada at present), and glatiramer acetate (GA/copolymer-1/Copaxone). The ability of these agents to affect both clinical and MRI activity parameters in RRMS provides support for the role of immune mechanisms in the pathogenesis of RRMS. Studies of the mode of action of these therapies have further contributed to our understanding of the immunopathology of the disease and are discussed later.

Because of differences in study design and outcome-measure definitions, direct efficacy comparisons among the approved therapies is problematic. Compared with placebo-treated RRMS control subjects, treatment with alternate-day subcutaneous injections of 8 million units of rhIFN-b1b (Betaseron) was shown to decrease the primary efficacy outcome measure of frequency of relapses by 34% after 2 years (413). A significant decrease in the accumulation of MRI lesions was observed with treatment (413), although no beneficial effect on clinical disability was seen over the study period. More recent 5-year follow-up data reported that disease progression in the rhIFN-b1b–treated group was 35%, compared with 46% progression in the placebo group (122). A 30% decrease in the annual exacerbation rate in the treated group was maintained, and MRI data showed significantly less accumulation of lesion burden in the rhIFN-b1b–treated group (3.6%) compared with the placebo-treated patients (30.2%) over 5 years.

rhIFN-b1a (Avonex, weekly intramuscular injections), a glycosylated recombinant IFN-b, was evaluated in a 2-year study of weekly intramuscular injections of 6 million units (30 µg). The primary efficacy outcome measure was time to the onset of a sustained deterioration in disability. The proportion of patients progressing by the end of the trial was 21.9% in the treated group compared with 34.9% in the placebo group. The annual exacerbation rate was decreased by 32% in the treated group versus the placebo group. Treatment was also associated with a 40% reduction in mean MRI lesion load (414,415). The mean number of new enhancing lesions on MRI over the 2 years was 0.80 in the rhIFN-b1a–treated group versus 1.65 in the placebo group. In the PRISMS trial, a double-blinded, placebo-controlled, phase III trial of rhINF-b1a (Rebif, subcutaneous, three times weekly) in RRMS, treatment was associated with significant improvement in MRI parameters, which extended the prior evidence of benefit on relapse rate and disease progression (416). Common side effects of the IFN-b include flulike symptoms and injection site reactions (rarely necrosis with IFN-b1b). Headache and depression are less common, and, rarely, hepatotoxicity or bone marrow suppression may occur. Neutralizing antibodies (NABs) have been reported for both IFN-b and remain a contentious issue. Some reduction in the biologic effect and clinical benefit of rhINF b in NAB-positive patients has been suggested (417). The relative antigenicity of rhINF-b1b (alternate-day subcutaneous administration) may be greater than that of rhINF-b1a (weekly

intramuscular administration); however, a prospective comparison has not been made. The effect of dose on the generation of NAB is also not established.

Treatment with glatiramer acetate/copolymer 1 (Copaxone, GA), a daily 20-mg subcutaneous injectable synthetic polymer, was associated with a 2-year relapse rate reduction (primary outcome measure) of 29%, compared with placebo control (418). A subsequent MRI study revealed a beneficial effect of GA on newly forming gadolinium-enhancing lesions (419), and a follow-up study not yet published suggests that the beneficial impact on MRI is maintained for several years. GA is relatively well tolerated, with typically mild injection site reactions, infrequent urticarial responses, and an occasional stereotypical vasomotor reaction. Laboratory abnormalities have not been reported, and NABs are not an issue.

The biologic mechanisms of action by which the approved immunomodulators mediate their significant, although limited, beneficial effects on the course of RRMS are of great interest. As a class, IFN-b appears to exert its effects on the pathophysiology of MS at several sites. Converging studies have suggested that IFN-b may inhibit the migration of activated inflammatory cells across the BBB and into the CNS parenchyma. The abnormally increased cellularity often seen in CSF from active patients with MS is diminished after therapy with IFN-b1a (420). IFN-b may exert this effect at the level of adhesion molecules or MMPs. As noted earlier, the adhesion molecule VCAM-1 has been identified on both microglia and endothelial cells in chronic-active MS lesions, and its ligand, VLA-4, has been identified on the perivascular inflammatory cells of MS lesions. Treatment with IFN-b1b was associated with decreased levels of VLA-4 on inflammatory cells in patients with MS, a finding that correlated with a decrease in the MRI lesion burden. (321,323). IFN-b1b has also been shown to suppress T-cell expression of MMPs and to inhibit T-cell migration across the BBB (348,349). The rapid effect of IFN-b on the gadolinium-enhancing lesions of MS (350,421) represents a promising biologic marker of treatment response and establishes the BBB as an important site of action of IFN-b therapy. A possible role for IFN-b treatment in shifting cytokines in MS from a proinflammatory profile to an antiinflammatory profile is suggested by reports that treatment may decrease levels of TNF-a while enhancing levels of IL-6 (422) and of immunosuppressive cytokines (423). Finally, a possible role in limiting T-cell activation is suggested by the observation that the increased levels of the costimulatory molecule B7-1, reported on mononuclear cells in MS blood and CSF, are reversed in response to treatment with IFN-b1a (181,424).

The differences in the side effect profiles of IFN-b and GA suggest that these treatments have distinct mechanisms of action. GA is a random-sequence polypeptide of the four amino acids alanine (A), lysine (K), glutamate (E), and tyrosine (Y). Initial reports on the putative mode of action of GA suggested that GA may interfere with myelin antigen binding to the MHC class II molecule, thereby inhibiting presentation to autoreactive T cells (425). In subsequent studies, TCR antagonism was suggested to occur in addition to competition for MHC class II binding (426). GA was found to bind selectively, and with high affinity, to MHC class II DR molecules HLA-DR1, HLA-DR2, and HLA-DR4, but not to HLA-DQ or MHC class I molecules (427,428). These studies suggested that GA contains multiple epitopes that enable it to bind promiscuously to a range of MHC class II molecules, conferring the potential to activate $CD4^+$ T cells broadly. Consistent with this finding, limiting dilution analysis revealed a surprisingly high frequency of GA-reactive T cells in the normal circulation, ranging from 1 in 5,000 to 1 in 100,000 PBMCs, and demonstrated that GA indeed represents a highly cross-reactive, MHC class II–restricted antigen (429). Duda et al. examined the effects of daily subcutaneous administration of GA in patients with RRMS on the profile of the T-cell immune response. *In vitro* T-cell responses to GA, to the immunodominant MBP epitope 84-102 (as a model myelin antigen), and to combinatorial peptide libraries derived from the MBP 84-102 sequence and from a completely random 13mer sequence were measured before and during a year of therapy with GA. T-cell responses to the combinatorial peptide libraries were examined as a measure of TCR degeneracy. The authors demonstrated that GA-reactive T-cell lines generated *in vitro* were deviated toward a Th2 cytokine profile after treatment with GA. Furthermore, the cross-reactivity of GA-reactive T-cell lines was increased after GA treatment, although the T-cell reactivity to the immunodominant MBP epitope 84-102 or to tetanus toxoid was not significantly altered during therapy. In combination, these results show that GA does not appear to have a direct effect on preexisting memory T cells, nor is it selectively cross-reactive with MBP (429). Rather, GA treatment appears to induce GA-reactive Th2-polarized T cells that are more degenerate in their antigen recognition. These activated Th2 T cells may enter the CNS, where they may mediate bystander suppression at sites of inflammation and lead to decreased disease activity and the observed efficacy of GA on both clinical and MRI parameters. Overall, the currently approved immunomodulating agents provide a measurable, although only partial, benefit in the treatment of RRMS. The suggestion that the mode of action of IFNs differs from that of GA raises the possibility that together these therapies may provide additive benefit, and such a combination trial is currently under way.

Corticosteroids are used widely in the treatment of MS, although data supporting their use are sparse. Two follow-up studies of patients with isolated optic neuritis (a common presenting episode of MS) suggested that treatment with a short course of high-dose intravenous methylprednisolone was associated with a lower risk of developing subsequent demyelinating episodes (430). Based on these results, intravenous methylprednisolone became the primary treatment used for optic neuritis and for debilitating attacks of MS. Five-year follow-up data have shown that the development of clinically definite MS after optic neuritis did not differ by treatment group. In general, treatment of acute relapses with intravenous methylprednisolone may lead to more rapid improvement in symptoms, but it does not appear to change the ultimate outcome of the flare or the subsequent disease course. Pulse steroid treatment has also been used for patients with primary and secondary progressive MS. The mode of action of corticosteroids is not established. Relatively nonspecific suppression of T-cell responses is suspected, although differential effects on T-cell subsets have been reported (431). Steroids have been shown to reduce the activity of MMPs, and MRI evidence of decrease in gadolinium-enhancing lesions after treatment with steroids supports a possible therapeutic role at the BBB (432).

Treatment of patients in the progressive phase of MS with immunomodulating therapies has been less successful. In early studies, IFN treatment appeared to improve the outcome in patients with SPMS. This was not reproduced in subsequent trials, probably because the initial observations reflected the favorable impact of the therapy on the relapse component of relapsing-progressive patients in the study. The potential efficacy of Copaxone in SPMS is currently under investigation.

Cyclophosphamide is an alkylating agent with potent cytotoxic and immunosuppressive effects. A randomized, triple-arm study demonstrated a positive effect in patients with SPMS treated with a 2-week course of cyclophosphamide/adrenocorticotropic hormone (ACTH) as compared with patients who received ACTH alone (433). These findings led to a randomized single-blind trial by the Northeast Cooperative Treatment Group that tested the efficacy of outpatient intravenous cyclophosphamide pulses every 2 months in 236 patients who had initially received an intravenous cyclophosphamide/ACTH induction (434). Patients with disease for shorter durations had a more beneficial effect from cyclophosphamide treatment as compared with patients not receiving the pulse cyclophosphamide treatment. The current cyclophosphamide protocol used at the Partners' Harvard Multiple Sclerosis Center had not yet undergone a randomized clinical trial, until now, when it is being investigated in b-IFN treatment failures. Moreover, there is great difficulty in using the present statistical tools necessary to analyze response to therapy over 5 to 10 years. The present treatment regimen recommended calls for monthly infusions of cyclophosphamide with methylprednisolone for 1 year, followed by a second year of infusions at 6-week intervals, a third year of infusions at 8-week intervals, a fourth year of infusions at 10-week intervals, and a fifth year of four infusions at 12-week intervals (see Website) http://neuro-oas.mgh.harvard.edu/ms/. The dose of cyclophosphamide is based on body surface area, and it is increased such that 6 to 12 days after infusion, the total white blood cell count is brought to less than 2,000 cells/mm^3. The clinical effect of this treatment regimen in patients with more severe, relapsing-remitting progressive disease can be dramatic, and patients stable over the taper from every 10 weeks to every 12 weeks most often remain stable on cyclophosphamide withdrawal. Nevertheless, the toxicities of cyclophosphamide, including infertility and a potential increase in the risk of bladder cancer, preclude the routine use of the drug in patients early in the disease course, except in instances of multiple accumulated disabilities at the disease onset.

Several laboratory observations have suggested that cyclophosphamide may positively affect the immune response in patients with MS. Elevated IL-12 levels identified in patients with SPMS were shown to correlate with disease activity and were normalized by pulse cyclophosphamide therapy (206). A follow-up study treating patients with SPMS with pulse cyclophosphamide and methylprednisolone suggested that response to therapy was linked to the duration of progressive disease (435).

Mitoxantrone is an antineoplastic agent that intercalates with DNA and potently suppresses cellular and humoral immune responses. It has demonstrated clinical benefit on relapse rate and disability progression in patients with relapsing-progressive MS with a concomitant decrease in the development of new enhancing lesions and cumulative total lesion burden. It has been approved in the United States for the treatment of SPMS. Although the drug is generally well tolerated, it has a limited use of 2 years because of cardiotoxicity. Other immunosuppressive agents that have shown some limited benefit in the treatment of SPMS include methotrexate (436), azathioprine (437), cladribine (2-CdA, Leustatin) (438), and intravenous Igs (IVIGs) (439).

It appears likely that immunomodulating and immunosuppressive therapies provide their greatest benefit early in the disease, during a period in which inflammatory responses are major contributors to tissue injury. As progressive disease sets in and irreversible axonal injury becomes the major process underlying clinical deterioration, the relative contribution of inflammation to ongoing injury diminishes and with it the role of antiinflammatory therapies. This finding underscores the importance of initiating therapy early in the disease and developing, in parallel, neuroprotective strategies.

CONCLUSIONS AND FUTURE DIRECTIONS

Major strides have been made in our understanding of the immunopathogenic processes underlying the development and course of MS. Classic themes have been revisited with the application of modern techniques. The demonstration of distinct pathologic patterns in MS plaques suggests that several different mechanisms may contribute to tissue injury, and the prevailing mechanism may not be the same across patients. In part, this may reflect the remarkable genetic diversity and broad range of environmental exposures that together define the human experience. Differences in pathogenic substrates may explain the observed heterogeneity of clinical disease course and severity and the differential response to therapy. A more meaningful classification of MS that is based on defining the underlying process in individual patients may lead to more effective therapeutic approaches.

Various imaging modalities have combined with pathologic studies to highlight the substantial degree of axonal injury involved in both MS lesions and in normal-appearing white matter. These abnormalities are detected early in the course of MS and may be better predictors of subsequent disability than clinical measures of disease activity. Indeed, neurologic disability in MS is likely to have at least two pathologic underpinnings: inflammatory demyelination and axonal transection. Episodic demyelination involving infiltration of inflammatory cells is the likely substrate of clinical flares. Recovery from these probably reflects resolution of

local inflammation and edema in the short term. Axonal transection may remain largely silent for extended periods, partly because of the redundancy and functional compensation potential of CNS pathways. The process of axonal loss, however, is irreversible, and beyond a certain threshold further degeneration translates into a slow progressive clinical decline (129,373,440). This underscores the importance of early diagnosis and intervention in MS.

Although proven effective, current treatment approaches have only a modest impact on disease progression. The development of more effective therapies will be predicated on advancing our understanding of the underlying disease process. Many animal and human studies have contributed to a model of MS immunopathogenesis in which activated autoreactive T cells are likely to play an important role. By a process of molecular mimicry, exposure to an infectious agent may activate cross-reactive autoaggressive T cells that may then enter the CNS and mediate injury. Alternatively, direct insult to the CNS, such as by a neurotropic virus or trauma, may expose CNS epitopes in the setting of local inflammation and may trigger autoreactive T cells in a susceptible host. Migration of proinflammatory immune cells across the BBB in MS may reflect dysregulation of the complex molecular interactions involving adhesion molecules, chemokines, and MMPs. It remains to be determined whether the abnormalities in expression levels of these molecules associated with MS reflect a true pathogenic role or a mere epiphenomenon of the inflamed state. The microenvironment in which autoreactive T cells become activated both in the periphery and in the CNS is defined in part by the local profile of cytokines and costimulatory molecules, and it influences the effector profile of the T cells that may adopt an inflammatory or antiinflammatory character. A proinflammatory environment is likely to promote epitope spreading and propagation of disease. In contrast, antiinflammatory cells may mitigate the injurious responses by bystander suppression. The roles of B cells and humoral responses as well as the contributions of innate immunity are receiving renewed attention. In some settings, antibodies have been implicated in augmenting or even inducing disease. In others, they may play a protective role. Studies into the neurobiology of MS and, in particular, the roles of microglia and astrocytes and the interactions of neural elements, endothelia/ and inflammatory cells have been revealing. Neural-immune interactions occur in the normal physiologic state and may represent important homeostatic mechanisms, capable of promoting repair and regeneration. Indeed, these principles must be incorporated in any serious attempt to understand MS comprehensively.

Finally, ongoing studies into the mechanisms of action of the available immunomodulators are contributing to our understanding of the immunopathology and neurobiology of MS, and these insights will guide the development of the next generation of safe and effective therapies. In addition to targeting inflammation, future approaches will undoubtedly explore neuroprotective strategies designed to prevent oligodendrocyte death and axonal transection and complementary approaches that promote remyelination and recovery.

57 AUTOIMMUNE HEMOLYTIC ANEMIA

Alan D. Schreiber, M.D.

Although it is clear that immunologic mechanisms play a significant role in the pathophysiology of many disease processes, there are relatively few situations where it is possible to gain a detailed understanding of the ongoing mechanisms of immune damage taking place *in vivo* in humans. Autoimmune hemolytic anemia (AIHA) is of particular interest in this regard. Because it is possible to sample the red cell compartment repeatedly, it is possible to define many of the immunopathologic processes that occur in this disease in molecular and cellular terms. AIHA represents a group of disorders in which individuals produce antibodies directed toward one or more of their own erythrocyte membrane antigens. This leads to destruction of the antibody-coated erythrocytes. The pathophysiology of the decreased erythrocyte survival in this disorder has been examined with increasing sophistication for many years. Although more recently quantitative immunologic techniques have been brought to bear on these pathophysiologic studies, the early work of Dacie, Mollison, Jandl, and their colleagues (1,2,3 and 4) led to several important conclusions. These investigators observed that the hemolysis in AIHA is most commonly extravascular rather than intravascular and that the liver and spleen play a major role in the clearance of the antibody-coated cells. The importance of complement in the destruction of IgM-coated cells also was recognized.

This chapter first discusses the underlying mechanisms responsible for the immune clearance of red blood cells. Next, it focuses on the clinical syndrome of AIHA and then considers the clinical syndrome of paroxysmal nocturnal hemoglobinuria (PNH), a complement-mediated hemolytic anemia characterized by intravascular hemolysis caused by a red cell membrane defect. The membrane proteins that are responsible for the defect and the biochemistry of those proteins are considered in other text. We contrast the clinical findings to those in AIHA, where extravascular destruction of red blood cells predominates. Finally, we discuss drug-induced immune hemolytic anemia.

EXPERIMENTAL MODELS

Some years ago, we established an experimental model of immune hemolytic anemia in the guinea pig, one approach that permits the dissection of the various steps involved in erythrocyte destruction (5,6). As with human erythrocytes, guinea pig erythrocytes are relatively resistant to the lytic action of complement, and their hemolysis, mediated by antibody and complement, is primarily extravascular. Each of the factors important in erythrocyte destruction defined in this model has been observed to be of importance in the disease as it occurs in humans. We focused on the role of antibody class, the role of complement, and the significance of the reticuloendothelial (mononuclear phagocyte) system in the pathophysiology of the hemolysis. For these studies, we isolated rabbit immunoglobulin G (IgG) and IgM antiguinea pig erythrocyte antibody. We then used this antibody to sensitize chromium 51 (^{51}Cr)-labeled guinea pig erythrocytes. The radiolabeled, antibody-coated erythrocytes were injected intravenously into the guinea pigs, and the rate and pattern of clearance as well as the site of organ sequestration of the antibody-sensitized cells were followed.

In these studies, we quantitated the number of antibody molecules per erythrocyte by both radiolabeling the antibody with iodine 125 so that we could directly assess the number of antibody molecules that attached to the red cells and by using a sensitive complement fixation method: the C1 fixation and transfer test. With the latter test, antibody per erythrocyte could be expressed in terms of the number of complement or C1 (the first component of complement)-activating sites generated by the antibody. A single molecule of IgM antibody bound to an erythrocyte by several of its binding sites will bind and activate one molecule of C1 to initiate the classical complement pathway. In the case of IgG, two molecules of antibody side by side are required for C1 binding and initiation of the classical pathway. With antigens widely distributed on the erythrocyte surface, such as the antigens recognized by the rabbit antiguinea pig erythrocyte antibody, many hundreds or thousands of antibody molecules must be deposited on the erythrocyte membrane before two bind sufficiently close to one another to permit complement activation. We studied erythrocyte survival curves in both normal guinea pigs and in guinea pigs congenitally deficient in the fourth component of complement. C4-deficient guinea pigs have a complete block in their classical complement pathway, and complement is not activated beyond the C1 step. A comparison of C4-deficient and normal animals enabled us to assess the role of antibody versus the role of antibody plus complement in altering erythrocyte survival. In addition, we depleted guinea pigs of the third component of complement, C3, as well as the later-acting components by treating the animals with cobra venom factor. In both animals genetically deficient in C4 or depleted of C3 through C9 by cobra venom factor, the complement activation sequence does not proceed through C3, and erythrocytes do not become coated with C3 *in vivo*.

In this model, IgG-sensitized erythrocytes were removed progressively from the circulation and sequestered predominately in the spleen (Fig. 57.1). Approximately 2,000 IgG molecules per erythrocyte were necessary to generate a single complement or C1-fixing site. Similar numbers of molecules were required to decrease erythrocyte survival. Erythrocyte survival was influenced by the number of antibody molecules per cell: Increasing the number of IgG molecules per cell progressively increased the splenic sequestration of these cells.

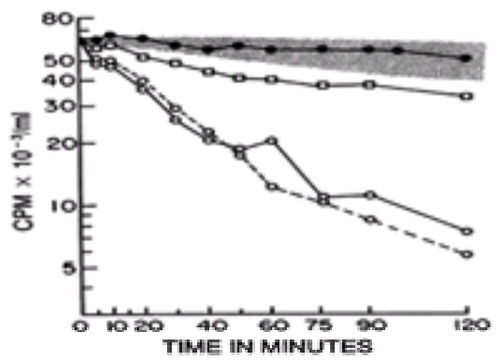

Figure 57.1. Survival of chromium 51 (^{51}Cr)-labeled guinea pig erythrocytes coated with immunoglobulin G (IgG) antibody in normal (*open circles*) and C4-deficient (*open squares*) guinea pigs. The survival of IgG-coated erythrocytes in C3-depleted guinea pigs was similar to that observed in C4-deficient guinea pigs. The *closed circles* represent the survival of ^{51}Cr-unsensitized erythrocytes. (*Shaded area*, 95% confidence limits.)

The IgG-coated erythrocytes were cleared from the circulation in an accelerated fashion in the absence of complement activation. This was evident from the studies with IgG-coated erythrocytes performed both in C4-deficient guinea pigs and in C3-depleted guinea pigs (Fig. 57.1). Complement-independent clearance of IgG-coated erythrocytes was predominately by macrophages in the spleen (by splenic macrophage Fc receptors). Larger numbers of antibody molecules per cell were required to

decrease erythrocyte survival in the absence of complement than in the presence of complement. As shown in Fig. 57.1, IgG-coated red cells were cleared more rapidly in normal guinea pigs compared with C4-deficient or C3- through C9-depleted animals.

We observed that the clearance of IgG-coated erythrocytes in the C3-depleted guinea pigs was identical to that in the C4-deficient animals. Animals treated with cobra venom factor have normal amounts of C1, C4, and C2, whereas C4-deficient guinea pigs have a normal alternative complement pathway. We believe the defect in the clearance of IgG-coated erythrocytes in both C4-deficient and C3- through C9-depleted animals resides in the failure of C3 to bind to the erythrocyte surface. The similar survival of IgG-coated erythrocytes in C4-deficient and C3- through C9-depleted guinea pigs suggests that the classical, rather than the alternative, complement pathway is of prime importance in the clearance of IgG-coated erythrocytes.

These studies also demonstrated that IgG-coated erythrocytes are cleared predominantly in the spleen regardless of whether complement activation occurs. When large amounts of IgG are bound to the erythrocytes or large numbers of complement-activating sites are generated, the liver becomes progressively more predominantly the organ of clearance. *In vitro* studies showed that macrophages of the reticuloendothelial system have several types of surface receptors for the Fc fragment of IgG (Fc receptors). These receptors are responsible for the binding and phagocytosis of IgG-coated erythrocytes. One of the Fc receptors is a high-affinity receptor present on macrophages and monocytes: FcRI. This receptor is more easily inhibited by plasma concentrations of IgG. There are two lower-affinity receptors on macrophages, FcRII and FcRIII (7,8). These receptors are likely important in the clearance of IgG-coated cells. Erythrocytes coated with multiple IgG molecules can interact with macrophages with multiple IgG Fc receptors, even in the presence of plasma concentrations of IgG. The multiple low-affinity Fc receptor binding sites may in aggregate lead to high-affinity binding of the erythrocytes to the macrophage surface, which in turn facilitates phagocytosis.

Macrophages also can alter IgG- or C3b/iC3b-coated erythrocytes in a manner that causes the red blood cells to form microspherocytes (9). These spherocytes are less able to pass through the splenic cords and sinuses and therefore have decreased survival. Their presence in the circulation is an indication of ongoing immune hemolysis. Macrophages also have receptors, designated CRI and CR3, for the activated third component of complement. These receptors recognize C3b and iC3b, respectively, and are capable of binding C3-coated erythrocytes. These receptors are discussed in greater detail in the chapters on complement. The receptors for the various C3 fragments do not recognize native C3; they only recognize fragments of C3 after C3 has undergone activation. Therefore, they are capable of efficient function in the presence of normal plasma concentrations of C3. The C3b- and IgG-coated cells can bind simultaneously to two different macrophage membrane receptors (10).

When erythrocytes are coated with IgM antibody and injected intravenously into guinea pigs, the pattern of clearance and site of organ sequestration are different from those of IgG-coated erythrocytes (Fig. 57.2). IgM-coated cells are cleared rapidly within the liver. Splenic clearance is secondary and usually amounts to less than 20% of the infused cells. In fact, no dose of IgM antibody leads predominantly to splenic sequestration. Erythrocyte survival is proportional to the number of IgM molecules per erythrocyte. With increasing numbers of IgM per red blood cell, erythrocyte clearance is progressively accelerated. About 60 IgM molecules (which generate 60 complement- or C1-fixing sites) are necessary to decrease the survival of IgM-coated cells. This finding contrasts with the single complement-fixing site generated by approximately 2,000 IgG molecules required to decrease the survival of IgG-coated cells. These studies established the absolute requirement for complement in the clearance of IgM-coated cells. This requirement was ascertained by examining the erythrocyte survival in C4-deficient and C3-depleted guinea pigs. IgM-coated erythrocytes survived normally in the complement deficient animals, even when agglutinating concentrations of IgM antibody were employed. *In vitro* studies showed that guinea pig macrophages neither detected nor bound IgM-coated erythrocytes in the absence of complement. Activation of the complement sequence by IgM resulted in the deposition of C3b on the erythrocyte surface. Erythrocyte-bound C3b and iC3b led to an interaction with hepatic macrophage C3b and iC3b receptors. This interaction was largely responsible for the clearance of IgM-coated erythrocytes.

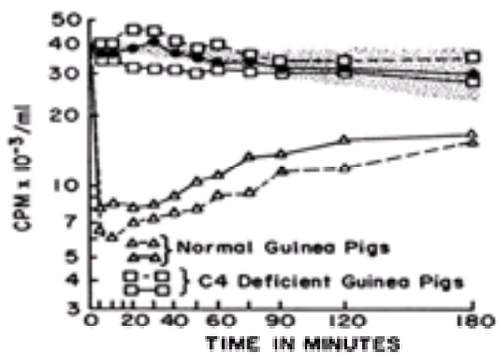

Figure 57.2. Survival of chromium 51-labeled guinea pig erythrocytes coated with immunoglobulin M (IgM) antibody in normal (*open triangles*) and C4-deficient (*open squares*) guinea pigs. The survival of IgM-coated erythrocytes in C3-depleted guinea pigs was similar to that observed in C4-deficient guinea pigs. (*Shaded area,* 95% confidence limits.) (From Frank MM, et al. Pathophysiology of autoimmune hemolytic anemia. *Ann Intern Med* 1977;87:210, with permission.)

Within the liver, IgM-coated erythrocytes are rapidly sequestered. Subsequently, they are either phagocytized and destroyed, or they are released from their C3 receptor attachment site back into the circulation, where they then survive normally, even though they still are coated with IgM and antigenically detectable C3. Extensive *in vitro* and *in vivo* studies showed that this release of IgM- and C3-coated erythrocytes from the macrophage C3 receptor attachment site is not due to elution of the antibody from the surface. Rather, the C3b/iC3b inactivator system, which involves several circulating plasma proteins, including factors I and H and a series of integral membrane proteins, for example, CR1 (see other text), causes the release of C3-coated erythrocytes from the macrophage C3b and iC3b receptor attachment sites (5,11). The C3-coated cells have on their surface an antigenically altered form of C3 that is no longer recognized by the macrophage C3 receptors. Thus, these erythrocytes survive normally. Increasing the concentration of IgM per erythrocyte accelerates the sequestration and also decreases the number of erythrocytes released from the hepatic macrophage receptor binding sites. Pretreatment of IgM- and C3b-coated erythrocytes with a source of serum C3 inactivator system proteins alters the erythrocyte cell-bound C3 and improves erythrocyte survival.

Therefore, these studies demonstrated that the two major classes of antibody that cause AIHA, that is, IgG and IgM, differ markedly in their biologic effects. IgG-coated erythrocytes are cleared predominantly in the spleen, whereas IgM-coated erythrocytes are sequestered predominantly within the liver. Splenic macrophage Fc receptors and C3 receptors are responsible for the clearance of IgG-coated cells. IgG-coated erythrocytes do not require complement for clearance; however, complement accelerates the clearance of IgG-coated erythrocytes in the spleen. The pattern of clearance of IgM-coated erythrocytes is entirely different. IgM-coated cells are cleared rapidly by the hepatic macrophage C3 receptors. The clearance is entirely complement dependent, and in the absence of complement activation, these cells survive normally. In areas of relatively rapid blood flow, that is, the liver, Fc receptor activity is likely at a relative disadvantage because FcRII and FcRIII, the predominant receptors, have extremely low affinity and the multiple interactions required for adherence are less likely to occur. Blood flow in the spleen is much slower and involves closer contact between sinusoidal phagocytes and circulating cells. This is believed to facilitate IgG-mediated splenic red cell clearance. The C3 inactivator system serves as an important control mechanism for the clearance of IgM-coated cells, mediating the release of IgM- and C3-coated cells from their hepatic macrophage C3 receptor attachment sites. Furthermore, exposure of IgM- and C3-coated erythrocytes to C3 inactivator system proteins can attenuate the clearance of these C3-coated cells by hepatic macrophages. In additional studies with cells coated *in vitro* with both IgG and IgM antibody, we observed that the addition of a small amount of IgM antibody to IgG-coated erythrocytes could shift the pattern of the sequestration from one predominantly involving the spleen to one predominantly involving the liver.

The effect of splenectomy and steroid hormones on the clearance of antibody- and complement-coated erythrocytes also was studied in the experimental model (12). Splenectomy markedly decreased the sequestration of IgG-sensitized cells. As the antibody concentration was increased, however, splenectomy became less effective in preventing the clearance of IgG-coated cells because the liver became the dominant organ in erythrocyte clearance. As expected, splenectomy did not alter the clearance of IgM-coated cells.

The effect of glucocorticoids and other steroid hormones on the clearance of IgG- and IgM-coated erythrocytes was examined (12,13,14 and 15). Pretreatment of guinea pigs with cortisone acetate or cortisol for 5 to 7 days impaired the splenic clearance of IgG-coated erythrocytes. Pretreatment of guinea pigs was necessary to observe this effect. Similar to the experience in humans, we observed that not all animals respond to steroids equally well, although the vast majority responded to steroids (13).

Several clinical observations suggest that glucocorticoids have a similar effect in humans. Patients with IgG antibody-mediated AIHA or immune thrombocytopenic purpura (ITP) treated with glucocorticoids often respond within days of the onset of therapy. At the time of response, the cells remain antibody coated, and there may be no decrease in antibody synthesis. Furthermore, some patients with IgG-mediated destruction of erythrocytes and platelets remained in clinical remission on steroid therapy, even when their cells remained antibody coated. These observations suggest that glucocorticoids affect the clearance mechanism in humans. Glucocorticoids were effective in inhibiting the clearance of IgG-coated erythrocytes, in both the presence and the absence of complement activation as shown by studies performed in normal and C4-deficient guinea pigs. In both types of animals, clearance decreased (16); however, the differences between the control groups and the

corticosteroid-treated animals were most marked when the studies were conducted in C4-deficient animals in whom IgG alone and Fc receptors alone were responsible for clearance. In each of these studies, glucocorticoid therapy decreased the extent, without altering the pattern, of erythrocyte clearance. One explanation of such findings is that glucocorticoids decrease either the number or the affinity of macrophage membrane receptors for Fc (Fc receptors). Further studies have established that this is the case (17).

Glucocorticoids also impaired the clearance of IgM-coated erythrocytes by the liver (12). This finding was not expected because these drugs are usually ineffective in patients with IgM-induced immune hemolytic anemia. These data suggested that high doses of corticosteroids might be effective in improving erythrocyte survival in some patients with IgM-induced immune hemolytic anemia whose red cells are coated with limited amounts of IgM and C3. This observation led to further clinical studies. Patients with a low-titer IgM (cold agglutinin)-induced immune hemolytic anemia, whose cells were coated with limited amounts of C3, may respond to corticosteroids (14), although extremely high concentrations of glucocorticoids were required to impair the clearance of IgM- and C3-coated cells in these patients. Thus, these studies indicated that glucocorticoids are most effective in reducing the clearance of IgG-coated cells. Glucocorticoids are least effective in preventing the clearance of IgM- and complement-coated cells. These observations were consistent with previous observations in humans with regard to the efficacy of steroids on the clearance of antibody and or complement-coated cells in immune hemolytic anemia.

We also examined the effect of agents that augment macrophage function. Guinea pigs were infected with the bacille Calmette–Guérin (BCG) vaccine strain of *Mycobacterium tuberculosis*. Such animals displayed markedly augmented macrophage clearance. These animals removed IgG-sensitized erythrocytes more rapidly from the circulation, both in the presence and in the absence of complement activity. The site of sequestration remained the spleen. The sensitized red cells were cleared from the circulation as if they were coated with large quantities of antibody. We postulated that the fixed macrophages of the reticuloendothelial system had an augmented number of Fc or C3 receptors on their surface, secondary to the infectious process. *In vitro* studies suggested that such is the case. In the case of IgM-sensitized erythrocytes, not only the extent of sequestration but also the pattern of sequestration changed. The IgM-sensitized cells were rapidly cleared in the liver as they are in the uninfected animal; however, the cells never were returned to the circulation. They were phagocytosed by hepatic macrophages. These studies may explain the accentuation of hemolysis in individuals with a compensated immune hemolytic anemia who develop an infection.

An additional series of experiments examined the effect of treatment with the cytotoxic agent cyclophosphamide on the clearance of IgG-coated cells. Cyclophosphamide treatment of guinea pigs did not delay the clearance of antibody-sensitized erythrocytes, suggesting that the therapeutic effect of these agents is due to their effect on synthesis of antibody by B-lymphocytes rather than to any effect on macrophage-mediated erythrocyte clearance.

More recently, we examined the capacity of other steroids and their analogs to modulate the clearance of the IgG-coated erythrocytes by splenic macrophages (13). We observed that estradiol, in contrast to cortisol, enhances the clearance of IgG-coated erythrocytes by splenic macrophages in a dose-dependent manner. On the other hand, estradiol does not alter the splenic macrophage clearance of heat-altered erythrocytes or the hepatic macrophage clearance of IgM- and C3b-coated erythrocytes (18). This finding suggests that the effect of estradiol is on the splenic macrophage Fc receptors responsible for the clearance of the IgG-coated cells. Neither deoxycorticosterone (a precursor in steroid synthesis) nor tetrahydrocortisone (an inactive steroid metabolite) influenced clearance. These studies suggesting that the macrophage Fc receptors may be modulated *in vivo* by hormonal mechanisms were supported by studies demonstrating that splenic macrophages isolated from estradiol-treated animals exhibited remarkably enhanced Fc receptor expression, but not C3 receptor expression, when compared with control animals. These data may explain the alteration in the clinical status of patients with immune hemolytic anemia and immune thrombocytopenia during changes in hormonal states, such as pregnancy. During pregnancy, estrogen levels rise to a level similar to that necessary to accelerate the clearance of IgG-coated erythrocytes in our guinea pig model (13). Similarly, during pregnancy, the course of IgG-induced AIHA is known to accelerate. Further studies showed that other steroid analogs also can alter the clearance of IgG-coated cells by affecting splenic macrophage Fc receptor expression.

More recent studies in knockout and transgenic mice further elucidated the pathophysiology of the clearance of IgG-coated cells (19,20,21 and 22). Studies in mice transgenic for the human Fc receptor FcRIIA suggest that this receptor plays a significant role in the clearance of IgG-coated cells. Extensive studies in knockout mice have demonstrated the critical importance of Fc receptors in the clearance of IgG coated cells. At the concentrations of IgG antibody employed in these studies, complement did not play a role in the clearance of IgG coated cells. Further studies showed that another Fc receptor, FcRIIB, may serve a regulatory role by inhibiting the phagocytosis of IgG-coated cells.

The data derived from the preceding studies help to elucidate the pathophysiology of immune hemolytic anemia in humans. The following section summarizes the application of these concepts to AIHA in humans.

IMMUNE HEMOLYTIC ANEMIA IN HUMANS

The occurrence of anemia was first described in ancient times, but until the modem era, it was difficult or impossible to ascertain whether the anemia was due to the shortened survival of erythrocytes. With the onset of transfusion therapy, it became clear that transfused cells had a limited survival in some anemic individuals. In some cases, the presence of hemoglobinuria could be related to the onset of intravascular hemolysis; it was impossible, however, to relate shortened survival, in the absence of hemoglobinuria, to an immunologic reaction to the red cells until the development of the antiglobulin test by Coombs and colleagues in 1945. This test allowed the detection of antibody and complement on circulating cells. Within a year after the first report of the antiglobulin test, the presence of immunoreactive material on the surface of erythrocytes in a patient with hemolytic anemia was noted, and the concept of AIHA was born. With the onset of methods for tagging erythrocytes with radioactive tracers, survival studies could be performed conveniently, and many studies of the pathophysiology of hemolytic anemia were performed. It is clear now that AIHA is most commonly caused by IgG antibody (2,23). The antigen to which the IgG antibody is directed is usually one of the Rh erythrocyte antigens, although often its precise specificity is not easily defined. This antibody usually has its maximal activity at 37°C, and thus this entity has been termed *warm antibody–induced hemolytic anemia*.

Immunoglobulin G-induced (warm antibody–mediated) immune hemolytic anemia can occur without an apparent underlying disease (idiopathic AIHA); however, it also can occur with an underlying immunoproliferative disorder, either malignant or nonmalignant, such as chronic lymphocytic leukemia, non-Hodgkin lymphoma, and systemic lupus erythematosus. Certain patients with immunodeficiency can develop AIHA as well. Rarely, IgG-induced immune hemolytic anemia has been observed in patients with an underlying malignant disease that is not an immunoproliferative disorder (Table 57.1). Such malignant disorders include ovarian tumors and myelofibrosis with myeloid hyperplasia. Additionally, bacterial infections, such as tuberculosis; viral infections, such as cytomegalovirus disease; and chronic inflammatory conditions, such as ulcerative colitis have been described as associated conditions.

Infections
Viral infections, especially respiratory infections
Infectious mononucleosis and cytomegalovirus
Mycoplasma, especially pneumonia
Tuberculosis
Disorders associated with autoantibody production
Systemic lupus erythematosus
Rheumatoid arthritis
Thyroid disorders
Ulcerative colitis
Chronic active hepatitis
Immunodeficiency syndromes
X-linked agammaglobulinemia
Dysgammaglobulinemia
Common variable hypogammaglobulinemia
IgA deficiency
Wiskott-Aldrich syndrome
Malignancies
Non-Hodgkin's lymphoma
Hodgkin disease
Acute lymphocytic leukemia
Carcinoma
Thymoma
Ovarian cysts and tumors

IgG, immunoglobulin.

TABLE 57.1. Diseases Associated with Autoimmune Hemolytic Anemia in Childhood

The incidence of idiopathic IgG-induced AIHA varies among different series; however, overall about half the patients with IgG-induced immune hemolysis do not have a detectable underlying disease at diagnosis. The other half have an underlying disease, such as those mentioned, or have a drug-induced immune hemolytic anemia (24). Some patients, both those with the “idiopathic” disease and those with disease associated with an underlying immunoproliferative disorder, have ITP in conjunction with IgG-induced AIHA (Evan syndrome) (25). Patients have been described with immune hemolytic anemia, immune thrombocytopenia, and immune granulocytopenia (D.B. Cines, D.S. August, and A.D. Schreiber, personal communication), with antibodies directed toward erythrocytes, platelets, and granulocytes. It is not clear whether such IgG antibodies directed against each blood cell line recognize a common blood cell antigen or represent antibodies with different specificities.

Although the destruction of red blood cells on exposure of a patient to cold was first reported in the mid nineteenth century, it was not until the turn of the century that Landsteiner first demonstrated the agglutination of blood by a patient's serum in the cold (26). Later, it was observed that IgM autoantibodies most commonly are found in patients who have cold agglutinin disease and that they are generally responsible for the clinical symptoms of the disease (27). The IgM antibody in cold hemagglutinin disease usually is directed against the I antigen or related antigens on the human erythrocyte membrane. As with all IgM antibodies, agglutinating

activity is particularly efficient because of the multiple antigen-combining sites on the IgM molecule. In this disorder, the IgM antibody has a particular affinity for its red cell antigen in the cold (0–10°C), and the affinity is lower at higher temperatures. Like warm antibody (i.e, IgG-mediated) AIHA, cold agglutinin disease can be divided into those cases considered primary or idiopathic or those associated with the presence of an underlying disease (i.e., secondary).

Chronic cold hemagglutinin is due to a clonal expansion of lymphocytes in which a monoclonal antibody that recognizes a polysaccharide antigen on red cells, termed I or i, is produced. The most common form of chronic cold agglutinin disease is the primary or idiopathic form. Usually a disease of older persons, its peak incidence is in the fifties and sixties (28). Most often, it presents as fatigue, anemia, and occasionally jaundice in an elderly patient, but it may be associated with the development of acrocyanosis as a result of sludging of blood in peripheral vessels on exposure to cold or with acute hemolysis. This disease is associated with the presence of a monoclonal IgM antibody, usually exhibiting a high cold agglutinin titer (>1:1,000). This IgM binds to erythrocytes avidly in the cold but shows no binding activity at 37°C. In most, but not all, patients, the antibody is of the klight-chain type and has specificity for the I antigen present on the erythrocytes of most adults. The I-antigenic determinants are closely related to the ABO core antigenic determinants. Although present on the erythrocytes of more than 99% of adults, the antigenic groupings recognized by the antibody develop during childhood and are not present on blood taken from the umbilical vein of the newborn. Thus, operationally, I-specificity is established by the ability of the antibody to agglutinate the blood of almost all adults but an inability to agglutinate the erythrocytes of newborns. The antibody responsible for the development of the cold agglutinin syndrome appears to reflect the expansion of a highly restricted or single clone of cells. The antibody appears to represent a highly restricted clonal response to the I-antigen. Antibodies among patients tend to share idiotypic determinants consistent with their uniform recognition of the I-antigen.

Secondary cold hemagglutinin disease, or IgM-induced immune hemolytic anemia, is associated most commonly with an underlying mycoplasma infection, particularly *Mycoplasma pneumoniae*, in which antibody with typical anti-I-specificity is produced. It can occur with other infections, however, such as infectious mononucleosis, cytomegalovirus, and mumps. With infectious mononucleosis anti-i (antibody to an antigen related to I but present on cord blood cells), cold agglutinins are produced, but overt hemolysis is unusual. Under most circumstances, with an underlying infection, the cold agglutinin (IgM antibody) is polyclonal, that is, immunochemically heterogeneous.

Cold hemagglutinin disease also can be seen in patients who have an underlying immunoproliferative disorder. The plasma of healthy adults and children contains low levels of IgM antierythrocyte antibodies, that is, low levels of IgM cold agglutinins. Rarely, cold-reacting autoantibodies have been observed with specificity directed against red blood cell antigens other than I or i, that is, the P and the PR antigens. Also, rarely, IgA cold agglutinins have been observed.

The reason for the preferential reaction of cold agglutinin with the human red blood cell membrane in the cold is not completely understood. Most cold agglutinins have no measurable activity above 30°C. Although it has been postulated that either the antibody or the antigen may undergo a structural change on exposure to cold, most data suggest that the antigen on the erythrocyte surface is altered in the cold. This may represent a cold-dependent conformational change in the antigen recognized by the antibody-combining site or a cold-induced change in the erythrocyte surface increasing antigen availability. When intact erythrocytes are studied, IgM anti-I interactions occur only in the cold; however, reactivity at 37°C is noted when the I-antigen is isolated from the erythrocyte membrane. In addition, polysaccharide antigens in general react more strongly with antibodies in the cold than do protein antigens. Presumably, the weak, nonionic interactions with polysaccharides are more easily disrupted as the reaction temperature is raised and brownian motion is increased than are the ionic reactions with proteins.

As in all patients with AIHA, erythrocyte survival is generally proportional to the amount of antibody on the erythrocyte surface. In cold hemagglutinin disease, the extent of hemolysis is a function of the titer of the antibody (cold agglutinin titer), the thermal amplitude of the IgM antibody (the highest temperature at which the antibody is active), and likely the level and activity of the regulatory proteins of the complement system.

Autoimmune Hemolytic Anemia in Children

Viral and respiratory infections are the diseases most commonly associated with AIHA in childhood (29). The anemia is generally mild in these cases, but occasionally there is brisk hemolysis. Associated infections are listed in Table 57.1, as are other disorders, such as systemic lupus erythematosus, also commonly associated with childhood AIHA. The hemolytic anemia may be the initial manifestation or may accompany other symptoms. AIHA also has been reported with a number of immunoregulatory disorders, including immunodeficiency. In some patients, the immunodeficiency is well defined (30), but other patients have the pattern of dysgammaglobulinemia (31). Many of these patients have chronic lymphadenopathy. Chronic hemolysis and immune pancytopenia are common in this group of patients, and there is an increased risk of malignancy. AIHA is rare in childhood malignancy, but it has been reported with acute lymphocytic leukemia, Hodgkin's disease, and non-Hodgkin lymphoma (32,33), in some cases preceding the appearance of the malignancy. Red cell autoantibodies may also be passively transferred from a mother with AIHA to the fetus. Although most reported cases in infants have described little or no intravascular hemolysis, severe anemia may result. Exchange transfusion has been successful in some cases (34).

Pathophysiologic Features

The factors that govern the survival of antibody- and complement-coated erythrocytes in humans are much the same as those that govern the clearance of these cells in animals. In cold hemagglutinin disease, the IgM antibody in the circulation of patients with the disease interacts with the erythrocyte surface, where the cells circulate to areas below core body temperatures, and activates the early steps of the classical complement pathway (35,36). Once C1 is bound to the IgM molecule and activated, it sequentially binds and activates the fourth and second components of complement. The first of these two steps clearly takes place at temperatures as low as 0°C. When the cells return to body temperature, activation proceeds, even though the cold agglutinin antibody can dissociate from the erythrocyte. The C3 convertase generated cleaves C3 into two antigenic fragments, one of which, C3b, may bind to the erythrocyte surface. At this step, there is considerable amplification of the IgM effect with a single classical pathway convertase capable of cleaving many C3 molecules and depositing many C3b molecules on the erythrocyte surface. In some cases, the complement sequence of reactions may be completed with resulting hemolysis, but this is unusual because of the presence of membrane-bound proteins that restrict complement action, the regulation of complement activation (RCA) gene cluster proteins, including DAF and CD59 (see chapter on complement). In the presence of factors H and I, the C3b may be converted to iC3b. These C3-coated erythrocytes are cleared via the complement receptor by mechanisms discussed earlier, even though antibody is no longer present on the red cell surface. The macrophage C3b and iC3b receptors bind, sphere, and may mediate phagocytosis of the C3-coated erythrocytes (14,15,37). Extravascular sequestration usually predominates in patients with this disease. In humans, as in the guinea pig model, there are no receptors on macrophages capable of interacting with IgM-coated cells in the absence of complement; thus, in the absence of an intact classical complement pathway, IgM-coated red cells have a normal survival.

Spherocytosis of erythrocytes is a clinical hallmark of AIHA. It is not possible to induce spherocytosis of erythrocytes *in vitro* by the addition of antibody and complement. Spherocytes will form only if macrophages are present in the reaction mixture. Whereas spherocytes may be due to the partial ingestion of opsonized red cell membranes by phagocytic cells, the exact mechanism for macrophage-induced spherocytosis is unclear (9,38). The erythrocyte can be released from its macrophage membrane attachment site and circulate until it is trapped within the splenic cords. The decreased ability of these microspherocytes to alter their shape and traverse the splenic cords and sinuses results in splenic entrapment and eventual macrophage-mediated destruction.

In humans, the clearance of IgM plus complement coated cells is rapid and takes place primarily in the liver (6,39). The human erythrocyte membrane, in contrast to the sheep erythrocyte membrane, is relatively resistant to the lytic action of complement. When large numbers of IgM molecules are present on the erythrocyte surface, however, complement activation is extensive. The terminal complement components then can place sufficient membrane attack complexes on the erythrocyte surface to lyse the erythrocytes in the intravascular space. The specificity of the IgM antibody is also important because some IgM antibodies appear to be quite efficient at inducing hemolysis.

Complement regulatory proteins, as discussed earlier, are likely particularly important in cold hemagglutinin disease (11) because cell destruction is mediated entirely by C3 and the later complement components. The complement regulatory proteins regulate the number of active C3 fragments on the cell surface. The C3-coated erythrocytes interacting with CRI and factor I are degraded to C3dg or C3d. These C3dg- or C3d-coated erythrocytes are not bound by the macrophage C3b receptors and have a normal survival (5,40,41). Thus, the presence of C3 (C3dg or C3d)-coated erythrocytes in cold hemagglutinin disease explains the observations of a normal erythrocyte survival in patients who still have C3, as detected by the antiglobulin test, on their erythrocyte membranes (42).

The thermal amplitude of the IgM cold agglutinin is important in determining the extent of hemolysis in cold hemagglutinin disease. At a relatively low level of cold agglutinin sensitization, patients with higher thermal amplitude antibodies (those antibodies that possess activity at temperatures approaching 37°C) still may have considerable hemolysis. Such patients have been described as having a low-titer cold hemagglutinin syndrome with a high thermal amplitude antibody. The correct diagnosis in such patients is important because they appear to respond to glucocorticoid therapy in a manner different from that in the usual patient with high-titer cold hemagglutinin disease (14). Furthermore, some unusual patients have an IgG cold agglutinin. The presence of such an IgG antibody is potentially important because it appears to indicate responsiveness to steroids or splenectomy (28).

In humans, as in guinea pigs, IgG antibody produces effects that are quite different from those of IgM antibody. Although complement activation is not necessary for the clearance of IgG-coated cells, complement can accelerate the clearance of IgG-coated erythrocytes. Generally, more IgG molecules on the erythrocyte surface are needed to bind and activate a single molecule of C1 (35) because two IgG molecules in close proximity to each other (a doublet) are required. Once C1 is bound and activated, C4 and C2 activation occurs in a manner similar to that described for IgM antibody, and C3 convertase is formed. C3 cleavage results, and C3b is deposited

on the erythrocyte surface. Macrophages within the reticuloendothelial system have Fc receptors for IgG (37,44). These macrophage Fc receptors bind IgG-coated erythrocytes and mediate spherocyte formation or phagocytosis. Once sufficient IgG is present on the erythrocyte surface so that C1 activation occurs, however, erythrocyte clearance is further accelerated. In such a circumstance, clearance represents the combined effect of the macrophage Fc receptors and the macrophage C3b/iC3b receptors. These receptors interact synergistically to induce the binding of erythrocytes coated with IgG and C3 (15). As in the animal models, IgG-coated erythrocytes are cleared progressively from the circulation, primarily in the spleen (77), and hemolysis is almost always extravascular.

NATURAL HISTORY

There appears to be little genetic predisposition to the development of AIHA (45). The occasional rare familial association of cases may be secondary to the familial predisposition to systemic lupus erythematosus or a similar underlying connective tissue disease. Thus, there are patients with AIHA who have a family history of other autoimmune diseases, such as autoimmune thrombocytopenia, rheumatoid arthritis, and glomerulonephritis. AIHA is not an uncommon disease. In large centers, 15 to 30 cases are seen yearly (46), with an annual incidence of approximately one case per 75,000 to 80,000 persons in the general population. As with any disease that may require careful serologic study for diagnosis, the level of sophistication and diagnostic capability of the institution influence the reported incidence. Nevertheless, AIHA occurs considerably less commonly than does autoimmune thrombocytopenia.

Autoimmune hemolytic anemia caused by either IgG or IgM antibody does not appear to be more prevalent in any particular racial group and can affect persons of any age. There is a general impression that AIHA occurs more commonly in women, although in most series the incidence is roughly equivalent between sexes (23). Any increased incidence in female patients may be due to the increased incidence of systemic lupus erythematosus in women. Although warm antibody (IgG-induced) immune hemolytic anemia can occur at any age, there appears to be a peak incidence in the 50-year-old age group. In contrast, idiopathic cold agglutinin disease is a disease predominantly of elderly persons.

The peak incidence of AIHA in childhood is in the first 4 years of life. Children older than 10 years at onset are most likely to have a chronic course and most likely to have an underlying disorder. In a study of the prevalence of the disease in childhood, the incidence in persons younger than 20 years of age was slightly less than 0.2 per 100,000 (47). In contrast to the situation in adults, in the reported series in children, there is a male preponderance, especially in acute cases and in patients younger than 10 years of age (48,49,50,51,52 and 53). Familial cases also have been reported (45).

Patients with AIHA vary considerably in their mode of clinical manifestation, and manifestations may be more acute in children than in adults. In children, the fall in hemoglobin may occur over a period of hours to days, with resolution of the disease often within months. In several large series of children with AIHA, a mean of 48% of cases were acute in onset and short-lived. Some cases are chronic, however, with intermittent relapses, as often seen in adults (48,49,50,51,52 and 53). The range in different series is considerable, with 25% to 70% of children having a chronic course. Children with chronic AIHA recover fully, whereas others have persistence of hemolysis or intermittent relapses. These series emanate from different geographic locations and from centers with different referral patterns. In the experience at the Children's Hospital of the University of Pennsylvania and the Duke University Children's Hospital, most cases of AIHA in the pediatric population have been acute and not associated with an underlying disorder.

Immunoglobulin M–induced immune hemolytic anemia, usually cold agglutinin disease, may be associated with a respiratory infection. Cases resulting from *M. pneumoniae* infections are the most common and have anti-I-specificity. Those IgM antibodies observed in infectious mononucleosis usually are directed against the I antigen. The Donath–Landersteiner cold hemolysin is an unusual IgG antibody with anti-P specificity that was originally noted in cases of congenital or acquired syphilis. The disease it causes is termed *paroxysmal cold hemoglobinuria*. Hemolysis in this syndrome most commonly occurs intravascularly, after the antibody has passed through a cell attachment phase in the lower temperatures of the peripheral circulation. The extravascular hemolysis is due to the unusual complement-activating efficiency of this IgG antibody. As its name implies, this antibody is associated with cold hemoglobinuria. At present, this antibody, though uncommon, is found most frequently in children with viral infections (54,55 and 56). Hemolysis, although sometimes severe, is usually mild, and tends to resolve as the infection clears.

Mortality in the pediatric age group has ranged from 9% to 29% (45,48,49,50 and 51,53,58). Death during the acute stage is usually due to severe anemia or to hemorrhage from associated thrombocytopenia. Mortality in chronic cases or in adults is higher and usually occurs because of an underlying serious disorder, such as Hodgkin disease or non-Hodgkin lymphoma or as a complication of therapy. Fatal sepsis, of course, has been observed following splenectomy (51).

CLINICAL AND LABORATORY FINDINGS

Many of the symptoms of AIHA, such as weakness, malaise, and light-headedness, are caused by the presence of anemia. Patients who have underlying cardiovascular disease may have significant dyspnea on exertion and peripheral edema as well as angina pectoris. If hemolysis is significant, mild jaundice may be noted, particularly in the presence of hepatic dysfunction. In addition, patients with an underlying disease often have symptoms associated with that disease, for example, fever and weight loss with an underlying malignant disease or joint symptoms secondary to an underlying systemic vasculitis. Physical findings are also generally referable to the underlying disease. For example, in patients with an underlying non-Hodgkin lymphoma, hepatosplenomegaly and lymphadenopathy are common. Mild splenomegaly may be present in patients with severe AIHA. Massive splenomegaly suggests an underlying disorder such as a lymphoma. Other signs that may result from the anemic state include those caused by congestive heart failure (edema, ascites, or pulmonary congestion). Severe jaundice is uncommon. Thus, the common presenting symptoms are pallor, jaundice, dark urine, abdominal pain, and fever. Pallor may precede the appearance of jaundice. The clinical status depends on the rapidity of the hemolysis and the severity of the anemia. In mild cases, fatigue may be the only symptom. In severe cases, the patient may appear acutely ill or even moribund, with tachycardia, tachypnea, signs of hypoxia, and cardiovascular collapse. In severe IgM-induced cold agglutinin disease, the skin may have a livedo reticularis pattern and the patient may demonstrate acrocyanosis on exposure to the cold.

Laboratory data reveal the presence of anemia and, if bone marrow function is adequate, reticulocytosis. Diagnosis rests on the presence of anemia, reticulocytosis, and a positive result on direct Coombs test. Examination of the peripheral smear may show spherocytes, polychromasia, nucleated red blood cells, and erythrophagocytosis. Rosettes of red cells around white cells may be visible in a buffy-coat preparation. Agglutination of the red cells may be evident in cold agglutinin disease. In severe cases, macroagglutination is visible on the microscope slide or in a capillary tube. The white cell count is usually normal or elevated. Autoimmune hemolysis also is associated with thrombocytopenia or leukopenia in a small number of patients. Indirect hyperbilirubinemia is common. It is the positive result on direct Coombs test, however, that alerts the clinician to the correct diagnosis.

Reticulocytopenia may be observed, especially in children in the first days of the anemia. In a small percentage of patients, the reticulocytopenia may persist for weeks to months (58,59 and 60). Bone marrow aspiration usually shows erythroid hyperplasia, but hypoplasia is present in a few patients (60). Autoantibodies directed against burst-forming unit, erythroid (BFU-E) colonies are believed to be responsible for the reticulocytopenia in some patients (60), although antibody directed at a blood cell antigen present primarily on reticulocytes is another possibility.

The diagnosis of AIHA is established most effectively by directly examining the patient's circulating red blood cells for the presence of antibody or complement components on their surface, which is done most easily by performing a direct Coombs antiglobulin test. Classically, in this test, the patient's red blood cells are made to interact with a rabbit or goat antihuman serum globulin reagent, and agglutination of the patient's red blood cells is assessed. It is also possible to use antibody to human immunoglobulin or complement components as a more specific test reagent. In this case, agglutination induced by anti-IgG indicates the presence of IgG on the surface of the red blood cells, whereas agglutination with an anti-C3 or anti-C4 (a positive result on nongamma Coombs test) is used to test for the presence of C4 and C3. In IgG-induced hemolytic anemia, IgG or IgG plus complement components are found on the surface of erythrocytes. Therefore, such patients usually have a positive result for IgG on the Coombs test but may have a positive result on the nongamma Coombs test as well. In IgM-induced hemolytic anemia (cold agglutinin disease), IgG is not found on the red cells, and the IgM cold agglutinin, because of its low affinity for red cell antigens at 37°C, is not found either; C3, stably bound at 37°C, is detected on the red cell membrane. Therefore, in cold agglutinin disease, usually only a positive result on nongamma (C3) Coombs test is observed.

Rarely, patients with IgG-induced immune hemolysis have levels of IgG per erythrocyte that are undetectable by the standard Coombs test, which requires the presence of hundreds of molecules of IgG on the erythrocyte surface for the result to be positive. When this phenomenon was originally described, the small amounts of red cell–bound IgG antibody were detected by using a complex antiglobulin consumption test (61,62). Now, however, a Coombs test using radiolabeled anti-IgG (63), which is ten times more sensitive than the standard Coombs test, also may be used to detect the antibody.

Thus, testing with Coombs antisera shows several patterns of reactivity (58). The red cells may be coated with IgG in the presence or absence of detectable complement (warm antibody IgG-mediated AIHA) or with complement protein alone (IgM-induced hemolysis, i.e., cold hemagglutinin disease). Rarely, IgM is detected as well. In one large series of patients, IgG with or without complement was found on the red cells in 85% to 95% of patients with chronic disease but in fewer (about 30%) of those with acute disease (50,58). Cold agglutinins (IgM-induced AIHA) and the coating of red blood cells with complement alone were more common in acute disease. Early studies suggested that the finding of IgG plus complement indicated a more guarded prognosis; however, it is now believed that it is not possible to predict the chronicity or severity of AIHA from the Coombs testing pattern.

A cold agglutinin titer is also diagnostically helpful. This test is performed by examining the patient's plasma for agglutinating activity at 0°C directed against normal ABO-compatible eurythrocytes containing the I-antigen. The cold agglutinin titer is the highest dilution of antibody that still agglutinates normal red blood cells in the

cold. Most patients with immune hemolysis secondary to cold hemagglutinin disease have cold agglutinin titers greater than 1 to 1,000.

THERAPY

In many patients with IgG- or IgM-induced immune hemolytic anemia, no therapeutic intervention is necessary because the hemolysis is mild. If an underlying disease is present, control of this disease often brings the hemolytic anemia under control as well. If the patient is having significant anemia secondary to hemolysis, however, therapeutic intervention is in order.

Glucocorticoids

Patients with IgG-induced immune hemolytic anemia respond, in general, to glucocorticoid therapy in dosages equivalent to 1 to 2 mg of prednisone per kilogram of body weight daily. These drugs are believed to decrease hemolysis in IgG-induced hemolytic anemia by three major mechanisms (12,64). First, they decrease the production of the abnormal IgG antibody. This is a common effect and can be expected to produce a gradual decrease in the strength of the Coombs test result and a rise in hemoglobin within 2 to 6 weeks. Second, glucocorticoids are reported to be associated with a fall in the amount of antibody detected by the direct Coombs test, as if they induced a decrease in antibody affinity. This has been associated with improved erythrocyte survival; it is probably an uncommon effect of glucocorticoid therapy. Third, glucocorticoids have been shown *in vitro* and *in vivo* to interfere with the macrophage Fc receptors responsible for clearance from the circulation of IgG-coated cells (12,15,64). The effect is to improve erythrocyte survival despite the continued presence of IgG and C3b on the erythrocyte surface. Thus, the Coombs test in some patients may remain positive in the face of an improved erythrocyte survival and rising hemoglobin. This effect of glucocorticoids may be rapid and may be responsible for the rise in hemoglobin noted in some patients to occur with 1 to 4 days of glucocorticoid therapy. In a number of animal studies, however, it was shown that glucocorticoids have no effect on erythrocyte survival until therapy has been continued for 5 to 7 days. Similarly, most patients will respond to glucocorticoid therapy within 2 to 3 weeks (and some within days). In some patients, 4 to 6 weeks of therapy may be required for a response to be evident.

Once a therapeutic response is achieved and the patient stabilizes, tapering of steroids should begin. This may take several weeks to many months. Alternate-day steroid therapy can be effective in some patients after the clinical course stabilizes. Interestingly, alternate-day therapy may be less effective in AIHA than in some of the inflammatory autoimmune diseases, and patients should be monitored carefully for an exacerbation. Care should be taken in stopping glucocorticoids if the patient continues to demonstrate a positive result on the direct Coombs test. Approximately 70% to 80% of patients have an initial response to high-dose glucocorticoids. In a small proportion of patients with chronic AIHA in adults, the steroids can be tapered and stopped with the patient remaining in remission. Some patients have control of their hemolytic process on continued low- to medium-dose steroid therapy. For patients who are steroid dependent, the initial and long-term side effects of these drugs restrict their long-term use. These effects include diabetes and hypertension, electrolyte imbalance, increased appetite and weight gain, moonlike facies, osteoporosis, myopathy, and increased susceptibility to infection. The severity of these side effects relates both to the duration of therapy and to dosage. Splenectomy should be considered in patients who are steroid unresponsive or require more than 10 to 20 mg of prednisone per day or substantial doses of steroids every other day for maintenance. Each patient requires individual evaluation of underlying diseases, surgical risk, extent of anemia, and steroid intolerance. In some patients, the presence of a mild hemolytic anemia may be preferable to splenectomy or other treatment options. The initial goal of therapy is to return the patient to normal hematologic values and nontoxic levels of glucocorticoid therapy, but for some patients, a modified goal of improvement in hemolysis to a clinically asymptomatic state with minimum glucocorticoid side effects is more realistic.

Glucocorticoids usually are not effective in cold hemagglutinin disease (27,64). This is probably due to the fact that these patients generally have large amounts of IgM antierythrocyte antibody and large numbers of C3 molecules deposited on their red cells. In addition, some of the hemolysis may be intravascular, and glucocorticoids do not inhibit complement-mediated lysis. A few patients with a low-titer cold hemagglutinin disease syndrome, in which the antierythrocyte antibody has activity at temperatures approaching 37°C, do respond to steroid therapy (14). In addition, the few patients described with an IgG cold agglutinin appear to be both steroid and splenectomy responsive (43). Patients with cold hemagglutinin disease respond best to the avoidance of cold and control of their underlying disease. Fortunately, in many patients, hemolytic anemia is mild.

Splenectomy

The red pulp of the spleen, with its resident macrophages, is the major site for sequestration of IgG-coated blood cells in humans as in animals. This appears to be due to the unique circulatory pathways in the spleen whereby hemoconcentration occurs in the splenic cords and erythrocytes make their way through fine fenestrations between macrophages. This results in intimate contact between macrophages (with their membrane Fc receptors) and IgG-coated blood cells possibly in the presence of a minimal amount of plasma IgG.

Removal of this major site of red cell destruction is an effective therapeutic strategy in IgG-induced immune hemolytic anemia. The response rate to splenectomy is approximately 50% to 70%; however, the vast majority of the responses are partial remissions. Interestingly, before glucocorticoid therapy became available for the treatment of AIHA, splenectomy was performed commonly, but the patient usually had a relapse. Presumably, as the sensitized erythrocytes continued to circulate, they bound more and more antibody. They finally achieved a degree of sensitization where the liver was able to mediate clearance. Probably, patients who are least responsive to splenectomy are those whose erythrocytes are coated with large amounts of IgG. In this circumstance, the liver plays a larger role in clearance. The partial remissions that occur with splenectomy are often quite helpful in that they result in a lessening of the hemolytic rate, with a rise in the hemoglobin value, and allow a reduction in the amount of glucocorticoid needed to control the hemolytic anemia. Because of the increased risk of sepsis (36), patients should be carefully selected. Patients who are unresponsive to glucocorticoids, who require moderate to high maintenance doses, or who have developed glucocorticoid intolerance can be considered for splenectomy.^{51}Cr-labeled red cell kinetic studies are probably not helpful because the procedure is time-consuming, expensive, and not a reliable indicator of response to splenectomy in most cases.

A second effect of splenectomy also has been suggested in AIHA and was shown to be important in autoimmune thrombocytopenia. Splenectomy may lead to a decrease in the production of the IgG antierythrocyte antibody because the spleen contains a large B-cell pool. Splenectomy, like corticosteroid therapy, is usually not effective for patients with cold hemagglutinin disease because IgM-coated erythrocytes are cleared predominantly in the liver. An occasional case in which a patient with an apparent IgM-induced hemolytic anemia responded to splenectomy was reported and may have been due to decreased production of IgM antibody by the spleen in these few patients or to the presence of an IgG cold agglutinin (28). Immunization with pneumococcal vaccine should be performed prior to splenectomy to decrease the likelihood of postsplenectomy pneumococcal infection.

Immunosuppressive Agents

Several immunosuppressive agents have been used in the treatment of AIHA. Commonly used agents include the thiopurines (6-mercaptopurine, azathioprine, and thioguanine) and alkylating agents (cyclophosphamide and chlorambucil). Immunosuppressive agents act to decrease the production of antibody, and therefore it generally takes at least 2 weeks before any therapeutic result is observed. A reasonable clinical trial consists of 3 to 4 months of therapy. These drugs are rarely needed in the treatment of childhood AIHA.

Patients are selected for immunosuppressive therapy when a clinically unacceptable degree of hemolytic anemia persists following treatment with corticosteroids and splenectomy. Altenatively, they may be corticosteroid resistant or intolerant and a poor surgical risk for splenectomy. Clinical benefit has been noted in about 50% of patients. Dosage of drug should be adjusted to maintain the leukocyte count greater than 4,000, the granulocyte count greater than 2,000, and the platelet count greater than 50,000 to 100,000 per microliter. The use of alkylating agents, such as cyclophosphamide, also may have long-term potential for increasing the incidence of malignancy, particularly acute leukemia. Such side effects require that the clinical indications for an immunosuppressive trial be strong and that patient exposure to the drug be limited.

Immunosuppressive therapy has been effective therapy in cold agglutinin disease. Alkylating agents (cyclophosphamide or chlorambucil) have been used and appear to have a beneficial effect in 50% to 60% of patients.

Transfusion Therapy

Most patients with AIHA do not require transfusion therapy because the anemia is developed gradually and physiologic compensation has occurred (65). Occasional patients experience acute or severe anemia, however, and require transfusions for support until other treatment reduces the hemolysis. Transfusion therapy is complicated by the fact that the blood bank may be unable to find “compatible” blood, usually because of the presence of an autoantibody directed at a core component of the Rh locus, which is present on the erythrocytes of essentially all potential donors, regardless of Rh subtype. The usual recommendation is for the blood bank to identify the most compatible units of blood of the patient's own major blood group and Rh type and to transfuse the patient with the most compatible units available. With this approach, it is unlikely that the donor blood will have a dramatically shortened red blood cell survival.

In cold hemagglutinin disease, it is important to warm all intravenous infusions, including whole blood, to 37°C because a decrease in temperature locally in a vein can enhance the binding of the IgM antibody to red cells and accelerate the hemolytic process. Furthermore, agglutination of the transfused chilled or even room

temperature cells in small peripheral blood vessels can result in severe ischemic changes and vascular compromise.

Miscellaneous Therapy

Intravenous gamma globulin, which has been used extensively in the treatment of ITP, may be effective in treating patients with AIHA, probably by interfering with the clearance of the IgG-coated cells (66). Treatment regimens vary from 400 mg to 2 g per kilogram of body weight daily for 5 days, with additional treatment as needed to maintain the effect. Intravenous gamma globulin appears less effective in AIHA than in ITP (67).

Plasmapheresis or exchange transfusion has been used to treat patients with severe IgG-induced immune hemolytic anemia but has met with limited success, possibly because more than half of the IgG is extravascular and the plasma contains only small amounts of the antibody (most of the antibody being on the red blood cell surface). Plasmapheresis has been effective, however, in IgM-induced hemolytic anemia (cold agglutinin disease) because IgM is a high-molecular-weight molecule that remains predominantly within the intravascular space, and at 37°C, most of the IgM is in the plasma fraction. Plasmapheresis is useful only as short-term therapy, but it may be lifesaving in the rare patient with severe uncontrollable hemolysis. Other measures that have been used effectively in some patients with IgG-induced immune hemolysis are vincristine, vinblastine infusions, and hormonal therapy. For example, there has been interest in the use of the synthetic weak or impeded androgen danazol (68). Interferon therapy and monoclonal antibodies directed at select lymphocyte antigens are in experimental use.

IMMUNE PANCYTOPENIA

Evans syndrome refers to AIHA accompanied by thrombocytopenia (25). It occurs in a small percentage of adults and children with acute AIHA. In an even smaller percentage of patients, it is also associated with marked neutropenia (D.B. Cines, D.S. August, and A.D. Schreiber, personal communication). AIHA in the presence of thrombocytopenia or neutropenia is more commonly associated with a chronic or relapsing course. Many patients have associated disorders, such as chronic lymphadenopathy or dysgammaglobulinemia. Some patients are hematologically normal between relapses, which may involve depressions in any of the three cell lines. Usually, prednisone therapy is effective in controlling the acute episodes and is not needed between relapses. Some patients, however, have persistent immune cytopenia and require prolonged steroid treatment or more aggressive therapy. Splenectomy may result in improvement, but the risk of infection is probably higher in children and adults with pancytopenia than in those with AIHA alone and relapses are more common (25,30,31,60,61,62,63,64,65,66,67,68,69,70,7172,73 and 74). Antibodies directed against red cells, leukocytes, and platelets have been demonstrated in some patients with immune pancytopenia (70,75). Suppression of hematopoietic cell maturation by T cells was demonstrated in one patient and circulating autoantibodies in another (69).

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

Paroxysmal nocturnal hemoglobinuria was first described in the late nineteenth century. It is an acquired disorder initially thought to consist of paroxysms of intravascular hemolysis reflected in nocturnal hemoglobinuria (44,77). It is now recognized that chronic intravascular hemolysis is the more frequent clinical presentation. PNH is a primary bone marrow disorder that not only affects the red cell lineage but also affects the platelet, leukocyte, and pluripotent hematopoietic stem cell lines. It is believed to be a disorder of stem cells of a clonal nature (78,79) and can arise from or evolve into other dysplastic bone marrow diseases, including aplastic anemia, sideroblastic anemia, and myelofibrosis. Rarely, PNH evolves into acute leukemia. A major clue to the cause of this disease was provided by the finding that patients have a somatic mutation in the DNA of the X chromosome coding for a protein (phosphatidylinositol 1 glycan class A, or PIGA) that is important in the pathway that controls the formation of the phosphatidylinositol anchor of various membrane proteins, including the complement control proteins (80). Many different mutations of the *PIGA* gene have been reported.

Although PNH is often a disease of young adults, it can occur in any age group and in persons of either sex (81). Chronic intravascular hemolysis of varying severity is the most common presentation. The severity of the hemolysis and the degree of hemoglobinuria depend on the number of circulating abnormal red cells and the degree of expression of the membrane abnormality among these cells. Two to three populations of abnormal red cells, termed PNH type I, II, and III cells, may be present simultaneously and differ in their expression of GPI-linked proteins and their lytic susceptibility. Patients commonly have iron deficiency anemia as well because of the large amount of iron lost in the urine during intravascular hemolysis with persistent hemoglobinuria and hemosiderinuria. Other frequent clinical complaints include abdominal, back, and musculoskeletal pain. Such pain may be associated with intravascular hemolysis and hemoglobinuria, or it may be ischemic, secondary to the complication of venous thrombosis of major or minor vessels. Thromboses of the hepatic veins (Budd-Chiari syndrome) and of portal, splenic, mesenteric, cerebral, and other veins may occur and are common causes of death. Acute intestinal infarction requiring surgical resection has been reported (82), and thrombotic episodes may require anticoagulant therapy (83). Platelets and leukocytes also appear to have unusual susceptibility to lysis, and thrombocytopenia or granulocytopenia or both may be the initial manifestation(s) of the disease; these are commonly present. The bone marrow is usually hyperplastic, but it may be hypocellular, consistent with aplastic anemia. The clinical course is variable and depends on the occurrence of the life-threatening complications of progressive bone marrow disease or venous thrombosis.

Paroxysmal nocturnal hemoglobinuria should be considered in anyone who has aplastic anemia (84). In general, patients are not predisposed to the development of infection. At least half of these patients live for many years. Diagnosis rests on the clinical picture and the clinical laboratory measurement of a population of circulating cells with unusual sensitivity to complement-mediated lysis. This sensitivity is most readily demonstrated by fluorescence-activated cell sorter (FACS) analysis of DAF, CD59, or other GPI anchored molecules that are defincient in PNH. The deficiency of GPI linked proteins is determined by flow cytometry using monoclonal antibodies. The size of the affected clonal population and the extent of GPI protein deficiency are important determinants of clinical symptoms. PNH also can be diagnosed by positivity in the sugar-water test and in the Ham acidified serum test. In the sugar-water test, the patient's serum is mixed with 5% dextrose in water and incubated with the patient's cells. In PNH, hemolysis ensues. Everyone has antibody molecules that recognize their own cells under conditions of low ionic strength. These antibodies activate the classical complement pathway. Normal erythrocytes resist lysis, but PNH erythrocytes are susceptible to lytic attack. In the Ham test, the patient's cells are incubated in acidified serum. Under these conditions, the alternative complement pathway is triggered and lysis of PNH, but not normal cells, follows. The Ham test result also is positive with some, but not all, normal sera from patients with a syndrome of congenital dyserythropoietic anemia (hereditary erythroblastic multinuclearity with a positive acid-hemolysis test, or HEMPAS).

Pathogenesis

Patients with PNH have an unusual sensitivity of their erythrocytes and often granulocytes and platelets to the lytic action of complement. Activation of complement by either the classical or alternative pathway results in the deposition of larger numbers of complement molecules on the PNH blood cell surface than on normal cells. The excessive binding of complement to blood cells in PNH is due to more efficient alternative-pathway C3-convertase activity on the cell surface (85). The surface of a PNH erythrocyte is a better acceptor for C3 than is the surface of a normal cell. This results in greater activation of the terminal complement components C5 to C9, causing more cell lysis than with normal cells. Furthermore, PNH cells are more effectively damaged by the C5 through C9 complex generated on the erythrocyte surface (86,87) because the C5b through C9 lytic complex penetrates the PNH cell membrane more efficiently than the normal cell membrane.

Patients with PNH lack the complement regulatory proteins present on the membranes of all normal blood cells, thereby causing the increased susceptibility to complement lysis of PNH erythrocytes. The fundamental feature of blood cells in PNH patients is that they are deficient in proteins linked to the membrane by a GPI anchor. DAF and CD59 are the complement regulatory proteins that are GPI linked and that are deficient on hematopoietic cells in patients with PNH. Many patients with PNH have several populations of abnormal erythrocytes. The complement lysis sensitivity test, which examines the susceptibility of antibody-sensitized erythrocytes to complement-mediated lysis, can be used to define the various PNH cell populations. PNH type 1 cells have a moderate increase in susceptibility to complement attack. They commonly express close to normal levels of GPI linked proteins. PNH type 2 cells exhibit decreased expression of GPI linked proteins. These erythrocytes appear to have decreased levels of DAF, but they do not have the membrane deficit (CD59) that leads to sensitivity to attack by the C5b complex. PNH type 3 cells are highly susceptible to complement attack. They appear to lack phosphatidylinositol-linked control proteins completely, lacking both DAF and CD59. As noted, the platelets and leukocytes in PNH are also abnormally sensitive to complement-mediated lysis, and this abnormality is likely to have the same cause (76,88). This may relate to the pathogenesis of the venous thromboses.

Therapy

Hemolysis is controlled with the use of prednisone in some patients. A dose of 15 to 40 mg every other day has been reported to decrease the rate of hemolysis in some adult patients (83), but a response is by no means certain. During acute episodes, a higher dose given daily for a short period may help to control the hemolysis. In patients with anemia, androgens, including the anabolic steroid danazol, may be effective (68,83). Several patients have been able to attain a modest increase in their platelet count while on androgen therapy. Bone marrow transplantation has been successful in some patients, but in general the treatment of PNH has not been satisfactory. Bone marrow transplantation is the only curative therapy for PNH. As discussed earlier, PNH patients may be iron deficient. Acutely, iron replacement may result in increased hemolysis because of the formation and release of a new cohort of sensitive red cells, and hemolysis on iron replacement has been noted. Oral replacement should be used if possible, but parenteral iron therapy may be necessary when iron losses are very large.

DRUG-INDUCED IMMUNE HEMOLYSIS

Drug-induced immune hemolytic anemia may be divided into three primary pathophysiologic entities. The clinical signs and symptoms are identical to those of AIHA. Patients may present with chronic hemolytic anemia or occasionally with catastrophic intravascular hemolysis (quinidine type). The diagnosis is established primarily by history and *in vitro* assay.

a-Methyldopa Type

a-methyldopa and its derivatives (such as levodopa) produce a clinical syndrome virtually identical to IgG-induced immune hemolytic anemia (2,89). This is the most common type of drug-induced immune hemolytic anemia. The mechanisms of the IgG antibody formation are poorly understood. This drug stimulates the production of IgG warm-reactive antibodies with anti-Rh specificity; it also may inhibit the splenic macrophage clearance of the IgG-coated cells. A primary mode of action of the drug in this disorder may be an alteration of immunoregulation, allowing B-lymphocytes that produce Rh antibodies to escape from suppression.

It is of interest that 15% of patients on a-methyldopa therapy develop antinuclear antibodies. Many patients, up to 25%, exposed to methyldopa develop a positive result on Coombs test for IgG. Of diagnostic importance is that almost all patients have IgG antierythrocyte antibodies present in their plasma as well. Most patients do not develop sufficient IgG coating for hemolysis; however, about 0.8% of patients exposed to a-methyldopa do develop significant hemolysis and hemolytic anemia 3 to 37 months after the onset of therapy (2). Diagnosis can be made by examining the patient's red blood cells and plasma. *In vitro*, it is not necessary to have the drug present for the patient's plasma to deposit IgG antibody on donor erythrocytes. The Coombs test result can remain positive in some patients up to 2 years after withdrawal of the drug (90). A similar syndrome has been reported with mefenamic acid.

As stated, many patients receiving a-methyldopa therapy develop a positive result on Coombs test (both direct and indirect) for IgG, but few patients develop significant hemolysis. It appears that the level of IgG per erythrocyte accounts at least in part for this observation because patients with the highest amount of erythrocyte-associated IgG appear to have the most significant hemolysis (2). A second feature, in my view, that may explain the high incidence of Coombs positivity without hemolysis in this syndrome is a low avidity antibody. The striking finding that almost all patients have antibody present in their plasma, as well as on the erythrocyte surface, contrasts with the finding in most other patients with IgG-induced AIHA, in which a positive result on indirect Coombs test (plasma antibody) is less common. Second, it appears that the IgG antierythrocyte antibody can be eluted easily from the erythrocyte surface (90). These observations suggest that a-methyldopa-induced IgG antierythrocyte antibody may be an antibody that has low avidity for its erythrocyte Rh antigen, which may partially explain its inefficiency in producing hemolysis.

Hapten Type

The hapten type of drug-induced immune hemolysis classically develops in patients exposed to high doses of penicillin. A portion of the penicillin molecule or its active metabolites combines with the erythrocyte surface, acting as a hapten. This induces an antibody response directed against the penicillin-coated erythrocyte membrane. This is usually an IgG response, and complement activation is common. The erythrocytes become coated with IgG and often with C3. This syndrome rarely develops unless patients have received 10 to 20 million units of penicillin per day. The diagnosis can be established by incubating the patient's serum with donor erythrocytes preincubated with penicillin. The deposition of IgG antibody will occur only in the presence of penicillin and can be detected by the Coombs test.

Quinidine Type

The quinidine type of AIHA usually occurs with quinidine, but it has been reported with quinine, stibophen, chlorpromazine, and sulfonamides (90). Commonly called an “innocent bystander” reaction, it is thought to be due to an antibody directed against quinidine having a low affinity for the red cell surface. Presumably, the drug binds weakly to the cell glycoprotein. The antibody recognizes the complex (91). This interaction results in activation of the classical complement pathway and deposition of C3 on the erythrocyte surface. It is believed that the immune complex transiently adheres to the red blood cell surface, activates complement, and then dissociates. With quinidine, an IgM antiquinidine antibody appears to be involved. The diagnosis can be established *in vitro* by examining the complement deposition on donor erythrocytes by patient serum, which occurs only in the presence of the drug, for example, quinidine. The Coombs test is used to detect the complement deposition on the erythrocyte surface.

Nonspecific coating of the erythrocyte surface has been observed with the antibiotic cephalothin, in which cephalothin becomes bound to the erythrocyte membrane and causes the red blood cell to be coated by many plasma proteins. The Coombs test result is positive. Hemolytic anemia does not occur. Cephalothin, however, can cause hemolytic anemia by acting as a hapten by a mechanism similar to that of penicillin. In all these drug-induced processes, patients respond to withdrawal of the offending drug. If necessary, a brief course of corticosteroid therapy can be administered effectively.

Many autoimmune or drug-related hemolytic anemias are accompanied by thrombocytopenia or neutropenia as a result of similar pathophysiologic processes. Postinfectious ITP also may result from similar mechanisms. The role of complement in antibody-mediated destruction of platelets or neutrophils seems to be analogous to its role in erythrocyte destruction. Thus, at low levels of antibody, complement accelerates clearance by the reticuloendothelial system, whereas at high levels of antibody, complement may cause direct intravascular cell lysis.

58 IMMUNE THROMBOCYTOPENIA

Russell E. Ware, M.D., Ph.D.

Circulating blood platelets play a critical role in the body's ability to achieve overall hemostasis. Platelets contribute to hemostasis after vascular injury in several ways, including adhesion to the subendothelium and extracellular matrix; aggregation at the site of vessel injury; participation in the coagulation cascade via receptors for coagulation factors; and involvement in the final clot that contains fibrin, erythrocytes, and platelets. Because platelets are integrally important for overall hemostasis, pathologic conditions that reduce their number or function are often clinically significant.

In contrast to thrombocytopenia that results from underproduction of platelets, immune-mediated thrombocytopenia is characterized by normal or increased thrombopoiesis but accelerated platelet destruction. Antiplatelet antibodies bind to platelets, which then are cleared by the reticuloendothelial system (RES). This disorder was formerly known as *idiopathic thrombocytopenic purpura*, but it is now better named *immune thrombocytopenic purpura (ITP)* in recognition of the antibody-mediated platelet destruction. In most cases, ITP is an autoimmune disorder characterized by isolated immune-mediated thrombocytopenia. ITP also can be associated with other clinical conditions, however, including pregnancy, systemic autoimmune disorders, immunodeficiency states, or drug exposure.

HISTORICAL FEATURES

Fifty years ago, Harrington et al. provided the first evidence for antibody-mediated platelet destruction by describing a circulating antiplatelet factor in adults with ITP (1). This factor, isolated from the gamma-globulin fraction of serum in most of the patients tested, was infused into normal volunteers (including Dr. Harrington himself) and induced severe but reversible thrombocytopenia. Subsequent work demonstrated that this factor was in the 7S immunoglobulin G (IgG) serum fraction, was species specific, and affected both autologous and homologous platelets (2). Twenty-five years later, antibodies were first quantitated accurately on the platelets of patients with ITP (3), an event that represented a great advance in our understanding of the pathophysiology of this disorder. Based on these results, ITP could be considered the platelet equivalent of antibody-mediated erythrocyte destruction that was well described in the setting of autoimmune hemolytic anemia. Over the past 25 years, we have begun to unravel slowly the humoral and cellular responses that lead to antiplatelet antibody formation.

Therapy for ITP was available long before immunopathologic mechanisms involved in antibody-mediated platelet destruction were understood. Splenectomy was first used successfully in ITP almost a century ago. After the immune basis of the disorder was established, corticosteroid therapy was introduced in the 1950s with success. Intravenous immunoglobulin (IVIG) became popular in the 1980s for the treatment of ITP following serendipitous observations in the setting of immunodeficient children with ITP (4). More recently, anti-D immunotherapy has emerged as a novel and effective therapeutic option for children and adults with ITP.

IMMUNOLOGIC HIGHLIGHTS

The primary immunologic defect in ITP involves autoreactive B-lymphocytes that secrete antiplatelet antibodies, but the role of T-lymphocytes (and other immune cells that orchestrate the B-cell immune response) in the pathophysiology of ITP has begun to emerge. The observation that the clinical course of ITP can range from brief and self-limited to long-term and unremitting, coupled with the widely variable responses to therapy, suggests that ITP may in fact be several heterogeneous immunologic disorders that culminate in a final common pathway of immune-mediated thrombocytopenia.

Antiplatelet antibodies, which are typically IgG, bind to budding platelets in the bone marrow and to circulating platelets in the peripheral blood. Antibody coating of platelets is not immediately cytolytic, but it leads to immune clearance of these “opsonized” platelets by the RES. Therapy can be directed against autoantibody synthesis, antibody–platelet interactions, or platelet clearance by immune effector cells.

EPIDEMIOLOGY

Acute

The patient with ITP will have either a brief self-limited illness known as *acute* ITP or will develop a long-term disorder termed *chronic* ITP. Acute ITP occurs primarily in childhood and can be defined as resolution of thrombocytopenia within 6 to 12 months of onset, although most patients improve within 3 months (5). About 80% to 90% of children who develop ITP will have an acute clinical course compared with only 5% to 10% of adults. The clinical presentation of acute ITP often begins with a virallike prodrome, followed several weeks later by the abrupt onset of hemorrhagic symptoms. Patients and their families are often extremely anxious and frightened because spontaneous large bruises (purpura) can develop on all parts of the body, along with showers of petechiae and mucosal bleeding. The peripheral platelet count is typically extremely low, frequently below 10×10^9 per liter, but the hemoglobin concentration, white blood cell count, differential, and peripheral blood smear are within normal limits except for decreased numbers of platelets. There is usually no family history of autoimmune disease.

Chronic

In contrast, patients with chronic ITP usually have a more insidious clinical presentation. The preceding history does not include a viral-like prodrome, but often several months of easy bruising and sporadic petechiae; dramatic spontaneous hemorrhagic signs and symptoms are atypical. The peripheral platelet count is modestly low, usually between 20 and 50×10^9 per liter, and the remainder of the blood count is normal. Most patients with chronic ITP are adults, and the incidence increases with age (6), although chronic ITP is also seen in children of all ages, even toddlers. Many patients with chronic ITP have a family history of autoimmune disease. Despite these apparent clinical and laboratory differences, there are frequently overlapping presentations between acute and chronic ITP. At the time of clinical presentation, no single parameter can reliably and accurately predict the clinical course of a patient with ITP. Table 58.1 summarizes some of the typical clinical and laboratory findings in patients with acute versus chronic ITP.

Parameter	Acute ITP	Chronic ITP
Age (yr)	<10	>10
Sex	M = F	F > M
Onset of symptoms	Abrupt	Insidious
Viral prodrome	Yes	No
Platelet count	<20 x 10^9/L	20-50 x 10^9/L
Platelet associated IgG	Markedly elevated	Modestly elevated
Family history of autoimmune disease	No	Occasionally
Other immunologic abnormalities	No	Occasionally

IgG, immunoglobulin G.

TABLE 58.1. Differentiation of Acute and Chronic Immune Thrombocytopenic Purpura (ITP) at Clinical Presentation

CLINICAL PRESENTATION

A variety of pathologic conditions result in thrombocytopenia, and each must be excluded before establishing the diagnosis of ITP. Sepsis, immunodeficiency, drug reactions, malignancy, disseminated intravascular coagulation, bone marrow failure, and systemic inflammatory or collagen-vascular disorders can have concurrent thrombocytopenia. ITP is therefore often a diagnosis of exclusion, which is based frequently on a compatible clinical history, appropriate physical examination, supportive laboratory tests, and the absence of a systemic illness. Queries regarding medication use, rheumatologic signs and symptoms, family history, and past medical history are necessary to establish the diagnosis of ITP.

Signs and Symptoms

The hallmark of ITP is a low platelet count, and typical signs and symptoms reflect the degree and duration of thrombocytopenia. Most patients with acute ITP describe the abrupt onset of bruises that seem “spontaneous” or inappropriately large for any preceding contact or trauma. Patients also describe 1- to 2-mm evanescent “red dots” (*petechiae*) that develop on the skin at pressure locations, such as those touched by elastic bands in clothing. Mucosal bleeding also can occur; nasopharyngeal bleeding (nares, gingiva) is frequently described, and for menstruating female patients, metromenorrhagia is a common presentation. More severe bleeding, such as gastrointestinal blood loss or intracranial hemorrhage, is rare in ITP.

Physical Findings

A careful physical examination is an important part of the initial evaluation of a patient with presumed ITP. Hemorrhagic symptoms in ITP are primarily mucocutaneous, characteristic of thrombocytopenic bleeding, rather than muscle and joint bleeding more typical of coagulation factor deficiency. Bruises can develop on all parts of the body in ITP, and large ecchymoses on the trunk of small children can lead to the suspicion of child abuse (Fig. 58.1). Petechiae are commonly found on the trunk, extremities, and even in the oropharynx. Mucosal bleeding usually is limited to the nasopharynx and gingiva; frank bleeding from the genitourinary or gastrointestinal tract is much less common. No lymphadenopathy or organomegaly suggestive of malignancy should be found; specifically, palpable splenomegaly is almost never found in ITP and should suggest an alternative diagnosis.

Figure 58.1. Large bruises (purpura) on the trunk and extremities in a young child with immune thrombocytopenia. (See Color Figure 58.1)

Laboratory Tests

There is no true consensus regarding the optimal initial laboratory evaluation for a patient with ITP (7), although most clinicians agree that testing need not be extensive. A complete blood count is necessary to document thrombocytopenia and to exclude abnormalities in other hematopoietic cell lines. The peripheral blood smear should reveal platelets that are larger than normal (Fig. 58.2), which is indicative of their young age and is due to rapid turnover. Extremely small platelets are more suggestive of the Wiskott–Aldrich syndrome. Leukocytes must be inspected carefully to exclude circulating malignant cells. Erythrocytes should be normal-sized and hemoglobin content; macrocytosis [e.g., mean cell volume (MCV) >100 fL] is more consistent with bone marrow failure syndromes such as aplastic anemia, Fanconi anemia, or paroxysmal nocturnal hemoglobinuria. In addition, the red cells should not show evidence of traumatic rupture (schistocytes) characteristic of thrombotic thrombocytopenic purpura (TTP).

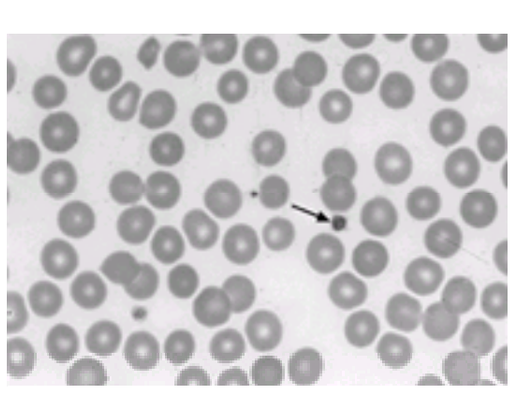

Figure 58.2. Peripheral blood smear of a patient with immune thrombocytopenia. Few platelets are present, but those that are newly released into the circulation (*arrow*) are larger than the normal diameter of 1 to 2 µ. (See Color Figure 58.2.)

Measurement of the erythrocyte sedimentation rate or antinuclear antibody (ANA) titer is often recommended in the initial laboratory evaluation as a screen for a systemic inflammatory or autoimmune disorder. In our experience, testing for antibodies to dsDNA or extractable nuclear antigens is indicated only if the ANA is positive (8). Quantitation of serum immunoglobulins and testing for exposure to the human immunodeficiency virus should be considered if there is a concern about immunodeficiency. Such testing always should be performed before treatment with immunoglobulin products.

The importance and clinical utility of measuring platelet antibodies is a subject of debate. Quantitation of platelet antibodies is frequently available only at selected institutions, and the technique varies among investigators. Unlike the analogous red blood cell system, in which autoantibodies can be identified readily using

agglutinating antisera, platelets often undergo spontaneous and nonspecific agglutination and aggregation. Direct assays using murine monoclonal antibodies that react with human IgG should be used to detect platelet-associated immunoglobulin (PAIgG). These direct-binding assays demonstrate that normal platelets have approximately 500 to 1,000 molecules of IgG on their surface (9). Using accurate direct-binding assays, the presence of surface-bound antiplatelet antibodies appears to be a sensitive but nonspecific marker for ITP (3,10). About 90% of patients with ITP will have elevated PAIgG (high sensitivity), but no more than 50% of patients with elevated platelet antibodies will have ITP (low specificity). Patients with other pathologic conditions such as collagen-vascular disease, malignancy, and infection also can have elevated amounts of PAIgG, which is consistent with the hypothesis that platelet-bound antibodies are at best a marker for immune-mediated platelet destruction of any type, and are clearly not specific for ITP.

The necessity of performing a bone marrow evaluation to assist in the diagnosis of ITP is sometimes an area of controversy, especially in children with a classic presentation. Examination of aspirated cells should reveal normal to increased numbers of megakaryocytes, reflecting increased marrow thrombopoiesis. The megakaryocytes are often young in nuclear appearance and maturation, however, and may not demonstrate budding platelets because of the destruction of platelets within the marrow. The primary reason for bone marrow evaluation in ITP is to exclude other diagnoses, such as acute leukemia, bone marrow failure syndromes, or myelodysplasia. Clues for these other diagnoses are often apparent on history and physical examination as well as on the peripheral blood smear, such as macrocytosis, neutropenia, or leukemic blasts. Although it can be argued that bone marrow aspiration is an unnecessary adjunct for the patient with a history, physical examination, and blood smear compatible with a diagnosis of ITP, many clinicians perform this relatively innocuous procedure to provide assurance for the patient and family that cancer is not present and to allow the therapeutic use of corticosteroids. In addition, bone marrow biopsy in selected cases can help distinguish ITP from myelodysplasia, aplastic anemia, or other platelet-production problems.

Pathology

Figure 58.1 shows large bruises on the trunk and extremities in a young child with ITP, and Fig. 58.2 shows a peripheral blood smear of a patient with ITP. Few platelets are present, but those that are newly released into the circulation are larger than the normal 1- to 2-μ diameter.

Therapy and Prognosis

Patients with acute ITP by definition have a brief, self-limited illness that spontaneously resolves within several months. Although patients may have severe thrombocytopenia and substantial mucocutaneous bleeding that is cosmetically displeasing, clinically significant or life-threatening hemorrhage is quite rare. Intracranial hemorrhage is the most serious bleeding complication of ITP, but it occurs in fewer than 1% of patients. The likely explanation for this apparent paradox is that, compared with normal platelets, circulating platelets in ITP are younger, larger, and more efficient at repairing vessel injury. Therapy for acute ITP should therefore either be limited to observation alone or designed to prevent severe hemorrhagic events when the platelet count is extremely low ($<10 \times 10^9$/L). Therapy for chronic ITP, in contrast, should be designed not only to prevent severe hemorrhage but also to induce immunologic remission, if possible. Many treatment modalities are effective in the treatment of ITP, although each has potential risks and benefits (11). Table 58.2 summarizes the most frequently used therapeutic options for the management of ITP.

Treatment	Dose	Comments
Corticosteroids	2 mg/kg/d p.o.	Short-term use preferred Sometimes useful in chronic ITP
Intravenous immunoglobulin	0.5–1.0 g/kg/d i.v. x 2	Rapid rise in platelet count Expensive, inconvenient
Splenectomy	—	Curative in 70% of patients Risk of postsplenectomy sepsis
Anti-D	50 μg/kg/d i.v. x 1	Rh-positive nonsplenectomized patients Less expensive, more convenient than IVIG
Azathioprine	50–200 mg/d p.o.	Immunosuppression
Cyclophosphamide	50–150 mg/d p.o.	Carcinogenesis
Danazol	200–800 mg/d p.o.	Hepatic dysfunction Androgenic side effects
Vincristine	1 mg/m² wk i.v.	Neurotoxicity
Platelet transfusions	Pooled or pheresis	Emergent, life-threatening bleeds Short responses, alloimmunization

i.v., intravenous; IVIG, intravenous immunoglobulins; p.o., orally.

TABLE 58.2. Treatment Modalities for Immune Thrombocytopenic Purpura (ITP)

Corticosteroids frequently are prescribed for the treatment of patients with ITP, although great controversy surrounds their routine or prolonged use. Randomized prospective trials demonstrated that a short oral course (2–3 weeks) of prednisone or prednisolone at 2 mg per kilogram of body weight daily will increase the platelet count in children with ITP faster than no treatment (12,13), and “megadoses” of intravenous methylprednisolone (30 mg/kg/dose) also have been reported to be beneficial (14). Corticosteroids should not be prescribed for more than 4 to 6 weeks' duration, however, because of the many well-described complications of long-term steroid therapy. Low-dose alternate-day corticosteroid usage is typically unable to sustain a reasonable platelet count in patients with ITP. Initial excitement about high-dose pulse dexamethasone for ITP (15) has faded, however, with additional reports of only modest efficacy. Possible mechanisms of action of corticosteroids in ITP include interference with antibody–platelet interactions with decreased antibody binding and increased serum antibody levels (Fig. 58.3), decreased platelet phagocytosis by the RES (5,16), improved capillary integrity with less vascular endothelial leakage (17), and diminution of platelet autoantibody production by splenic and bone marrow lymphocytes (18).

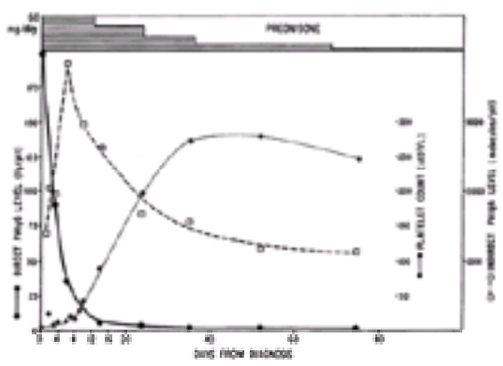

Figure 58.3. Serial platelet counts and platelet-associated immunoglobulin G (PAIgG) levels in a young male patient with acute immune thrombocytopenia purpura. He was treated with oral corticosteroids at high dose for 2 weeks and then slowly weaned. His platelet count exceeded 100×10^9 per liter after 3 weeks of therapy. Serial measurements of PAIgG levels demonstrated that the direct PAIgG rapidly normalized, whereas the indirect PAIgG was initially normal, temporarily increased in the first week, then returned to normal levels.

Since the initial report almost two decades ago by Imbach and co-workers (4), intravenous immunoglobulin (IVIG) has become a popular therapeutic option for ITP. IVIG will increase the platelet count in either acute or chronic ITP (19,20), typically within several days of treatment. Comparisons of IVIG with corticosteroids in acute ITP suggest similar response rates, although IVIG may increase the platelet count to >30 x 10^9/L slightly faster than corticosteroids or observation alone (21). In chronic ITP, IVIG can be given every 3-4 weeks as a maintenance therapy (20). The typical therapeutic dose of IVIG is 1 g per kilogram of body weight, given either as a single dose or on two consecutive days (22). Mechanisms of action for IVIG in ITP include RES blockade with saturation of macrophage Fc receptors and survival of antibody-coated platelets (23), interference with platelet clearance by decreasing Fc receptors and their affinity for IgG (24), interference of antibody binding to platelets (25), and suppression of autoantibody synthesis by antiidiotype antibodies (26). Despite its efficacy, IVIG has several drawbacks, including its expense, long infusion time, frequent side effects (headache, nausea, and fever), and risk of transmission of an infectious agent. Neurologic complications have been recognized as frequent side effects of IVIG therapy (27); renal failure also may occur, perhaps related to the sucrose load and osmolality of the product (28,29). As of September 1999, the United States Food and Drug Administration MEDWATCH program has received 114 adverse event reports of renal dysfunction or acute renal failure associated with IVIG administration, including 17 deaths.

More recently, anti-D therapy has become available for the treatment of ITP. Anti-D antibodies recognize the Rhesus (Rh) D erythrocyte antigen and are commonly used to prevent erythrocyte sensitization following pregnancy in an Rh-negative mother. In ITP, anti-D is used to coat the patient's own D-positive erythrocytes, thereby

inducing temporary RES blockade similar to IVIG. Unlike IVIG, however, anti-D does not appear to have other mechanisms of action on the immune system (30). The use of anti-D is limited to ITP patients who are Rh positive (85% of the population) and those who have not undergone prior splenectomy; antibody-coated erythrocytes evidently require functioning splenic tissue to induce RES blockade (31). Commercially available anti-D licensed for the treatment of ITP (WinRho SDF manufacturer: Cangene Corp., Winnipeg, Canada, distributor: Nabi, Boca Raton, Florida) is produced from a limited number of hyperimmunized human volunteers. Anti-D is administered intravenously at 50 µ per kilogram of body weight per dose over 2 to 5 minutes. Platelet response is maximal about 5 days postinfusion and lasts for 3 to 4 weeks (32). The primary side effect of anti-D infusion, which is both predictable and necessary, is mild erythrocyte hemolysis that manifests as hemoglobinuria for 12 to 36 hours and an eventual 1 to 2 g per deciliter drop in hemoglobin concentration. The MEDWATCH program, however, has collected 15 cases of intravascular hemolysis following anti-D infusion that caused clinically compromising anemia and renal insufficiency, including four deaths.

Surgical splenectomy in ITP has the theoretical benefit of eliminating both the main site of autoantibody production as well as the primary site of platelet clearance and destruction. Great care must be taken during splenectomy to ensure that all accessory spleens are removed; this is a particularly important consideration when a laparoscopic procedure is performed. Splenectomy has no role in the management of the child with acute ITP unless an intracranial hemorrhage has occurred; in this setting, emergency splenectomy should be performed with platelets transfused after the splenic pedicle is clamped. In chronic ITP, splenectomy should be considered when other therapeutic alternatives have become unsafe, inconvenient, or ineffective. Splenectomy is curative for only about 70% of children with ITP, however, and it leaves the recipient at a low but theoretical risk for postsplenectomy sepsis. For this reason, children are generally prescribed twice-daily penicillin following splenectomy. Although there is currently no accurate method of predicting response to splenectomy, identification of the spleen as the site of sequestration may predict the efficacy of splenectomy (33). The recent observation that persons who respond to IVIG are more likely to benefit from splenectomy (34) has now been called into question (35). The appropriate timing of splenectomy, especially for adults with ITP, should be determined on an individual basis with consideration of therapeutic responses to IVIG and anti-D therapies.

A variety of alternative therapeutic agents usually are reserved for patients with ITP refractory to conventional therapy, particularly those who have no benefit from splenectomy. Azathioprine (daily oral dose, 50–200 mg) can decrease autoantibody production and perhaps interfere with macrophage function. Because the beneficial effects of azathioprine may require 3 to 6 months of therapy, it is often given in combination with other agents. Cyclophosphamide is prescribed at 50 to 150 mg orally per day, with dose adjustments based on bone marrow suppression. Danazol, a semisynthetic androgen, can be effective when oral doses of 200 to 800 mg per day are used; limiting toxicities include hepatic dysfunction and masculinizing side effects. Vincristine (1 mg/m^2/week) can be used for rapid but short-lived responses, especially when waiting for other chemotherapy to take effect. Because vinca alkaloids bind to tubulin within the platelets, they can be incubated with allogeneic platelets prior to a transfusion. Such “vinca-loaded” platelets are effective presumably by delivering the cytotoxic drug directly to the RES. The use of multiagent chemotherapy should be reserved for severe refractory cases. Additional agents that have limited or anecdotal reports of efficacy include dapsone, cyclosporin A, and a-interferon. In certain settings, splenic irradiation may be beneficial (36).

Platelet transfusions in ITP should be limited to severe hemorrhage (e.g., intracranial hemorrhage) and other life-threatening clinical situations but can be effective in increasing the platelet count temporarily (37). Circulating antiplatelet antibodies will bind to transfused platelets and lead to their rapid clearance by the RES but may provide temporary protection against bleeding. A dose of IVIG (0.5–1.0 g/kg) prior to the platelet transfusion can blockade the RES and lead to improved survival of the transfused platelets (22). In addition, administration by continuous infusion may prolong the *in vivo* life span of the transfused platelets.

The prognosis for patients with ITP is generally good. For children with ITP, the vast majority will have a self-limited illness with no sequelae. Clinical relapses following resolution of acute ITP are extremely rare and suggest an underlying immunodeficiency or systemic autoimmune disorder. Direct PAIgG levels typically return to normal following acute ITP (38), and women with previous childhood ITP only rarely deliver infants with thrombocytopenia (39). Some patients with chronic ITP have gradual improvement in their platelet count to levels that do not require therapy. For these patients as well as those who achieve remission after successful splenectomy, the PAIgG level also normalizes (38). Long-term follow-up data are scant, but one series of adults with ITP reported a disease-free survival of 83% following splenectomy (40). Some patients believed to be in “remission” actually may have a well-compensated state of antiplatelet antibody production, accelerated platelet destruction, but increased platelet production.

IMMUNOPATHOLOGY

Humoral Response

The platelet surface contains numerous glycoproteins (gp) that can act as autoantigens, but the absence of circulating antiplatelet antibodies in many cases of ITP has hindered their identification and characterization. Some patients have plasma antibodies that react with the gp IIb/IIIa complex (41), and others have circulating antibodies against the gp Ib/IX complex (42), whereas a few have antibodies that react with both glycoproteins (43). Using platelet eluates to release platelet-bound IgG, however, van Leeuwen et al. found that 35 of 42 patients with ITP had antibodies reactive with normal platelets but not with platelets lacking IIb/IIIa (44), confirming that the IIb/IIIa complex is the most common autoantigen in ITP. Epitope mapping of anti-IIb/IIIa antibodies in chronic ITP has suggested reactivity primarily against the cytoplasmic (intracellular) domain (45) as well as a requirement for the cation-dependent intact conformation of IIb/IIIa (46). Newer methods of antiplatelet antibody detection may improve the identification of specific platelet autoantigens in ITP and help our understanding of how plasma antiplatelet antibodies bind to platelet antigens and effect immune clearance.

Antiplatelet antibody production in ITP occurs primarily within the spleen. Splenic leukocytes from ITP patients produce more than five times the IgG of normal persons, with sufficient platelet-directed antibody to coat all estimated antigen sites (47). The frequently curative effect of splenectomy provides additional evidence for splenic antibody production because the PAIgG level normalizes in pediatric patients who enter remission following splenectomy (38). Not all patients respond to splenectomy, however, and so alternative sites of antibody production must exist, such as the liver, bone marrow, and perhaps even peripheral lymphoid tissue. Accessory spleens, which are present in 10% to 20% of persons, can cause a relapse of ITP.

In addition to surface-bound IgG, increased amounts of complement proteins C3 and C4 also have been identified on platelets in ITP (48). IgG synthesized *in vitro* by splenic leukocytes from patients with ITP can fix complement (49); so presumably antiplatelet antibodies can bind to the platelet surface and fix complement through the classic pathway of complement activation. Platelet complement is sometimes identified without elevated PAIgG, however, and also in nonimmune thrombocytopenic states (50), making the origin of the platelet-bound complement still open to debate. Once bound, it is possible that complement contributes to platelet destruction because macrophages possess C3b receptors that can accelerate platelet clearance. In the analogous system of immune-mediated erythrocyte destruction, the presence of surface-bound complement markedly increases phagocytosis of IgG-coated erythrocytes. Platelet-bound complement also could lead to clearance by hepatic or marrow macrophages, perhaps accounting for the failure of splenectomy to be curative in all cases.

Similarly, the role of immune complexes in ITP has not been clearly delineated. Antigen–antibody complexes can attach to platelets nonspecifically and lead to immune-mediated clearance of platelets as “innocent bystanders” (51). Particularly in acute ITP, which often has a preceding virallike prodrome, a normal immune response to the pathogen could inadvertently damage the platelet either directly or through immune complex deposition. Alternatively, antibodies against the pathogen may cross-react with a platelet antigen (molecular mimicry) and lead to immune-mediated clearance.

Cellular Response

Although the primary immunologic defect in ITP likely involves autoreactive B-lymphocytes that secrete platelet antibodies, a lack of self-tolerance by T-lymphocytes and other cells that orchestrate the antibody response also may be important in the pathogenesis of this disorder. A variety of immunoregulatory defects involving cellular immunity have been described in ITP, including abnormal cell-mediated proliferative responses to mitogens and platelets, a diminished autologous mixed lymphocyte reaction, and decreased suppressor cell number and activity (52). Abnormal T-lymphocyte subpopulations in some patients with ITP also have been reported, including an inverted CD4/CD8 ratio, the presence of circulating $CD4^+/CD8^+$ T-lymphocytes, and elevated numbers of class II major histocompatibility complex (MHC)-positive activated T-lymphocytes (53). Increased numbers of oligoclonal T-lymphocytes have been identified in patients with ITP (54), suggesting a dysregulation of lymphocyte responses. Finally, the significant overrepresentation of human leukocyte antigen (HLA) DRB1*0410 in Japanese patients with ITP (55) supports the hypothesis that genetically determined immune responses are important in this disorder.

A possible mechanism by which T-lymphocytes could mediate platelet destruction is by enhancing autoantibody synthesis. Antiplatelet reactivity mediated by $CD4^+$ T-helper lymphocytes in adult patients with chronic ITP has been reported (56). Furthermore, the subpopulation of $CD4^+$ lymphocytes known as the *suppressor-inducer subset* was found to be quantitatively reduced in those ITP patients who demonstrated antiplatelet T-cell proliferative responses. Reduced numbers of suppressor-inducer T-lymphocytes were previously reported in other autoimmune diseases, including systemic lupus erythematosus, Sjögren syndrome, rheumatoid arthritis, and progressive multiple sclerosis. We established T-cell clones from patients with ITP that demonstrated proliferative reactivity against allogeneic platelets (57); six clones were $CD4^+$ helper inducer and two were $CD8^+$ lines.

Other cellular responses that may play an important role in the platelet destruction of ITP relate to cytokine production. Children with chronic ITP have been reported to have increased serum levels of interleukin-2 (58) as well as interferon-g and interleukin-10 (59). Cytokine-mediated g-interferon production can lead to class II MHC expression on platelets (59,60), thereby contributing to the autoimmune process. Elevated levels of macrophage colony-stimulating factor in ITP patients also have been reported (61), suggesting that soluble cytokines may influence macrophage-mediated platelet destruction. Taken together, these data suggest that cellular

responses may be important in the pathogenesis and pathophysiology of ITP.

Immune-mediated Platelet Destruction

Platelet clearance in ITP occurs following an interaction between the IgG- or complement-coated platelets and the RES. Macrophages within the RES recognize the coated platelets through either their Fc or C3b receptors and presumably destroy the platelets by direct phagocytosis. Although radiolabeled platelet studies in ITP have documented uptake by the spleen, thorax (representing bone marrow and pulmonary macrophages), liver, and indeterminate areas (possibly representing peripheral lymphoid tissue), the spleen is believed to be the most important site of platelet clearance. The large numbers of platelets that normally reside within and circulate through the spleen are in intimate contact with a high concentration of antiplatelet antibody and splenic macrophages. Coupled with the slow blood flow within splenic tissue, these factors make the spleen an extremely potent milieu for immune-mediated platelet clearance and destruction.

Immunopathogenesis of ITP: Summary

Patients with acute ITP have a transient disturbance of the immune system, possibly involving molecular mimicry, characterized by the synthesis of antibodies that bind to autologous platelets. These antibodies may be in the form of immune complexes, but they appear to recognize platelet glycoprotein epitopes. In chronic ITP, there is a fundamental abnormality in the humoral and cellular compartments that allows auto reactive T-lymphocytes to proliferate and B-lymphocytes to produce antiplatelet antibodies. In both acute and chronic ITP, the presence of IgG on the platelet surface (with or without complement) leads to rapid platelet clearance by macrophages within the spleen and other parts of the RES.

IMMUNE THROMBOCYTOPENIA IN OTHER CLINICAL SETTINGS

Although ITP is, by definition, a hematologic disorder that occurs in the absence of other systemic illnesses or identifiable etiologies, several clinical conditions are frequently associated with immune-mediated thrombocytopenia. These variants of ITP are listed in Table 58.3 and are discussed in the following sections.

Pregnancy
Maternal vs gestational ITP
Neonatal alloimmune thrombocytopenia
Autoimmune disorders
Systemic lupus erythematosus
Thyroiditis
Inflammatory bowel disease
Immunodeficiency
Congenital
Acquired
Drug exposure
Antibiotics
Anticonvulsants
Quinidine/quinine
Heparin
Alloimmunization
Platelet transfusions
Posttransfusion purpura
Miscellaneous
Sepsis
Malignancy
Preeclampsia

TABLE 58.3. Clinical Settings Frequently Associated with Immune-Mediated Thrombocytopenia (ITP)

Pregnancy

The diagnosis and management of immune-mediated thrombocytopenia during pregnancy can be challenging. In many cases, a mother has no previous history of ITP but develops thrombocytopenia in the second or third trimester of pregnancy. Termed *gestational thrombocytopenia* or *gestational ITP*, this condition is benign. Gestational ITP is only rarely associated with severe fetal thrombocytopenia (62) and should be managed conservatively.

The term *maternal ITP* usually is reserved for women with previously documented ITP who become pregnant. The mother is a potential source of antiplatelet antibodies, which can cross the placenta and induce immune-mediated thrombocytopenia in the developing fetus. A mother with previous acute ITP (perhaps as a child with complete resolution) has low risk of problems during pregnancy (39). As noted earlier, circulating antiplatelet antibodies do not persist in women with a history of acute ITP (38).

A woman with chronic ITP who becomes pregnant has a higher risk of fetal thrombocytopenia. Unfortunately, the maternal platelet count is not always predictive of the fetal platelet count. High circulating levels of maternal antiplatelet antibodies (not platelet-bound) may identify infants at risk for transplacental passage of antibody (63,64). Additional risk factors for fetal thrombocytopenia include previous splenectomy, severe maternal thrombocytopenia during pregnancy, and a previous child born with thrombocytopenia (65,66). Direct measurement of the fetal platelet count by scalp-vein sampling is not always possible before the onset of labor, and percutaneous umbilical blood sampling carries a risk of fetal bleeding and induction of labor. The clinical management of maternal ITP remains controversial, therefore, although most clinicians no longer recommend routine elective cesarean section to avoid fetal head trauma during vaginal delivery. If maternal thrombocytopenia is severe, antenatal corticosteroid therapy and even splenectomy have been used, as has IVIG, which crosses the placenta and presumably induces fetal RES blockade. Following delivery of an affected infant, therapy is typically unnecessary but can include corticosteroids or IVIG.

A related condition known as *neonatal alloimmune thrombocytopenia* occurs when maternal and paternal platelet antigens differ substantially at Br (gpIa), Bak (gpIIb), or PL^A (gpIIIa) epitopes. Presumably as a result of small fetomaternal hemorrhages, the mother becomes sensitized to “foreign” paternal antigens expressed on fetal platelets and develops antiplatelet alloantibodies that can cross the placenta and destroy fetal platelets. Severe thrombocytopenia can result in intracranial hemorrhage, and, unlike the analogous erythrocyte Rh antigen incompatability and sensitization, first-born infants can be affected (67). Effective therapy traditionally includes the postnatal transfusion of washed maternal platelets into the infant, but the efficacy of antenatal or postnatal IVIG in this setting also has been described.

Systemic Autoimmune Disorders

Mild thrombocytopenia (50–100 × 10^9/L) in patients with systemic autoimmune or inflammatory diseases such as thyroiditis, primary biliary cirrhosis, or inflammatory bowel disease is well recognized but usually is not associated with hemorrhagic symptoms. The precise prevalence of thrombocytopenia in these clinical settings is not known, but one study found 21 of 295 patients with systemic lupus erythematosus (SLE) to be affected (68).

The pathophysiology of thrombocytopenia in patients with systemic autoimmune disorders typically has been ascribed to generalized immune dysregulation because multiple polyclonal autoantibodies against platelets, leukocytes, and erythrocytes can be detected. Platelet autoantigens may differ in SLE or ITP compared with classic ITP (69), with a higher prevalence of antibodies reactive with the platelet protein vinculin (70). Therapy specific for the thrombocytopenia is not usually necessary, although IVIG can be beneficial in this setting. Treatment should be reserved for severe thrombocytopenia or active bleeding.

Immunodeficiency

Patients with congenital immunodeficiency are at risk for the development of immune-mediated thrombocytopenia, presumably resulting from improper regulation of their immune system. We recently described two children with unsuspected common variable immune deficiency who developed ITP characterized by an acute but relapsing course (71). Treatment of ITP in immunodeficient patients is complicated by the presumed need to avoid immunosuppressive therapy.

Acquired immunodeficiency also is associated with thrombocytopenia and can occur in the settings of antineoplastic chemotherapy, chronic lymphocytic leukemia, bone marrow transplantation, or infection with the human immunodeficiency virus (HIV). Immune mechanisms of platelet destruction in HIV and ITP may differ substantially from those described for classic ITP in that higher levels of PAIgG and complement components are present on the platelets of patients with HIV–ITP (72). Autoantibody specificity is not different in HIV–ITP, but the presence of many platelet-bound immune complexes may contribute to the pathogenesis of this disorder. Direct infection of megakaryocytes by HIV may also be important in the pathogenesis of thrombocytopenia (73). Treatment for HIV–ITP usually includes corticosteroids and IVIG but has not been entirely satisfactory; the thrombocytopenia of HIV–ITP may respond best to antiretroviral therapy such as zidovudine (74). Beneficial reports of ainterferon, anti-D, anti-CD16 monoclonal antibody, and splenectomy for HIV–ITP may lead to improved therapy for this condition.

Drug-Induced Thrombocytopenia

Numerous medications induce immune-mediated platelet destruction, characterized by severe thrombocytopenia and elevation of PAIgG levels (75). In most cases, the thrombocytopenia is dose independent and idiosyncratic and occurs several weeks after the first dose. Platelet destruction may result from the medication itself, a metabolite, or the drug delivery vehicle. Many drugs have been associated with immune-mediated thrombocytopenia, including a variety of antibiotics and anticonvulsants.

Quinidine and its analog quinine represent a prototype for drug-induced thrombocytopenia. Quinidine-dependent antibodies initially were thought to form an immune complex with the drug, which then fixed to platelets and led to RES clearance and destruction. Quinine- and quinidine-dependent platelet antibodies have been reported to react with several platelet glycoprotein antigens, however (76). Quinine actually causes widespread but specific conformational changes in platelet membrane surface antigens, thereby exposing neoantigens that can induce drug-specific antibodies (77).

Heparin is another important cause of drug-induced thrombocytopenia that results from frequent use of the drug and an observed incidence of about 5%. A mild dose-dependent form of heparin-induced thrombocytopenia (type 1 HIT) occurs within the first few days of therapy, is characterized by only mild thrombocytopenia, and resolves spontaneously (78). Type 2 HIT is an immunologically mediated form of thrombocytopenia that persists unless heparin is discontinued. In type II HIT, thrombocytopenia typically develops after 1 week of intravenous standard heparin therapy, although it can also occur following subcutaneous administration or even intravenous flushes. The pathophysiology of type 2 HIT initially involves the binding of heparin with platelet factor 4 (PF4), a secreted platelet a granule protein, to form large complexes. Heparin-dependent antibodies, usually IgG, then interact with the heparin–PF4 complexes to activate platelets and endothelial cells (78). Arterial or venous thrombosis develops in a small proportion of affected patients, presumably because of thrombin formation in the circulation. Therapy involves cessation of heparin as well as alternative antithrombotic agents.

Gold and methyl-dopa (Aldomet) appear to induce changes in platelet antigens that are cross-reactive with antidrug antibodies. Other drugs that induce immune-mediated thrombocytopenia have not been investigated in full detail. Therapy typically includes the discontinuation of the drug, if possible, or the use of immunomodulating agents such as corticosteroids or IVIG.

Alloimmunization

Immune-mediated clearance of platelets also can occur following exposure to allogeneic platelets, with development of alloantibodies against “foreign” platelet antigens. Alloantibodies are by definition directed against surface antigens not expressed on autologous platelets and therefore should lead to destruction only of allogeneic platelets. The most common clinical settings of platelet alloimmunization are pregnancy and multiple platelet transfusions. In the latter condition, the patient develops antiplatelet alloantibodies directed against HLA class I antigens, although ABO blood group antigens and many platelet-specific antigens also can be immunogenic. The use of leukocyte-depleted or ultraviolet B–irradiated platelets can greatly reduce the incidence of platelet alloimmunization (79).

Once a patient is alloimmunized, transfused platelets are quickly bound by alloantibodies and rapidly removed by the RES. Matching donor and recipient HLA types often improve platelet transfusion outcome by avoiding the alloantigens. Platelet cross-matching techniques (80) can aid the transfusion center in identifying compatible platelets for transfusion, and laboratory advances have made this procedure more cost-effective. The use of IVIG for alloimmunized patients remains controversial because conflicting results have been reported.

A related condition, known as *posttransfusion purpura* (PTP), is a rare but serious syndrome characterized by the development of platelet alloantibodies approximately 1 week after a platelet transfusion. Unlike typical alloimmunization, however, the patient's own platelets (which lack the alloantigen) are also destroyed by the antibodies. The classic clinical scenario involves a PL^{A1}(–) patient who is transfused with PL^{A1}(+) platelets, although other antigen systems have been described. Following development of anti-PL^{A1} alloantibodies and clearance of the transfused platelets, autologous platelets are also destroyed. In PTP, the thrombocytopenia is often severe and may be associated with clinical hemorrhagic symptoms.

The immunologic events that unfold in PTP have not been clearly delineated but may involve the deposition of circulating immune complexes (consisting of the alloantibody bound to soluble antigen) on autologous platelets. Alternatively, autologous platelets may bind soluble antigen and become transiently (+) for surface expression, and, therefore, susceptible to alloantibody binding and RES-mediated clearance. A third explanation is that alloimmunization somehow lifts suppression and allows the emergence of autoreactive clones. Therapy includes the avoidance of platelet transfusions and either plasmapheresis or exchange transfusion. The use of IVIG has also been used successfully in this disorder.

Miscellaneous

In addition to the previously described conditions, various other clinical settings occasionally are associated with immune-mediated thrombocytopenia. Septicemia, malignancy, solid-organ transplantation, cardiopulmonary disease, and preeclampsia can cause shortened platelet survival, in part as a result of immune mechanisms.

FUTURE DIRECTIONS

Over the past century, some important advances have been made in our understanding of immune-mediated thrombocytopenia. The identification and quantification of specific antiplatelet antibodies, recognition of the important role played by the RES in autoantibody synthesis and platelet destruction, and the emergence of several effective therapies have improved our ability to diagnose and manage patients with ITP. Challenges remain, however, in our understanding of the immunologic processes by which platelet autoantibodies develop, especially why certain persons manifest autoreactive antibodies that interact specifically with autologous platelets. A better understanding of the immune cell interactions that normally restrict autoantibody synthesis and expression are necessary to advance our knowledge in the coming years.

59 BLOOD GROUPS, IMMUNOLOGIC HAZARDS OF TRANSFUSION, AND HEMOLYTIC DISEASE OF THE NEWBORN

Marilyn J. Telen, M.D.

Although the first blood transfusions were recorded in the seventeenth century, the modern era of transfusions was born with the discovery of the ABO blood group by Karl Landsteiner in 1900 (47). The first pretransfusion ABO typing and cross-matching were performed in New York in 1907 (87), but problems with anticoagulation hampered development of transfusion therapy until World War I, when sodium citrate began to be used as an anticoagulant. By World War II, Loutit and Mollison (58) had pioneered the use of acid–citrate–dextrose, a solution that allowed a higher and clinically more useful blood-to-anticoagulant ratio.

The 1940s saw the beginning of a rapid increase in the knowledge of red cell antigens, beginning with the Rhesus (Rh) system and the relationship of the D antigen to hemolytic disease of the newborn (HDN) (53). Since then, hundreds of red cell antigens have been discovered (42). Other advances during the ensuing 50 years included improvements in sterile collection and storage as a result of the advent of plastics and the institution and expansion of infectious disease testing, which now renders blood transfusion an extremely safe procedure.

As the ability to provide safe blood products has grown, so too has the clinical need for them. Complex surgery and especially organ transplantation have created large demands for blood products, as has the increasing use of myelosuppressive chemotherapy for oncologic diseases. Thus, whereas whole blood is now rarely transfused, blood components, such as red cells, platelets, plasma, plasma components, and occasionally leukocytes, are frequently used to support complex medical and surgical therapies. Transfusion is also now used to enhance immune-mediated resistance to malignant disease, such as in the infusion of donor lymphocytes for their antileukemic effect after allogeneic hematopoietic stem cell transplantation for leukemia (32).

Although blood transfusion is only rarely associated with major morbidity and mortality, we have learned much about the less evident effects of transfusion. In addition to the ability of various blood products to stimulate alloimmune responses, we now know that blood transfusion can have other types of immunologic effects. Some of these effects are mediated by transfused immunocompetent cells, such as lymphocytes and monocytes, whereas others are mediated by soluble factors, such as cytokines.

IMMUNOCHEMISTRY AND GENETICS OF ERYTHROCYTE BLOOD GROUP ANTIGENS

The red cell membrane is a lipid bilayer, undergirded by a highly regular membrane cytoskeleton composed primarily of spectrin and actin (7). A complex of membrane proteins assortment is attached to and permeates the lipid bilayer (96). Integral membrane proteins traverse the bilayer one or more times and have both extracellular as well as cytoplasmic domains. Other surface proteins, such as those attached by glycophosphatidylinositol anchors, are peripheral membrane proteins whose peptide portions are entirely extramembranous and extracellular. The cytoplasmic peripheral proteins are attached to the membrane by fatty acylation or interaction with integral or cytoskeletal proteins.

Although several hundred blood group antigens have been identified on erythrocytes, many of these antigens are of only rare clinical importance because of factors such as low levels of expression, low rates of polymorphism, and low immunogenicity. A few dozen, however, are clinically important because antibodies to them frequently are encountered and account for substantial reduction in antigen-positive cell survival. The antigen systems most frequently identified in transfusion medicine, along with phenotypic frequencies, are listed in Table 59.1.

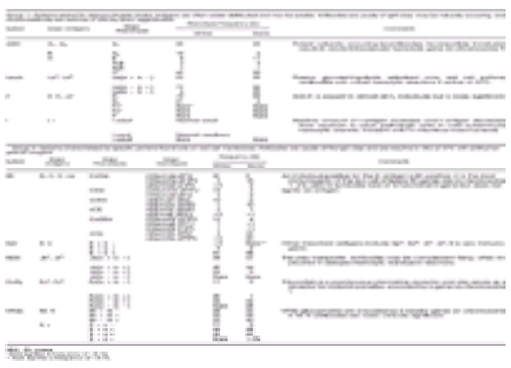

TABLE 59.1. Major Blood Group Systems

ABO, Lewis, and P Systems

The ABO system is clearly the most important alloantigen system for transfusion medicine, although one should remember that A and B antigens are really histocompatibility antigens with wide tissue distribution. The ABO blood group system is unique because of the fact that healthy individuals who lack either the A or the B antigen invariably have antibodies to these antigens from early infancy onward. These antibodies, which are primarily immunoglobulin M (IgM) but may comprise a substantial amount of IgG in group O persons, probably develop in response to A- and B-like immunogens that are present ubiquitously in nature. Most fatal hemolytic transfusion reactions result from ABO incompatibility.

The ABO blood group system represents the interaction of two unrelated gene loci. The H (*FUT1*) gene on chromosome 19q13.3 encodes a fucosyltransferase that adds fucose in an a1–2 linkage to a terminal galactose residue (48). The resulting H antigen is expressed by group O cells and is further modified in group A and B individuals. When no active H enzyme is present, the genotype is *hh*, and the cells express no H antigen, exhibiting the O_h, or Bombay, phenotype. In this situation, no A and B antigens can be formed, even when there are functional genes at the ABO locus.

The genetic locus responsible for formation of the A and B antigens is located on chromosome 9q34.1–q34.2, in linkage with the *NP* (nail-patella hereditary onychoosteodysplasia) and *AK* (adenylate kinase) loci (84). The *A* and *B* genes act as codominant alleles. The group O phenotype results from the presence of two recessive, inactive (*amorph*) alleles at the *ABO* locus. In the North American white population, distribution of the various ABO phenotypes in the population is approximately as follows: group A, 42%; group B, 9%; group O, 45%; and group AB, 3%. The group B antigen is considerably more common in Asian and African

populations, in whom it is found with frequencies of 27% and 20%, respectively.

The A and B antigens are present when an *N*-acetylgalactosamine or galactose, respectively, is attached to a substrate consisting of type 2 paragloboside to which a fucose has been attached by the product of the *H* gene (74) (Fig. 59.1). Thus, the *A* and *B* genes encode glycosyltransferases that modify the H structure. The complementary DNAs (cDNAs) encoding the A and B transferases differ from each other because of four nucleotide substitutions that account for the differing specificity of A and B transferases (113,114). Occasionally, members of a family are observed to have the *cis-AB* phenotype. In such families, the *A* and *B* genes appear to be transmitted to progeny as linked genes; however, the genetic basis for this phenomenon is usually the unusual existence of a single gene encoding a variant transferase with both A and B transferase activity (115).

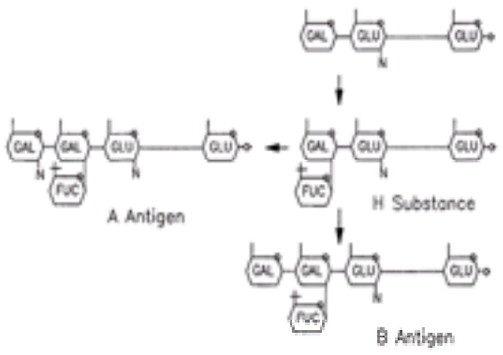

Figure 59.1. The formation of A and B antigens from H substance. (*Arrows* indicate action of the H, A, and B enzymes.) GAL, galactose; GLU, glucose; FUC, fucose; N-GLU, *N*-acetylglucosamine. (From WF Rosse. Clinical immunohematology: basic concepts and clinical applications. Boston: Blackwell, 1990, p. 197, with permission.)

The Lewis blood group system is another example of interaction between two separate genes. The Lewis antigens reside on soluble substances (glycosphingolipids) that are not an intrinsic part of the red cell membrane but are adsorbed onto cells from the plasma (89). The *Le* gene (*FUT3*) encodes a transferase that adds a fucose to the penultimate sugar (*N*-acetyl-galactosamine) of soluble ABH precursor chains (type 1 paragloboside), forming Le^a substance. When the terminal sugar of type 1 paragloboside is also fucosylated by the transferase that is the product of the *Se* (*FUT2*)gene], the antigen formed is Le^b. Thus, in the genotype *lele*, in which the *Le* gene does not encode a functional transferase, neither Le^a nor Le^b is expressed. If neither *Se* gene is functional (genotype *sese*), then the phenotype will be Le(a + b–) in the presence of a functional *Le* gene or Le(a–b–) in the presence of the *lele* genotype.

The P antigens likewise represent the stepwise action of several glycosyltransferases (89). The three P system antigens, P^k, P, and P_1, are produced by the action of three glycosyltransferases. Seventy-five percent of individuals have P, P_1, and P^k antigens on their red cells, whereas about 25% express P and P^k but not P_1. Rarely, red cells may be positive for P^k and negative for P and P1 or negative for all three antigens. This latter condition, designated the *Tj(a–) phenotype*, often leads to the production of a broadly reactive alloantibody and carries with it an increased risk of spontaneous abortion (54).

The P system is important in two clinical situations. The P antigen, or globoside, serves as the receptor for B19 human parvovirus, the agent responsible for most aplastic crises in patients with hemolytic anemias and human immunodeficiency virus (HIV) infection as well as for erythema infectiosum (fifth disease) (116). The P antigen is also typically the target of the autoantibody produced in paroxysmal cold hemoglobinuria (55).

Rhesus Blood Group System

Outside the ABO system, the Rh blood group system is clinically the most important in transfusion medicine. The Rh system is quite complex and encompasses at least 45 antigens. The five major antigens are encoded by two genes residing close to one another on chromosome 1 (12,13 and 14): One gene encodes the D antigen, and the other encodes the protein that bears the antithetical antigens C or c and E or e. The proteins that bear these antigens are quite unusual; they are all about 30-kd, nonglycosylated integral membrane proteins with multiple membrane spanning domains and relatively small peptide domains exposed at the cell surface (24,30). Nevertheless, the D antigen is highly immunogenic; about 80% of Rh-negative recipients of 1 U of D-positive red cells will form anti-D. The C/c and E/e antigens are also quite immunogenic. Together, antibodies to these five antigens account for most cases of HDN, even since inception of the use of Rh immune globulin to prevent maternal alloimmunization to D.

The Rh proteins appear to exist in the membrane as a macromolecular complex of about 170,000 Da (34) that includes the nonglycosylated Rh polypeptides as well as the Rh-associated glycoprotein (RhAG) encoded by a gene on chromosome 6 (83). Other membrane glycoproteins, such as glycophorin B (GPB), LW, CD47, the Duffy (Fy) protein, and band 3, also may associate with the Rh complex in the red cell membrane. The evidence for interaction among these proteins is provided by immunochemical studies using a variety of murine monoclonal as well as human antibodies (59,109) as well as by studies of protein expression (6) and studies of the molecular basis of the Rhnull phenotype (40). Expression of the Rh genes on chromosome 1 is limited to erythroid and early megakaryocytic lineage, whereas RhAG is expressed by leukocytes as well as erythrocytes. The function of the membrane Rh complex is uncertain. The configuration of the Rh polypeptide is similar to that of membrane transport proteins, and the Rh peptides have about 20% homology to methylamine permease and ammonium transporters of yeast, bacteria, and some plants. Nevertheless, the function of the Rh proteins in red cells remains undefined.

Rh_{null} red cells are totally deficient in Rh polypeptides and RhAG and express no Rh antigens. They have a number of physiologic abnormalities, including their stomatocytic shape, increased osmotic fragility, increased activity of Na, K-adenosine triphosphatase (ATPase), reduced intracellular cation and water content, and relative deficiency of membrane cholesterol (2). Their decreased membrane surface area, combined with intracellular dehydration, predisposes them to osmotic lysis. Most Rh_{null} phenotypes (*regulator type*) are due to lack of expression of RhAG caused by a variety of genetic alterations, whereas a few (*amorph type*) are due to mutations in the *RhCE* gene in the absence of a functional *D* gene (i.e., in an Rh-negative background).

The RhD and RhCE proteins are highly homologous, as are the structures of the genes encoding them. These two genes have been found to give rise to an extremely rare degree of diversity of haplotypes and variant antigens in the Rh blood group system.Although some phenotypes arise through point mutations, small deletions, or sets of mutations that occur in concert, many Rh genes have been described to contain transposed segments (i.e., *D* genes that contain one or more exons and introns from the *RhCE* gene and vice versa (Fig. 59.2).

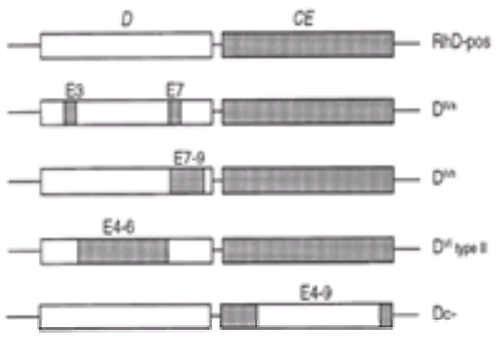

Figure 59.2. The *RHD* and *RHCE* genes have given rise to numerous variants. As shown here, some *RhD* genes contain coding sequences derived from the *RhCE* genes (shown in gray), as in the D^{IVa}, D^{IVb}, and D^{VI} type II phenotypes. The *RhCE* genes also may contain sequences derived from the *RhD* gene (shown in white), as in the Dc– phenotype. E, exon.

Sialoglycoprotein (Glycophorin) Antigens

The MNSs antigens are determined by variations in the amino acid sequences of two highly related glycoproteins, glycophorin A (GPA, MN glycophorin) and GPB (NSs glycophorin). These two proteins account for 95% of the periodic-acid Schiff (PAS)-staining proteins seen in gel electrophoresis of erythrocyte membrane proteins and are highly glycosylated proteins encoded by neighboring genes on chromosome 4 (15,79). The M and N antigens of GPA (M-GPA and N-GPA, respectively) depend on paired polymorphisms at amino acid residues 1 and 5 (Fig. 59.3): serine and glycine in M-GPA, and leucine and glutamine in N-GPA (16,106). The N-terminal 26 amino acids of GPB are homologous to N-GPA; thus, GPB also carries the N antigen. The S and scantigens of GPB are determined by a methionine/threonine polymorphism at residue 29 (17). Although the M and N antigens depend on amino acid polymorphisms, human antibodies to these antigens often require the presence of normal glycosylation of the serine and threonine residues at positions 2, 3, and 4 (Fig. 59.3) (86).

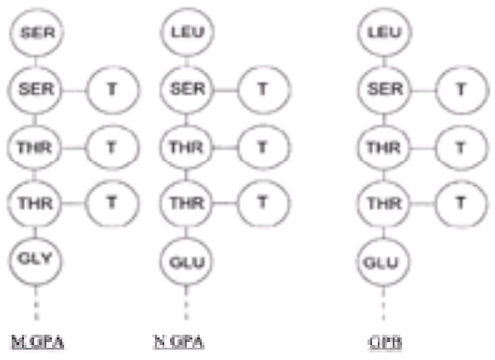

Figure 59.3. Terminal sequences of MN and Ss glycophorins (glycophorins A [GPA] and B [GPB], respectively). The S and s antigens are determined by a methionine/threonine polymorphism at amino acid position 29 on GPB. SER, serine; THR, threonine; GLY, glycine; LEU, leucine; GLU, glutamine; T, tetrasaccharide.

Lack of GPA expression is denoted En(a–) and is associated with clinically important anti-En^a (anti-GPA) alloantibodies. Autoantibodies seen in autoimmune hemolytic anemia also may have En^a specificity. Lack of GPB is denoted the S-s-U- phenotype; the U antigen is lacking, although the biochemical basis for this antigen is uncertain and may involve interaction with another membrane protein. When both GPA and GPB are absent (the MkMk phenotype), cells are M-N-S-s-U-. Lack of GPA, GPB, or both entails no physiologically important cellular changes.

The genes that encode GPA and GPB are highly homologous, a fact that apparently has been responsible for frequent uneven crossing-over and gene conversion events and consequently a large number of variant phenotypes. Some variants are due to creation of hybrid molecules by unequal crossing over, such as is seen in hemoglobin, whereas others are due to complex mutations or gene conversion events.

A third set of “glycophorin” antigens constitute the Gerbich blood group system, which resides on molecules called glycophorins C (GPC) and D (GPD) (10). These two proteins are unrelated to GPA and GPB and derive from a single gene on chromosome 2 through alternative translation start sites. Unlike GPA and GPB, however, the absence of Gerbich antigens and the total deficiency of GPC/D are associated with a rare form of hereditary elliptocytosis (3,82).

Other Major Protein Antigens

The Kell, Kidd, and Duffy blood group antigens are frequently polymorphic and immunologically important barriers to blood transfusion. All antigens in these systems thus far have been identified only on red cells, and all antigens reside on membrane proteins.

The Kell antigens reside on a 93,000-molecular-weight glycoprotein (81) whose cDNA exhibits considerable homology with a number of other neutral zinc-binding endopeptidases, including the common acute lymphoblastic leukemia antigen (CALLA) (50). The Kell gene resides on chromosome 7 (117). The most important antigens in this system are K1 (K) and K2 (k). The K1 antigen occurs in about 9% of the white population and 2% of the black population; the K2 antigen occurs in more than 99% of both blacks and whites. The K1 antigen is extremely antigenic, causing antibody production in about 5% of K1-negative recipients of K1-positive blood. After D, K1 and E are the two most commonly identified blood group alloantibodies. Although it has now been shown that the Kell protein retains endopeptidase activity, the physiologic importance of this activity is unclear (51).

Two rare phenotypes occur in the Kell system. The K_0 phenotype is associated with lack of all Kell system antigens and increased expression of an antigen encoded by the X chromosome, Kx. The McLeod phenotype, on the other hand, is associated with absence of Kx antigen and weak expression of inherited Kell system antigens. The Kx antigen resides on a 34,000-molecular-weight protein whose expression appears necessary for normal expression of the Kell protein and its antigens on red cells. Lack of Kx is accompanied by acanthocytosis and mild hemolytic anemia (101). The disorder, known as *neuroacanthocytosis,* also is associated with deficiency or abnormality of Kx (112). Because the protein is encoded by the X chromosome, the female carrier state for the McLeod phenotype can be identified by analyzing peripheral blood for a subpopulation of acanthocytic, Kx-negative red cells. The McLeod phenotype is also sometimes linked to the X-linked form of chronic granulomatous disease and Duchenne muscular dystrophy, both of which may result from a partial deletion of the X chromosome.

The Duffy system comprises two antithetical antigens, Fy^a and Fy^b; a “null” Fy(a–b–) phenotype is relatively common in blacks. Interestingly, red cells with the Fy(a–b–) phenotype are resistant to invasion by *Plasmodium vivax* and *Plasmodium knowlesi* malarial parasites (60,61); however, they are not resistant to invasion by the common African parasite *Plasmodium falciparum*. Investigation of the molecular basis of the Duffy blood group led to the discovery that the Duffy protein is a promiscuous chemokine receptor capable of binding both C-C and C-X-C chemokines (11, 38). Its absence from the red cells of many people of African origin is due to a mutation in the GATA site that regulates expression in erythroid cells rather than to a mutation in the coding region (107); individuals with this mutation express the Duffy protein in nonerythroid tissues, where other transcription regulatory regions are more important (43). The Kidd system also comprises two antithetical antigens, Jk^a and Jk^b, and has a null Jk(a–b–) phenotype. The latter phenotype is associated with abnormal urea transport (28,36). Although Jk(a–b–) cells appear to survive normally *in vivo*, this defect is demonstrable *in vitro*. The 50-kd protein identified as the carrier of Kidd antigens (97) has now been shown to be a urea transporter (72). Antibodies to antigens of the Kell, Duffy, and Kidd systems are most often IgG antibodies that react optimally at 37°C and may fix complement. Kidd antibodies especially have been associated with unusually severe delayed hemolytic transfusion reactions. Antibodies to Jk^a and Jk^b often decline rapidly in titer following primary immune stimulation so that they are not detected prior to subsequent transfusions. Also, these antibodies almost uniformly activate complement well. Therefore, they may be responsible for severe anamnestic hemolytic transfusion reactions.

Blood Group Antigens on Other Functionally Interesting Proteins

The antigens Chido (Ch) and Rogers (Rg) reside on variants of the C4 component of complement encoded by chromosome 6 (73). These antigens are adsorbed from plasma and are weakly expressed by red cells. Antibodies to Ch and Rg most often react weakly in agglutination reactions, are able to be inhibited by plasma from the phenotypically appropriate donor, and rarely if ever cause decreased red cell survival.

The Knops (Kn), McCoy (McC), and York (Yk) antigens reside on the complement receptor type 1 (CR1, CD35) (65,80), whose gene lies within the regulation of complement activation (RCA) cluster on chromosome 1 (85). This receptor occurs in four isoforms distinguishable by molecular mass (190, 220, 250, or 280 kd under reducing conditions) (66). As yet, however, no clear linkage between any of these isoforms and specific Kn/McC/Yk antigens has been made. Antibodies to these antigens are relatively common but have little if any role in causing hemolytic transfusion reactions or HDN.

The Cromer antigens reside on another complement regulatory protein, decay accelerating factor (DAF, CD55) (103). This 70-kd protein is also encoded from within the RCA cluster on chromosome 1 and bears homology to several other complement regulatory proteins. Antibodies to Cromer antigens are usually IgG in nature and are of variable but sometimes significant clinical importance.

The Colton antigens reside on the water channel protein aquaporin-1 (98). This red cell water channel was the first protein of this family to be discovered. Interestingly, persons lacking this protein from their red cells and who are thus Co(a–b–) do not have a significant clinical disorder. Another red cell membrane transport protein that carries blood group antigens is band 3, also called AE-1 (anion exchanger-1); it carries both ABH and the Diego antigens (9). Although antibodies to the Colton and

Diego antigens can be clinically significant, they are rarely encountered.

Red cells also express a number of adhesion molecules on their surfaces. Although these red cell proteins are believed to be inactive under normal circumstances, they do bear blood group antigens. For example, the LW blood group antigens reside on the LW protein, a member of the Ig superfamily with homology to intercellular adhesion molecule-2 (ICAM-2); it is capable of binding leukocyte integrins (5). Lutheran antigens reside on another IgSF member, which can serve as a laminin receptor (108), and Indian antigens reside on CD44, which is a hyaluronan receptor (104).

PLATELET-SPECIFIC BLOOD GROUP ANTIGENS

Increasing use of myelosuppressive chemotherapy to treat many different types of malignancies, as well as growing use of stem cell transplantation, has markedly increased the number of platelet products that are transfused. Thus, changing medical practice, along with the technology of molecular genetics, led to the identification of protein polymorphisms that underlie platelet-specific blood groups. Although they are found almost exclusively on platelets among circulating blood cells, platelet-specific antigens are actually found in other tissues as well.

Five major human platelet blood groups have been identified (110) (Table 59.2). In all but one system (HPA-3), the high-frequency antigen is present in 85% or more of the white population. The most commonly encountered antibody to a platelet-specific antigen is directed against the PlA1 (HPA-la) antigen. Antibodies to this antigen are the most common cause of both neonatal alloimmune thrombocytopenia as well as posttransfusion thrombocytopenic purpura.

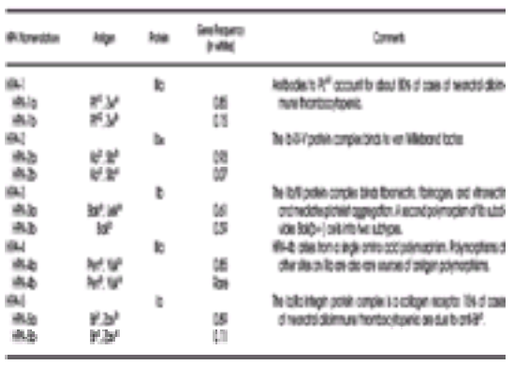

TABLE 59.2. Human Platelet Blood Group Antigens (HPA)

In the setting of platelet transfusion, immune clearance of transfused platelets is most commonly accounted for by antibodies directed against human leukocyte antigen (HLA) class I molecules rather than against platelet-specific antigens. HLA alloimmunization is largely preventable by reducing the leukocyte content of both red cell and platelet transfusions to fewer than 10^6 leukocytes per unit; this can be routinely accomplished using leukoreduction filtration. Platelets also bear antigens in common with red cells, including those of the ABO, P, Ii, and Lewis systems. The clinical importance of ABO incompatibility is variable; studies have shown that ABO incompatibility may, but will not always, negatively influence survival of transfused platelets (35,49).

NEUTROPHIL-SPECIFIC BLOOD GROUP ANTIGENS

Neutrophil-related blood group antigens are less well characterized than red cell and platelet antigens. One system, NA1/NA2, is well understood and of known clinical importance. These antigens represent two alleles of the FcRIII low-affinity IgG receptor (CD16 molecule) (41). Analysis of cDNA from NA1 and NA2 homozygotes predicts four amino acid substitutions differentiating NA1 from NA2. In addition, these substitutions modify glycosylation sites so that NA1 FcRIII has four potential N-linked glycosylation sites, and NA2 FcRIII has six. The FcRIII molecule is the most common target in neonatal alloimmune neutropenia. Maternal alloantibodies most often are directed against the NA1 polymorphic determinant; however, complete maternal deficiency of FcRIII with associated anti-FcRIII antibody also has been described as a cause of neonatal neutropenia (100).

IMMUNOLOGIC HAZARDS OF BLOOD TRANSFUSION

The transfusion of whole blood, blood components, or blood-derived products has a plethora of immunologic and other effects on their recipients. Described immunologic effects include stimulation of alloantibodies to both cellular and plasma protein antigens, passive transfer of antibody against similar antigens, passive transfer of cytokines and other effector molecules, passive transfer of immune effector cells (lymphocytes), and transmission of infectious agents that affect the immune system (e.g., HIV). Antigen-antibody interactions lead additionally to a variety of immune-mediated events, including hemolysis, pulmonary compromise, allergic reactions, and anaphylaxis. Transfusion also has been reported to cause immunosuppression, although the mechanism and clinical significance of this remain controversial.

Factors Associated with Immune Red Cell Destruction

Transfused red cells may be cleared from the recipient's circulation in an accelerated manner as a result of humoral factors, that is, isoantibodies or alloantibodies, or because of a combination of humoral and cellular immune mechanisms. The rate of clearance of cells bearing an alloantigen to which the recipient has been sensitized varies greatly, however. Some antibodies effect hemolysis or clearance by the reticuloendothelial system (RES) within minutes, whereas others cause only relatively slow immune clearance over days to weeks. Although the factors that influence this process are complex, the rate of clearance of transfused erythrocytes often can be predicted by knowledge of the target antigen involved. Antibody responses to other cell types, such as platelets, are less well studied and understood.

The factors that determine the rate at which transfused red cells are cleared from the circulation during an alloimmune response include the following:

Plasma concentration of antibody
Thermal range of antibody
Immunoglobulin class and subclass
Red cell antigen density
Red cell antigen biochemical characteristics (e.g., mobility in the membrane)
Extent of complement activation
Interactivity of RES macrophages
Amount of incompatible red cells transfused
Presence of plasma complement components

Antibody-Dependent Factors

Several factors integral to the antibody molecules involved dictate much about the course of destruction of antigen-positive red cells. *Thermal amplitude* refers to the temperature range within which an antibody will react with target cells. For most alloantibodies to blood group alloantigen systems, *in vitro* and presumably *in vivo* reactivity is optimal at 37°C. Some alloantibodies and many autoantibodies are “cold reacting” and bind much better at lower temperatures. In general, alloantibodies that react only at temperatures below 30°C are not clinically significant because they are usually IgM molecules that dissociate from red cells at body temperature (62). Cold-reacting autoantibodies occasionally have wide thermal ranges, however, reacting optimally at 0 to 4°C but maintaining activity at temperatures seen in the extremities (> 30 and < 37°C). These antibodies often fix complement readily and can cause *in vivo* hemolysis of both autologous and transfused red cells.

The number of available immunoglobulin molecules is also a key factor dictating the rate of clearance of transfused cells (75). Although the likelihood of an antibody causing significant hemolysis may be predicted by the strength of reactions observed *in vitro* and by the titer of the antibody, titer may change dramatically over days, and other factors also influence the rate of cell clearance. For example, red cells coated *in vitro* with varying amounts of anti-D will be cleared *in vivo* in direct proportion to the amount of antibody bound to the cells; but antibodies to the Kn^a, McC^a, Hy, and Yt^a antigens are typically present in relatively high titers and yet only rarely cause hemolytic transfusion reactions.

The immunoglobulin class and subclass to which most immunoglobulin molecules of a particular specificity belong also influence the mechanism and rapidity of cell destruction. IgM antibodies are often the first formed in a primary immune response, although IgG antibodies are typically the first detected antibodies to many antigens, including D and K1. Some alloantigens, such as M and N, Le, and P1, rarely stimulate significant IgG responses. Some autoantibodies, including those to H, I, and P, are also typically IgM, are low in titer, have low thermal amplitudes, and are usually of no clinical consequence.

The IgG alloantibodies are typically warm-reactive (optimal at 37°C) and are most commonly directed against antigens of the Rh, Kell, Duffy, and Kidd blood group systems. These antibodies occur almost exclusively after immune stimulation by transfusion or pregnancy and constitute the most common causes of delayed transfusion reactions resulting from anamnestic responses when they are not detected in pretransfusion testing. IgG antibody responses often include a mixture of IgG subclasses, and it is well recognized that different subclasses can mediate cell clearance to different degrees and by different mechanisms. RES macrophages have three types of immunoglobulin Fc receptors. All three types of receptors will bind immunoglobulin-coated red cells *in vitro* (45), but binding of FcRI appears to be necessary for lysis of sensitized red cells *in vivo* (45,56). FcRI appears to bind primarily IgG1 and IgG3. Moreover, when cells coated with anti-D are injected, *in vivo* clearance increases with the proportion of IgG3 in the antisera used (105). IgG2 and IgG4 antibodies are not thought to mediate cell destruction. Rare alloimmune antibodies to red cell antigens consist primarily of IgA.

Complement Activation

Complement activation plays a major role in the clearance of immunoglobulin-sensitized red cells. The complement system is discussed extensively elsewhere in this book, and its role in blood cell clearance has been well defined (90). Coating of red cells by antibody may permit binding of C1q and initiation of the complement cascade and ultimately will produce enough terminal complement complexes (C5b–9) to cause direct cell destruction. This mechanism typically accounts for the fulminant hemolysis seen in major ABO hemolytic transfusion reactions (90). IgG alloantibodies, however, rarely cause large-scale hemolysis by complement-mediated lysis. Unlike IgM, IgG must present a doublet configuration on the red cell membrane to fix C1q. Furthermore, whereas IgG1 and IgG3 can act strongly to activate complement, IgG2 does so only weakly, and IgG4 cannot activate complement. Antibodies to Kidd antigens typically activate complement well, whereas those directed against Rh antigens do so rarely if ever. Differences in the likelihood of complement activation by an immune response to a particular antigen depend also on the nature of the antigen, position of the epitope, and density and mobility of the antigen within the membrane.

Fixation of complement also plays a role in RES clearance of antibody-coated cells. In most instances, early complement components are bound to red cells coated with alloantibody, but the factors that downregulate complement activation succeed in forestalling formation of enough C5-9 complexes to lyse the cells directly. Such downregulation may occur at the amplification stage, in which C3/C5 convertases can be inactivated by spontaneous dissociation as well as through the action of specific complement regulatory proteins. Such regulatory proteins include the plasma proteins factor H (111) and C4-binding protein (29) as well as the membrane proteins CR1 (CD35) (88) and DAF (CD55) (71). Downregulation of complement activation also occurs at the stage of formation of the membrane attack complex (C5–9). The plasma protein vitronectin (also known as S protein) inactivates C5b–7 complexes formed in fluid phase (77), whereas the membrane protein membrane inhibitor of reactive lysis (MIRL, protectin, CD59) interferes with the generation and effectiveness of membrane-bound C5–9 complexes (37).

The complement components C3b and C4b, however, are capable of mediating immune adherence to many cell types, including polymorphonuclear leukocytes, monocytes, macrophages, and some lymphocytes, through the CR1 receptor. Other complement receptors, including CR2 and CR3, also are expressed on many hematopoietic cells. Immune adherence mediated by complement components stimulates phagocytosis poorly, however, whereas the simultaneous interaction of cell-bound IgG with macrophage Fc receptors is a more powerful stimulus to phagocytosis. Complement component-mediated immune adherence, however, can stimulate antibody-dependent cellular cytotoxicity (ADCC) (46, 76). The importance of ADCC *in vivo* during hemolytic transfusion reactions is not known.

In rare instances, deficiency of complement components or of complement regulatory factors has remarkable effects on complement-mediated immune destruction. For example, occasional ABO-mismatched transfusions elicit only slow hemolytic reactions when complement deficiency is present as a result of congenital or acquired conditions. In the acquired disease paroxysmal nocturnal hemoglobinuria, deficiency of the membrane complement regulatory proteins DAF and MIRL make cells more susceptible to complement-mediated lysis.

Antigen-Dependent Factors

Antigens differ from one another in many respects, including biochemical makeup, density, and mobility in the membrane. In addition, antibodies to different epitopes on the same molecule may cause significant differences in severity of transfusion reactions. For example, alloanti-M and anti-En^a both bind to the GPA protein, which is expressed at approximately 1×10^6 copies per cell. Anti-M is rarely clinically significant, however, whereas anti-En^a is usually so. Numerous factors may play a role in this dichotomy. Anti-M may be IgG or IgM, is usually relatively cold reacting, and binds to an epitope near the N-terminus of the protein; anti-En^a is usually warm-reacting IgG that binds considerably closer to the membrane. It is difficult to determine why these antibodies tend to differ in thermal amplitude and clinical significance, but antigen characteristics almost certainly play a role.

On a theoretic level, it seems reasonable to suppose that limitations in antigen mobility would hamper the ability of IgG antibodies to cluster and activate complement. Limitations in protein mobility most likely arise from the interaction of integral membrane proteins with the membrane skeleton or from interaction with each other.

Serologic Detection of Blood Group Antibodies

The technology used for the detection of red cell-directed alloantibodies traditionally relied on detection of antibody-mediated agglutination in the presence or absence of antiglobulin serum. Although these techniques are relatively simple, they have been adequate for the detection of hundreds of separable antigens and for the accumulation of an impressive amount of knowledge regarding the genetics of blood group antigen systems. More recently, new and, in some cases, mechanized techniques have been developed; these methods have not, however, proven clearly superior in the detection of clinically significant alloantibodies.

Agglutination Reactions

Normal red cells repulse each other because of the negative charge, called the z potential, that is derived from the millions of ionized sialic acid carboxyl groups on the erythrocyte surface. When antibody molecules bind to cell surface antigens, however, they can form “bridges” from one cell to another, thus forming agglutinates. Current agglutination testing methods are designed to maximize this process by a variety of means.

Detection of the isoagglutinins anti-A and anti-B and typing of cells by reagent anti-A and anti-B are usually performed at room temperature. Because the antibodies involved are primarily IgM, and the antigens are present in relatively high copy number, direct agglutination is usually obtainable after short incubation times. Some red cell alloantibodies can be detected with similar methods, but for most IgG alloantibodies, the Coombs, or antiglobulin, test is used.

When pretransfusion screening is performed to detect alloantibodies, serum from the prospective recipient is mixed with a small panel of group O reagent red cells whose antigenic phenotype in at least the Rh, MNSs, P, Kell, Kidd, and Duffy systems has been determined. In this manner, the serum is ensured to have been tested for antibodies to the major antithetical antigens within these systems. Incubation is done at 37°C, which is optimal for most of these alloantibodies, except P and MN. In addition, incubation may be performed in the presence of solutions designed to enhance antibody binding or agglutination.

In most instances, agglutination is not visible after incubation of cells with IgG alloantibodies. Thus, cells that have been incubated with serum are then washed with a saline solution to remove excess unbound immunoglobulins and incubated with an antiserum containing antibodies to the Fc portion of human immunoglobulins as well as to human complement, usually the C3 component. This procedure was pioneered by Moreschi in animal studies in 1908 (64) and later was applied to human red cell serology by Coombs (67). Although originally involving heterologous antisera, usually produced in rabbits, modern Coombs reagents are often blends of murine monoclonal antibodies to IgG heavy chains and human C3. Thus, these reagents may fail to detect binding of IgA alloantibodies as well as IgG4 immunoglobulins.

In Vivo Red Cell Survival Studies

Rarely, an antibody that produces *in vivo* cell destruction is not detectable by agglutination testing, and thus *in vitro* testing is not sufficient to determine which erythrocytes may be safely transfused. A second indication for *in vivo* testing arises when an antibody of uncertain clinical significance is identified. In such a case, *in vivo* testing can determine whether cells phenotypically negative for the target antigen are required for transfusion; when the target antigen is of high frequency or when the recipient has made multiple alloantibodies, documentation of a lack of clinical significance of an antibody can greatly facilitate the selection of blood for transfusion.

Although small volumes of blood may be transfused and the patient monitored for signs and symptoms of hemolysis, such transfusion “trials” are not generally as sensitive and are of greater risk than are red cell survival tests using small volumes (1–2 mL) of chromium 51 (^{51}Cr)-labeled red cells. After injection of such cells, blood is usually sampled first at 3 minutes; this value may be taken as 100% survival in most cases. Cells presensitized with antibody or cells subject to clearance by a

particularly strongly reactive antibody may undergo some clearance within 2 to 3 minutes. Blood then is sampled several times during the first 10 to 15 minutes and again at 1 hour and 24 hours; later samples are also sometimes appropriate. When there is normal cell survival, both the 1-hour and the 24-hour survival rate is greater than 95%. Rapid intravascular lysis, such as seen with ABO antibodies, may reduce cell half-life to less than 10 minutes (22). Less rapid cell destruction may occur with either one-phase or two-phase kinetics. Red cells sensitized by primarily noncomplement-fixing IgG antibodies usually are cleared gradually from the circulation with a destruction curve defined by a single exponential; the slope of the curve depends on the factors discussed previously, including concentration of antibody, antigen density, and RES macrophage function. Most red cell destruction takes place extravascularly, by phagocytosis and perhaps ADCC. The half-life of chromium-labeled cells cleared by this mechanism can be quite variable, from minutes to days. When complement-fixing IgM antibodies, such as alloanti-Le^a or autoanti-I, are involved in cell clearance, a two-phase process may be seen. At first, an initial amount of the transfused cells (usually up to 30%) is cleared, after which the remaining cells survive relatively normally. The initial rapid clearance is presumed to be due to fixation of complement and ensuing phagocytosis or ADCC. On the surviving cells, however, C3b is converted to inactive C3 fragments that are not recognized and bound by complement receptors. These fragments tend to protect the cells from further complement fixation, and thus the cells subsequently survive relatively normally.

Performing the appropriate sampling in a ^{51}Cr survival study is important, as a cold-reacting antibody that causes destruction of 30% of cells in a short period, followed by normal survival of the remaining cells, may sometimes be safely ignored. A one-phase curve in which 30% of the cells are destroyed in 24 hours by an IgG antibody may presage a significant delayed hemolytic transfusion reaction.

Hemolytic Transfusion Reactions

Accelerated immune destruction of transfused red cells is the cardinal feature of a hemolytic transfusion reaction. Acute reactions occur within minutes to hours of transfusion; delayed reactions are observed days to weeks after transfusion. In general, acute reactions involve a larger element of intravascular hemolysis, whereas delayed reactions predominantly involve extravascular red cell clearance. Much overlap occurs, however. Acute reactions most often are associated with preformed antibody, especially naturally occurring isoagglutinins against the A and B antigens. Delayed hemolysis most often occurs as part of an anamnestic response to an antigen to which the blood recipient has been previously exposed through transfusion or pregnancy. Most antibodies that cause delayed hemolytic transfusion reactions target antigens within just a few blood group systems, including Rh, Kell, Kidd, and Duffy. The RhD (D) antigen is especially immunogenic; 1 U of D-positive blood stimulates antibody production in about 80% of D-negative recipients. Because it is now common practice to transfuse group O D-positive blood to men and to women past childbearing age in emergency situations, anti-D remains a commonly encountered alloantibody, despite the fact that D-positive blood normally is not given to D-negative recipients once the recipient's blood type is known.

Intravascular Hemolytic Reactions

Intravascular hemolysis occurs when sufficient complement is fixed on transfused red cells to lead to formation of enough terminal attack complexes (C5–9) to lyse circulating transfused red cells. Again, it is the ABO system antibodies that are most often the culprits, but other antibodies (such as anti-Jk^a, anti-Vel, and anti-Tj^a) also can produce brisk intravascular hemolysis. When intravascular hemolysis is rapid, such as with ABO reactions, the physician will often observe hemoglobinemia, hemoglobinuria, vascular collapse, disseminated intravascular coagulation (DIC), and renal failure. During operative procedures, intractable bleeding may be the first sign of a hemolytic transfusion reaction.

The sequence of events that causes the clinical signs and symptoms of hemolytic transfusion reactions is quite complex. Activation and fixation of complement components lead both to red cell destruction and release of vasoactive substances (e.g., C5a) and procoagulant materials; large numbers of immune complexes also are formed. Leukocytes are activated, and multiple cytokines are released (18,20,21). Some of these cytokines are associated with expression of procoagulant molecules by both leukocytes and endothelial cells, and these changes may contribute to the DIC sometimes observed in acute hemolytic transfusion reactions (19). Renal failure probably results from immune complex deposition as well as hypoperfusion. If sufficient hemoglobin is released to overwhelm the transport mechanism of the proximal renal tubules, hemoglobin chains may precipitate in the renal tubules, where a combination of acidification and water reabsorption may make the hemoglobin insoluble; this process can also result in failure of tubular function. It is also known that, under other conditions, large amounts of free hemoglobin can be excreted by the kidney without untoward effects (78).

In vitro models of immunologic events associated with antibody-induced hemolysis have begun to be investigated. Among the cytokines produced by circulating leukocytes when exposed to red cells and ABO-incompatible plasma are interleukin (IL)-8 and tumor necrosis factor (TNF-a) (18,20). When IgG antibodies were involved, a similar *in vitro* model documented production of IL-1b, TNF, IL-6, and IL-8 by monocytes (21). The high-affinity immunoglobulin FcRI appeared to be involved in the pathway leading to production of IL-8 and erythrophagocytosis; however, neutralization of IL-1 and TNF did not prevent production of IL-8 (21).

If the clinician observes signs or symptoms frequently associated with a major hemolytic transfusion reaction (e.g., cyanosis, sensation of choking or substernal pressure, abdominal pain, hypotension, unusual bleeding, hemoglobinuria, and oliguria), the blood transfusion should be stopped immediately. Intravenous access should be maintained, however, and fluid support (with pressors when necessary) and diuresis, if possible, should be aggressively initiated. Long-term support may require dialysis if renal shutdown is complete or of long duration.

Investigation of such a reaction should include demonstration of signs of hemolysis, such as plasma-free hemoglobin and urine hemoglobin, as well as identification of the causal antibody and delineation of the circumstances leading to the transfusion reaction. Most major hemolytic transfusion reactions occur because of errors in patient sample labeling, clerical errors, and misidentification of the blood or patient at the time of transfusion. Thus, all records and labels should be carefully checked, and new samples should be drawn to reconfirm the recipient's ABO type, especially for a patient who has not been typed prior to the sample used for the implicated transfusion. Normally, all typing, antibody screening, and cross-matching should be repeated with both the blood sample previously obtained as well as a second sample obtained at the time of the reaction.

Extravascular Hemolytic Reactions

Extravascular hemolysis is most often caused by IgG antibodies produced after exposure to foreign antigens through transfusion and pregnancy. The antigens most often involved are those of the Rh, Kell, Kidd, and Duffy systems. These antibodies rarely fix complement adequately to cause predominantly intravascular hemolysis, but membrane-bound IgG and complement components bind to specific receptors on RES macrophages (91). Antibody-coated cells may be partially or completely phagocytized or destroyed by natural killer (NK) cells through ADCC lysis.

Although IgG alloantibodies largely cause extravascular hemolysis, the clearance induced by some antibodies can occur over a relatively short time and may be associated with constitutional symptoms, including fever, chills, and vague back, flank, or abdominal pain. Hemoglobinemia, hemoglobinuria, and hyperbilirubinemia are often present, and laboratory testing may demonstrate elevated lactate dehydrogenase (LDH), absent haptoglobin, and positive serologic findings, including a positive result on the direct antiglobulin test (DAT) and the presence of specific serum antibody.

In general, delayed hemolytic transfusion reactions usually involve extravascular hemolysis induced by antibody produced during an anamnestic response to an erythrocyte alloantigen. Although delayed hemolytic reactions can occur after a primary exposure to antigen, this is rare because of the length of time needed for a primary response (several weeks) and the initial IgM character of that response. Instead, delayed transfusion reactions occur because the antibody produced in a previous primary immune response has decreased to undetectable levels by the time of pretransfusion testing; antibodies may also be missed due to technical errors during testing or due to the specific type of testing performed.

More often than not, delayed alloimmune transfusion reactions are clinically insignificant (69). Accelerated red cell destruction is often unnoticed or inapparent. Thus, the blood bank may detect evidence of posttransfusion sensitization (“delayed serologic transfusion reaction”) when the clinician is unaware of signs or symptoms of hemolysis. As many as 1 in every 1,500 transfusions may be followed by serologic evidence of incompatibility between the transfused blood and the recipient's posttransfusion serum (102). The mortality rate of delayed hemolytic transfusion reactions is probably less than 1%, however, and major morbidity such as renal failure, although reported, is also exceedingly rare. Exceptions include a high morbidity and mortality of delayed hemolytic transfusion reactions in patients with sickle cell disease and an increased incidence of renal failure in patients with already compromised renal function, such as chronic renal insufficiency due to diabetes.

Expected laboratory findings in delayed hemolytic transfusion reactions include (a) positive results on the DAT with or without complement and (b) the presence of a previously unidentified alloantibody either in the serum or in the eluate made from circulating red cells. When a patient has received several units of blood, the circulating cells may not all be positive for the implicated antigen, and thus a mixed-field agglutination pattern in which not all red cells are involved in agglutinates might be expected. As the antigen-positive red cells are cleared from the circulation, the DAT result might be expected to become negative, whereas the titer of the responsible antibody would be expected to increase, at least over the short term.

Immunologic Hazards of Platelet Transfusions

Transfusion of stored packed red blood cells entails transfusion of all cellular blood elements, including leukocytes and platelets, unless the blood product is first

modified (e.g., by washing or filtration) to remove nonerythroid cells. Thus, many red cell recipients are also exposed to platelet and leukocyte antigens, although an increasing percent of red cell units are now processed through leukocyte-depletion filters, which reduce both the leukocyte and platelet content. Therapeutic use of platelet concentrates carries a significant risk of alloimmunization to HLA antigens and a somewhat lower risk of immunization to platelet-specific antigens. The rate of alloimmunization is dependent on the number of transfusions received, the underlying disease, and the type of concomitant therapy. Patients being treated for leukemia may become alloimmunized less often than patients being treated for aplastic anemia, especially when the latter are not receiving immunosuppressive therapy. As many as 60% to 70% of recipients of multiple unmodified platelet concentrates become alloimmunized to HLA antigens (39), whereas only a small percentage develop antibodies to platelet-specific blood group antigens. Platelets also bear ABH antigens but do not express antigens of the highly immunogenic Rh, Kell, Kidd, and Duffy blood groups. The identification of HLA alloantibodies in patients who appear alloimmunized and refractory to platelet transfusions is routinely accomplished using a standard lymphocyte cytotoxicity test, discussed elsewhere in this book.

The high rate of alloimmunization to HLA antigens after platelet transfusion led to intensive efforts focusing on prevention of HLA alloimmunization and provision of platelets that will survive despite HLA alloantibodies. At present, alloimmunization to HLA antigens appears best to be preventable by filtration of all red cell and platelet products with leukoreduction filters. When used appropriately, such filters can reduce the number of leukocytes per transfused unit to fewer than 5×10^6. This procedure alone reduces the incidence of HLA sensitization in a population that receives multiple transfusions to 30% or less.

For patients who become alloimmunized during therapy or who start transfusion therapy after having already become alloimmunized (e.g., via pregnancy) and who are thus “refractory” to transfusion with random donor platelets, several approaches have been taken in an effort to provide platelets with normal or near-normal survival. One straightforward method is to provide the patient with platelets from a donor whose platelets carry the same class I HLA antigens. Only about 1 in 4,000 donors will provide a perfect, four-antigen match for a random patient, however. The odds worsen if the patient is black or Hispanic because of the largely white donor population in the United States and the different frequencies of certain alleles in racially different populations. Platelet units that match two or three of the alloimmunized recipient's HLA antigens have been shown to survive better than non-HLA-matched platelets (57), but the success of such partially matched units is highly variable. One factor shown to be important is whether the “mismatched” antigens belong to the same “cross-reactive groups” as the recipient's antigens (25). When mismatched antigens belong to the same cross-reactive group, survival of transfused platelets is improved over that of platelets expressing non–cross-reactive antigens (25). Even with modified antigen matching, however, providing HLA-matched platelets requires a large, previously typed donor pool from which to draw, especially because the half-life of compatible transfused platelets dictates the need for two to three platelet transfusions weekly for many patients and even more for those with surgical or hemorrhagic problems.

Several investigators have looked into the value of “cross-matching” platelets to select non-HLA antigen–matched platelets that might survive markedly better than randomly chosen ones. Although such tests are not now standardized, one is commercially available. Studies of outcomes following transfusion of such “compatible” platelets to alloimmunized patients have shown at least some value for these procedures (27,44).

Although HLA alloimmunization is usually the primary cause of failure of platelet transfusions in multiply transfused recipients, several other factors also deserve mention. Because platelets carry ABH antigens, the role of ABO incompatibility has been examined (4,26,35,49). In at least some patients, ABO incompatibility significantly reduces platelet survival (35,49), whereas in other patients, the recipient's anti-A or anti-B titer may be at least initially insufficient to effect clearance of significant numbers of platelets. Thus, although ABO matching is not required for platelet transfusion, such matching should be the first step in dealing with a patient who is refractory to transfusion of platelets from random donors (49).

Finally, when both ABO and HLA matching are unsuccessful in identifying platelets that will survive in an alloimmunized recipient, the possible existence of alloantibodies against platelet-specific blood group antigens must be considered. Identification of such antibodies and testing for expression of such target antigens are not yet routine and widespread. Serum with which to type platelets is generally scarce because such antibodies are relatively rare. The molecular bases of many platelet blood group antigen polymorphisms are now known (for review, 70), and some laboratories are able to genotype patients for these antigens.

Posttransfusion Purpura

Occasionally, an alloimmune reaction directed against a platelet-specific blood group antigen gives rise to the syndrome known as *posttransfusion purpura*. This syndrome usually occurs 5 to 12 days (mean, 7 days) after transfusion, when the blood recipient experiences profound thrombocytopenia, with the platelet count usually falling precipitously to below 10,000 per microliter. Although the full mechanism of this syndrome is not understood, it clearly results from an anamnestic response to a platelet antigen. Usually, the affected patients are women who have been previously immunized during pregnancy. The inciting event may be a platelet transfusion but is much more often a product transfused for its red cell content (i.e., whole blood or packed red cells). Most often, the antibody demonstrated is anti-PI^{A1}, but rare instances in which antibodies to other antigens caused this syndrome have been documented. The ability to develop antibodies to the PI^{A1} antigen appears to be linked to HLA genes because only about 10% of exposed women make anti-PI^{A1}, and women who produce anti-PI^{A1} as a result of pregnancy have a high incidence of HLA-Drw52 (23).

The antibody response associated with posttransfusion purpura is uniformly IgG, and the platelet count usually correlates inversely with the antibody titer during the course of the illness, despite the fact that the antibody produced is an alloantibody. Thrombocytopenia appears to occur as an anamnestic response to a platelet alloantigen, although the mechanism whereby the patient's own antigen-negative cells are destroyed remains unclear.

The clinical course of posttransfusion purpura is that of rapid development of severe thrombocytopenia within 12 to 24 hours, accompanied by moderate to severe hemorrhage. An overall mortality of about 10% can be deduced from various studies. Bone marrow examination, if done, usually shows increased numbers of megakaryocytes, so that this syndrome resembles most drug-induced purpuras. The history of recent transfusion, however, along with either prior pregnancy or prior transfusion, should signal consideration of the diagnosis of posttransfusion purpura. If serology is available, demonstration of anti-PI^{A1} in the patient's serum is usually easily achievable, although platelet antigen phenotyping may be prevented by the extremely low platelet count. If left untreated, thrombocytopenia usually resolves over 1 week to 1 month. The most effective treatments are plasmapheresis (plasma exchange) and intravenous gamma globulin (94). Steroids alone do not appear to be of significant benefit, and transfusions of either antigen-positive or antigen-negative platelets neither improve nor worsen the thrombocytopenia.

Leukocytes and Febrile Reactions

Up to several percent of transfusions are associated with febrile reactions, which since the 1950s (8,33), have been attributed to the presence in the recipient of leukoagglutinating antibodies. Typically, the patient is more or less asymptomatic during the early phase of the transfusion (30–60 minutes). Then chills and fever intervene, usually along with increased blood pressure. Some patients also experience headache, nausea, or back pain. Occasionally, the fever is quite high, reaching 40°C. When a febrile reaction occurs, the transfusion should be stopped and the patient assessed for signs and symptoms of hemolysis and sepsis, the latter being a rare but serious complication of transfusion. Antipyretics may be used, and for patients who experience repeated febrile reactions, blood products processed through leukoreduction filters will abolish or cause less severe febrile reactions.

Not all febrile reactions are caused by recipient leukoagglutinins. Apparently, leukocytes in blood during storage may produce a variety of pyrogens and leukokines, including TNF-, IL-1, and IL-6. Platelet concentrates containing a relatively high level of TNF-a and IL-6 are associated with an increased risk of febrile transfusion reactions (68).

One of the most devastating sequelae of the transfusion of leukocytes, usually as unwanted companions of red cells or platelets, is transfusion-related graft-versus-host disease (GVHD). This syndrome ensues when transfused viable lymphocytes set up a graft-versus-host response in a blood recipient unable to mount a host-versus-graft response. Most often, this occurs because the blood recipient is immunocompromised due to an underlying medical condition or therapy. Transfusion-related GVHD has been convincingly documented in immunocompetent patients, however. For example, it has occurred when lymphocytes from a donor homozygous for a specific HLA-A/B allele are transfused to a recipient heterozygous for the same allele. Such a situation would allow a graft-versus-host response but not a host-versus-graft response on the basis of HLA-A/B antigens. Interestingly, no case of transfusion-related GVHD has been reported in HIV-infected patients. Patients most at risk for this syndrome appear to be those with congenital immunodeficiencies and those with hematologic malignancies.

Transfusion-related GVHD can be prevented by irradiation of cellular blood products prior to transfusion. Doses of 25 to 30 Gy are commonly used for this purpose.

Reactions to Plasma and Plasma Products

Plasma contains a complex mixture of proteins, including albumin, coagulation and complement components, and immunoglobulins. Many of these factors can engender a variety of reactions in patients who receive transfusions of either plasma or cellular blood products in which varying amounts of plasma remain.

Passive Transfer of Antibody

Plasma from healthy donors may contain both isoagglutinins (anti-A and anti-B) and alloantibodies to red cell, platelet, or leukocyte antigens. Transfusion of small

amounts of isoagglutinins, such as might be found in the plasma of group O packed red cells, is usually harmless. Transfusion of group O platelets usually involves a larger volume of plasma, however, and both positive DAT results and hemolysis have occasionally been observed following such transfusions (118). Transfusion of alloantibodies to red cell antigens is usually harmless because the amount of antibody transfused is usually insufficient to effect appreciable immune clearance of cells, even when the recipient's cells are antigen positive. At least one case in which anti-K from one unit destroyed antigen-positive cells from a second transfused unit in a K-negative recipient has been documented (1).

Transfusion of alloantibodies to platelet antigens has been documented to cause thrombocytopenia in several antigen-positive recipients (92). In at least some recipients, such antibodies may be of sufficiently high titer that only 10 mL of plasma is required to cause marked thrombocytopenia (95).

Transfusion of alloantibodies to leukocyte antigens may cause a unique and sometimes severe syndrome referred to as *transfusion-related acute lung injury* (TRALI). This syndrome is characterized by fever, chills, nonproductive cough, dyspnea, and hypotension. Radiographic examination of the chest most often demonstrates numerous nodular opacities in the lung fields, predominantly in the perihilar area and lower lung fields; vascular congestion and cardiac enlargement, typically found in the setting of cardiogenic pulmonary edema, are absent. The target antigens of the causative antibodies may be either HLA antigens or neutrophil-specific antigens. Most often the syndrome results from transfusion of leukoagglutinins, although the recipient's own leukoagglutinins also can cause a similar picture (31). Complement activation appears necessary for production of the syndrome in an animal model (93).

Immunoglobulin A-Specific Hypersensitivity Reactions

Approximately 1 in 700 individuals lack both serum and secretory IgA, and a substantial number of them develop anti-IgA class specific antibodies, sometimes without a history of a clear immunizing exposure. When the recipient has anti-IgA antibodies, only a few milliliters of plasma can elicit an immediate anaphylactic reaction, with initial sweating and nausea followed quickly by hypotension, cyanosis, seizures, and death. Thus, any patient with known IgA deficiency or with a history of a severe transfusion reaction of this nature should be given blood products that do not contain IgA. Red cells can be rendered plasma free by freezing and thawing (deglycerolizing) but not by routine washing. Other products must be obtained from IgA-deficient donors.

Urticaria

Hypersensitivity reactions marked by some degree of urticaria with or without other allergic symptoms (e.g., wheezing) are quite common, occurring in 1% to 3% of all transfusion episodes. Some may be due to anti-IgA of limited allotype specificity present in IgA-positive recipients, whereas others may be due to sensitivity to other donor plasma proteins.

NEONATAL ALLOIMMUNE CYTOPENIAS

All fetal blood cells, including erythrocytes, leukocytes, and platelets, carry antigens capable of stimulating maternal alloimmune responses when the mother's own cells lack the antigen. This was first recognized when maternal antibody was identified as the cause of HDN (52,93). Since then, cases of neonatal (and intrauterine) hemolytic anemia, thrombocytopenia, and neutropenia have been recognized as caused by maternal alloantibody.

HEMOLYTIC DISEASE OF THE NEWBORN

The immunologic basis of HDN is the combined existence of (a) paternal antigens expressed on fetal red cells, (b) incomplete separation of the fetal circulation from that of the mother, and (c) active transport of maternal IgG across the placenta. These three factors allow the mother to detect fetal antigens and to produce alloantibody in response and then allow the alloantibody to be transported into the fetal circulation. The vast majority of HDN is caused by maternal antibody to the Rh_o (D) antigen. This antigen is the most immunogenic of the Rh antigens. Because the mother is D negative but the fetus is D positive in about one in ten pregnancies in whites (63), a significant number of pregnancies are at risk for producing maternal alloimmunization to the D antigen. Because fetomaternal hemorrhage is often minimal until the time of delivery, when the average fetomaternal hemorrhage is 1.2 mL, fewer than 1% of at-risk women will have detectable anti-D at the time of delivery of a first D-positive child. Maternal anti-D will be detectable in 10% to 20% of pregnancies in which a D-negative woman bears a D-positive fetus for the second time. Before the era of immunoprophylaxis, about 1 in 100 second pregnancies was complicated by HDN, indicating that not all at-risk mothers produce anti-D, either because of insufficient exposure to fetal D-positive cells or because of maternal nonresponsiveness to this antigen. In addition, the ABO types of the fetus and mother also affect the likelihood of maternal alloimmunization. When small amounts of D-positive blood were transfused into ABO-compatible and ABO-incompatible recipients, more than 70% of ABO-compatible recipients made anti-D, whereas only about 15% of ABO-incompatible recipients responded similarly (99). When recipients of incompatible D-positive blood were then given ABO-compatible D-positive cells, their response rate was similar to that of the group that originally received the ABO-compatible D-positive cells. Maternal sensitization to D is similarly affected by fetomaternal ABO compatibility.

Since the inception of immunoprophylaxis and better treatment methods for HDN when it does occur, HDN occurs less frequently and causes even lower mortality. Pregnant women now undergo ABO and Rh typing early in pregnancy, along with screening for the presence of red cell alloantibodies. Rh-negative women often receive one or two doses of anti-D at between 28 and 34 weeks' gestation. Then, shortly after delivery, Rh-negative mothers receive anti-D if their infant's red cells are D positive. This combination of prenatal and postpartum immunoprophylaxis has reduced the incidence of anti-D HDN to well below 1 in 1,000.

Nevertheless, some cases of HDN do occur, as a result of either other (non-anti-D) alloantibodies or failure of the prophylactic approach. When an alloantibody is found in the serum of a pregnant woman, several factors contribute to decisions about management of the pregnancy. Antibodies with certain specificities tend to cause minimal or no HDN, whereas antibodies to other antigens typically cause moderate to severe disease. In addition to the factors discussed already for immune clearance, the strength of expression of particular antigens on fetal cells and the fact that IgM antibodies do not cross the placenta help determine whether an antibody causes significant HDN. Although ABO mismatch between mother and child is frequent, clinically significant ABO HDN is rare. The A and B antigens are poorly developed on fetal and neonatal red cells. Also, A and B antigens are expressed widely in the body, so that the IgG portion of maternal isoagglutinin that crosses the placenta to the fetus is adsorbed by numerous tissues other than red cells.

Following the titer of an alloantibody during pregnancy is usually not helpful in predicting the severity of HDN, although a rapidly rising titer is a relatively poor prognostic sign when the antibody is one generally associated with significant HDN. Amniotic fluid can be obtained by amniocentesis and examined spectrophotometrically for the presence of hemoglobin breakdown products (bilirubin), and this procedure provides quite a good indicator of the status of the fetus. As fetal maturity also can be assessed via amniocentesis, management then can include intrauterine transfusion of blood compatible with maternal antibody or premature delivery, followed by *ex utero* therapy, if these procedures are indicated. Once an infant is born, therapy may include phototherapy to break down bilirubin and exchange transfusion, with the aims of ameliorating anemia and prevention of hyperbilirubinemia (> 20 mg/dL), which can damage brain cells from bilirubin deposits (kernicterus).

60 IMMUNOLOGIC ASPECTS OF FERTILITY AND INFERTILITY

Joan S. Hunt, Ph.D., and Kenneth S. K. Tung, M.D.

Genetic diversity in the population has numerous advantages, including increased resistance to disease and avoidance of inheritance of undesirable traits. Yet achieving diversity in humans, where the immune system is primed to prevent intermixing of host and foreign entities, is a formidable task. It requires special arrangements of tissues and cells in reproductive organs as well as profound local and systemic changes in normal immune responses.

Gametes and fertilized eggs are at risk and must be protected from both alloimmune and autoimmune processes. The gametes, sperm, and ova express novel surface and intracellular molecules that differ biochemically from somatic cell proteins and are therefore foreign to the host. Protection against autoimmmunity is required in both the ovary and testis. Sperm, which bear molecules that are entirely foreign to females, enter the female reproductive tract and must be protected against alloimmune reactions. Finally, mechanisms must be devised to prevent mothers from rejecting the semiallogeneic fertilized egg, which expresses both paternal and maternal genes during implantation and throughout the course of pregnancy.

Diverse approaches are used to ensure successful reproduction in humans and other mammals. Special tissue barriers are erected to avoid dissemination of gamete antigens into the blood and lymphatic circulations; unique cells called *trophoblasts* sequester the developing embryo from maternal immune cells; and multiple immunoevasive strategies are called into action on a local basis. These latter factors include recruitment of specialized subsets of leukocytes, production of immunosuppressive substances, as well as regulated expression of genes encoding complement regulatory proteins, major histocompatibility antigens, and display of apoptosis-inducing molecules. In short, the same devices used by tumors to escape surveillance and destruction are used during pregnancy to protect the developing embryo.

Not surprisingly, mechanisms erected to avoid autoimmunity and alloimmunity in gamete development and pregnancy may be overcome. Multiple disorders of reproduction are evident in the general population, and immune dysfunctions are likely to account for a certain proportion of cases of infertility and pregnancy failure.

This chapter first lays out the anatomic structures and components of the male and female reproductive systems and discusses the basic features that have evolved to prevent autoimmunity and alloimmunity during gamete development, fertilization, implantation, and pregnancy. Mechanisms that have developed to promote tolerance and avoid graft rejection during reproduction will be presented in detail. Features of autoimmunity and alloimmunity in reproductive organs are discussed, with emphasis on aspects of infertility that have emerged from studying natural disorders and conducting research in experimental systems.

TOLERANCE AND IMMUNE PRIVILEGE IN GAMETE DEVELOPMENT

Autoantigens of the testis and the ovary differ greatly in their ontogeny of expression and accessibility to the immune system. Thus, mechanisms of local immunoregulation and the extent of systemic tolerance to antigens of the two organs also differ.

Ovary

In mammals, the ovary is an almond-shaped structure characterized by an epithelial covering, an outer zone called the *cortex* where follicles develop, and an inner zone called the *medulla* where blood vessels emerge and depart. Stroma surrounding the follicles and vessels contains various populations of leukocytes, including macrophages. Developing follicles are composed of an outer layer of theca cells, an inner compartment of granulosa cells, and a central oocyte. The oocyte is surrounded by a thick glycoprotein coat known as the *zona pellucida* (ZP).

Ovarian Antigens

The ovary-specific antigens that might stimulate autoimmunity that have been investigated most extensively are located in the ZP and include the antigen ZP3 (1) and the oocyte cytoplasmic antigens, which include OP1 (2). In mice, these antigens can be recognized *in vivo* by circulating antibody and antigen-specific T cells in the first 3 days of life (3). Figure 60.1D shows an experimental situation where ovarian ZP is fully accessible to circulating IgG antibody and circulating immune complexes (4,5). This antigen also disseminates to the regional lymphoid nodes and organs to activate ZP-specific B cells in normal mice (6). ZP and oocyte antigens derived from apoptotic oocytes may serve as target T-cell antigens. Many oocytes in prepuberal ovaries and most developing oocytes in cycling adult women undergo apoptosis and are subsequently known as *atretic follicles*. In adult ovaries, the atretic follicles contain oocyte antigens as well as major histocompatibility (MHC) class II positive macrophages and dendritic cells. The oocyte antigens are the main target of $CD4^+$ pathogenic T cells (7,8).

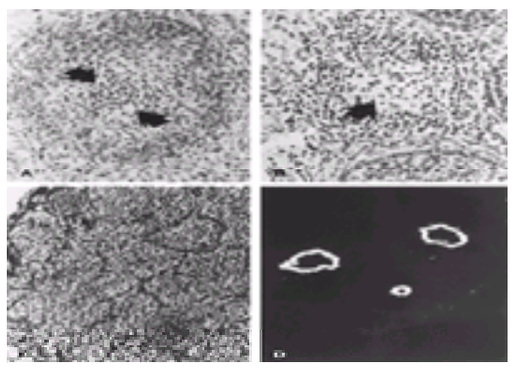

Figure 60.1. Immunopathology of murine autoimmune ovarian disease (AOD) induced by immunization with pZP3 in adjuvant.

Tolerance to Ovarian Antigens

Tolerance to the gender-specific ZP antigen has been demonstrated by comparing ZP3-specific peptide immune responses of normal female mice with male or ovariectomized female mice, which lack ZP (3). This study, which reported pathology in the ovarian graft and antigen specific T-cell cytokine production, suggests that antigen exposure during the neonatal period is not sufficient for tolerance to ZP; continuous ovarian antigen presence is required. Indeed, adult female mice depleted of ovarian antigens for only 7 days are no longer tolerant to the ZP antigen.

Tolerance to murine oocyte antigens includes a critical role for regulatory T cells (reviewed in 9). The thymus and peripheral lymphoid tissues of normal adult and neonatal female mice contain $CD4^+$ T cells with the capacity to induce autoimmune ovarian disease (AOD). These $CD4^+$ T cells do not express the interleukin-2 (IL-2) receptor a-chain (CD25) until activated (10,11). Regulatory T cells develop in the thymus as $CD25^+$ $CD4^+$ mature thymocytes (5%) and exist as a subset of $CD25^+$ $CD4^+$ T cells (5%–10%) in peripheral lymphoid organs (11,12). When $CD25^+$ thymocytes or peripheral T cells from normal mice are depleted, endogenous ovarian antigens rapidly stimulate pathogenic T cells, leading to severe AOD and oocyte antibodies spontaneously (13). Table 60.1 lists a number of murine experimental models for dissecting autoimmunity, of which several involve deletion of the thymus (11,14,15). In all these models, AOD is prevented on reconstitution with $CD25^+$ $CD4^+$ T cells from normal euthymic donors (reviewed in 9). These experiments led to the conclusion that pathogenic autoreactive T cells are present in normal female mice and that they are normally regulated by $CD25^+$ regulatory T cells. $CD25^+$ regulatory T cells operating to ensure self-tolerance also are found in tolerance to autoantigens of testis, thyroid, stomach, prostate, salivary and lacrimal glands, pancreatic islet, and the eye (Table 60.1).

Experimental autoimmune (allergic) orchitis (EAO) and experimental autoimmune oophoritis that result from immunization with tissue antigen:	
Classic EAO induced by immunization with testis antigen with adjuvant	(16–18)
EAO induced by immunization with testis antigen without adjuvant	(19,20)
Autoimmune oophoritis induced by immunization with a murine ZP3 peptide	(1)
Autoimmune diseases of ovary, testis (or other organs) that result from manipulations of the normal immune system:	
Thymectomize mice between d 1 to 4 after birth (DBX model)	(14,21–23)
Transfer adult murine $CD5^{low}$ or $CD25^-$ T cells to athymic mice	(10,24,25)
Treat normal mice with antibody to CD25	(15)
Treat neonatal mice with cyclosporine A	(26)
Engraft fetal rat thymus in athymic mice	(27)
Engraft neonatal mouse thymus in athymic mice	(28)
Transfer T cells from adult or neonatal thymus, neonatal spleen to athymic mice	(10)
Mice with a transgenic V_α protein of the T-cell receptor	(28)
Transfer RT6-depleted rat spleen T cells to athymic rats	(29)
Transfer $OX22^{high}$ (or $CD45RC^{high}$) rat spleen T cells to athymic rats	(30)
Other modes of autoimmune orchitis:	
Spontaneous autoimmune orchitis in dog (31), mink (32), rat (33), human (34)	
Postvasectomy autoimmune orchitis	(35,36)
Orchitis in rats with the transgenic HLA/B27 molecule	(37)

TABLE 60.1. Autoimmune Ovarian and Testicular Disease Models

Mechanisms of $CD25^+$ T-cell Regulation

$CD25^+$ T cells suppress the response of $CD25^-$ T cells *ex vivo,* and this approach has been exploited to investigate the mechanism of T-cell regulation (12,38). For effective suppression, the regulatory and the effector T cells may recognize the same or different antigenic peptides. Regulation requires antigen-presenting cells (APCs), T-cell receptor (TCR) engagement on both $CD25^+$ regulatory and $CD25^-$ effector T cell subsets, T-cell contact, and an anergic state in the $CD25^+$regulatory T cells. Some well-documented antiinflammatory cytokines, including IL-4, IL-10, and transforming growth factor-b (TGF-b), seem not to be involved.

Testis

The male reproductive tract has several compartments of which the testis is the major site of germ cell development. The testes comprise an outer epithelial cell covering and a series of folded seminiferous tubules embedded within stroma. The tubules are sequestered from the stroma by a thick basement membrane. Germ cell development occurs in waves emanating from the outermost border of the tubule, within which reside the Sertoli cells, toward the lumen, where mature sperm are released.

Testis Antigens and the Blood–Testis Barrier

Most testicular autoantigens are expressed in the haploid germ cells. Of these autoantigens, many are unique testicular isoforms of somatic antigens. Because these autoantigens first appear at puberty, they do not interact with lymphocytes early in life (reviewed in 39) and may not, unlike the situation in the ovary, induce early tolerance. Male germ cell antigens may be invisible, entirely ignored by the immune system because of being protected by a complete immunologic blood–testis barrier. In the seminiferous tubule, a formidable tissue barrier is formed by the peritubular myoid cells and the junctional complexes between the somatic Sertoli cells. This barrier effectively separates the haploid germ cells from circulating lymphocytes and antibodies, both of which reach the testis interstitium (40). Presumably, the barrier also limits the access of germ cell autoantigens to APCs outside the seminiferous tubules.

The idea that male germ cells are completely sequestered was challenged by data from experimental autoimmune orchitis (EAO) research. Studies in mice demonstrate that (a) antibody enters the rete testis to bind to spermatozoa (41); (b) autoantigens accessible to circulating autoantibodies exist on the diploid germ cells outside the blood–testis barrier (including the preleptotene spermatocytes that first appear in the second week of life) (Fig. 60.2) (42); (c) in the straight tubules, which link the seminiferous tubules to the rete testis, luminal germ cell antigenic peptides can reach MHC class II positive APCs outside the barrier to stimulate germ cell–specific $CD4^+$ T cells and elicit severe inflammation in that location (Fig. 60.3B) (9,43,44). These findings argue against the concept of a complete blood–testis barrier and emphasize the regional variations in the integrity of the blood–testis barrier within the normal testis.

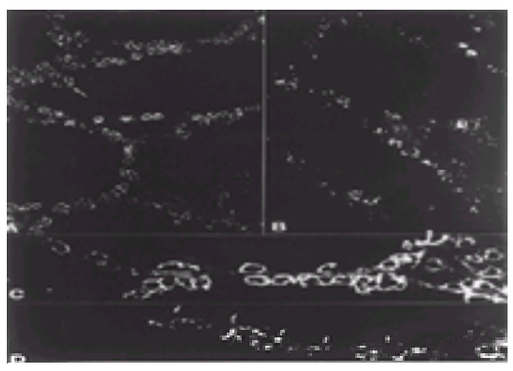

Figure 60.2. Autoantigenic germ cells are present outside the blood–testis Sertoli cell barrier. Mice were injected with testis homogenate in adjuvant and then tissue sections of testis were tested by direct immunofluorescence for bound immunoglobulin G (IgG) at day 7, 5 days before the onset of experimental autoimmune orchitis.

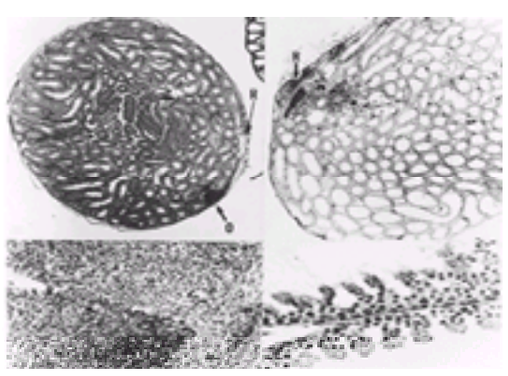

Figure 60.3. Patterns of inflammation in experimental autoimmune orchitis (EAO) are different when EAO is induced by active immunization and by adoptive transfer with pathogenic T cells.

Tolerance and Immune Privilege in the Testis

Immunoregulation against testis autoimmunity is dependent on mechanisms operative at three levels: (a) confinement of most of the germ cell autoantigens within a strong but regionally incomplete tissue barrier, (b) maintenance of tolerance by the same systemic regulatory T cells common to the ovarian autoantigens (22), and (c) local immunoregulation or immune privilege.

Immune privilege in the testis is demonstrated by the prolonged survival of tissue allografts, including parathyroid and pancreatic islets in the testis interstitium (45). Survival is extended despite the presence of circulating antibodies that readily enter the testis interstitium, which is drained by elaborate afferent lymphatics. The testis interstitium contains Leydig cells, resident macrophages, peritubular myoid cells, and Sertoli cells, which communicate via hormones, paracrine factors, and cell junctions (46). Factors produced by these cells may suppress T-cell response to mitogens or anti-CD3 antibody *in vitro*. Candidate suppression factors include IL-1, TGF-b, basic fibroblast growth factor, transglutaminase, prostaglandin E_2, and activin (47,48,49,50 and 51). Although Fas ligand is expressed in the testis, the contribution of Fas ligand to immune privilege by conferring T-cell apoptosis remains speculative (52,53).

ANATOMIC AND CELLULAR CONSTITUENTS OF THE UTERUS AND THE IMPLANTATION SITE

The preceding paragraphs document the special arrangements of tissues and developing gametes in the ovary and testis and discuss how these conditions may permit the development of autoimmune disease. Following release of the ovum from the follicle and fertilization, which occurs in the oviduct (also known as the fallopian tube), the fertilized egg descends into the uterus, which is hormonally and immunologically prepared for implantation.

Cycling Uterus

The uterus of women and experimental animals such as mice and rats is roughly separated into (a) the myometrium, which is composed of smooth muscle cells interspersed with connective tissue containing some leukocytes such as mast cells and macrophages; and (b) the endometrium. A transverse section of rat cycling uterus is illustrated in Fig. 60.4 (left panel). The major components of the endometrium, where implantation takes place, are the luminal epithelia, which continue as a lining for the endometrial glands, and the stromal compartment. In the endometrial stroma, leukocytes are scattered randomly and occasionally are gathered into lymphoid aggregates.

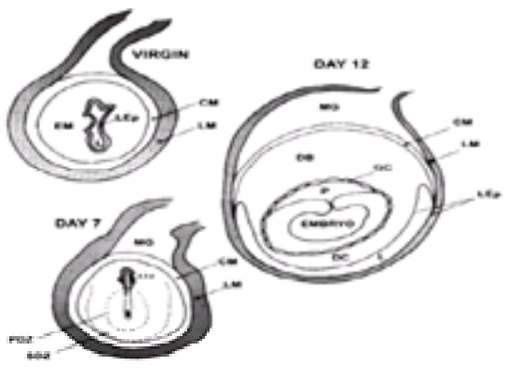

Figure 60.4. Schematic illustration of the cycling mouse uterus, postimplantation changes (gestation day 6) and arrangement of the uterus, placenta, and embryo at gestation day 12. A, amnion membrane; CM, circular muscle of the myometrium; DB, decidua basalis; DC, decidua capsularis; EM, endometrial stroma; GC, giant trophoblast cell layer of the placenta; L, uterine lumen; LEp, luminal epithelium; MG, metrial gland; P, placenta; PDZ, primary decidual zone; SDZ, secondary decidual zone; LM, longitudinal muscle. The position of the blastocyst within the lumen (day 6) and the embryo (day 12) are shown. (Adapted from Chen H-L, Kamath R, Pace JL, et al. Gestation-related expression of the interferon-g gene in mouse uterine and embryonic hematopoietic cells. *J Leuk Biol* 1994;55:617–625, with permission.)

Dramatic cyclic changes take place in the endometrium in response to ovarian steroid hormones circulating in the blood, that is, estrogens and progesterone. In general terms, estrogens drive cell proliferation during the first half of the cycle and progesterone production from the midpoint of the cycle onward supports implantation and pregnancy. Bulmer (55) systematically documented the specific types of leukocytes that populate the human endometrium during the menstrual cycle (Table 60.2). These leukocytes are likely to provide a measure of innate or natural protection against infectious disease and a limited degree of cell mediated immunity, but the uterus is not a major site of immune reactivity. Antibody in uterine secretions is derived mainly from blood, and the organ is refractory to stimulation of local immunity to sexually transmitted organisms (56,57).

Stage	Marker Expression[a]			
	CD45	CD56	CD3	CD14
Proliferative	160	85	75	52
Early secretory	190	95	80	52
Late secretory	325	190	75	80
Early pregnancy	320	250	60	120

[a] CD45 marks all leukocytes; CD56 marks natural killer lineage cells; CD3 marks T-lymphocytes; CD14 marks macrophages.

TABLE 60.2. Leukocytes in the cycling and early pregnant uterus (Mean Cell Numbers per Four High-Power Fields)

Implantation Site

Implantation takes place during the late proliferative phase (human) or estrus phase (mouse, rat) (Fig. 60.4, center panel). During the time of transit of the fertilized egg from the fallopian tube (also referred to as the *oviduct*) to the uterus, the uterine epithelium is altered into a receptive profile, which includes reduction of cilia on luminal epithelial cells, changes in the integrins and other cell-to-cell and cell-to-substratum adhesion molecules, and alterations in the secretory profiles of endometrial cells (58,59). The changed state is referred to as the *implantation window* and is temporary in nature.

Implantation has been termed a mild inflammatory reaction. When the blastocyst penetrates the endometrial epithelial cell lining, extensive tissue damage occurs that is readily identified by blood pools and leukocytic accumulations (Fig. 60.5). Importantly, examination of tissues by histologic techniques reveals no evidence of graft rejection at the normal implantation site or during the course of uneventful pregnancy. Although events are not clear at the early human maternal–fetal interface, which is difficult to obtain and study, experiments in mice show that inflammatory cytokines such as IL-1 and interferon-g (IFN-g) are produced (60,61). These are not only present at the interface but also circulate in the mother's blood, where they could affect systemic immunity. Following implantation, the uterine epithelium seals over the implant, which then is sequestered within the modified endometrium, now called the *decidua*.

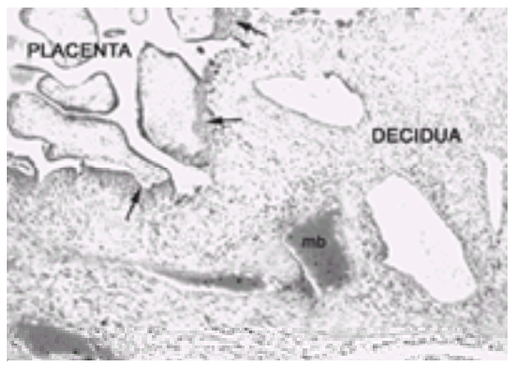

Figure 60.5. Histologic section of a gestation week 8 human placenta showing attachment and invasion of the decidua by extravillous trophoblast cells emerging from villi (*arrows*). Modified maternal arteries surrounded by fibrinoid maternal and containing pools of maternal blood (mb) mark the implantation site in the decidua. Stained with hematoxylin and eosin. Original magnification, ×100. (From the Boyd Collection, Department of Anatomy, Cambridge University, courtesy of G. Burton.) (See Color Figure 60.5.)

Growth and development of the embryo and extraembryonic membranes require many of the same factors as those used in the bone marrow to promote leukocyte maturation and development. These include both colony-stimulating factors and cytokines. One of the first examples of this overlap in function was colony-stimulating factor-1 (CSF-1), or macrophage CSF (M-CSF), which is produced at extraordinarily high levels in uterine epithelial cells during the periimplantation period in mice and in trophoblast cells in mice and humans (reviewed in 62). Both proinflammatory and antiinflammatory cytokines are present at early stages; tumor necrosis factor-a (TNF-a) is an example of the former (63), and TGF-b is an example of the latter (64). The specific functional roles of these powerful cytokines are as yet poorly documented but may well include programming placental cell growth and differentiation. TNF-a is, for example, known for its cell lineage-specific, differentiation-altering properties in the bone marrow (65,66).

TOLERANCE AND IMMUNE PRIVILEGE IN IMPLANTATION AND PREGNANCY

In the mid-twentieth century, immunologists were just beginning to understand the dimensions of transplantation and graft rejection. At this time, Medawar proposed the first set of potential explanations for the surprising willingness of mothers to tolerate genetically different tissues during pregnancy (67). His explanations included anatomic separation between the mother and fetus, antigenic immaturity of the fetus, and immunologic tolerance in the mother. Although the situation is considerably more complex than originally envisioned, it is now known that essentially all the explanations proposed by Medawar have an element of truth. Multiple mechanisms permit mothers to tolerate tissues expressing both self (maternal) and nonself (paternal) genes, and these include major accommodations and contributions from both the mother and the fetus (Fig. 60.6).

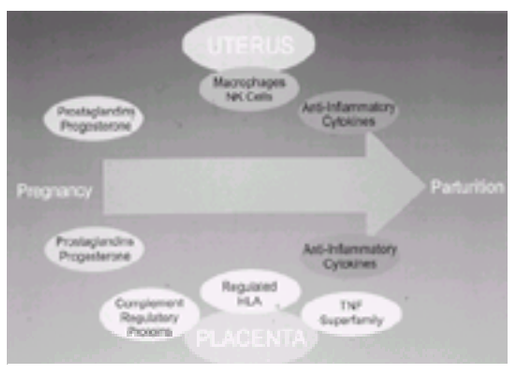

Figure 60.6. Schematic illustration of the progress of pregnancy toward parturition wherein maternal elements (uterus) and fetal elements (placenta) contribute to immunologic protection of the semiallogeneic fetus. NK, natural killer; HLA, human leukocyte antigens; TNF, tumor necrosis factor.

Maternal–Fetal Interface

Protection for the embryo against the maternal immune system components dedicated to ridding the host of foreign objects rests with the trophoblast layer. As illustrated schematically in Fig. 60.7, the inner cell mass from which the embryo proper develops is secluded beneath multiple layers of trophoblastic cells throughout pregnancy. These cells are derived from the external trophectoderm layer of the blastocyst. As illustrated in Fig. 60.8, one trophoblast subpopulation migrates into the decidua, where the cells are exposed to maternal leukocytes resident in this tissue. Later in pregnancy, these so-called extravillous cytotrophoblast cells form the chorion membrane. Another subpopulation syncytializes to form the outermost layer of the floating villi; this subpopulation is continually exposed to maternal blood leukocytes. New studies implicate the HERV-W endogenous retrovirus in syncytialization (68), and viruses also may play a role in the selection of certain human leukocyte antigen (HLA) class I genes for display by trophoblast (69).

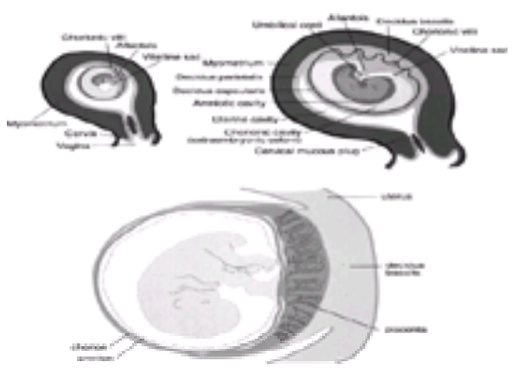

Figure 60.7. Schematic illustration of three stages of human pregnancy, from early implantation to late gestation. In the upper left-hand panel, the first trimester embryo resides in the uterus. In the upper right-hand panel, growth of the embryo and differentiation and development of both fetal and maternal structures have taken place in the second trimester. In the lower panel, the term fetus floats in amniotic fluid encased with the extraplacental membranes (chorion, amnion) and placenta. Note that at no time is the embryo/fetus directly exposed to maternal blood or tissues; the embryo/fetus is continuously secluded within a trophoblastic shell.

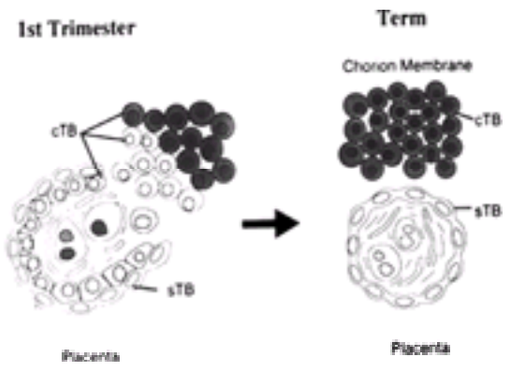

Figure 60.8. Schematic drawing of trophoblast subpopulations and their expression of membrane-bound human leukocyte antigen (HLA) class I molecules. Progenitor cytotrophoblast cells (cTB) merge to form syncytiotrophoblast (sTB) in the floating villi or proliferate and migrate in columns into the decidua to anchor the placenta and replace the endothelial cells of the maternal spiral arteries. Later in pregnancy, these migrating cells form the chorion membrane. Note that only these latter cells (*dark gray*) express membrane-bound HLA class I antigens.

The physical intimacy of fetal and maternal tissues during pregnancy raises the critical question of how protection against the maternal immune system might be provided. Several decades of study showed that multiple mechanisms have evolved that are contributed by both the mother and the extraembryonic tissues of the fetus (70,71). Some of the major systems are illustrated schematically in Fig. 60.6. Less emphasis has been placed on the reverse situation; the fetal immune system develops gradually and is unlikely to be capable of developing antimaternal immunity until mid to late pregnancy. For example, macrophages in the placenta do not express HLA class II antigens until the second trimester (72,73); so until that time, they are incapable of acting as fully effective APCs. The extent of the contributions of fetal immune mechanisms in relationship to maternal–fetal immunologic interactions remains to be explored in depth.

Uterine Privilege

Immune privilege in the pregnant uterus is provided by a number of mechanisms that are not operative in the cycling uterus.

Cellular Alterations in Pregnancy

A dramatic change in the relative proportions of uterine cells involved in innate and acquired immunity marks the first visible immunologic adjustment made in the mother to accommodate the semiallogeneic embryo. The invading fetal trophoblastic cells are met by vast numbers of natural killer (NK) cells and macrophages, which outnumber T- and B-lymphocytes (Table 60.2). The macrophages likely provide a measure of innate immunity to the decidua, as suggested in the early studies on mice (73). Functions of the uterine NK cells remain obscure; although they contain granzymes, TNF-a and perforin, knockout models fail to identify any major reproductive problems in the absence of these cytolytic molecules (74,75,76 and 77). Their major roles may be unique to pregnancy. For example, murine uterine NK cells appear to participate in both decidual and placental growth (77,78) as well as in development of blood lacunae around the placenta through production of nitric oxide (NO) (79). Some g/d T cells appear to be present, and there is evidence for a population of double-negative (DN, $CD4^-/CD8^-$) T-lymphocytes (80,81). The roles of these latter cells remain unclear; even though small in terms of absolute numbers, the cells could have critical functions.

Soluble Immunosuppressive Agents Progesterone, prostaglandins, and T-helper cell 2 (Th-2)-type cytokines.

Uterine immune privilege is provided in part by immunosuppressive molecules. Progesterone is the dominant hormone of pregnancy and has the ability, in high concentrations, to simulate corticosteroids, a well-known suppressor of immune responses. For example, progesterone inhibits the production of TNF-a mRNA and protein in macrophages (82,83). Other critical soluble modulators include prostaglandin E_2 from resident macrophages and decidual cells as well as antiinflammatory cytokines, such as IL-10. Wegmann and co-workers first proposed that pregnancy is a Th2 phenomenon (84), and studies in mice confirm that high levels of Th2-type cytokines are typical of pregnancy (61). Because Th2-type cytokines drive antibody-mediated responses in preference to cell-mediated immune responses, the cytokines probably account for the systemic bias in mothers favoring antibody production. This condition of pregnancy has a major impact on women with preexisting autoimmune disease, exacerbating some, such as systemic lupus erythematosus, and alleviating others, such as rheumatoid arthritis (85).

Placental Privilege

The placenta and its attached membranes, which interface directly with maternal blood and tissues, have a remarkable ability to protect themselves from maternal immune cell attack. The mechanisms utilized by trophoblast cells vary with their state of differentiation and anatomic location. As mentioned, it is this unique cell type that protects the embryo and components of the extraembryonic membranes derived from the inner cell mass. As illustrated in Fig. 60.6, multiple devices are used by these tissues to avoid maternal immune cells and antibody cytotoxicity.

Protection Against Cell-Mediated Immune Attack: Membrane-Bound Placental Molecules [HLA, indoleamine 2,3-dioxygenase (IDO), TNF superfamily]

Regarding prevention of immune cell attack, perhaps the best studied of the mechanisms is control of expression of the major histocompatibility antigens. In human placentas, extravillous trophoblast cells migrating into the decidua express a unique pattern of class I HLA, with HLA-G, HLA-E, and HLA-C predominating (86,87). Figure 60.9 shows HLA-G protein and mRNA in these cells. The HLA-G and -E antigens encoded by these genes, which have few alleles in comparison with HLA-A, HLA-B, appear to interact with uterine NK cell and possibly also uterine macrophage inhibitory receptors, which include CD94/NGK2A, ILT2, and immunoglobulin-like transcript 4 (ILT4) (88). Class I antigens on trophoblast also interact with TCRs on $CD8^+$ cells (89). Based on interactions in other contexts, the consequences probably include activation of killer inhibitory pathways in NK cells and macrophages and possibly death of $CD8^+$ T cells because of activation of the Fas/Fas ligand programmed cell death pathway by soluble HLA class I antigens (90,91).

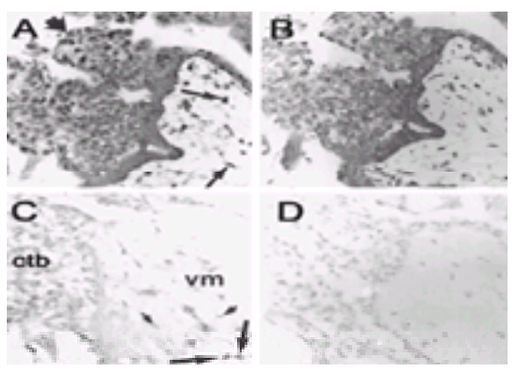

Figure 60.9. *In situ* hybridization and immunohistochemical staining demonstrate that human leukocyte antigen-G (HLA-G) mRNA and protein are present in discrete populations of cells in first-trimester placentas. **A**: HLA-G mRNA is evident in migrating trophoblast cells (*large arrow*) as well as macrophage-like villous stromal cells (*smaller arrows*). **B**: A sense version of the HLA-G probe does not hybridize to placental tissues. **C**: HLA-G protein is identified using the mouse monoclonal antibody, 87G, specific for HLA-G1. Signal is present in migrating cytotrophoblast cells (ctb) and in some villous mesenchymal cells (vm). **D**: The immunostaining control is negative. Paraformaldehyde-fixed tissue was used for (A,B), and flash frozen, acetone-fixed tissue was used for (C,D). Original magnifications: ×250. (See Color Figure 60.9.)

In contrast to the migrating extravillous cells, syncytiotrophoblast forming the outermost layer of the placental floating villi, which is exposed to maternal blood, seems to express no membrane-bound HLA class I antigens, although there is evidence for class I message and for the presence of soluble class I antigens in this layer early in pregnancy (92,93). Syncytiotrophoblast in term placentas lacks HLA class I mRNA (94), and this is reflected in a lack of membrane-bound HLA class I protein (86,87). None of the subpopulations of trophoblast cells expresses HLA class II antigens *in vivo*, which may be due to the trophoblast-specific repressor of gene expression

identified by Murphy and Tomasi (95). Thus, the overall pattern in trophoblast is of strict control over the expression of genes that could encode potentially dangerous, paternally derived foreign MHC (HLA-A, -B, -D). This is accompanied by expression of antigens that effectively prevent killing by cells of the innate immune system (HLA-G, -E).

Recent experiments in mice suggest that a second mechanism preventing attack on trophoblast by maternal T-lymphocytes is expression of an inhibitor of tryptophan metabolism, IDO in trophoblast cells. T-lymphocytes require tryptophan and in its absence are inactivated. Studies by Munn et al. point to a role for this system in protection of early mouse trophoblast and suggest that there is an MHC-related aspect (96).

Apoptosis-inducing members of the TNF supergene family also may have an important role in protecting the placenta and its membranes from killing by maternal immune cells. The ligands identified in or on human trophoblast cells include TNFa, Fas ligand, and TNF-related apoptosis-inducing ligand (TRAIL) (97). TRAIL localization to the syncytiotrophoblast microvillous membrane in early human pregnancy is shown in Fig. 60.10. These powerful molecules, which are expressed in both membrane and soluble forms, could kill activated immune cells that bind to trophoblast by transducing an apoptotic signal through specific receptors on activated leukocytes, as is the case in other immune privileged organs, such as the eye (98). Studies in mice suggest that FasL may be of particular importance (99), with trophoblast cell FasL preventing maternal immune cell attack on the placenta by interacting with leukocyte receptors (Fig. 60.11). These include TNF-R1, Fas, and the TRAIL apoptosis-inducing receptors, DR4 and DR5. Evidence for this active, aggressive pathway in placentas is not strong at present, but the placenta is clearly protected from the reciprocal pathway. Killing of placenta cells is abrogated by synthesis of soluble receptors (TNF), exhibition of nonfunctional receptors (Fas), and expression of decoy receptors (TRAIL DcR1) (100,101 and 102).

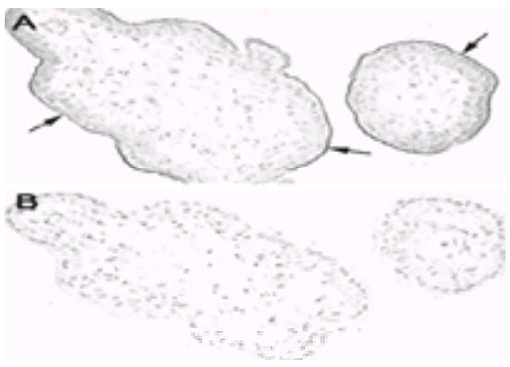

Figure 60.10. Immunohistochemical stain shows that TNF-related apoptosis-inducing ligand (TRAIL), a member of the tumor necrosis factor (TNF) supergene family, is localized to the microvillous membrane of early human early syncytiotrophoblast (*arrows*).

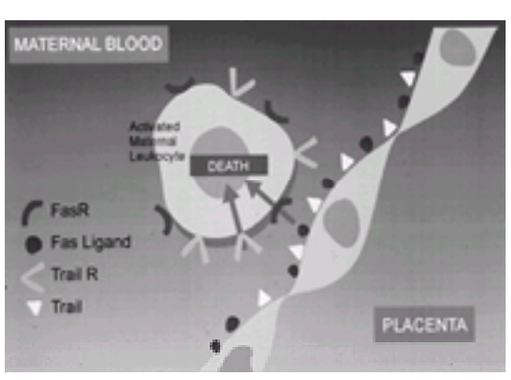

Figure 60.11. Schematic drawing of a potential pathway by which two tumor necrosis factor (TNF) superfamily molecules, FasL and TRAIL, could protect placentas from leukocyte toxicity. The two ligands, when expressed on trophoblast, could interact with specific receptors on leukocytes and transduce apoptosis-inducing signals, resulting in death of the leukocyte.

Protection Against Cell-Mediated Immune Attack: Soluble Immunomodulators

In placentas, as in pregnant uteri, immune privilege is also conferred by immunosuppressive molecules. For example, production of progesterone, prostaglandin E_2, and antiinflammatory cytokines, such as IL-10 and IL-4, characterize the human placenta (103,104,105,106,107 and 108). Production of antiinflammatory cytokines by placental cells may be driven by progesterone, as is the case with lymphocytes (109). IL-10 may have an additional role, that is, stimulation of production of HLA-G (110). As in the uterus, Th1-type cytokines also are produced; these appear to have major roles in (a) the initial event of implantation, (b) immune privilege throughout pregnancy, (c) differentiation and development of the placenta, and (d) parturition.

Protection against Cytotoxic Antibodies

Trophoblast is noted for its extremely high expression of the complement regulatory proteins, that is, CD46 (membrane cofactor protein, MCP), decay-accelerating factor (DAF), and CD59 (111). This system is believed to be of critical importance; mothers routinely produce high titers of antibodies to paternally derived HLA and unique trophoblast antigens such as placental alkaline phosphatase. Figure 60.12 shows that two of these molecules, CD46 and DAF, are differentially distributed in trophoblast subpopulations in first-trimester placentas, and are well positioned to prevent complement-mediated lysis. A study in gene-deleted mice showed that, in the absence of the complement regulatory protein encoded by the *Crry* gene, complement is deposited in the placenta and a major inflammatory reaction results in placental disruption and fetal demise (112). This constitutes the first direct evidence supporting a role for this family of proteins in placental immune privilege.

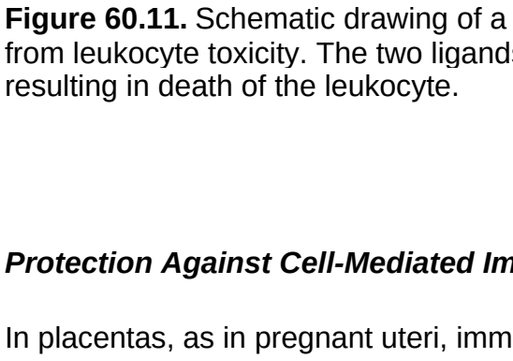

Figure 60.12. Immunohistochemical staining of human first-trimester placentas for membrane cofactor protein (MCP, CD46) and decay accelerating factor (DAF, CD55). Note that both these complement regulatory proteins are expressed but are differentially located, with MCP being prominent on villous cytotrophoblast (left panel, *arrows*) and DAF being prominent on migrating cytotrophoblast cells (right panel, *arrows*). Original magnifications: ×250. (See Color Figure 60.12.)

Type of Placentation and Immune Responses

The systems described here seem to have developed slowly during the course of evolution. It is generally held that the more extensive the invasion of the uterus by placental cells, which is great in humans, less vigorous in rodents, and not a feature of the horse implantation site, the more sophisticated, restrictive, and diverse are

the mechanisms developed to provide protection to the embryo from elements of the host (maternal) immune response.

Antibody Transport into the Fetus

Many maternal antibodies reach the fetal blood circulation, where they constitute the major immunologic protection of the infant up to the age of 6 months. IgG antibodies are routinely transported across the syncytiotrophoblast via a specific class I–like molecule, the neonatal FcR (113,114), and into the stromal of the placenta, which is contiguous with the cord and embryo. Stromal cells and ultimately the embryo itself are protected from potentially harmful maternal antipaternal IgG antibodies by the placental macrophages known as *Hofbauer cells*, which ingest immune complexes (115). When the antibody load is excessive, as is the case in hemolytic disease of the newborn due to anti-Rh and other erythrocyte antibodies, the placenta is overburdened. Harmful antibodies reach the fetal circulation, and damage to fetal cells ensues. These destructive antibodies are likely to employ the same pathway from mother to fetus via syncytiotrophoblast transport, diffusion through the placental villous stroma, and transport across the fetal capillary endothelium (116) that is used by the beneficial antibodies.

Maternal Systemic Immune Responses

The question of whether mothers are immune compromised in a systemic sense has been difficult to resolve; however, the consensus of considerable experimentation is that there is little or no generalized depression of immune responses in pregnancy. Instead, selective suppression may occur. As discussed, Th2 cytokines circulate in mothers and maternal production of antibodies remains intact; multiparous women are excellent sources of antibodies to paternal HLA. Yet there is evidence that maternal B-lymphocytes specific for paternal HLA are partially deleted during pregnancy (117). Similarly, T-lymphocytes specific for paternal HLA are difficult to demonstrate (118). Experiments in transgenic mice suggest that pregnancy selectively depresses maternal T cells recognizing paternal H-2 class I (119). This suppression in pregnancy extends protection to tumors of the same haplotype as the embryo but not to tumors of other haplotypes.

Mothers harbor circulating trophoblast cells for as long as 27 years (120,121). It has been shown that some of these cells localize to lesions in scleroderma, suggesting that certain “autoimmune” diseases may have an alloimmune basis (122).

IMMUNOLOGIC BASIS OF INFERTILITY: GONADS AND GAMETES

Basic research on autoimmunity has generally outpaced our understanding of clinical autoimmune disease. Human ovarian and testicular autoimmune diseases remain incompletely defined with respect to prevalence, mechanism, diagnosis, and treatment. On the other hand, the clinical relevance of experimental models for most autoimmune diseases has not been firmly established. Nevertheless, research based on models of experimental autoimmune disease of the gonads has contributed significantly to the overall concepts of autoimmune disease pathogenesis and prevention.

Autoimmune Disorders in the Ovary: Clinical and Experimental Conditions

Autoimmune disorder in the ovary (AOD) is a known cause of human premature ovarian failure and is also a component in the different forms of autoimmune polyendocrinopathy (123,124). The diagnosis of human AOD depends on the detection of serum autoantibodies to ovarian antigens and, in rare ovarian biopsies, the histologic finding of noninfectious inflammation (reviewed in 125). The most commonly detected autoantibodies react with steroid-producing cells common to ovaries, placenta, adrenal, and testis, with the P_{450} side-chain cleavage enzyme and the 17a-hydroxyl enzyme as candidate antigenic molecules (126,127). Indirect immunofluorescence studies also detect antibodies to oocyte cytoplasm and the ZP (128). The clinical diagnosis of AOD is often elusive, however, because of the paucity of ovarian immunopathologic data and the uncertainties associated with the method and target antigens for measurement of autoantibody and autoreactive T-cell responses. As a result, the true prevalence of immunologic human premature ovarian failure has not been defined.

Pathogenesis

The pathogenesis of AOD has been investigated in several murine models (Table 60.1). Two of these are particularly informative: (a) AOD induced by immunization with a murine ZP3 peptide (pZP3) that contains both T-cell epitopes and a native B-cell epitope (1), and (b) AOD that develops spontaneously in mice thymectomized between days 1 and 4 after birth, usually on day 3 (14). This model is referred to as D3TX. Figure 60.13 summarizes the recent findings and presents a working hypothesis for mechanisms underlying the pathogenesis of murine AOD.

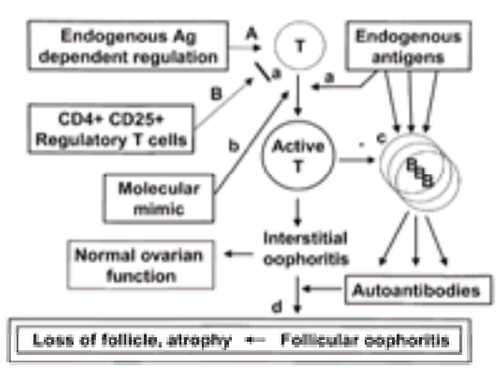

Figure 60.13. Proposed mechanisms for autoimmune disease prevention and induction based on studies of murine autoimmune ovarian disease (AOD). In the pathway marked (**A**), persistent endogenous antigen is required for maintenance of tolerance to oocyte antigen. The pathway marked (**B**) illustrates one known tolerogenic mechanism where $CD25^+$ regulatory T cells play a central role. Disease may occur when (a) the $CD25^+$ T cells are depleted, which permits endogenous antigens to stimulate a pathogenic T cell response; (b) T cells are stimulated by nonovarian peptides that mimic ovarian peptides; (c) autoreactive B cells are rapidly stimulated by endogenous antigen to produce autoantibodies to the ZP3 antigen; (d) antibody binds to the zona pellucida and T cells are retargeted, leading to ovarian atrophy. In the absence of autoantibodies, T-cell reactivity does not interfere with normal ovarian function.

Autoimmune disorder of the ovaries is induced when regulatory $CD25^+$ T cells are depleted by D3TX. In these mice, endogenous ovarian antigens spontaneously stimulate pathogenic T-cell responses within 2 to 3 weeks, and this leads to ovarian inflammation, followed rapidly by ovarian atrophy and development of oocyte antibodies. AOD also can be induced by stimulation by exogenous antigens through the mechanism of T-cell epitope molecular mimicry. Thus, immunization with foreign or unrelated self-peptides with partial sharing of amino acid residues appears critical for T-cell induction, which can occur commonly; of 16 randomly selected nonovarian peptides, 44% induced AOD (129,130). At least one infectious agent has been implicated in the pathogenesis of AOD. The enteric nematode (the rodent pinworm) operates as a cofactor and, together with a nonimmunogenic form of ovarian pZP3, elicits AOD in neonatal mice. Infected mice are imprinted with long-term memory for the autoantigen and mount a rapid and intense autoimmune response when challenged at a later date (131). Although most pathogenic T cells that elicit AOD belong to the Th1 $CD4^+$ subset, there is evidence that Th2 $CD4^+$ T cells also elicit AOD and result in eosinophilic oophoritis. In pinworm-infected mice, autoreactive T cells produce IL-4 and IL-5 but not IFN-g, and the ovaries are infiltrated by numerous eosinophils (131). Human ovarian inflammation with dominant eosinophilic inflammation also has been reported (132).

An unexpected mechanism of autoantibody induction and an unexpected action of autoantibody in tissue inflammation were uncovered during the study of murine AOD induced by pZP3 (Fig. 60.13). Ovarian antibodies are stimulated spontaneously and rapidly by endogenous ovarian antigens in mice where T cells for ovarian antigen have been activated (133,134). Thus, mice immunized with a pZP3, which lacks native B-cell epitopes, develop IgG ZP3 antibodies that recognize distant B-cell epitopes of ZP3, and the antibodies do not cross-react with the pZP3 immunogen. The antibody response is abrogated in mice with ovarian ablation. Thus, autoreactive B cells to ovarian antigens are not tolerized but are primed by endogenous antigens. This discovery, made in parallel with studies on diversification of autoantibody responses to lupus autoantigens, provides the critical evidence that endogenous antigens can drive a diversified antibody response. Although ZP antibodies do not cause AOD, they strongly influence the distribution of AOD induced by $CD4^+$ T cells. As mentioned earlier, atretic follicles in the ovarian interstitial space are the prime targets for pathogenic T cells. Although T cell-mediated interstitial oophoritis may be severe, its occurrence is compatible with normal ovarian function (Fig. 60.1B) (7). When ZP antibody is also present, the T cell-mediated inflammation is retargeted or shifted to the ovarian follicles, leading to ovarian atrophy (Fig. 60.1A,C) (8). Finally, the critical costimulatory molecules required for pZP3 T-cell activation and AOD induction have been identified; both CD28 and CD40 ligand pathways are required and sufficient for pZP3 pathogenic T- and B-cell activation (135).

In yet another approach to studying the pathogenesis of AOD, disease-associated genetic loci were mapped and their mechanisms elucidated. Studies on genetic loci that influence AOD induced by D3TX have uncovered six non-H2 chromosomal loci associated with ovarian inflammation, autoantibody induction, and ovarian atrophy

(Table 60.3) (136,137, Roper et al., in preparation).

Locus	Phenotype	Chromosome (cM)[a]	Colocalization[b]

Autoimmune Disorders in the Testis: Clinical and Experimental Conditions

Immunopathology

Male infertility can result from autoimmune disease that affects the testis or its excurrent ducts. Spontaneous autoimmune orchitis has been reported in spontaneously infertile animals, including mink, dogs, and rats (31,139). Some human testicular diseases have immunopathologic features that resemble the testicular changes of autoimmune orchitis of the infertile mink. They include (a) granulomatous orchitis of noninfectious basis that presents as enlarged testis, a differential diagnosis of testicular tumor (140); and (b) aspermatogenesis without orchitis in testis with local immune complexes (34). Epididymal granulomas of noninfectious origin also may have an autoimmune basis (reviewed in 125).

Model System and EAO Development

As in AOD, there are many murine models of EAO (Table 60.1). EAO can be induced by immunization with testis antigen, including the testis-specific isoform of hyaluronidase (PH20), or it can occur spontaneously following D3TX (Table 60.1) (22,141). In addition, vasectomy leads to autoimmune responses to spermatozoa in human and animals, and EAO is a known complication of vasectomy in the guinea pig and rabbit (35,36). Cloned T cells that transfer EAO are predominantly of the Th1 type, and passive transfer of EAO by Th1 cell clones is largely ameliorated by neutralizing antibody to TNF-a (44). T cell transfer results in testicular inflammation that is initiated in a unique region, the straight tubules, blocking the outflow of sperm and fluids from the seminiferous tubules (Fig. 60.3) (9). In contrast, EAO induced by active immunization of testis antigen in adjuvant results in diffuse EAO that affects the seminiferous tubules and the straight tubules equally. Thus the differential permeability of the blood–testis barrier dictates the distribution of EAO within the target organ.

A major question is how inflammation, which initiates in the testis interstitium, overcomes immune privilege and bypasses the blood–testis barrier. EAO is induced by immunization with testis antigen in adjuvant (23). Following injection of testis antigen and adjuvant (or adjuvant alone), and before the onset of EAO, there is a dramatic accumulation of MHC class II–positive, F4/80-positive cells in the interstitium. Thus, recruitment or activation of local APC to the testis, including macrophages and dendritic cells, occurs in response to adjuvants. The relevance of this finding to EAO is supported by an *in vitro* study on Sertoli cell responses to cytokines (142). When puberal Sertoli cells are stimulated by TNF-a, they express intercellular adhesion molecule-1 (ICAM-1), become more adhesive to T cells, and secrete the proinflammatory cytokine IL-6. It is therefore possible that, in response to cytokines produced in the testis microenvironment, activated macrophages that are induced or recruited into the testis interstitium may provide the proinflammatory cytokines that can alter integrity of the blood–testis barrier and direct the antigen specific T cells to the boundary of the tubules. This leaves unanswered the question of the location and nature of the APCs and the source of the germ cell peptide. In addition to macrophages, other testicular cells also produce TNF-a and IFN-g (143,144). Thus, once tissue injury has occurred, endogenous proinflammatory cytokines may propagate the inflammatory destruction in EAO. The intrinsic testis cytokines may be perhaps of greater relevance in murine EAO induced by testis cell injection without adjuvant (20) (Table 60.1).

Genetic Components

Genetic analysis of inbred mouse strains indicates that the susceptibility or resistance to EAO is strongly influenced by both H2 and non-H2 genetic loci. As shown in Table 60.3, nine chromosomal regions have been linked to EAO. As in the case of the *aod* gene loci, many of the *eao* loci are found in chromosomal regions that govern the susceptibility to other autoimmune diseases, such as experimental autoimmune encephalomyelitis and insulin-dependent diabetes of the nonobese diabetic (NOD) mice.

AUTOIMMUNE AND ALLOIMMUNE RESPONSES TO SPERM

Male and female infertility may result from antibody to sperm-specific antigens, and the response may originate in either the male or the female reproductive tract. Sperm antibodies have been reported in patients with cystic fibrosis, and development of antibodies follows vasectomy, testicular trauma, torsion, biopsy, tumor, and infection (145,146,147,148,149 and 150). Most sperm antibodies, however, are detected without associated abnormalities in the reproductive tract. In these idiopathic cases, the trigger of the immune response to sperm is not known. It has been postulated that defective local immunoregulatory mechanisms in the male or female reproductive tract may be important.

Despite many years of research, a direct link between antisperm antibody and male or female infertility has not been conclusively established. Most research effort has been devoted to develop reliable methods for sperm autoantibody detection. Popular methods include the mixed agglutination reaction (151) and immunobead assays (152). It has been reported that altered semen quality is more frequent when both IgM and IgG antibodies are detected and less frequent when IgG alone is present (153). Retrospective analysis suggests that a low fertilization rate may be associated with sperm decorated with combined IgA and IgG head-bound antibodies (154,155). Antisperm antibodies may impede sperm penetration of the cervical mucus in the postcoital test, where the number and motility of sperm within the cervical mucus are evaluated 8 to 12 hours after sexual intercourse (156). Antibodies also may alter and affect various stages of sperm–egg fusion (157), including the acrosome reaction (139,158,159), ZP binding (160,161 and 162), oocyte fusion (32,163,164,165,166 and 167), and early cleavage of fertilized oocytes (168). Although medical treatment of infertility associated with sperm antibodies is not satisfactory at present, some successes have been reported with the use of assisted reproduction techniques (169).

Research on contraceptive vaccines has driven new efforts to identify functional sperm and oocyte antigens involved in fertilization events. Complete infertility has been documented in female guinea pigs immunized with the testis isoform of hyaluronidase, PH20 (170). Significant reduction of fertility has been observed in female mice injected with a chimeric peptide that contains a B-cell epitope of mouse ZP3 (171,172). Additional sperm antigens that conferred significant infertility in female mice also included the testis-specific LDH-C4 (173) and SP17 (174). In addition, many potentially important human and animal sperm and oocyte molecules have been identified by means of serum antibody from infertile patients or with monoclonal antibodies that affect fertilization events (175,176).Therefore, research on a contraceptive vaccine based on sperm and oocyte antigens will help to determine their relevance in fertilization events and therefore their role in human infertility.

IMMUNE FACTORS IN EARLY PREGNANCY TERMINATION

The preimplantation human blastocyst produces chorionic gonadotropin (hCG), which facilitates the identification of potential pregnancy. Using this biochemical marker and sensitive assays, it has become clear that perhaps as many as 50% of potential pregnancies are lost prior to or during implantation (177). Whether any of these losses can be accurately referred to as “immunologic,” that is, based on maternal recognition and rejection of normal embryos expressing foreign (paternal) antigens, is problematic, and cause and effect relationships are unclear.

Implantation and Maternal Immunorejection

In mothers who spontaneously abort their fetuses, Th1 rather than the expected Th2-type cytokines are produced when their blood mononuclear cells are incubated

with preparations made from tumor-derived trophoblast cell lines (178). In inbred mice, macrophages producing high levels of NO flood into resorption sites (179). These observations support the idea that some mothers perceive embryos as foreign and mount immune rejection responses. If the blastocyst is fully adequate and intact, however, the embryo should be entirely protected from trophoblasts using the mechanisms described previously. If the blastocyst is genetically deformed and not fully intact, the mother might perceive exposed paternally derived antigens and mount a graft rejection response. In cases of recurrent abortion, a secondary immune response would be expected to cause early rejection. Alternatively, some mothers may lack essential components of the networks that provide immunologic protection to the embryos, such as appropriate expression of complement regulatory proteins, apoptosis-inducing TNF superfamily members, and HLA-G or -E. These and other aspects of infertility remain poorly explored.

Infection

The periimplantation period is the time at which interruption of pregnancy is most common. Yet pregnancy still may be disrupted by various physiological conditions. Infection of the decidua and membranes appears to be one of the most disastrous situations, although vaginosis is also common (180,181). The pathways leading from infection to preterm labor are not fully understood, but clearly involve immune mechanisms and cells. Chemotactic substances such as IL-8 are produced, and both neutrophils and macrophages swarm into infected membranes. In many cases, lipopolysaccharides (LPS) from Gram negative bacteria activate the leukocytes, leading to further inflammation, production of prostaglandins and other potent modulatory substances such as TNF-a. The sum of these interactions is stimulation of a cascade that culminates in myometrial contractions and the induction of labor. A major therapeutic tool in these situations is the administration of glucocorticoids to the mother.

Recurrent Pregnancy Loss and Leukocyte Immunization

Based on early clinical results (182), some fertility specialists are committed to immunizing potential mothers with paternal or third-party leukocytes as a means for improving reproductive success. This strategy developed because homozygosity within couples, particularly at some HLA loci, is associated with reduced fertility (183,184), and some researchers thought that leukocyte immunization would introduce a needed measure of immune recognition and stimulation. A multicenter study showed conclusively that leukocyte immunization is not effective and strongly suggested that reproductive outcomes might be worsened rather than improved (185).

SUMMARY AND FUTURE PERSPECTIVES

The complexity of the reproductive process results in multiple points at which immunologic factors might impinge on reproductive success (Table 60.4). These range from potential recognition of secluded gamete antigens to overwhelming cytokine responses in infections. Information emerging from studies on specific aspects of immunity have permitted recognition and dissection of many of these factors and can be expected to yield further insights in the future. Conversely, the situation of pregnancy, where the immune system is diverted for the benefit of diversity, has permitted a better understanding of several aspects of transplantation and tumor immunology.

Disorder	Potential Causes
In situ loss of gametes	Autoimmune disease (recognition of unique gamete antigens)
Destruction of sperm	Alloimmune recognition in the uterus by maternal immune system
Implantation failure	Inappropriate expression of HLA on trophoblast
	Lack of production of IDO (tryptophan inhibitor) in trophoblast
	Inappropriate expression of complement regulatory proteins
	Incorrect balance of Th1- and Th2-type cytokines
	Inadequate progesterone to drive Th2 response
Preeclampsia	Lack of production of IL-10 and/or HLA-G
	TNF-2 allele producing excessive TNF-a
IUGR	Lack of nitric oxide
Immunorejection	Defective or deficient complement regulatory proteins
	Aberrant expression of TNF superfamily ligands/receptors
Premature labor	Infection and excessive Th1-type cytokines, prostaglandins
Scleroderma	Residual trophoblast in mothers

HLA, human leukocyte antigen; IDO, indoleamine 2,3-dioxygenase; IL-10, interleukin-10; IUGR, intrauterine growth retardation; Th-1, T-helper cell type 1; Th-2, T-helper cell type 2; TNF, tumor necrosis factor.

TABLE 60.4. Disorders of Fertility Associated with Immunologic Factors

Fertility remains suboptimal in the general population. Although many pregnancy losses are attributable to genetically incorrect fetuses, others result from inappropriate or inadequate measures to protect the fetus in either the embryo/fetus or the mother. As subtle features of the immune system are elucidated, it is reasonable to expect application to this problem and improvement in fertility rates and the overall success in pregnancy.

ACKNOWLEDGMENT *Studies in the Kansas City laboratory are supported by grants from the National Institutes of Health to J.S.H. (HD24212, HD26429, HD29156, AI38502, HD35859), the Kansas P30 Reproductive Sciences Center (HD33994), and the Kansas Mental Retardation Research Center (HD02528). Studies in the Charlottesville laboratory are supported by grants from the National Institutes of Health to K.S.K.T. (AI41326, AI10298, HD29099, AR45222) and the Cell Science Core of HD28934. We thank the numerous trainees and technical assistants who have contributed to the studies presented here, and we are indebted to J.S. Platt for preparation of the figures.*

61 ALLERGENS

Judith A. Woodfolk, M.D., Ph.D., and Thomas A.E. Platts-Mills, M.D., Ph.D.

In 1873 Charles Blackley (26) published *Researches on Cattarhus Aestivus*, which established that grass pollen was the cause of hay fever in England. At the same time, Wyman (286) demonstrated the association between ragweed pollen and hay fever that occurs during late summer in the United States. Blackley introduced skin tests, pollen counts, and nasal and bronchial challenges; but perhaps most important, he demonstrated that patients with positive wheal-and-flare skin tests to pollen extracts developed symptoms at that time of the year when grass pollen grains were airborne. Thirty years later Noon (156), convinced erroneously that pollen caused symptoms because it was toxic, started immunizing patients with pollen extracts and reported the first successful trial of desensitization. Over the next 30-year period, a series of enthusiasts applied skin testing and desensitization injections to many allergens and diseases. Studies on these extracts established that most allergens were proteins, although the activity in grass pollen extracts was so heat stable that some authors initially thought the allergens could not be proteins.

During the early twentieth century, antibodies were generally demonstrated by precipitin reactions, and sera from patients with hay fever did not give rise to precipitin reactions with extracts of the relevant pollen. This led to the erroneous description “supersensitivity without immunity” (265). That the serum of allergic patients contained a specific active substance was first demonstrated by Prausnitz and Küstner in 1921 (190). They showed that local injection of serum from a person who was allergic to fish (Küstner) could passively transfer wheal-and-flare skin sensitivity to a nonallergic individual (Prausnitz). This P-K test was used extensively to establish the specificity of the response to allergens. However, the nature of the active substance (or reagin) remained unclear. In 1935 Cooke et al. (49) demonstrated that patients treated with desensitization injections develop neutralizing antibodies in their serum in addition to the P-K activity.

Further progress in understanding allergens and the immune response to them did not come until the 1960s when modern immunochemistry made possible both the purification of allergens and the purification of immunoglobulin E (IgE). First, King (119) purified ragweed antigen E (now Amb a 1), and then Marsh (137) purified rye grass allergen I, rye I (now Lol p 1). The terminology for purified allergens was established by an International Union of Immunologic Societies (IUIS) subcommittee report: each allergen is assigned the first three letters of the genus, followed by the first letter of the species (not italicized) and an arabic number for the order of purification (121,138). Thus Fel d 1 was the first allergen purified from the domestic cat, *Felis domesticus*. In 1966 Ishizaka et al. (105) proved that the active factor in serum was a novel class of immunoglobulin, IgE, and went on to establish that IgE binds to a specific high-affinity receptor on mast cells and basophils (104). These studies proved that the “toxicity” of allergens was directly attributable to their interaction with specific antibody, which in turn triggers the release of histamine and other mediators from mast cells and basophils. Crude extracts of allergens contain many different proteins as well as low-molecular-weight substances that may irritate the skin or cause symptoms when inhaled. Furthermore, many proteins may have biologic activities that influence the immune response. However, most purified allergens have no effect on the skin, nose, or lungs of nonallergic individuals (119,137,172). The purification of IgE led to the production of anti-IgE and the development of the radioallergosorbent test (RAST) by Wide et al. (275). It also became possible to radiolabel allergens and, with double-antibody assays, to study further the immune response in allergic individuals (171,181). As the assays improved, it became clear that patients with immediate hypersensitivity have serum IgG antibodies, nasal IgG and IgA antibodies, and serum IgE antibodies. Some nonallergic individuals have IgG antibodies, but most have no antibody response to allergens (172). This conclusion led to a general view of allergy as a state of enhanced immune responsiveness such that repeated low-dose exposure (usually by the inhaled route) produces an immune response that includes local IgA antibodies as well as serum IgG and IgE antibodies. Thus an allergen is an otherwise benign protein that commonly gives rise to IgE responses in individuals who are genetically predisposed. In practice, most allergens are soluble proteins that are repeatedly inhaled because they become airborne either outside or indoors.

OUTDOOR ALLERGENS

Pollen Grains

Most flowering plants are fertilized by pollen grains landing on the stigma and triggering the production of a pollen tube. This process is rapid, is absolutely specific, and depends on the fact that all pollen grains rapidly release species-specific proteins. The plants can be broadly divided into those that are wind pollinated and those that are insect pollinated. The wind-pollinated plants release large numbers of pollen grains, which can float for miles (Table 61.1). In contrast, the insect-pollinated plants (e.g., roses, tulips, magnolia trees) produce relatively few grains, and these grains are generally not found in the air. Some pollens are released but are so large (larger than 40 µm) that they remain airborne for only a short time (e.g., the pollens of the Virginia pine and most cereal crops). Most important wind-borne pollens are 20 to 30 µm in diameter and have a surface that is specifically designed to help them remain airborne (Fig. 61.1). Thus the number of pollen grains airborne is influenced by the number of plants, the number of grains released, and their aerodynamic properties. In most areas where these factors have been studied, there is a good correlation between the number of pollen grains that become airborne and their importance as causes of sensitization and seasonal hay fever. Grass pollen is the most common outdoor pollen and the dominant cause of hay fever in northern California, New Zealand, England, and many other countries. In Sweden the highest pollen count by far is from birch trees, which is the primary cause of hay fever there (19,264).

TABLE 61.1. Major Sources of Pollen Associated with Hay Fever

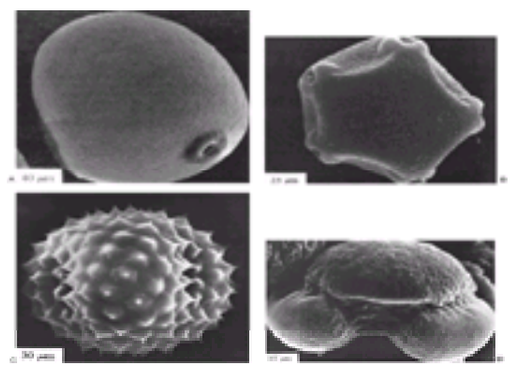

Figure 61.1. Scanning electron micrograph of pollen grains showing pores and overall size.

In the United States, there are dramatic regional and seasonal variations. In much of the Midwest and East Coast, short ragweed is the most common airborne pollen during the fall season and the most common cause of hay fever (159). In the Rocky Mountains and the Southwest, mountain cedar and the chenopod amaranth group are the major sources of pollen and the most important causes of symptoms. Release of pollen from a wind-pollinated plant varies from day to day and during the day. The main factor influencing release appears to be decreasing relative humidity (for ragweed, 70% or less). Therefore most plants release the largest quantity of pollen during the early morning on sunny days, but this release is delayed by mist, clouds, or rain. The pollen seasons for various plants vary dramatically in different parts of the country (223,279). The trees and grasses generally pollinate in the spring or early summer; and the farther south they are geographically, the earlier pollination occurs. By contrast, many of the summer-flowering weeds, including ragweed, pollinate slightly later in the South.

The seasons for most plants are based more on changes in the length of the day than on temperature (223,279). The release of allergens from pollen grains has been studied in detail for ragweed, grass, and birch (19,137). In each case, release is rapid, although the rate may be slower for some proteins. Estimates of the quantity of major allergen in grass, ragweed, or tree pollens are generally close to 0.5 ng per grain (137). Thus a pollen grain can be seen as ideally designed to deliver proteins to the nasal mucosa, and the most important plants are those that release a large number of pollen grains that remain airborne.

Fungal Spores

Fungal spores are released by many varieties of fungi and are often present in the air in large numbers (i.e., more than 1,000/m^3) (Table 61.2). Fungal spores vary in size from about 2 µm in diameter (e.g., *Penicillium*or *Aspergillus*spp.) to about 20 µm in length (e.g., *Alternaria*spp.) (30,220). Spores of 2-µm diameter have a volume about 1/1,000 that of a pollen grain, which is 20 µm in diameter. The biologic role of a spore is as a seed, designed to germinate when the conditions are optimal (Fig. 61.2). Spores have no need to release proteins rapidly and indeed are commonly protected by a waterproof shell. Spores of *Aspergillus fumigatus*do not contain measurable quantities of the allergen Asp f 1 but start to produce it within 6 hours of germination (10,225). These results suggest that *A. fumigatus*spores become a source of this allergen only after germination. In contrast, easily measurable quantities of the *Alternaria*allergen, Alt a 1, are found in the outside air during the late summer (162). It is not clear whether this allergen is associated with spores, hyphae, or some other fragment. Fungal spores germinate in conditions of high humidity (i.e., 80% or greater relative humidity); in addition, many fungi, particularly mushrooms, release spores at times of high humidity. Spore dispersal is triggered by absorption of humidity (i.e., the opposite of the conditions for pollen release). The Basidiomycetes produce large numbers of airborne spores. In New Orleans, it has been reported that epidemics of asthma occur during the peak appearance of Basidiomycete spores (202). In addition, surveys of patients with asthma have confirmed that 15% to 20% of them have positive skin tests to extracts of Basidiomycete spores (128). Although it is clear that large numbers of fungal spores are airborne in the outside air, their role in allergic disease is difficult to define. Many fungal spores are much smaller than pollen grains, but these small spores should not be regarded as quantitatively or qualitatively equivalent to pollen grains as a cause of allergic symptoms. The thermophilic Actinomycetes produce large numbers of spores, which are an important cause of hypersensitivity pneumonitis. They grow in moldy hay, garbage heaps, and bagasse, but they have not been associated with immediate hypersensitivity or asthma.

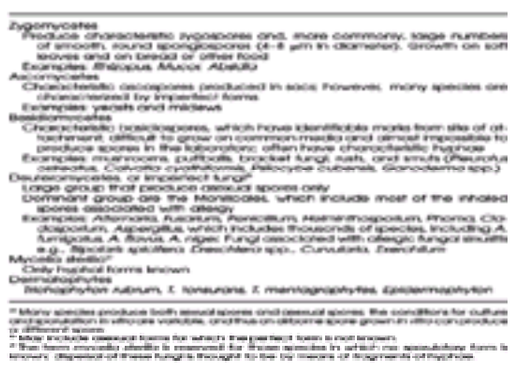

TABLE 61.2. Fungi in Allergic Disease[a]

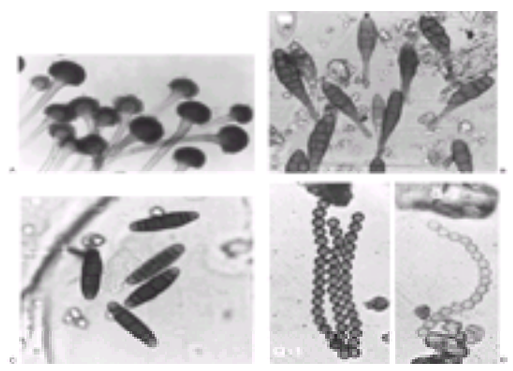

Figure 61.2. Fungal spores and spore heads.

Other Outdoor Allergens

The outside world contains hundreds of animals and plants that could produce inhaled allergens. In addition to the large numbers of insect species, there are nematodes, many species of mites, algae, protozoa (including *Naegleria*and *Acanthamoeba*species), and ferns that can release antigenic material. Thus the allergic symptoms that many patients report when mowing lawns, moving leaf mold, or simply on a windy day could be due to a wide range of antigens in addition to pollen grains or fungal spores. For many of these sources, skin test extracts are not available or are poorly characterized. Indeed, for most of these allergens, in the absence of a seasonal increase in the quantity of the antigen airborne or good extracts for skin testing, it is difficult to evaluate their importance as a cause of symptoms. The origin of allergens produced by insects is variable. The scales on the wings of some moths are an important source of allergen particles. For the nimitti fly, allergens are

components of hemoglobin present in the single particle of meconium that these flies produce after they hatch (113,140). The allergen in Japanese river flies also is a hemoglobin that some species produce in larger quantities when they are growing in polluted (i.e., oxygen-poor) streams (106).

The relevance of outdoor insects has been clearly established in several parts of the world. In the Sudan, the nimitti fly breeds in pools of stagnant water along the Nile. It hatches in vast numbers and can give rise to both IgE antibodies and allergic symptoms (113). Similarly, hatching of lake flies in Wisconsin and river flies in Japan has been clearly associated with local epidemics of allergic disease including severe asthma attacks (106). Positive skin tests have been reported to a variety of other outdoor species, including moths, crickets, ants, beetles, and cockroaches. It is safe to assume that symptoms develop in some patients because of exposure to these insect species. However, in the absence of epidemics occurring at the time of increased exposure, it is difficult to assess their importance relative to other outdoor sources.

INDOOR ALLERGENS

Estimates suggest that North Americans spend at least 23 hours per day indoors, much of this time in their own houses, and the time spent outdoors is likely to decrease further (189). Positive wheal-and-flare tests with extracts made from house dust were first reported in 1921 (115). During the 1920s and 1930s, various antigens that contribute to house dust were defined, such as cat dander, fungi, horsehair, and kapok (Table 61.3). However, several investigators believed that there was antigenic activity in house dust that was not explained by the then-known allergen sources. Indeed, some postulated the existence of a specific house dust "atopen," suggesting that the antigen is derived from human dander. Many species of mites were known during the nineteenth century, but they were not recognized as a major feature in houses. The first suggestion that mites were an important source of house-dust allergens came from Dekker (56) during the 1920s, who recognized mites in bedding dust. His work was largely ignored, though, perhaps because it was not possible to grow mites or produce extracts at that time. In 1967 Voorhorst et al. (267) demonstrated a strong correlation between the allergenicity of house dust and the presence of mites of the genus *Dermatophagoides*. More important, they developed techniques for growing mites so that it became possible to study mites and to produce skin-test extracts (266). In many parts of the world, a strong association between asthma and dust-mite sensitivity was rapidly recognized (44,142,217). This association was not so evident in the United States, and reports from Chicago, Kansas City, and Boston suggested that cockroach sensitivity might be as important in relation to inner-city individuals with asthma (23,98,250). Similarly, studies in the dry climate of northern Sweden showed that among individuals with asthma, animal-dander sensitization was more common than mite sensitization (62). For dust-mite allergens, there is consistent evidence that higher domestic exposure correlates with a higher percentage of children who become sensitized. However, the evidence is not clear for exposure to animals; indeed, several studies have suggested that children living in a house with a cat or a dog have a *decreased* risk of asthma and sensitization (87,200,228,235). There are reports of separate areas with a strong association between chronic asthma and sensitivity to dust mites, cockroaches, and animal-dander allergens (227,229). However, these findings do not diminish the conclusion that the allergens most commonly associated with chronic asthma are primarily indoors and that they show much less seasonal variation than do the outdoor allergens (174,176).

Arachnids
Dust mites
Dermatophagoides pteronyssinus
Dermatophagoides farinae
Euroglyphus maynei
Blomia tropicalis
Storage mites
Predator mites: Cheyletidae
Spiders
Insects
Cockroaches
Blattella germanica (German)
Periplaneta americana (American)
Blatta orientalis (Asian)
Others: crickets, flies, beetles, fleas, moths, midges, wood roaches
Mammals
Cats, dogs, ferrets, horses, rabbits, guinea pigs, Vietnamese pigs
Fungi
Growing indoors: multiple species, including *Penicillium*, *Aspergillus*, *Rhizopus*, and *Mucor* (growing on surfaces or rotting wood)
Growing outside: enter with incoming air (e.g., *Alternaria*, *Cladosporium*)
Pollens
Derived from or entering the house*
Miscellaneous
Horse hair in furniture, tepees
Food dropped by inhabitants
Rodents
Pets: Mice, gerbils, guinea pigs, hamsters
Wild mice, rats

* In domestic houses, the only source of incoming air is leakages (i.e., doors, windows, unused chimneys, ventilation systems). Humidifiers and systems for air entry. Air exchanges in domestic houses varies from 0.3 to 0.5 air changes per hour.

TABLE 61.3. Sources of Indoor Allergens

Dust Mites

Mites are eight-legged members of the order Acari (Fig. 61.3). They are photophobic, sightless, and absorb water from the environment through a hygroscopic material exuded from their leg joints. The pyroglyphid mites, which live on human skin scales and dominate the fauna of house dust, include *Dermatophagoides pteronyssinus, Dermatophagoides farinae,* and *Euroglyphus maynei* (7,24,256,274). The only other mites that are found with any regularity in bedding dust (in the United States, United Kingdom, and Australia) are predator mites of the genus *Cheletidae* and the tropical *Blomia tropicalis* (7,24). Many species of storage mites contaminate stored grain and other foods; they are common in barn dust and may be found in house dust. Farmers often develop immediate sensitivity to them (257). Exposure of these allergic individuals to dust containing storage mites can cause immediate symptoms of "barn asthma," distinct from farmer's lung disease, which is a delayed response not associated with immediate hypersensitivity (50). Mites found in houses are referred to as domestic mites, but the term house-dust mites is reserved for pyroglyphid mites. Mites excrete fecal pellets with a chitinous peritrophic membrane that maintains their size but does not prevent the proteins in them from escaping (Fig. 61.3B). The digestive enzymes produced by mites are important allergens, and fecal pellets are a major form in which these mite allergens accumulate and become airborne (37,246,247). Mites reproduce by laying eggs, which hatch in approximately 10 days; the larvae then go through several stages before becoming adults. The adult male and female mites of the major species are relatively easy to distinguish by microscopy, but the larval stages are difficult to distinguish. In the United States *D. farinae* was reported to be the most common mite in some areas (256). In contrast, in southern England, Brazil, and coastal Australia, *D. pteronyssinus* is the most prominent mite (11,166,226). The primary reason for these differences appears to be that one of the *D. farinae* larval stages can survive long periods of low humidity. Thus *D. farinae* is the most common mite in areas where there is a dry winter but a hot, humid summer [e.g., Cincinnati (8)], but *D. pteronyssinus* is generally more common in areas of the United States that have continuous humidity (i.e., the Southeast, Pacific Northwest, and Gulf Coast).

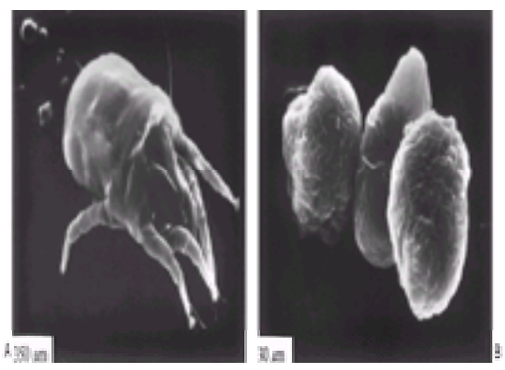

Figure 61.3. Adult dust mite *Dermatophagoides pteronyssinus*. The mite has eight legs, and the pads are clearly visible on the front legs. Several fecal pellets also are visible to illustrate the difference in size.

Because of their photophobia and susceptibility to dehydration, mites require a nest in which to live and breed. Mattresses, sofas, carpets, bedding, pillows, and clothing are suitable sites for growth if humidity and temperature conditions are adequate (24,274). In most houses, the highest levels (up to 1,000 mites/g of dust) are found in bedding or sofas, although high levels can be found in any fabric or soft material (177). Mites have "sticky" pads on their feet. Consequently, when dust is collected from carpets or sofas, the mites recovered are mostly dead; even repeated vacuum cleaning does not reduce the number of live mites in a carpet. Effective measures to reduce exposure to mites include the following: physical barriers that are impermeable or have pores small enough to exclude fecal particles [i.e., 6 µm or less in diameter] (261); washing bedding weekly at temperatures that kill mites (130°F) (135,165); removing carpets, upholstered furniture, and curtains that can act as nests for mite growth; controlling humidity with air conditioning or dehumidifiers (relative humidity less than 55% or absolute humidity less than 7 g/kg) (125,177); and regular vacuum cleaning with a cleaner that has a good filtration system (262,282). In areas where the humidity and temperature are high during the summer, houses should either have air conditioning or be kept simple, without carpets, curtains, or upholstered furniture.

Cats and Other Domestic Animals

The importance of cats (*Felis domesticus*) as a cause of sensitization has been clear since the introduction of skin tests. Indeed, a history of increased symptoms on exposure to a cat or on entering a house with a cat is one of the most reliable features of an allergic history. After purification of Fel d 1 by Ohman et al. (161), it became possible to assay for cat allergen. Initially, it appeared that saliva was the major source of cat allergen. Although it was known that allergen came off the cat when air passed over it, it was assumed that the allergen reached the fur when the cat groomed itself (Fig. 61.4) (239). A series of experiments has now cast doubt on the importance of saliva. First, when a cat was shaved and physically restrained from licking itself, allergen accumulated on the skin (39). Second, when cats were repeatedly washed, the allergen on the fur or the allergen that was becoming airborne was dramatically reduced 1 week later, although cats lick themselves for hours after being washed (51,76). Finally, when the gene for Fel d 1 was cloned, it was possible to develop RNA probes and demonstrate that the gene for Fel d 1 is expressed strongly in the glands of the skin (146). It now seems likely that the skin is the main source of cat allergen, and that small flakes of dander are the likely form in which the allergen becomes airborne. Although cat urine contains some allergen, it is not an important source of Fel d 1 in house dust.

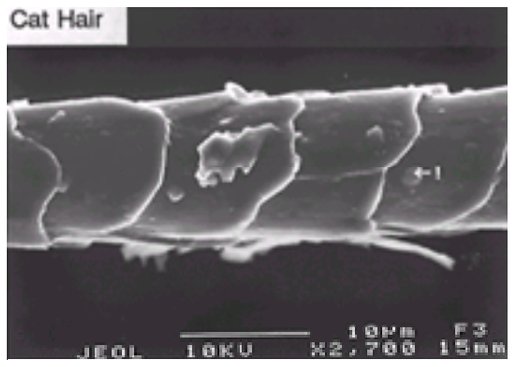

Figure 61.4. Scanning electron micrograph of a cat hair showing typical structure and multiple small “flakes” that may be typical of the dander that becomes airborne. The actual particles that become airborne have not been identified (×2700).

The allergen released by cats appears to be “sticky”; it adheres to walls and accumulates in large quantities in carpets and sofas (281). Between 90% and 98% of the cat allergen in a house has been estimated to be in the furnishings; therefore, it is not surprising that cat allergen persists in a house for many weeks after the cat has been removed (280). Rapid cleaning of a house after the cat has been removed requires removing the carpet and furniture and washing all surfaces (281). Although it is clear that cat allergen is present in the furnishings and that the allergen remains airborne after the cat is removed, the relative contribution of the cat and of the reservoirs (carpets, sofas, walls) to airborne allergen is not clear (51,71,258,281). Individual cats show tremendous variation in the total quantity of Fel d 1 that they carry (15). Based on airborne allergen measurements and estimates of the total quantity of Fel d 1 on cats, the amount of Fel d 1 shed has been calculated to be ~0.002% of the total allergen present on the cat (15). Thus other factors that influence how particles carrying cat allergen become airborne may be as important as the amount of allergen on the animal. There is currently much debate regarding the role of cat washing in reducing airborne allergen levels and the quantity of allergen in the reservoirs. In a blinded, comparative controlled study, weekly washing of cats was reported to have no effect on airborne Fel d 1 levels (123); however, this study did not measure quantities of allergen removed by washing. There is no doubt that washing cats, and even the simple measure of wiping cats with a damp cloth, can remove large quantities of cat allergen and cause a reduction in airborne Fel d 1 levels immediately after washing (15,51,168). However, it appears that, for most cats, reductions in airborne Fel d 1 are not maintained 1 week later (15).

Dogs also are an important source of airborne allergens, and the major allergen Can f 1 can be measured. However, in most countries, dogs seem to be less important than cats in this regard, in large part because they spend more time outdoors. Studies in Virginia and Delaware strongly suggest that animals kept outside are less likely to provoke sensitization. In addition, washing the dog is often a weekly routine for dog owners. Nevertheless, it has been reported that, to control airborne levels of Can f 1, it would be necessary to wash the dog at least twice a week (93).

Cockroaches and Other Insects

Cockroaches were first recognized as a significant allergen among inner-city patients during the 1960s (23,98,250). These results have been confirmed and linked to results on exposure levels in houses (32,73,185). Although direct comparison of cockroach allergen levels with other indoor allergen levels is not yet possible, the relative levels of cockroach allergen in Chicago, Wilmington (Delaware), and central Atlanta are high relative to mite or cat allergens (32,73). Many species of cockroaches live in houses, but the German (*Blattella germanica*) and American (*Periplaneta americana*) varieties are the most common. More is known about the allergens of *B.germanica*. When roaches are grown in the laboratory, large quantities of debris (or frass) accumulate at the bottom of the bottle. Frass, which consists of feces, shed skin, and saliva, is rich in allergens. The feces contain allergen, but allergen also accumulates on the outside of the insects and can be recovered by washing (187,252). This finding suggests that cockroach allergens are secreted or excreted. Indeed, the aspartic proteinase, Bla g 2, is probably a digestive enzyme secreted in the feces (12).

Various insects are used for biology research and pharmaceutical testing protocols. There are many reports of laboratory personnel who become allergic to the locusts, moths, crickets, and cockroaches with which they work. There is little doubt that a wide range of insects is capable of sensitizing humans, but the relevance of other insects in homes is not clear. Although homes can be heavily infested with crickets, beetles, flies, or spiders, the situation is usually transient and is less common than infestation with cockroaches. Occasionally, individuals become allergic to a wide range of indoor arthropods, but these cases are not common compared with those related to allergens from mites, cats, dogs, or cockroaches.

Rodents

IN ANIMAL HOUSES

Rodents are by far the most common mammals used for medical research, and allergic reactions to them are a major problem among professional animal handlers and research workers (2,45,117,191). The main source of allergen is protein in the rodents' urine (153,154,178). This finding is not surprising because rodents, especially male rats, have heavy proteinuria (154). Assays have been developed for measuring mouse (Mus m 1) and rat (Rat n 1) allergens, but only limited data are available for allergen levels in domestic houses (170). The urinary allergen accumulates in the bedding of the rodents and probably becomes airborne as a dried layer on small fragments of the bedding material. Several factors increase the exposure and symptoms of laboratory workers, including the use of fine sawdust rather than large wood chips or an absorbent paper material, drying the bedding, and the direction of the airflow in the animal house (178,238,240). Especially designed biodegradable foams and other synthetic bedding materials have been recommended as a method of decreasing exposure. Because some animals, particularly rats, develop pneumonia without high levels of airflow, federal law requires that animal houses have high air-exchange rates (at least 10 air changes per hour). High quantities of rat, mouse, guinea-pig, and rabbit urinary allergens accumulate in cages. Therefore IgG antibodies develop in a large proportion (i.e., ~50%) of animal handlers, regardless of whether they become allergic. As many as 20% of exposed individuals develop positive wheal-and-flare skin tests and serum IgE antibodies. In general, symptoms of rhinitis and asthma on exposure to experimental animals correlate well with the presence of IgE antibodies (or positive skin tests), whereas those individuals with IgG antibody alone generally report no symptoms (179). The high prevalence of IgG antibodies without allergy to rat allergen among animal handlers may, in part, reflect “selection bias” by the workers. However, exposure is very high, and it has been reported that these IgG antibodies are predominantly of the IgG4 isotype. Thus the response of the animal handlers to rat urinary proteins may reflect a modified T-helper type 2 (Th2) response.

IN HOMES

Rodents are found in houses as pets (usually in cages) or as pests. The many case reports of children and adults who become allergic to pet rodents and improve after the animal is removed leave no doubt that a rodent in a cage can give rise to sensitization and symptoms. Although there are no studies on the distribution of pet rodent allergens in houses, it is assumed that the cage is the dominant source. Rodent cages should not be allowed in the bedrooms of children with symptoms or a strong family history. That wild rodents in domestic houses can be a problem is established by positive skin tests to rodent urine among individuals with asthma, particularly in New York City, and by measurements of airborne rat and mouse allergen in their houses (237). The lack of positive skin tests among individuals with asthma living in the suburbs suggests that the levels of allergen in houses with an occasional wild mouse are not sufficient to give rise to sensitization or symptoms.

NONINHALED ALLERGENS

Commensal Fungi

The human body carries many commensals, including bacteria and both opportunistic (e.g., *Aspergillus* spp.) and nonopportunistic (e.g., dermatophytes or yeast on the skin) fungi. Although these organisms do not usually provoke symptoms, they can, ranging from trivial irritation such as tinea versicolor to major problems such as trench foot or bacterial sinusitis. During the 1930s, it was thought by some that bacteria and fungi could become allergens (48). However, the lack of antibiotics and systemic antifungal agents made it difficult to determine if these “intrinsic” allergens contribute to allergic disease. Nonetheless, there were repeated reports of positive immediate hypersensitivity skin tests to a wide range of commensal organisms.

The first noninvasive fungus to be recognized as an allergen was *Aspergillus fumigatus.* The association between positive skin tests to *A. fumigatus* and allergic bronchopulmonary aspergillosis (ABPA) was established before the discovery of IgE (18). It is now understood that this fungus can give rise to several diseases associated with different immune responses, including allergic asthma, ABPA, allergic sinusitis, aspergilloma, and locally or systemically invasive aspergillosis (18). The genus *Aspergillus* includes many species that are widely distributed, and it is not clear why the single species, *A. fumigatus*, is so common in the lung. In part it may reflect the thermotolerance of this species, which unlike most other fungi can flourish at temperatures from 10°C to 38°C. Evidence suggests that *A. fumigatus* produces specific toxins that may contribute to both its colonization of the lung and its toxicity (10). *Aspergillus* is a colonizing organism in the lungs of children with cystic fibrosis (65,291). As judged by the total IgE level, and specific IgE and IgG antibodies, this colonization may start as early as age 5 years. Given the evidence that the *A. fumigatus* allergen Asp f 1 is produced only after germination of the spores, the presence of an antibody response indicates that the patients are (or have been) colonized. The important issue is whether *A. fumigatus* colonization of the lungs of patients with cystic fibrosis contributes to their lung damage. Approximately 20% of children with cystic fibrosis have IgE antibodies to *A. fumigatus*, although most have IgG antibodies alone. There is no reason to assume that colonization is more damaging in individuals with an allergic response than in those with IgG antibody alone, because the enzymes and toxins produced by *A. fumigatus* may be directly damaging to the lung. Indeed, *A. fumigatus* serine proteinase has recently been shown to degrade human lung elastin and collagen and to produce lower respiratory tract destruction when injected intratracheally in a mouse model (100). To date, the main treatment for ABPA has been systemic glucocorticoids; however, a recent trial of the systemic antifungal, itraconazole (231), reported improvement in patients with ABPA. This antimicrobial therapy provides promise for the treatment of this chronic debilitating condition.

Although *A. fumigatus* dominates colonization of the lungs in those with mycetomas or ABPA, other fungi have been implicated. In particular, allergic bronchopulmonary curvulariosis and candidiasis have been documented. There also is a rare but important condition called allergic fungal sinusitis (77), which is characterized by production in the sinuses of an “allergic” mucus with the consistency of peanut butter and containing Charcot-Leyden crystals. Although this allergic mucus can erode bone, this erosion results from pressure, and there is no penetration of the periosteal or meningeal layers. It is possible to have extension into the orbit and even the frontal lobe without infection of the bone, orbit, or meninges. Cases have involved several fungi but most commonly those of a group including *Bipolaris spicifera, Drechslera*, or *Excerohilum* spp. (Fig. 61.2). In all cases, the patients are atopic and have positive skin tests to the relevant fungus. Other investigators have suggested that fungal infection contributes to a large proportion of cases of chronic sinusitis (188,293). However, general experience is that fungal colonization is present in only about 6% to 7% of cases (46). Fungi also can colonize the lungs of patients with asthma and those with chronic obstructive pulmonary disease with or without an IgE antibody response. Perhaps the most common organism involved is *Candida albicans*. Currently it is difficult to assess whether *C. albicans* is a harmless saprophyte or whether it has a pathogenic role in allergic disease. Serum IgE antibodies to *C. albicans* have been reported in patients with allergic bronchopulmonary candidiasis, hyper-IgE syndrome, and allergic asthma (21,79). The yeast *Malassezia furfur* (previously known as *Pityrosporium ovale*) also has been recognized as an allergen in patients with atopic dermatitis (108). *M. furfur* is a “cause” of both seborrheic dermatitis and tinea versicolor, but the nature of the immune response is not established. Recently, moderate-to-severe atopic dermatitis has been shown to be strongly associated with sensitization to *M. furfur* (205); these findings suggest that fungal allergens contribute to the severity of allergic disease.

Perhaps the single most common fungal colonization of humans is with dermatophytes of the genus *Trichophyton*. Worldwide, *T. mentagrophytes* and *T. rubrum* are the most common cause of athlete's foot and infection of the toenail beds (onychomycosis). *Trichophyton* is unusual in that it is associated with distinct immune responses in different individuals. Positive immediate hypersensitivity skin tests have been associated with chronic infections characterized by low-grade inflammatory lesions that tend to persist and the presence of high titers of serum IgG and IgE antibodies to *Trichophyton* antigens (85,110,224,270). In contrast, delayed type hypersensitivity, a form of cell-mediated immunity, has been reported in individuals with acute, highly inflamed lesions; sera from subjects with delayed-type hypersensitivity contain only low-titer IgG antibodies (81,111,112,283). The association between the severity of the clinical dermatophytosis and different immune reactions has led researchers to speculate that delayed-type hypersensitivity responses are required to eradicate *Trichophyton* infection, and immediate hypersensitivity responses are not protective. Chronic dermatophytosis appears to be associated with atopy; the prevalence of allergic history in patients with chronic dermatophytosis (36% to 49%) is higher than in the general population (85,109,111). Furthermore, as early as the 1930s, Wise and Sulzberger (278) suggested a relation between dermatophyte colonization of the feet and allergic symptoms. Subsequent studies proposed that a variety of allergic diseases including asthma, chronic sinusitis, and urticaria were related to dermatophytosis (173,270,273). This theory was supported by anecdotal reports of improvement of allergic symptoms after the use of antifungal drugs. Although allergic patients may exhibit positive immediate or delayed-type hypersensitivity skin tests to *Trichophyton*, in a few patients with positive immediate skin tests and chronic fungal colonization, *Trichophyton* appears to play a role in their allergic disease. The availability of highly efficacious systemic antifungal therapies has made it possible to examine the role of *Trichophyton* in allergy. A significant improvement of allergic symptoms in a group of patients with late-onset asthma treated with fluconazole has recently been reported (271); these findings provide strong evidence of a role for *Trichophyton* antigens in allergic disease. Such cases are intriguing, given that *Trichophyton* has never been isolated from the respiratory tract. It is assumed that sensitization may occur by absorption of antigen from the skin or nail beds. Several *Trichophyton* antigens have now been characterized; two allergens designated Tri t 1 (30 kd) and Tri t 4 (~80 kd), derived from *T. tonsurans*, were purified with standard immunochemical techniques (59,283). Subsequent studies used molecular cloning techniques to identify allergens derived from *T. rubrum* that exhibit a high degree of amino acid sequence identity with distinct families of serine proteinases: the prolyl oligopeptidase Tri r 4 (~80 kd) and the class D subtilase, Tri r 2 (29 kd) (285). The availability of purified natural and recombinant *Trichophyton* allergens made it possible to study humoral and cellular responses to these antigens. Immediate hypersensitivity responses were found to be associated with high titers of antigen specific IgG and IgG4 antibodies and with the presence of IgE in the serum, whereas delayed-type hypersensitivity responses were associated with only low titers of IgG (283,285). Furthermore, T cells derived from individuals with different immune responses had distinct cytokine profiles (214). These recent advances open the door to further studies aimed at understanding the relation between dermatophyte colonization, the immune response to dermatophyte antigens, and allergic disease.

Bacterial Allergens

Early investigations of bacterial allergy were marred by inadequate evidence about the nature of the antigens and a lack of controlled trials (48). This situation led to the consensus opinion that immunotherapy with bacterial antigens is not efficacious. This view should not be interpreted as evidence that patients do not make IgE antibody responses to bacteria. Although positive wheal-and-flare skin responses to a wide range of bacteria have been reported, there is less evidence about the nature of the allergens or about serum IgE antibodies. Good evidence for IgE antibodies to *Staphylococcus aureus* has been reported for patients with hyper-IgE syndrome (21). Patients with atopic dermatitis may also have IgE antibodies to enterotoxins of *S. aureus* (130,203). The staphylococcal enterotoxins have many of the properties of a superantigen, which may influence the immune response (89,130). Recently, an IgE antibody–binding protein derived from *S. aureus* was identified by screening a genomic DNA library with sera from patients with atopic dermatitis (101). This finding suggests that previously unidentified bacterial antigens may play a role in allergic disease. Thus there seems to be a strong case for reevaluating the immune response to common bacterial commensals in atopic patients, particularly those with atopic dermatitis or chronic sinusitis (152).

Venom Antigens

The venom produced by members of the order Hymenoptera—honeybees, yellow jackets, wasps, hornets, and fire ants—consists primarly of low-molecular-weight peptides (MW, 1,000 to 3,000), which are potent causes of pain and local swelling (119,120,244). The venom also includes proteins such as phospholipase A_2 and hyaluronidase; and in a few patients who are stung, IgE antibodies develop to these proteins. Such patients are at risk of large local reactions or anaphylaxis on subsequent stings. Detailed study of these patients has revealed various degrees of cross-reactivity among venoms (197). Patients who are allergic to honeybees, yellow jackets, wasps, or hornets can be skin-tested and treated with “pure” venom, a form of immunotherapy that is highly successful (99,289). It has long been known that beekeepers can become tolerant to stings, and that they have IgG antibodies to phospholipase A_2. In addition, Aalberse et al. (1) reported that this antibody was predominantly of the IgG4 isotype. Several honeybee venom proteins have been cloned and the recombinant proteins expressed; these proteins have been used for diagnosis and treatment (68,122,145,149,219). Recently peptides of bee venom phospholipase A_2 that contain T-cell epitopes have been shown to induce T-cell anergy, which is associated with interleukin (IL)-10 production (3,4,148). In contrast to bee venom, fire ant venom is difficult to obtain, and patients are generally treated with whole-body extracts, although the venom can be used for diagnosis (230). Fire ant stings also produce pustules, which may reflect an added toxicity of one of the peptides. There is considerable interest in cloning fire ant venom proteins for use in diagnosis and treatment (207).

Biting Insects

Although many biting insects (e.g., mosquitoes, deer flies, black flies, horse flies, and fleas) can produce local reactions resembling immediate hypersensitivity, systemic reactions are rare. In most cases, the quantity of protein delivered with the bite is probably inadequate to produce a systemic reaction, even if the patient has developed IgE antibodies (94). Two salivary allergens from mosquitoes (Aed a 1 and Aed a 2) have been cloned and expressed, and monoclonal antibodies that recognize other salivary proteins have been produced (167,287). Occasional cases of anaphylaxis and IgE antibodies have been reported after bites by deer flies or

reduvid bugs of the genus *Triatoma. Triatoma*is a large insect that feeds on mammals including humans; it has a painless bite, leading to its designation, the “kissing bug.” The allergen of *Triatoma protracta*is an 18-kd salivary protein (36), and successful immunotherapy has been reported with salivary gland extract (198).

THE IMMUNE RESPONSE TO ALLERGENS

A major objective of purifying and defining allergens has been to understand why these antigens selectively induce one type of immune response. Immediate (type I) hypersensitivity is mediated by IgE antibodies, and this form of immunity is the classic response to allergens. Although antibodies are the primary effector molecules of type I immunity, T lymphocytes of the Th2 phenotype play a major role in induction of the allergic response. This subset of T cells produces an array of cytokines including IL-4, IL-5, IL-6, and IL-13, which exert their effects on T lymphocytes themselves but also on other cell types including B cells and antigen-presenting cells such as monocytes and dendritic cells. IL-4 serves as a growth factor for B cells and induces antibody isotype switching to IgE and IgG4 production. On initial exposure to allergen, T lymphocytes are primed, and IgE antibody production is induced; these antibodies bind to receptors on the surface of mast cells. On subsequent exposures to allergen, cross-linking of these IgE antibodies by allergen triggers degranulation of the mast cells and release of histamine, which causes allergic symptoms. Thus, to experience allergic symptoms, an allergic individual must be repeatedly exposed to allergen. Although the events that initiate a Th2 response are not yet clear, the detailed understanding of allergens has not changed the view that low-dose, crepeated exposure to a soluble protein is the best way to induce IgE antibody responses. Knowledge of allergens is currently being used to develop strategies to abrogate the allergic response in susceptible individuals. Such approaches include altering B-cell epitopes so that they are no longer capable of binding IgE and identifying T-cell epitopes (allergenic peptides) that may be used to induce preferentially a cellular response, while failing to stimulate the humoral arm of the response (see later). One theory that has gained favor in the last decade is that by stimulating a distinct subset of T lymphocytes (Th1 type) it may be possible either to modulate an ongoing allergic response or to induce protective immunity to allergens. Cell-mediated (delayed-type hypersensitivity) responses are mediated by Th1 cells; these cells are characterized by a cytokine profile that is distinct from that of Th2 cells (i.e., IFN-g and IL-2), and their development is dependent on IL-12. Although allergen-specific cells with a Th2 phenotype have been isolated from allergic patients (27,251,276), there is limited evidence that in humans, immunotherapeutic strategies have provoked a Th1 type of response (199) (discussed at the end of the chapter). Our current knowledge of allergen structure, including the definition of T-cell and B-cell epitopes, provides a basis for investigating the immune response and for designing new approaches to immunotherapy.

IMMUNOCHEMISTRY OF ALLERGENS

Properties of Purified Allergens

A major objective of the early studies on allergens was identification of the special properties of “atopic allergens” that induce immediate hypersensitivity. The wide range of allergen sources (see Table 61.1,Table 61.2 and Table 61.3), however, made it unlikely that these proteins would have common features. The allergens that have now been purified are soluble proteins or glycoproteins with molecular masses between 5 and ~80 kd (Table 61.4). For inhaled allergens, the primary immune response occurs in the lymph nodes draining the nose, tonsils, or peritonsillar lymphoid tissue (141,171,241). Because particles landing on the nasal epithelium are propelled posteriorly and swallowed within about 15 minutes, proteins must be released rapidly in mucus to be able to penetrate the epithelium and basement membrane. The respiratory tract basement membrane has an approximate molecular-mass cutoff of 60 kd (208). Respiratory epithelium includes a dense network of Ia-positive dendritic cells that collect foreign antigens (96,155,209). These cells then pass via the lymphatics to the local lymph nodes (96). Any foreign protein that can penetrate the mucous membrane is likely to be highly immunogenic. The primary characteristics of an allergen are that it is a soluble foreign protein that is delivered repeatedly to the nasal mucosa in sufficient dose to cause an immune response.

TABLE 61.4. Important Allergens

Allergens can be identified in several ways. Most of the allergens listed in Table 61.4 were initially purified by classic immunochemical techniques based on salt concentrations (e.g., ammonium sulfate), size (Sephacryl), and charge (electrophoresis or anion-exchange resins). The purified proteins were studied by RAST, skin testing, or crossed radioimmunoelectrophoresis (CRIE) to establish the importance of the allergen. The term *major allergen*has been used loosely and is usually taken to mean that at least 60% of the individuals with IgE antibody to the source material (e.g., rye grass pollen or dust mites) have IgE antibody directed against this particular protein (e.g., Lol p 1 or Der p 1) (119,137,172). However, when CRIE is used to determine if IgE antibody is present against a given protein band, the technique is so sensitive that many proteins are considered to be major allergens. Similarly, estimates that an extract contains 15 or more allergens based on CRIE or Western blot after sodium dodecylsulfate–polyacrylamide gel electrophoresis (SDS-PAGE) are difficult to evaluate. In general, allergens should be purified to establish their allergenicity and importance relative to other proteins in the same extracts. For many allergens (e.g., those derived from dust mites, grass pollen, cat, and alder pollen), the major allergens represent a large proportion of the protein in the extract (28,37,119,137). This finding would be expected if the quantity of allergen reaching antigen-presenting cells in the nasal epithelium were the limiting factor in the immune response. However, other allergens, which represent only a small proportion of the total protein, are “highly immunogenic” for some individuals (143). Another criterion for the importance of a protein allergen is an estimation of the percentage of serum IgE antibody against the source material that is specific for the purified allergen (37,74,206). Reliable estimates of this kind have been reported for the major allergens of ragweed, rye grass, *D. pteronyssinus, D. farinae*, and cat (37,55,74,181,206). In each case, patients have been identified in whose sera more than 50% of the IgE antibody against the source is directed against the purified *major*allergen.

Sequencing of Allergens: Biochemical Properties

The first sequence of an allergen was reported by Elsayed and Apold (66) for codfish muscle allergen M in 1973 and was followed by the sequence of Amb a 5 by Mole et al. in 1975 (143). At that time, it was still considered possible that the amino acid sequence of allergens would reveal a characteristic feature or that allergens would have repeated epitopes that allowed them to cross-link IgE antibodies. It is now considered unlikely that any proteins of this size would include repeated B-cell epitopes (20). Furthermore, because essentially the whole surface of a protein can be immunogenic, it is unlikely that the sequence data alone would give any information regarding allergenicity (20). The partial amino acid sequences of many purified natural proteins have been obtained by Edman degradation (e.g., Der p 1, Der p 2, Lol p 1, Fel d 1; Table 61.4). More recently, molecular cloning techniques have resulted in determination of the full amino acid sequence of numerous allergens. The amino acid sequence of Der p 1, reported in 1988 (43), showed a high degree of sequence identity with actinidin and papain (43,233). Subsequently, other mite allergens were identified as enzymatic homologs and their function characterized *in vitro*; for example, the trypsinlike serine protease Der p 3 and a-amylase Der p 4 both showed enzymatic activity (182,233). Many major allergens show no sequence identity with known enzymes (e.g., Fel d 1 and Der p 2) (34,42,90,146); furthermore, enzymatic homologs may lack enzymatic activity (285). Although it seems unlikely that the allergenicity of a protein can be attributed solely to its enzymatic properties, several groups have speculated that the biochemical activity of dust-mite allergens may enhance their immunogenicity or allergenicity. The cysteine proteinase, Der p 1, was shown to cleave the low-affinity IgE antibody receptor (FceRII) from human B-cell lines; this results in the release of soluble CD23, which is thought to be involved in stimulating the growth and differentiation of a variety of cell types, including T and B lymphocytes, and in the autocrine regulation of IgE antibody production (88). More recently, Der p 1 has been shown to cleave the a subunit of the IL-2 receptor (CD25) from the surface of human peripheral blood T cells (211). Thus it has been proposed that Der p 1 may suppress propagation of Th1 cells, thereby promoting a Th2 bias. Other studies have shown that Der p 1 (and Der p 9) stimulates IL-6 and granulocyte-macrophage colony-stimulating factor (GM-CSF) production by bronchial epithelial cells (118) and that several group 3 allergens can generate anaphylatoxins by proteolysis of the complement components C3 and C5 (139); each of these effects was inhibited by protease inhibitors. A more recent study showed that Der p 1 disrupts intercellular tight junctions *in vitro*by cleaving the adhesion protein occludin, thereby facilitating transepithelial allergen delivery (269). Pollen enzymes also have been reported to detach airway epithelial cells from their substratum *in vitro*(83), suggesting that epithelial injury can be mediated by different allergens. Thus by a variety of different mechanisms, the proteolytic activity of some allergens may contribute to the pathogenesis of allergic disease. However, there is still no evidence for the relevance of enzymatic properties *in vivo*in humans. In addition, it remains to be determined whether enzymatic activity plays a role in the induction of the allergic response. Given the diverse nature of allergens, this seems unlikely.

Allergenic Cross-Reactivity

Classically, cross-reactivity between allergens has been determined by testing the ability of one allergen to inhibit antibody binding to another. Such experiments are typically carried out with human sera containing allergen-specific IgE or monoclonal antibodies (mAbs). mAbs may give a different impression of cross-reactivity from that of natural human IgE antibodies. For example, IgE specific for Der p 1 can be largely absorbed from serum on a solid phase of Der f 1 (91). In contrast, almost all mAbs raised against either Der p 1 or Der f 1 do not bind to other group 1 proteins (35,131). Thus group 1 mite allergens have common (or group-specific) determinants (recognized by human IgE and mAb 4C1-B8), as well as species-specific determinants (recognized by different mAbs).

Knowledge of the amino acid sequence of proteins has provided insight into cross-reactivity between allergens. For example, the major grass pollen allergens such as the group 1 allergens of rye grass, timothy, and June grass show sequence homology and extensive cross-reactivity (6,137). Many proteins have highly significant sequence identity (30% to 40%) but do not cross-react immunologically (e.g., the group 5 allergens of short and giant ragweed, or Lol p 1 and Lol p 2 allergens of grass pollen). As a rule, proteins with more than 70% identity cross-react to some degree (e.g., group 1 mite allergens), whereas those with 85% or more homology show extensive cross-reactivity (e.g., group 2 mite allergens). Amino acid sequencing of allergens has revealed potential cross-reactivity between allergens from diverse sources. For example, tropomyosin was recently identified as a major cockroach allergen (204). Shrimp and house dust mite tropomyosin were recently identified as allergenic, and there is now strong evidence for cross-reactivity of tropomyosin allergens derived from diverse organisms (14,196,204). An association between sensitization to pollen and symptoms from specific foods has long been recognized (22,61). The ubiquitous actin monomer–binding protein, profilin, derived from birch pollen, was first identified as an allergen by Valenta et al. (254). Subsequent studies described profilins as allergens in grasses, weeds, fruits, and vegetables, and thus it was postulated that profilins may be responsible for the cross-reactivity between pollen and foods in allergic patients. Many profilins have now been cloned from different plants, yielding clues regarding cross-reactivity of allergens from diverse sources (13). Perhaps the best-defined cross-reactivity is between birch pollen and a group of foods that includes apples, plums, and hazelnuts (61). Approximately 30% of patients with hay fever related to birch or the closely related alder pollen are aware of tingling of their lips and itching at the back of the throat with or without visible swelling on exposure to these foods ("oral allergy syndrome"). Molecular cloning has identified homologs of the birch pollen allergen, Bet v 1, in different food sources, which may explain this cross-reactivity (see footnote to Table 61.4). The sensitizing allergen source (pollen or plant food) remains controversial; because apple sensitization is far more common in countries where birch pollen is an important allergen, it seems likely that the primary sensitization in most cases is induced by exposure to birch pollen. This theory is supported by recent findings that most IgE epitopes in plant food recognized by patients with oral allergy syndrome are present in pollen allergens (114).

Recombinant Allergens

Once an allergen has been cloned, it can often be produced *in vitro* with bacterial (e.g., *Escherichia coli*), yeast (e.g., *Pichia pastoris*), or mammalian (Baculovirus) expression systems. Pure allergens expressed in this way have major advantages for diagnosing and treating allergic disease and for standardization. With molecular cloning techniques, it is now possible to identify IgE reactive clones from cDNA or genomic DNA libraries and to sequence these putative proteins. However, the possibility still remains that not all B-cell epitopes will be present in the recombinant protein. Full definition of an allergen generally requires (a) purification of the natural allergen and demonstration of its importance, (b) development of mAbs that react with the natural protein, and (c) amino acid sequencing of the full-length protein. However, molecular cloning techniques are increasingly being used to identify novel allergens, particularly those of bacterial and fungal origin, for which the natural form has not been characterized. Many recombinant allergens have now been produced and their immunoreactivity tested (255). Initially, although production of recombinant protein was achieved, some allergens exhibited reduced immunoreactivity, as judged by IgE antibody binding compared with the natural form. However, in general, such problems can been overcome by using different expression systems for production of the recombinant protein. For example, the immunoreactivity of recombinant Fel d 1 (r-Fel d 1) expressed in bacteria was not comparable with that of the natural protein, but r-Fel d 1 produced in baculovirus showed essentially the same IgG- and IgE-binding properties as natural Fel d 1 (102). Reasons for variations in immunoreactivity of recombinant proteins produced in different expression systems are not clear but may include incomplete or incorrect folding of the peptide chain and lack of (or altered) disulfide bond formation or posttranslational modification. Several allergens, including Fel d 1, the *Trichophyton* allergen Tri r 2, and the major cockroach allergen Bla g 2, are glycoproteins; recent advances in eukaryotic expression systems have allowed the production of recombinant allergens that are glycosylated to a degree comparable with the natural form. In a few cases, for reasons often unknown, it has not been possible to express certain allergens in their recombinant form. However, problems in protein expression have occasionally been overcome by altering the DNA sequence encoding the allergen, so that codon use is more appropriate for the host expression system. The availability of recombinant allergens is a valuable advance in the field of allergy. It provides unlimited source material for immunologic studies of allergens and for the development of novel treatments. For those allergen sources in which the immune response is directed against a limited number of proteins, it is possible that recombinant proteins will replace native extracts for diagnosis and immunotherapy.

Allergen Structure: B-Cell Epitopes

The development of mAbs made it possible to "map" B-cell epitopes on the surface of allergens and investigate the relation between epitopes that bind IgE and those that bind murine mAbs. Studies of this kind have been reported for many allergens, including those derived from mite, cat, and pollen (34,38,67). These studies were useful for studying cross-reactivity (see earlier) and, more recently, for evaluating techniques used to modify the antibody-binding properties of allergens with a view to developing molecules with reduced allergenicity. Various techniques used to alter the reaction of allergens with IgE antibodies have incorporated different conditions of heat and pH, and chemical treatment with glutaraldehyde, urea, and tannic acid (104,137,160). Often a slight modification of the molecule could prevent interaction with IgE antibodies (22,119,132). Some proteins are highly sensitive to denaturation, whereas others are resistant. For instance, Der p 1 is labile, and Der p 2 is relatively stable to heat and chemical denaturation (132).

Epitope mapping of conformational determinants does not yield information about the structure of the epitope but merely about the relation of one epitope to another (i.e., distinct or overlapping). Elucidating the tertiary structure of allergens is critical for defining B-cell epitopes and for producing recombinant allergens with reduced allergenicity. Knowledge of the amino acid sequence of several allergens has allowed computer-assisted molecular modeling based on sequence identity with proteins of known structure. More recently, nuclear magnetic resonance techniques have been used to determine the structure of recombinant Phl p 2 (58), Der p 2 (147), and Der f 2 (103). Furthermore, the structure of several allergens has been determined by x-ray crystallography, including profilins derived from birch pollen (69) and *Arabidopsis thaliana* (245); the major horse allergen, Equ c 1, and the bovine lipocalin, Bos d 2 (78,126,201); and the major grass allergen Phl p 2 (Fig 61.5) (70). Such studies have allowed identification of major epitopic regions involved in IgE binding (69,70,194) and have provided valuable insight into allergenic cross-reactivity.

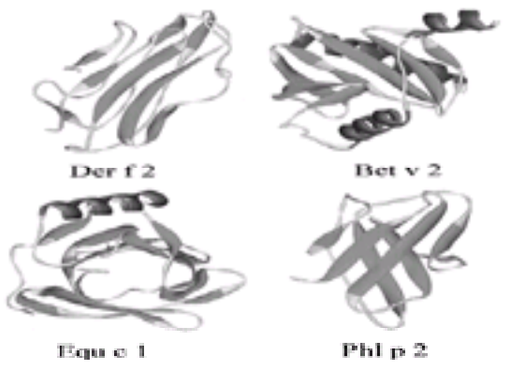

Figure 61.5. Three-dimensional structures of the mite allergen, Der f 2 [Protein Data Bank file 1AHK.pdb (103)], the birch pollen profilin, Bet v 2 [1CQA.pdb (69)], the horse allergen, Equ c 1 (126), and the major timothy grass pollen allergen, Phl p 2 [1WHO.pdb, (70)]. Figure kindly prepared by Dr. Anna Pomés. (See Color Figure 61.5.)

After the amino acid sequences of mite and other allergens were determined, several groups synthesized peptides and tested their interaction with IgE antibodies (107,259). These experiments assumed that some allergens contained linear B-cell antigenic determinants. This concept remains controversial because B-cell antigenic determinants are typically conformational. In 1991, Van't Hof et al. (259) defined a peptide of 14 amino acids (residues 65 to 78) derived from Der p 2 that bound IgE antibodies (259) and determined that the IgE response was polyclonal (260). In the case of Der p 1, four peptides were selected for study using modeling of the molecule based on its homology with papain and actinidin (107). In that study, peptides of 14 to 17 amino acids were shown to cause histamine release *in vitro* that correlated with IgE antibody levels to Der p 1. The authors speculated that allergenic peptides could bind to albumin to create divalent molecules capable of triggering histamine release. Recently, epitope-mapping studies of group 2 mite allergens have been carried out with site-directed mutagenesis to disrupt disulfide bonds (80,215,216,242). The findings of these studies support a role for conformational, *not* linear, B-cell antigenic determinants in IgE antibody binding. In contrast to allergens derived from dust mites, there is considerable evidence that food-derived allergens contain linear B-cell epitopes. For example, epitope analysis of the peanut allergen Ara h 3 identified four peptides (10 to 15 amino acids in length) that bound serum IgE (193). In this study, antibody binding was reduced or abrogated by single amino acid substitutions. Furthermore, heat-induced conformational changes of Ara h 1 have no effect on IgE antibody binding (124). These findings support a role for

linear IgE epitopes in peanut allergy. Despite this evidence, it seems most likely that conformational B-cell epitopes dominate the allergic response to most allergens.

T-Cell Responses to Allergens: T-Cell Epitopes

Although allergic responses are mediated by IgE antibodies, T lymphocytes of the Th2 subset play a major role in these responses (see earlier). For T cells to carry out their effector functions, they must first be activated to proliferate and differentiate into armed effector T cells capable of producing the relevant cytokines and rapidly responding to antigen. T cells are activated upon recognition of foreign antigen presented on the surface of an antigen-presenting cell in the form of peptide bound to a major histocompatibility complex (MHC) molecule. Antigenic peptide is generated within the antigen-presenting cell by enzymatic cleavage. Th2 lymphocytes are $CD4^+$ T lymphocytes that recognize antigenic peptide in the context of MHC class II molecules. Antigenic peptides that bind to MHC class II molecules are heterogeneous in length, ranging from 15 to more than 20 residues. These peptides or T-cell epitopes are *linear*epitopes. Most allergic patients have circulating T cells that proliferate and produce interleukins *in vitro*in response to allergen extracts, purified allergens, and specific peptides (25,169,195). Knowledge of the amino acid sequence of allergens has made it possible to identify T-cell epitopes using synthetic peptides derived from allergens to stimulate T-cell proliferation *in vitro*. Immunodominant antigenic determinants for a wide variety of allergens have been identified by this method: these include group 1 and group 2 mite allergens (97); the major cat allergen, Fel d 1 (136); the major birch pollen allergen, Bet v 1 (63); and many other pollen-derived allergens (210). Other studies have mapped T-cell epitopes of the major olive allergen, Ole e 1 (33), the group 5 grass pollen allergen, Phl p 5 (150), and the major cow dander allergen, Bos d 2 (292). T-cell epitopes of fungal allergens derived from *Aspergillus*(Asp f 1) and *Trichophyton*(Tri r 2) have also recently been mapped (41,284). The initial aim of such studies was to identify epitopes associated with allergic disease that may serve as targets for novel therapeutic strategies. Although in principle this theory was attractive, studies revealed that most individuals exhibit a unique pattern of T-cell epitope recognition; thus no specifically “allergenic” epitopes derived from any major allergen have been identified. An alternative approach was to compare atopic and nonatopic individuals to identify significant differences between these two groups. However, many of these studies were confounded by several factors. First, insufficient numbers of patients were selected for study. Second, the assay design was not optimized; this is critical, given that many allergens are relatively weak inducers of T-cell proliferation *in vitro*. In addition, the chances of a single antigenic peptide stimulating T-cell proliferation *in vitro*are restricted by the low precursor frequency of antigen-specific T cells in the peripheral blood. Thus it is imperative that T-cell proliferation assays using antigenic peptides incorporate a high number of replicate wells (at least 12 per peptide). A recent study used rigorous assay design and statistical techniques to identify highly significant differences in the T-cell repertoires associated with immediate and delayed hypersensitivity to the *Trichophyton*allergen, Tri r 2 (284). This study identified an amino-terminal immunodominant T-cell epitope specifically associated with delayed hypersensitivity. A peptide containing this epitope failed to stimulate proliferative responses in T cells derived from individuals with immediate skin tests. The mechanism of T-cell hyporesponsiveness in individuals sensitized to *Trichophyton*is not yet clear.

Peptide immunotherapy has been proposed as a method for modulating T-cell function, thereby abrogating the allergic response. In the early 1990s, subcutaneous injection of Fel d 1 peptides was reported to induce T-cell “tolerance” to whole antigen in a mouse model (29). Similar models were developed for other allergens; however, initial studies in humans failed to demonstrate this effect (213). Nevertheless, recent studies have demonstrated that allergen-derived peptides injected intradermally can induce a late asthmatic reaction in individuals allergic to cat (82). These findings suggest that antigenic peptides may indeed have the capacity to modulate the immune response. It is possible that the use of better techniques for defining T-cell epitopes and the testing of different immunotherapy regimens will allow the rational design of peptide therapies. Testing the clinical and immunologic responses to injections of “T-cell epitopes” is one of the most interesting experiments in immunotherapy since Noon (156) first introduced desensitization in 1911.

STANDARDIZATION OF ALLERGENS

Before the discovery of IgE and the purification of major allergens, extracts were standardized by measuring protein [1 protein nitrogen unit (PNU) = 0.01 µg protein N] or by the weight of pollen used for extraction (1 Noon unit = the allergen extracted from 1 µg of pollen). When good-quality pollen is extracted in saline at 4°C for 24 hours, these units or a simple weight/volume ratio provides a reasonable guide to the potency of the extract. However, when the source material is more complex (e.g., fungi, cat, mites, or insects) or the extraction conditions are altered, these assays are not reliable. For example, extraction in pyridine at pH 13.0, which increases protein, destroys many allergens, including Amb a 1 and Der p 1 (16,17). Therefore standardization of allergen extracts should include either a direct assessment of potency on the skin (or basophil count) of allergic individuals or, preferably, an *in vitro*measurement of the allergen content.

The first generally applicable *in vitro*measurement of allergen was RAST inhibition, which is still widely used for standardization. It is therefore important to understand the arguments against continuing to base standardization on RAST inhibition. The technique uses a solid-phase, cellulose disc or beads covalently linked to a known allergen extract. This step is inherently difficult because the choice of extract used for the solid phase influences the results and implies some preexisting decision about the correct form of the extract. (A typical example is the difference between mite extracts made from whole culture and those made from “purified” mites.) The second problem with RAST inhibition is that it requires a serum pool derived from individuals who have high levels of IgE antibodies to the relevant allergen. In theory, a large serum pool can be established and maintained as a reference. However, RAST inhibition uses “large” quantities of serum, and even the serum pools established at the U.S. Food and Drug Administration (FDA) have lasted only a few years. Thus all results based on RAST inhibition must be qualified and are reproducible only if the solid phase and the serum pool are the same (75). In conclusion, RAST inhibition is a reasonable technique for comparing the potency of a series of extracts or monitoring the consistency of batches of extract manufactured with an exact protocol. However, RAST inhibition cannot provide a system of units that remains constant over time or that can be compared between one allergen extract and another.

Skin testing allergic patients with a series of extracts as a method of standardization has been rejected in the past because of the difficulty in establishing that the patients tested on different occasions were equally allergic. Indeed, the World Health Organization (WHO) specifically rejects the idea of using any *in vivo*test of a standard to establish the potency (157). Nonetheless, skin testing has the advantage that the extract is tested on allergic patients, and it has been recommended by several groups as a technique of standardization.

More recently, the Center for Biologics Evaluation and Research (CBER) at the FDA in the United States adopted the allergy unit (AU), which also is based on a system of skin testing (249). The primary unitage for AU is established by skin testing 15 patients who are “typically allergic” with an intradermal end-point dilution system (13 to 15 = 100,000 AU; 11 to 13 = 10,000 AU; nine to 11 = 1,000 AU). The primary problem is the method of choosing “typical” allergic individuals; the current protocol suggests that patients are chosen on the basis of their history and a positive prick test. Because the extract to be tested is used to identify allergic individuals, this method is not ideal. Furthermore, the choice of patients based on allergic history may not be applicable to many fungi or to the main perennial indoor allergens. For each new supplier, the allergy unitage of the extract must be established and then each batch standardized by RAST inhibition. Thus the AU system, owing to reasons described earlier and its expense in time and reagents, cannot be regarded as a stable unitage system. In 1993 a modified AU, or bioequivalent unit (BAU), was introduced, in which the mean skin test dilution is converted to BAU. This system was initially adopted for cat allergen extracts; and although it avoids problems of discontinuity of the AU, it still is not ideal.

The alternative method of standardization is the use of measurements of defined allergens in absolute units. This method is possible only for those allergen extracts from which the major allergen (or allergens) have been purified and for which there are suitable methods for measurement (Table 61.4). For the indoor allergens and for many pollens, major allergens can be measured with mAbs and results derived by reference to international standards. Each international standard has been allotted international units (IU) by WHO, but these standards can be used to standardize assays using absolute units. Because the mAbs represent a constant resource and the two-site immunometric assays use little extract to establish a control curve, it is possible to maintain units based on an international standard over many years. The WHO international standard for *D. pteronyssinus*was established in 1980; it is maintained as glass-sealed, freeze-dried ampules, is stable, and has already provided fixed unitage (micrograms of Der p 1 per gram of dust) in a prospective study over a 10-year period (72,182,226).

Recombinant allergens have clear potential advantages for standardizing extracts. Although in theory it is possible to create a defined mixture with known concentrations of all the important allergens, there are still significant problems. All recombinant proteins must be expressed in bacteria, yeast, or mammalian cells, and thus they may be contaminated with other cellular proteins. In addition, some recombinant proteins are expressed as fusion proteins (typically glutathione *S*-transferase), which allow affinity purification but then must be cleaved from the allergen. Some purification techniques also can contaminate recombinant proteins; for example, purification over an mAb column may introduce a trace of mouse immunoglobulin, which is a potential allergen. Hence, there are potential risks involved when attempting to produce pure recombinant proteins. Nevertheless, development of new expression systems (e.g., *Pichia pastoris,*which secretes expressed proteins extracellularly) and refinement of existing ones has made it possible to produce large quantities of pure recombinant proteins. However, before these proteins can be used for clinical diagnosis or treatment, the reactivity of each recombinant protein must be compared with purified natural allergen.

In conclusion, the current situation with allergen standardization is unsettled and includes skin testing, RAST inhibition, protein nitrogen units, and the measurement of major allergens. There are arguments for using recombinant allergens as a source of standards, but such use depends on establishing that the recombinant proteins truly match the native proteins. The area in which the most progress has been made and that offers the simplest approach is measurement of representative major allergens. With mAb technology, technically simple assays for many allergens are now available or possible and can provide standardization of allergen content in absolute units.

QUANTITATION OF ALLERGEN EXPOSURE

Identification and Measurement of Outdoor Allergens

During the nineteenth century, the pollen count was introduced with the use of a sticky slide and microscopic identification of adherent pollen grains (26). Hundreds of airborne (wind-pollinated) pollens have been identified, and excellent atlases give seasonal variations in specific pollens in different geographic areas (223,279). Pollen can be collected in many ways. Techniques that depend on sedimentation and wind velocity, such as gravity slide (or Durham) samplers, give only semiquantitative information. Because sedimentation is affected by particle size and the volume of air sampled is unknown, it is not possible to derive data on the number of pollen grains in the air from these methods. Currently, the standard for analyzing pollen levels is a rotorod sampler, in which the sticky rods are rotated for 20 to 60 seconds every 10 minutes (222). The volume of air sampled is calculated from the size and velocity of the rods, and the results are expressed as pollen grains per cubic meter of air. The rotorod has been estimated to be about 90% efficient at collecting pollen grains of about 20 µm diameter, and the results have been validated by comparison with techniques in which a known volume of air is sampled through an impactor. All pollen-counting techniques depend on microscopic examination of the pollen grains. Interpretation of pollen counts depends to a large degree on local experience. In some areas, the pollen count is an excellent guide to symptoms, and it is possible to predict from a given count that many or most of the patients who are at risk will develop symptoms, although some patients require several days of exposure before they reach maximal sensitivity. This phenomenon, originally described as “priming” by Connell (47), probably reflects in part the recruitment of basophils and mast cells to the nasal epithelium (84). In addition, some patients who have strong positive skin tests and IgE antibodies do not develop symptoms on exposure. Thus there cannot be a specific number for the pollen count that predicts that all skin test–positive individuals will develop symptoms. Nonetheless, at a pollen count of 200 grains/m^3, all patients who are going to get hay fever do experience symptoms; and when the pollen count is less than 5 grains/m^3, it is unusual for patients to experience symptoms.

In general, immunochemical techniques for assaying airborne pollen allergens are not yet simple enough to replace the pollen count. A luminescence immunoassay has recently been used to quantitate airborne birch (Bet v 1) and grass (Phl p 5) allergens (95). Interestingly, in these experiments, allergen levels correlated with pollen grains during dry weather; but after rainy days, large amounts of grass allergen were present in the absence of pollen grains. These results suggest that the development of allergen-specific quantitative assays will provide a more accurate method for measurement of outdoor allergens. The airborne ragweed allergen Amb a 1 also has been measured (221,290). The results showed that some allergen is airborne on particles less than 5 µm in diameter, which is far smaller than the size of a ragweed pollen grain. The quantities of allergen on small particles relative to large particles are not clear (31,221). There has been considerable speculation about the source of small particles carrying grass and weed pollen allergens; fragments of grains and other parts of the plant have been proposed (221,232). Grass pollen can fragment in a wet environment and release multiple starch granules, which then become airborne in a form that could enter the peripheral lung (234). At present, it remains true that the primary correlate of seasonal hay fever symptoms is the number of whole pollen grains airborne on a given day. For some patients allergic to pollen, there is a clear correlation between the pollen count and increased asthma symptoms (186). In many areas, particularly on the East Coast of the United States, the correlation between ragweed pollen counts and asthma is not close, which could be explained if asthma symptoms relate to inhalation of a different particle. It has not been shown, however, that “pollen asthma” correlates with airborne levels of a different ragweed particle. It is more likely that inhalation of small numbers of pollen grains causes progressive increases in bronchial hyperreactivity over a period of weeks. Thus the poor temporal correlation between asthma and pollen counts reflects the cumulative and delayed inflammatory effects of pollen exposure.

Outdoor fungal spores also can be collected on a rotorod and identified microscopically. However, the smaller fungal spores are collected inefficiently on the rod, with perhaps as few as 10% of 1- to 2-µm particles being collected (222). Identification of fungal spores is more difficult than identification of pollen grains. The large spores of *Alternaria* and *Helminthosporium* are highly characteristic and can be identified rapidly; in contrast, the spores of *Aspergillus, Penicillium* spp., and *Basidiomycetes* are small, round, and difficult to distinguish. Many samples include fragments of hyphae that cannot be identified; whether these fragments carry significant allergen has not been determined. Immunochemical assays for airborne fungi have been developed for *Alternaria* antigen Alt a 1, and they appear to correlate with *Alternaria* spore counts (162). *Alternaria* and *Cladosporium* spores can release preformed allergen rapidly in saline. However, *Basidiomycetes* and *Aspergillus* spores release protein only when they are ruptured (10,128,225). One of the *Aspergillus* allergens, Asp f 1, is expressed only after the spore germinates (9). Alternative techniques for collecting fungal spores include the Burkhard trap and various modifications of an Anderson multistage sampler. With the Burkhard (or Hirst) trap, air is drawn through an orifice and hits a slowly moving sticky surface. The surface is then examined for fungal spores. With the Anderson sampler, each stage has a sticky surface or a culture medium, so that individual colonies of viable particles can be identified. The problem is confounded because the various fungi grow better on different media and may require special media to produce spores. There is no satisfactory approach for all fungi; for many species, the small, round spores (1- to 2-µm diameter) are indistinguishable microscopically, whereas others, notably the *Basidiomycetes*, do not germinate on normal culture media.

Measurement of Indoor Allergens

Measurement of indoor allergens is necessary for understanding their role in allergic disease, for evaluating the relevance of indoor exposure to an individual patient, and for developing improved avoidance measures. Many of the sources of indoor allergens (e.g., cats, cockroaches, pet rodents) are easily identifiable. In addition, mites can be identified microscopically and counted in dust samples. Apart from a few fungal spores, none of the particles carrying indoor allergens (cat dander, mite fecal particles, *Penicillium* spores, rodent urinary residues, or cockroach debris) can be identified microscopically in dust or air. There is no indoor equivalent of the pollen count, and we must depend on immunochemical techniques.

Before the discovery of dust mites and the purification of indoor allergens, there was no method for evaluating the allergen content of house dust extracts. Thus, the house dust extracts used in allergy practice had no standardization other than protein nitrogen units (PNUs) or the weight/volume ratio (wt/vol), both of which were almost meaningless. With RAST inhibition, it is possible to evaluate the mite allergen content of house dust or mite extracts, using mite extract on the solid phase (248). However, RAST inhibition cannot be used to evaluate the overall potency of a house dust extract because the dust extract is too heterogeneous.

After its purification, Fel d 1 was measured in samples from houses or in allergen extracts by radial immunodiffusion (161). This work was followed by radioimmunoassay of Der p 1 and other mite allergens (37,247). Since the early 1980s, exposure to indoor allergens has been measured by RAST inhibition or assay of representative major allergens (e.g., Fel d 1, Der p 1, Der f 1, Bla g 2, Can f 1). The use of a single major allergen as an index of exposure implies only that concentrations of this allergen correlate with the levels of other allergens derived from the same source, not that this antigen is the only or even the most important allergen. The assays for major allergens have progressively incorporated mAbs and are standardized relative to national or international standards (34,35,72,131,133). The assays used most widely today are two-site mAb enzyme-linked immunosorbent assays (ELISAs); they are sensitive down to about 1 ng of antigen, are highly specific, and are technically simple (133).

There are two approaches to obtaining samples from a house (collecting reservoir samples and airborne samples) and it is important to understand the basis for each. Because these allergens are inhaled, it would be logical to measure the quantities that are airborne. Such measurements can provide important information about the quantities inhaled and the size(s) of the particles carrying allergens (71,175,178,237,239,258,288). However, the quantities that are airborne are often 5 ng/m^3 or less, and the airborne concentration is dramatically influenced by domestic disturbance. Therefore, collecting airborne samples is technically difficult and requires sampling large volumes of air (a disturbance in itself) or using sensitive assays (175). In modern houses, the air-exchange rate is often low (£ 0.2 air changes per hour), so particles the size of a pollen grain fall rapidly (Table 61.5). In contrast, outdoor air is almost never still, and pollen grains can fly for hundreds of miles. For analyzing the reservoirs of allergen in a house, dust samples can be obtained from carpets, sofas, mattresses, bedding, and kitchen floors with a hand-held vacuum cleaner. These samples are then sieved, weighed, and extracted. Typically, 100 mg of fine dust is extracted in 2 mL of buffered saline. Inasmuch as the relevant allergens are freely soluble, extraction for 4 hours is adequate; and the extracts can be stored frozen. Results are generally expressed as micrograms (or units) of antigen per gram of dust. The reasons for expressing results as a concentration of allergen rather than as the total quantity recovered were considered in detail by two international workshops (176,182). The main argument for using the allergen concentration is that it is difficult to standardize recovery of dust; the current conclusion regarding dust mites is that measurement of the *concentration* of group 1 mite allergen in a reservoir sample is the most reliable index of exposure.

Allergen	Diameter (µm)	Estimated quantity of major allergen/particle (ng)
Outdoor		
Pollen		
Virginia pine	~90	—
Rye grass	30	0.5
Short ragweed	20	0.5
Birch	25	—
Fungal spores		
Aspergillus spp.	2	<0.01
Penicillium spp.	2	—
Alternaria	20 × 10[a]	?
Cladosporium	10 × 5[a]	—
Indoor		
Dust-mite fecal pellets	15–30	0.2
Rat urinary allergen	~7	—
Cat allergen	2–20	—
Bronchial provocation		
Droplets produced by nebulizer	~2	~10^{-5}

[a] Dimensions of nonspherical spores given as length × width.
NOTE: Particle size dictates the maximum quantity of allergen that can be carried, the floating velocity, and to some extent, the distribution in the respiratory tract.

TABLE 61.5. Apparent Aerodynamic Size of Particles Carrying Airborne Allergens

When assessing a house, it is normal practice to collect four or five samples of dust from the bedding, bedroom floor, living room floor and sofa, and kitchen (Table 61.6) (32,73,182). In most houses, the highest level of mite allergen is present in bedding but may be present in dust from a downstairs sofa or from a carpet on an unventilated (typically a concrete slab) floor. In general, there is good correlation between the number of mites and the concentration of mite allergen (100 mites/g is almost equivalent to 2 µg of group 1 mite allergen/g of dust). For cat allergen, the highest level is generally found on the living room floor or sofa. In a house with a cat, these dust samples almost always contain at least 8 µg Fel d 1 per gram; however, the concentration is variable and can be as high as 4,000 µg/g. Comparable highest levels of mite allergen in bedding or carpets are about 100 µg/g. Cat allergen may also be present in houses where a cat is not present, and Fel d 1 levels as high as 80 µg/g have been reported. It is assumed that this cat allergen is transported from other houses on the clothing of the occupant or visitors. Cat allergen is present at high concentration in dust collected from the clothing of individuals who live in a house with a cat. Cockroach allergen is generally found in the highest levels in dust samples obtained from kitchen cupboards or floor. Although there is a good correlation between the presence of cockroach allergen and the identification of cockroaches, high levels of Bla g 2 have been found in houses without signs of roaches (32,73). In most published studies, the highest level of allergen in the house has been taken as the index of exposure for each allergen. In situations in which it has been analyzed, this approach appears to be more reliable than use of the mean level of allergen in the house. However, high concentrations of allergen in the bedding or pillow of a child are probably more important than a comparable level in the furniture or carpets in a room that the child does not use. Thus although the highest concentration of allergen found in the house is most often used as the index of exposure, there may well be situations in which an alternative approach is more appropriate.

Area	Site	Mite		Cat	Cockroach	Gras

TABLE 61.6. Allergen Levels in House-Dust Samples from Various Areas in the United States

AIRBORNE INDOOR ALLERGENS

The objective of measuring indoor allergens is to provide an estimate of the allergen entering the lungs. Ideally, this would be done with personal monitors. These types of monitors have been used to assess the exposure of children to cat allergens in school (5). In addition, nasal filters have been developed that can identify particles carrying inhaled allergens (163,164). However, measurements of personal exposure are made difficult by major differences in domestic exposure during domestic activity; changes in exposure when the face is in close proximity to allergen reservoirs (e.g., sofas and pillows); and air disturbance caused by air cleaners. Airborne cat allergen was first measured by collecting air samples and testing them for their ability to release histamine *in vitro*(71). Subsequently, airborne cat allergen was measured with RAST inhibition or immunoassays for Fel d 1 (134,237,239,258). These experiments have used filters, cascade impactors, and cascade impingers to separate the various particle sizes (Fig. 61.6). Although the details of the studies were different, the overall conclusions were similar: (a) detectable cat allergen is airborne in most houses with a cat; (b) some of the airborne Fel d 1 is associated with particles 5 µm or smaller in diameter; and (c) during disturbance (e.g., vacuum cleaning), the quantities of airborne allergen in houses associated with small particles were comparable to those necessary to produce acute bronchial provocation (134,239,258). Detailed study of houses with a cat suggests that both the cat and the reservoirs contribute to airborne allergen. The cat itself releases large quantities of cat allergen in a range of particle sizes. If the ventilation rate is low (i.e., 0.2 to 0.5 air changes per hour, which is typical of a *tight*domestic house), small particles accumulate. As the ventilation rate increases, the proportion of large particle allergen increases; so in an animal-house room with 12 cats in cages and a ventilation rate of ten air changes per hour, almost all the airborne cat allergen was associated with large particles (51,134). In a house with a cat, allergen can be controlled only by reducing the reservoirs, performing regular vacuum cleaning, and arguably by regularly washing the cat (see earlier) (15,51).

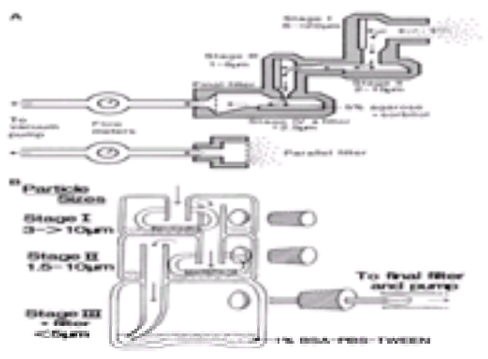

Figure 61.6. Evaluation of particle size of airborne allergens indoors with techniques that depend on terminal velocity; that is, they measure the size of the particles as an equivalent sphere of unit density.

Airborne mite allergens were not measured until a radioimmunoassay for Der p 1 was developed in 1980. Those studies demonstrated that mite allergen became airborne almost exclusively on particles 10 micrometers or larger in diameter (247). Furthermore, the major route by which mite allergen became airborne was as fecal particles. In keeping with this size particle, mite allergen is not airborne under undisturbed conditions, and its concentration decreases rapidly after disturbance (178,239,247,288). The techniques for determining particle size measure terminal velocity and depend on the impaction of particles as they pass through progressively smaller openings. Thus the particle sizes given are those of an equivalent sphere (Fig. 61.6). For the dust mite, it seems likely that the airborne particle is approximately spherical; however, for cat allergen, it is equally possible that the airborne particles are flakes, which behave aerodynamically, similar to a sphere of 2 to 5 µm in diameter. Group 2 mite allergen also is airborne on large particles, although they may not be fecal particles, as the quantity of airborne group 2 allergen is too high to be explained by fecal particles (52). The observation that mite allergen is airborne only during disturbance has been confirmed (288). It is not possible to standardize household disturbance among the various studies, so it is difficult to evaluate the level of exposure of patients in houses based on airborne levels of mite allergen (175,182,192).

The quantities of airborne mite allergen during disturbance have been reported as 5 to 200 ng/m^3. Given that fecal particles contain about 0.2-ng group 1 mite allergen, this figure represents 25 to 1,000 fecal particles per cubic meter. Because of the strong association between mite allergy and asthma, it would be useful to know how much inhaled antigen enters the lung. Some early studies suggested that few inhaled ragweed pollen grains entered the lungs, but those studies assumed that particles this size would induce acute changes in the forced expiratory volume at 1 minute (FEV_1); they also used forced inspiration, which would tend to decrease the number of particles entering the lung (31,277). In two studies on the entry of different-sized particles into the lung (236,243), it was found that under conditions of quiet breathing, particles of 20-µm diameter land predominantly on the pharynx, and only 5% to 10% enter the lungs. Even for optimally sized particles of about 2-µm diameter, only 30% to 40% enter the lungs. Thus for 1 hour of disturbance or equivalent activity, it is possible to estimate that between 5 and 100 mite fecal particles per day enter the lungs. This exposure is dramatically different from that used for bronchial provocation, where 10^7 to 10^8 droplets of about 2-µm diameter are inhaled within 2 minutes. For airborne cat allergen, there is a wide range of particle sizes; and if the particles are not spherical, the actual mass could be greater than the equivalent sphere. The clinical response when a patient who is highly allergic to cats enters a house with a cat suggests that there can be a sufficient *number*of particles airborne to produce acute bronchospasm. In contrast, it is unusual for a patient who is allergic to mites to report rapid onset of symptoms on entering a house, even if the furniture and carpets are highly infested with mites. These observations suggest that exposure to mite allergens occurs at the time of disturbance and that exposure consists of a few particles per day. As with pollen grains, it appears that the primary role of fecal particles in asthma is to contribute to a chronic increase in bronchial hyperreactivity rather than to cause acute symptoms at the time of exposure (180).

The data on airborne levels of other indoor allergens are less complete. Cockroach and rodent urinary allergens have been measured in houses (237). Airborne cockroach allergen is associated with particles 10 µm or larger in diameter, is detectable with disturbance, and falls rapidly (53,54,57,144). Rat and guinea-pig urinary

allergens have been measured in animal quarters (178,238). The results for urinary allergens are similar to those for cat allergen, because allergen is airborne most of the time, and the particle sizes are smaller than those of mite or pollen allergens (178). In keeping with this fact and the high overall airborne levels, some allergic patients have acute attacks of asthma on entering an animal house. Until recently, measurement of indoor fungal allergens was not practical because of the paucity of sensitive immunoassays and the large differences in the expression of allergens on different spores (30,220). Recently an enzyme immunoassay for extracellular polysaccharides of *Aspergillus* and *Penicillium* was developed as a marker of fungal exposure (60). In that study, levels of extracellular polysaccharide were found to be correlated with total culturable fungi and with house dust mite allergens. In addition, an ELISA for measurement of Alt a 1 has allowed quantitation of this allergen in samples of house dust (253). Such assays are critical for determining the relationship of exposure to fungal allergens in houses to development of allergic disease.

RELATIONSHIP BETWEEN EXPOSURE TO ALLERGENS AND DISEASE: ESTABLISHING THRESHOLD LEVELS FOR EXPOSURE
