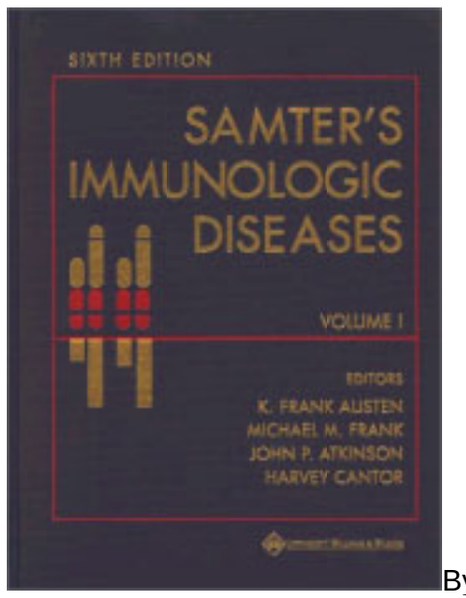
Samter's Immunologic Diseases 6th edition (September 15, 2001): By K. Frank, Md. Austen (Editor), Michael M., Md. Frank (Editor), Harvey I., Md. Cantor (Editor), John P., Md. Atkinson (Editor), Max Samter (Editor) By Lippincott Williams & Wilkins Publishers



By OkDoKeY

Samter's Immunologic Diseases

CONTENTS

VOLUME I

SECTION VI. ORGAN-SPECIFIC DISEASES

SECTION VII. ALLERGIC DISEASES

SECTION VIII. EVASION, ACTIVATION AND INEFFECTIVE IMMUNITY

SECTION IX. TRANSPLANTATION

SECTION X. THERAPEUTIC IMMUNOLOGY

CONTRIBUTING AUTHORS

Abul Abbas, M.D.
Professor and Chair, Department of Pathology, University of California San Francisco, San Francisco, California; Chair, Department of Pathology, Moffit-Long Hospital, University of California, San Francisco Medical Center, San Francisco, California

Norio Abiru, M.D.
Clinical Fellow, The First Departmental Internal Medicine, Nagasaki University, Nagasaki, Japan

Ramzi A. Ajjan, M.D.
Department of Medicine, Clinical Sciences Center, Northern General Hospital, Sheffield, United Kingdom

Maria-Luisa Alegre, M.D., Ph.D.
Assistant Professor, University of Chicago, Department of Medicine, Section of Rheumatology, Chicago, Illinois

Grant J. Anhalt, M.D.
Professor, Department of Dermatology and Pathology, Johns Hopkins University School of Medicine, Baltimore, Maryland; Department of Dermatology, Johns Hopkins Hospital, Baltimore, Maryland

Sophia M. Arackal, B.S.
Washington University School of Medicine, Division of Medical Oncology, St. Louis, Missouri

Barry G. Arnason, M.D.
The University of Chicago, Department of Neurology, Chicago, Illinois

John P. Atkinson, M.D.
Samuel B. Grant Professor of Medicine, Professor of Molecular Microbiology, Washington University School of Medicine, St. Louis, Missouri; Physician, Barnes-Jewish Hospital, St. Louis, Missouri

K. Frank Austen, M.D.
Theodore Bevier Bayles, Professor of Medicine, Department of Medicine, Harvard Medical School Boston, Massachusetts; Director, Inflammation and Allergic Diseases Research Section, Brigham and Women's Hospital, Boston, Massachusetts

Amit Bar-Or, M.D.
Assistant Professor, Department of Neurology and Neurosurgery, Montreal Neurological Institute and McGill University, Montreal, Canada

Robert A. Barrington, Ph.D.
Department of Pathology, Harvard Medical School, Boston, Massachusetts

Nancy L. Bartlett, M.D.
Associate Professor of Medicine, Division of Medical Oncology, Barnard Cancer Center, Washington University School of Medicine, St. Louis, Missouri; Associate Physician, Barnes-Jewish Hospital, St. Louis, Missouri

Jay A. Berzofsky, M.D.
Chief, Molecular Immunogenetics and Vaccine Research Section, National Institute of Allergy and Infectious Diseases/National Institutes of Health — Metabolism Branch, Bethesda, Maryland

Barbara E. Bierer, M.D.
Chief, Laboratory of Lymphocyte Biology, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland

Eugene R. Bleecker, M.D.
Co-Director, Center for Human Genomics; Professor of Medicine, Department of Internal Medicine, Associate Director, Department of Pulmonary & Critical Care Medicine, Wake Forest University Baptist Medical Center, Winston-Salem, North Carolina

Barry R. Bloom, Ph.D.
Dean of Faculty and Professor of Immunology and Infectious Diseases, Harvard School of Public Health, Boston, Massachusetts

Jeffrey A. Bluestone, Ph.D.
A.W. Clausen Distinguished Professor, UCSF Diabetes Center, University of California San Francisco, San Francisco, California

Bruce S. Bochner, M.D.
Professor, Department of Medicine; Division of Clinical Immunology, Johns Hopkins Asthma & Allergy Center, Johns Hopkins University School of Medicine, Baltimore, Maryland

Mark Boguniewicz, M.D.
Department of Pediatrics, National Jewish Medical and Research Center, Denver, Colorado

Marcy B. Bolster, M.D.
Associate Professor of Medicine, Department of Internal Medicine, Medical University of South Carolina, Charleston, South Carolina

Persephone Borrow, Ph.D.
Group Leader, The Edward Jenner Institute for Vaccine Research, Compton, Newbury, Berkshire, United Kingdom

Joshua A. Boyce, M.D.
Assistant Professor of Medicine, Harvard Medical School and Brigham and Women's Hospital, Boston, Massachusetts

Thomas J. Braciale, M.D., Ph.D.
Professor, Department of Pathology, University of Virginia Health Systems; Director and Professor, Department of Pathology and Microbilogy, Beirne B. Carter Center for Immunology Res, University of Virginia, Charlottesville, Virginia

Karl A. Brokstad, Ph.D.
Senior Scientist, Broegelmann Research Laboratory, University of Bergen, Bergen, Norway

Jean-Claude Brouet, M.D., Ph.D.
Professor, Department of Immunology, University of Paris; Chief, Department of Immuno-Haematology, Hopital Saint-Louis, Paris, France

Rebecca H. Buckley, M.D.
James B. Sidbury Professor, Department of Pediatrics, Duke University Medical Center, Durham, North Carolina

Harvey Cantor, M.D.
Professor of Pathology, Harvard Medical School, Chairman, Department of Cancer Immunology and AIDS, Dana-Farber Cancer Institute, Boston, Massachusetts

Michael C. Carroll, Ph.D.
Professor, Department of Pediatrics, Harvard Medical School, Boston, Massachusetts

A. Brent Carter, M.D.
Assistant Professor, Department of Internal Medicine, University of Iowa; Assistant Professor, Division of Pulmonary, Critical Care, and Occupational Medicine, University of Iowa Hospitals & Clinic, Iowa City, Iowa

Rafael Casellas, M.D.
Graduate Fellow, Howard Hughes Medical Institute/Rockefeller University, New York, New York

Edwin S.L. Chan, M.B., Ch.B.
Instructor of Medicine, Division of Clinical Pharmacology, New York University School of Medicine, New York, New York

Yueh-Hsiu Chien, Ph.D.
Professor, Department of Microbiology and Immunology, Howard Hughes Medical Institute, Stanford University, Stanford, California

Oren J. Cohen, M.D.
Assistant Director for Medical Affairs, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland

Joseph E. Craft M.D.
Professor of Medicine and Immunobiology, Chief, Section of Rheumatology, Department of Internal Medicine, Yale University School of Medicine, Chief of Rheumatology, Yale-New Haven Hospital, New Haven, Connecticut

Anthony D. Cristillo, M.D.
Visiting Fellow, Laboratory of Lymphocyte Biology, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland

Bruce N. Cronstein, M.D.
Professor of Medicine and Pathology, Department of Medicine, Director, Division of Clinical Pharmacology Associate Chairman of Medicine for Research, New York University School of Medicine, New York, New York

Kevin A. Davies, Ph.D.
Clinical Director of Medicine; Reader, Section of Rheumatology, Div of Medicine, Imperial College of Science, Tech.,& Med., Hammersmith Campus, London, United Kingdom

Mark M. Davis, Ph.D.
Professor, Department of Microbiology and Immunology, Howard Hughes Medical Institute, Stanford University, Stanford,

California

Glenn Dranoff, M.D.
Assistant Professor of Medicine, Department of Medicine, Harvard Medical School; Department of Adult Oncology, Dana Farber Cancer Institute, Department of Medicine, Harvard Medical School, Boston, Massachusetts

Michael Dustin, Ph.D.
Department of Pathology, Washington University School of Medicine, St. Louis, Missouri

George S. Eisenbarth, M.D., Ph.D.
Executive Director, Barbara Davis Center for Childhood Diabetes; Professor, Department of Pediatrics, University of Colorado Health Sciences Center, Denver, Colorado

Hani S. El-Gabalawy, M.D.
Professor and Head, Arthritis Centre, Winnipeg, Manitoba, Canada

R. Alan B. Ezekowitz, M.B., Ch.B., D.Phil., F.A.A.P.
Chief, Pediatric Service, Massachusetts General Hospital, Boston, Massachusetts; Professor, Department of Pediatrics, Harvard Medical School, Boston, Massachusetts

John David Farrar, Ph.D.
Research Associate, Howard Hughes Medical Institute, Washington University School of Medicine, Department of Pathology, St. Louis, Missouri

Anthony S. Fauci, M.D.
Director, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland

Marc Feldmann, Ph.D., F.R.C.P., FRC
Pathology Professor, Kennedy Institute of Rheumatology Division, Imperial College School of Medicine, London, United Kingdom

Thomas Ferguson, Ph.D.
Associate Professor of Ophthalmology and Pathology, Department of Ophthalmology and Visual Sciences, Washington University School of Medicine, St. Louis, Missouri

Prof. Jean-Paul Fermand, M.D., Ph.D.
Assistant Chief, Department of Immuno-Haematology, Hospital Saint-Louis, Missouri; Professor, Department of Immunology, University of Paris, Paris, France

Jordan N. Fink, M.D.
Professor, Department of Pediatrics and Medicine, Medical College of Wisconsin, Milwaukee, Wisconsin

Fred Douglass Finkelman, M.D.
McDonald Professor of Medicine, Director, Division of Immunology, Department of Internal Medicine, University of Cincinnati College of Medicine, Cincinnati, Ohio; Director, Division of Immunology, Cincinnati Veterans Administration Medical Center, Cincinnati, Ohio

Thomas A. Fleisher, M.D.
Chief, Department of Laboratory Medicine, Warren G. Magnuson Clinical Center, National Institutes of Health, Bethesda, Maryland

Mary H. Foster, M.D.
Department of Medicine, Veterans Affairs Medical Center, Durham, North Carolina; Associate Professor, Department of Medicine, Duke University, Durham, North Carolina

Michael M. Frank, M.D.
Samuel L. Katz Professor and Chairman, Department of Pediatrics, Professor of Immunology and Medicine, Duke University Medical Center, Durham, North Carolina

Iain P. Fraser, M.B.Ch.B., D.Phil.
Instructor, Department of Pediatrics, Harvard Medical School, Boston, Massachusetts; Assistant in Pediatrics, Laboratory of Developmental Immunology, Department of Pediatrics, Massachusetts General Hospital for Children, Boston, Massachusetts

John I. Gallin, M.D.
Director, Clinical Center, National Institutes of Health, Bethesda, Maryland

David N. Glass, M.D.
Professor, Department of Pediatrics, University of Cincinnati College of Medicine; Director, William S. Rowe Division of Rheumatology, Children's Hospital Medical Center, Cincinnati, Ohio

Lisa J. Glickstein, Ph.D.
Assistant Professor of Medicine, Department of Medicine/ Rheumatology, Tufts University School of Medicine, Boston, Massachusetts; Research Associate, Department of Medicine/

Rheumatology, New England Medical Center, Boston, Massachusetts

Peter D. Gorevic, M.D.
Professor of Medicine, Chief, Division of Rheumatology, Mt. Sinai Hospital, New York, New York

Douglas Green, Ph.D.
Head, Department of Cell Immunology, La Jolla Institute of Allergy and Immunology, San Diego, California

Rebecca J. Greenwald, Ph.D.
Postdoctoral Fellow, Department of Pathology, Brigham and Women's Hospital, Boston, Massachusetts

Alexei A. Grom, M.D.
Attending Physician, Department of Pediatrics, Division of Rheumatology, Children's Hospital Medical Center; Research Assistant, Professor of Pediatrics, University of Cincinnati College of Medicine, Cincinnati, Ohio

Rebecca S. Gruchalla, M.D., Ph.D.
Associate Professor of Internal Medicine, Section Chief, Division, University of Texas, Southwestern Medical Center, Department of Internal Medicine, Dallas, Texas

Pércio S. Gulko, M.D.
Assistant Professor in Pediatrics and Medicine, Divisions of Autoimmune and Molecular Diseases and Rheumatology, Columbia University College of Physicians and Surgeons, New York, New York

Laura P. Hale
Associate Professor, Department of Pathology, Duke University Medical Center, Durham, North Carolina

David A. Hafler, M.D.
Sadie, David and Jack Breakstone Professor of Neurology and Neuroscience, Harvard Medical School, Boston, Massachusetts; Director, Laboratory of Molecular Immunology, Department of Neurology/Center for Neurologic Disease, Brigham and Women's Hospital, Boston Massachusetts

Frederick P. Heinzel, M.D.
Staff Physician, Department of Medical and Research Service, Cleveland VAMC; Associate Professor, Geographic Medicine, Case Western Reserve University, School of Medicine, Cleveland, Ohio

C. Garren Hester, B.S.
Research Specialist, Department of Pediatrics, Duke University Medical Center, Durham, North Carolina

Stephen T. Holgate, M.D., BSc, FRCP, FRCPE
Divisional Director, Molecular Biology Division, School of Medicine, University of Southampton and, Southampton General Hospital, Southampton, United Kingdom

Steven M. Holland, M.D.
Senior Clinical Investigator, Head, Immunopathogenesis Unit, Clinical Pathophysiology Section, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland

Timothy D. Howard, Ph.D.
Assistant Professor of Pediatrics, Center for Human Genomics, Wake Forest University School of Medicine, Winston-Salem, North Carolina

Gary W. Hunninghake, M.D.
Sterba Professor, Department of Medicine, University of Iowa Hospitals and Clinics, Iowa City, Iowa

Joan S. Hunt, Ph.D.
University Distinguished Professor, Department of Anatomy and Cell Biology, University of Kansas Medical Center, Kansas City, Kansas

Stephen P. James, M.D.
Professor, Department of Medicine, Head, Division of Gastroenterology and Hepatology, University of Maryland Medical Center, Moses and Helen Paulson Professor of Medicine, School of Medicine, University of Maryland, Baltimore

Andrés Jaramillo, Ph.D.
Research Assistant Professor, Department of Surgery, Washington University School of Medicine, St. Louis, Missouri

Roland Jonsson, D.M.D., Ph.D.
Consultant, Department of Rheumatology, Haukeland University Hospital; Professor, Broegelmann Research Laboratory, University of Bergen, Bergen, Norway

Dr. Insoo Kang, M.D.
Assistant Professor, Department of Internal Medicine, Yale

University; Attending Physician, Department of Internal Medicine, Yale-New Haven Hospital, New Haven, Connecticut

Allen P. Kaplan, M.D.
Professor, Department of Medicine, Medical University of South Carolina, Charleston, South Carolina

Paul Katz, M.D.
Anton and Margaret Fuisz Professor and Chairman, Physician-in-Chief, Department of Medicine, Georgetown University Medical Center, Washington, DC

Stephen I. Katz, M.D., Ph.D.
Director, National Institute of Arthritis and Musculoskeletal and Skin Diseases, National Institutes of Health, Bethesda, Maryland

Clifford J. Kavinsky, M.D., Ph.D.
Assistant Professor of Medicine, Rush Medical College, Assistant Director, Section of Cardiology, Assistant Fellowship Program Director, Rush Presbyterian-St. Luke's Medical Center, Chicago, Illinois

Garnett Kelsoe, DSc
James B. Duke Professor of Immunology, Department of Immunology, Duke University Medical School, Durham, North Carolina

Norman R. Klinman M.D., Ph.D.
Professor, Department of Immunology, The Scripps Research Institute, La Jolla, California

Gary A. Koretsky, M.D., Ph.D.
Director, Signal Transduction Program, The Leonard and Madlyn Abramson Family Cancer Research Institute; Professor, Department of Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, Pennsylvania

Stephen Krilis, M.B., BS, Ph.D., FRACP
Director, Department of Immunology, Allergy and Infectious Diseases, The St. George Hospital; Professor, Department of Medicine, University of New South Wales, Kogarah, New South Wales, Australia

Lewis L. Lanier, M.D., Ph.D.
Professor, Department of Microbiology and Immunology, University of California, San Francisco Cancer Research Center, San Francisco, California

James W. Larrick, Ph.D.
Panorama Research, Inc., Mountain View, California

Donald Y.M. Leung, M.D., Ph.D.
Professor, Department of Pediatrics, University of Colorado Health Sciences Center; Head, Division of Allergy – Immunology, National Jewish Medical Research Center, Denver, Colorado

Michael B. Levy, M.D.
Assistant Professor, Department of Pediatrics and Medicine, Medical College of Wisconsin, Milwaukee, Wisconsin

Peter E. Lipsky, M.D.
Scientific Director, National Institute of Arthritis and Musculoskeletal and Skin Diseases, National Institutes of Health, Bethesda, Maryland

Daniel L. Longo, M.D.
Scientific Director, National Institute on Aging, National Institutes of Health, Gerontology Research Center, Baltimore, Maryland

Robin G. Lorenz, M.D., Ph.D.
Assistant Professor, Pathology and Immunology, Washington University School of Medicine, St. Louis, Missouri

Kim Lu, M.D.
Resident in General Surgery, Department of Surgery, Washington University School of Medicine, St. Louis, Missouri

Andrew D. Luster, M.D., Ph.D.
Associate Professor of Medicine, Harvard Medical School; Chief, Division of Rheumatology, Allergy and Immunology, Director, Center for Immunology and Inflammatory Diseases, Massachusetts General Hospital, Charleston, Massachusetts

James A. MacLean, M.D.
Assistant Professor, Department of Medicine, Harvard Medical School, Boston, Massachusetts; Assistant Physician, Department of Medicine / Allergy, Massachusetts General Hospital, Boston, Massachusetts

Ravinder N. Maini, FRCP, FMedSci
Professor, Head of Kennedy Institute of Rheumatology Division, Imperial College School of Medicine, London, Professor of Rheumatology and Head of Department, ICSM at Charing Cross

Hospital, London, United Kingdom

Michael B. Maris, M.D.
Senior Oncology Fellow, Clinical Research Division, Fred Hutchinson Cancer Research Center, University of Washington, Seattle, Washington

Dale E. McFarlin, Ph.D.
Deceased

John D. McKinney, Ph.D.
The Rockefeller University, New York, New York

Dean D. Metcalfe, M.D.
Chief, Laboratory of Allergic, Diseases, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland

Deborah A. Meyers, Ph.D.
Professor of Pediatrics, Wake Forest University School of Medicine; Co-Director, Center for Human Genomics, Wake Forest University Baptist Medical Center, Winston-Salem, North Carolina

Frederick W. Miller, M.D., Ph.D.
Chief, Environmental Autoimmunity Group, National Institute for Environmental Health Sciences NIH, Bethesda, Maryland

Robert L. Modlin, M.D.
Professor of Dermatology and Microbiology and Immunology, Chief, Division of Dermatology, Department of Medicine – Dermatology, UCLA School of Medicine, Los Angeles, California

Thalachallour Mohanakumar, Ph.D.
Director, HLA Laboratory, Barnes/Jewish Hospital; Jacqueline G. and William E. Maritz, Professor, Department of Surgery, Pathology, and Immunology, Washington University School of Medicine, St. Louis, Missouri

Kenneth M. Murphy, M.D., Ph.D.
Associate Investigator and Professor of Pathology, Department of Pathology and Immunology, Howard Hughes Medical Institute, Washington University School of Medicine, St. Louis, Missouri

Gary J. Nabel, M.D., Ph.D.
Director, Vaccine Research Center, National Institutes of Health, Bethesda, Maryland

Rodney D. Newberry, M.D.
Assistant Professor of Medicine, Division of Gastroenterology, Washington University School of Medicine, Assistant Physician, Barnes-Jewish Hospital, St. Louis, Missouri

Lyse A. Noria, Ph. D.
Postdoctoral Fellow, Department of Urology, The University of Iowa, Iowa City, Iowa

Philip S. Norman, M.D.
Professor, Department of Medicine, Johns Hopkins Asthma & Allergy Center, Baltimore, Maryland; Physician, Department of Medicine, Johns Hopkins Hospital, Baltimore, Maryland

Hossein C. Nousari, M.D.
Assistant Professor and Co-Director of Immunodermatology, Department of Dermatology, Johns Hopkins School of Medicine, Baltimore, Maryland

Michel C. Nussenzweig, M.D., Ph.D.
Professor of Molecular Immunology, Department of Molecular Immunology, Howard Hughes Medical Institute/Rockefeller University, New York, New York

Thomas B. Nutman, M.D.
Head, Helminth Immunology Section, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland

Kevin O'Connor, Ph.D.
Fellow in Neurology, Harvard Medical School; Brigham and Women's Hospital, Center for Neurologic Diseases, Brigham and Women's Hospital, Boston, Massachusetts

Michael B.A. Oldstone, M.D.
Professor, The Scripps Research Institute, LaJolla, California

Lauren M. Pachman, M.D.
Professor, Department of Pediatrics, Division of Immunology, Children's Memorial Hospital, Chicago, Illinois

Joseph E. Parrillo, M.D.
James B. Herrick Professor of Medicine, Rush Medical College, Chief, Section of Cardiology, Chief, Section of Critical Care Medicine, Medical Director, Rush Heart Institute, Rush

Prebyterian–St. Luke's Medical Center, Chicago, Illinois

Elahna Paul, M.D., Ph.D.
Department of Pathology, Children's Hospital, Boston, Massachusetts

John F. Penrose, M.D.
Assistant Professor of Medicine, Harvard Medical School and Brigham and Women's Hospital, Boston, Massachusetts

Mark B. Pepys, M.D., Ph.D., F.R.S.
Professor of Medicine, Head of Department, Department of Medicine, Royal Free & University, College Medical School, London; Honorary Consultant Physician, Department of Medicine, Royal Free Hospital, London, United Kingdom

Jeffrey L. Platt, M.D.
Professor of Surgery, Immunology and Pediatrics, Department of Transplantation Biology, The Mayo Clinic, Rochester, Minnesota

Thomas A.E. Platt-Mills, M.D., Ph.D.
Professor of Medicine and Microbiology, Department of Medicine, Division of Allergy, University of Virginia Medical Center, Charlottesville, Virginia

Hidde Ploegh, Ph.D.
Mallinckrodt Professor of Immunopathology, Harvard Medical School, Boston, Massachusetts

Stephen Reddel, M.B., B.S.
Immunology Research Laboratory, Department of Medicine, St. George Hospital, University of New South Wales, Sydney, Australia

Jerome Ritz, M.D.
Professor of Medicine, Dana Farber Cancer Institute, Boston, Massachusetts

David T. Robles, B.S.
M.D., Ph.D. Student, University of Colorado Health Sciences Center, Denver, Colorado

John W. Rose, M.D.
Professor, Department of Neurology, University of Utah, Salt Lake City, Utah; Assistant Chief of Neurology, Department of Veterans Affairs, Virginia Medical Center, Salt Lake City, Utah

Helene F. Rosenberg, M.D.
Senior Investigator, National Institute of Allergy and Infectious Diseases/Laboratory of Host Defenses, National Institutes of Health, Bethesda, Maryland

Alan D. Schreiber, M.D.
Professor, Department of Medicine, Assistant Dean for Research, University of Pennsylvania School of Medicine, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

John Schroeder, Ph.D.
Assistant Professor, Department of Medicine, Johns Hopkins University, Baltimore, Maryland

Arlene H. Sharpe, M.D., Ph.D
Professor of Pathology, Department of Pathology, Brigham and Women's Hospital, Boston, Massachusetts

Richard M. Silver, M.D.
Professor of Medicine and Pediatrics, Director, Division of Allergy and Immunology, Medical University of South Carolina, Charleston, South Carolina

Jonathan Sprent, M.D., Ph.D.
Professor, Department of Immunology, The Scripps Research Institute, La Jolla, California

E. Richard Stanley, Ph.D.
Renee and Robert A.Belfer Professor, University Chairman, Department of Departmental and Molecular Biology, Albert Einstein College of Medicine, Bronx, New York

Mark D. Steel, M.D.
Honorary Specialist Registrar, Department of Respiratory Medicine, Southampton General Hospital; MRC Clinical Research Fellow, Division of Respiratory Cell and Molecular Biology, School of Medicine, University of Southampton, Southampton, United Kingdom

Allen C. Steere, M.D.
Zucker Professor of Medicine, Department of Medicine/ Rheumatology, Tufts University School of Medicine; Chief, Rheumarology/Immunology, New England Medical Center, Boston, Massachusetts

William F. Stenson, M.D.
Professor of Medicine, Division of Gastroenterology, Washington University School of Medicine Physician, Barnes-Jewish Hospital,

St. Louis, Missouri

Rainer F. Storb, M.D.
Professor, Department of Medicine, University of Washington, Seattle, Washington; Head, Department of Transplantation Biology Program, Fred Hutchinson Cancer Research Center, Seattle, Washington

Charles D. Surh, Ph.D.
Assistant Professor, Department of Immunology, The Scripps Research Institute, LaJolla, California

Paul Szabo, M.D.
Weill Medical College, Cornell University, New York, New York

Marilyn J. Telen, M.D.
Professor of Medicine, Chief, Division of Hematology, Co-Director, Tranfusion Service, Duke University Medical Center, Durham, North Carolina

David W. Thomas, Ph.D.
Senior Vice President, Department of Research and Development, Tanox, Inc., Houston, Texas

David A. Thorley-Lawson, Ph.D.
Professor, Department of Pathology, Tufts University School of Medicine, Boston, Massachusetts

Kenneth S.K. Tung, M.D.
Professor, Department of Pathology, University of Virginia Health Sciences Center, Charlottesville, Virginia

Emil R. Unanue, M.D.
Pathologist-in-Chief, Department of Pathology and Immunology, Barnes-Jewish Hospital; Mallinckrodt Professor and Chairman, Department of Pathology and Immunology, Washington University School of Medicine, St. Louis, Missouri

Martin D. Valentine, M.D.
Professor of Medicine, Department of Immunology, Johns Hopkins School of Medicine and Maryland Asthma and Allergy Center, Baltimore, Maryland

Russell N. Van Gelder, M.D.
Department of Ophthalmology and Visual Sciences, Washington University School of Medicine, St. Louis, Missouri

Steven M. Varga, Ph.D.
Postdoctoral Fellow, Beirne B. Carter Center for Immunology Research, University of Virginia Charlottesville, Virginia

George Vratsanos, M.D
Associate Research Scientist, Section of Rheumatology, Department of Internal Medicine, Yale University School of Medicine, Attending in Rheumatology, Yale-New Haven Hospital, New Haven, Connecticut

Mark J. Walport, Ph.D., FRCP, FRCPath
Professor of Medicine, Chairman and Head of Division of Medicine, Imperial College School of Medicine, London, England

Russell E. Ware, M.D., Ph.D.
Professor of Pediatrics, Division of Hematology/Oncology, Duke University Medical Center, Durham, North Carolina

Anthony P. Weetman, M.D.
Honorary Consultant, Department of Endocrinology, Northern General Hospital, Sheffield; Professor of Medicine, The Medical School, University of Sheffield, Sheffield, United Kingdom

Marc E. Weksler, M.D.
Wright Professor of Medicine, Weill Medical College of Cornell University, New York, New York

Peter F. Weller, M.D.
Professor of Medicine, Harvard Medical School, Chief, Allergy and Inflammation Division, Co-Chief, Infectious Diseases Division, Beth Israel-Deaconess Medical Center, Boston, Massachusetts

Eric H. Westin, M.D.
Section of Hematology/Oncology, Laboratory of Clinical Investigation, National Institute on Aging/National Institutes of Health, Baltimore, Maryland

Robert J. Winchester, M.D.
Professor and Director Rheumatic Diseases Division, Department of Pediatrics, Columbia University College of Physicians and Surgeons, New York, New York

Judith A. Woodfolk, M.D., Ph.D
Assistant Professor of Medicine, Department of Medicine, Allergy

Division, University of Virginia, Charlottesville, Virginia

Alexandra Worobec, M.D.
Adjunct Investigator, Laboratory of Allergic Diseases, National Institute of Allergy and Infectious Diseases, National Institute of Health, Bethesda, Maryland

Catherine J. Wu, M.D.
Center for Hematologic Oncology, Dana-Farber Cancer Institute, Boston, Massachusetts

“Our rate of progress is such that an individual human being, of ordinary length of life, will be called upon to face novel situations which find no parallel in his past. The fixed person, for the fixed duties, who in older societies was such a godsend, in the future will be a public danger.”

Alfred North Whitehead (1861-1947)

“We shall not cease from exploration
And the end of all our exploring
Will be to arrive where we started
And know the place for the first time.”

T.S. Eliot (1888-1965)

“It might be suggested that, in time, the amount of knowledge needed before a new discovery could be made would become so great as to absorb all the best years of a scientist’s life, so that by the time he reached the frontier of knowledge he would be senile. I suppose this may happen some day, but that day is certainly very distant. In the first place, methods of teaching improve. Plato thought that students in his academy would have to spend ten years learning what was then known of mathematics: nowadays any mathematically minded schoolboy learns much more mathematics in a year.”

Bertrand Russell

“I find the great thing in this world is not so much where we stand as in what direction we are moving.”

Oliver Wendell Holmes

“Of, of course, at the end of a day of experimental work during which I found facts that seemed interesting to me, I let my mind wander into the land of fancy and dreams and let it rove in the garden of illusions which dissipated during the night and had cleared away when I entered my laboratory in the morning. Thus acts the mother after a hard day’s work: at the cradle of her sleeping child, she dreams of his future. A sweet smile lights her face, when she sees the successive stages of his life evolve, of a life that must all be joy, of happiness, of success and triumph. When the sun rises, she resumes her daily task, strict and serious again in contact with the realities.”

From Arthus’ delightful preface to De L’anaphylaxie à l’immunité

PREFACE

We have just put to rest the sixth edition of *Immunologic Diseases*. The last chapter is in. The four editors and our colleagues at Lippincott, Williams and Wilkins all let out a collective sigh of relief as “it” is now in the production house. This textbook, the initial edition of which was published in 1965, was the first of its type for immunology. In our student, fellowship, and early faculty member days, if we wanted to know the “immunology” of, for example, sarcoidosis or Grave’s disease, this textbook was the “gold standard.” “Samter” was where we went to obtain a comprehensive and authoritative discussion and review of the immunologic underpinnings of a human disease. We often next searched the primary literature, a process facilitated immeasurably by the extensive bibliography that always has been an important feature of this textbook. “Samter” was a mainstay in our efforts to broaden our knowledge base in immunology and an absolute “must” for our small but growing personal library of books on immunology.

This textbook was expertly guided and “coached” by Max Samter for four editions. His thought-provoking and instructive quotes from these four editions added poignancy to the prefaces of the first four editions. We have included several of our favorites at the end of our comments. In the preface to the fifth edition, we honored Max and we want to continue this tradition by restating those words:

“This edition of *Immunologic Diseases* is the second that has not been led by Max Samter. Max, a brilliant clinical allergist and immunologist, was one of the first to anticipate the majestic structure into which basic immunology would develop and to realize that this discipline would have enormous impact on our understanding of clinical illness. The first edition of *Immunological Disease,* published three and a half decades ago with his co-editor Harry Alexander, came to the world at a time when clinician-investigators were just beginning to recognize and group together seemingly disparate diseases with possibly similar immunologic mechanisms. We, the other editors, applaud Max’s extraordinary insight, intelligence, and good humor. We are committed to continue Max’s long tradition of excellence with an edition that vastly expands our understanding of modern immunologic diseases.”

The sixth edition follows the format that has made this book successful. Namely, the book begins with scholarly discussions by noted experts of the basic tenets of immunology. This forms a foundation for the “student” of immunology and provides a background for the more disease- and organ-focused chapters to follow. These latter sections cover in-depth the immunologic aspects of the disease but, in most cases, no longer provide an all-encompassing discussion of a disease. Rather, if the reader desires to learn more about, for example, cardiac involvement in sarcoidosis or SLE, a visit to a cardiology or rheumatology textbook would be appropriate. The purpose of this edition is to primarily focus on the immunologic aspects of these diseases.

In this sixth edition we continue to emphasize the immune system of humans and the immunologic basis of human disease. The bibliographies are still rather extensive but have the added intent of providing a pathway to “finding the right additional information.” Many authors are new and the emphasis in some chapters has changed as might be expected in a fast-moving field such as immunology. Overall, however, this edition is similar to the previous one in content and emphasis. We faced an issue in this edition of how to handle infectious diseases in which, in most cases, the immune system was just doing “its thing.” The major question in infectious diseases for the immunologist is to understand its limitations and compromises in an agent related fashion and to understand how infection contributes to the development of immunologic diseases. Consequently, we have included overviews of how the immune system deals with microbes rather than, in most cases, discussing each disease entity separately.

The advances in immunology over the past decade are astonishing. As one reads the immunologic literature, one cannot but be impressed by our ability to: knock-out or knock-in an immunologic gene of interest; define the actual shape of our proteins (beginning, of course, with wonderful pictures of the major histocompatibility complex protein containing a peptide in the groove); peer into the cell’s interior to explore its signaling pathways; correct oversights such as the almost forgotten innate immune system whose recognition was jumpstarted by the discovery that the Toll-like receptors of the fruit fly had their homologous proteins in humans; and utilize immunologic tenets to create inhibitors of important immune regulators including tumor necrosis factor. These regulators have had amazing success in such diseases as rheumatoid arthritis or inflammatory bowel disease.

One might predict that each key cytokine will play a role in one or more human diseases and that soon we will have a specific inhibitor for each. One goal, therefore, of the clinical immunologist will be to put the right inhibitor or group of inhibitors with the right disease. Moreover, in the preceding example of tumor necrosis factor inhibitors not only is an immunologic protein being inhibited that is a key orchestrator of the inflammatory response, but the agent mediating the inhibition is an immunologic molecule itself – either a humanized monoclonal antibody to tumor necrosis factor or a fusion protein of an antibody and two copies of the tumor necrosis factor receptor. With these agents, the action of tumor necrosis factor is inhibited and the patient’s inflammatory disease becomes less active. As this example illustrates, molecular technology has allowed us to approach immunologic issues with a precision unimagined just a few years ago. Many of our critical reagents and other “tools of the trade” are derived from and based on the technology of molecular biology.

The future of immunology is bright indeed. However, we have much to learn and much to do. We have yet to understand at the most fundamental level the two common scourges of an immune system in disarray – allergy and autoimmunity. We still do not have an adequate idea as to why an individual mounts an immune response to a ubiquitous (in some parts of the world at least) and innocuous substance like ragweed pollen or, in the second situation, synthesizes large quantities of antibodies or T cells that react with self tissue. In many cases we know the structure of the antigen and even what epitope is recognized by an autoantibody or an autoreactive T cell, but we do not know why this self reactive protein or cell developed in the first place or why its production is not turned off. Also, we have yet to adequately harness the great effector activity of the immune system to rid the body of undesirable elements such as malignant cells. While we have had some clinical success, such as with a monoclonal antibody to B-cell and T cell antigens, we have a long way to go in implementing successful strategies to kill most types of tumor cells. Theoretically it seems eminently accomplishable but practically it has been difficult, perhaps because tumor cells are nearly indistinguishable from self except for growing more efficiently. Consequently, which tumor antigens to target and how to target them for destruction are largely unanswered questions.

As we proceed into the new millennium a few cautionary notes are in order. First, the terms “autoimmunity” and “allergy” tend to be employed too generally and to diseases where it is far from certain that, for example, autoimmunity is the problem. Two possible examples of this situation are rheumatoid arthritis and inflammatory bowel disease. In both cases, no specific antigen or effector molecule has been identified. Also, the finding that a major fraction of juvenile rheumatoid arthritis in some parts of the United States is caused by a spirochete (Lyme disease) and that what at one time was called idiopathic mixed cryoglobulinemia is caused by chronic viral infections of the liver should produce a certain level of caution in all of us. Second, of all the major organ systems in the body, none is evolving as rapidly as the immune system. This is not surprising since its role is to respond to swiftly and efficiently mutating microbes. The immune system of the mouse has evolved to deal with mouse pathogens while ours evolved to deal with a different set of pathogens. Thus, advances made in animal models need to be placed into this context. Third, we sometimes tend to neglect the fact that the immune system’s primary job is to handle infectious organisms. Other functions, if any, are quite ancillary. A definitive textbook of immunology will someday be written together with experts in infectious diseases. The design of the book will be such that, for each patient who develops an infection such as pulmonary tuberculosis, the immunologist and infectious disease specialist will analyze the patient’s immune system and then specifically explain why this individual was susceptible and the rest of the family members who were similarly exposed were not. Fourth, the immune system is an organized and interacting “whole” but we immunologists tend to focus on one or another part of the system (trendy immunology, if you will). “Immunology is more than a lymphocyte,” as one author noted.

It is our hope and belief that the basic and clinical immunologic discussions presented in this textbook will be a resource and catalyst for our students of immunology in trying to further understand and apply their tenets to the betterment of humankind. We salute the past and future pioneers in our field of immunology. We recall that our discipline continues to contribute to the field of vaccination – one of the three or four greatest advances in promoting the health of mankind. The reduction in morbidity and mortality from this application of immunologic principles is incalculable. Now we face the daunting task of preventing as well as curing allergic and autoimmune diseases and employing this system to vanquish tumor cells and to enhance immunity against infections.

Finally, we want to thank our assistants, friends and colleagues who made this new edition possible. Our editorial assistants, Alison Angel, Jeanette Clayton, Joanne Miccile, and Lorraine Whiteley carried much of the burden of organizing the day-to-day activities of correspondence, proofreading, reviewing proofs, and vigilance relative to our timetables. Ms. Arlene Stolper Simon spent countless hours editing chapters and reviewing those proofs. We thank the authors who used their vanishing and increasingly valuable time to write these remarkable chapters. One consolation that we each have is that a scientist who writes a chapter always learns the most, even about a field in which he/she is one of the experts. Lastly, we are indebted to our two senior editors at Lippincott, Williams and Williams, Raymond Reter and Jonathan Pine. Their unfailing good humor and optimism about us, our authors, and the book itself is greatly appreciated. By the time this textbook is in print, the genomic sequence will be complete for humans as well for our favorite experimental animal, the mouse. This should provide a fertile data set for immunologists to explore in this millennium. In closing, we hope this textbook meets our goal of making “immunology instructive to the initiated as well as the innocent.”

1 INNATE IMMUNITY: LINKAGES TO ADAPTIVE RESPONSES

Robert A. Barrington, Ph.D., Elahna Paul, M.D., Ph.D., and Michael C. Carroll, Ph.D.

Innate immunity is a host defense system with an immense repertoire of cellular and humoral components ranging from the skin as a physical barrier to serum proteins that possess highly specific recognition sites for molecular structures common to pathogens. This chapter reviews several major constituents of innate immunity and emphasizes the basic concept recognized by Janeway in 1989, that the innate immune system is critical for turning on the adaptive response (1). Absolutely necessary for effective inflammatory and humoral responses against external pathogens, the innate immune system also seems to guard against autoreactivity and thus protects against autoimmune disease. Innate immunity's involvement during inflammation is discussed, and complement's role in humoral responses and in tolerance is reviewed to illustrate the linkages between the innate and adaptive immune systems.

In general, the innate immune system consists of three major components: (a) phagocytic cells, which eliminate microorganisms by ingesting and degrading them; (b) soluble plasma proteins and glycoproteins that bind microorganisms and target them for phagocytosis (i.e., opsonization) or for attack by the complement system, leading to microbial death by cytolysis; and (c) natural killer (NK) cells, a subset of primitive T cells pivotal for cell-mediated destruction of tumor cells and virally infected cells (Table 1.1). Detailed descriptions of each of these effector arms of innate immunity are provided in later chapters. In contrast to the adaptive immune system with its somatically rearranging, epitope-specific T- and B-cell receptors (TCRs and BCRs), components of the innate immune system do not mutate during the life of the host and do not exhibit memory when confronted with recurrent infections. Instead of somatic memory as defined by the adaptive immune system, the innate immune system has “evolutionary memory” with conserved components that recognize broad classes of molecules from common infectious agents. As a result, genetic deficiencies in various components of the innate immune system can have significant effects on the host's protective immune response.

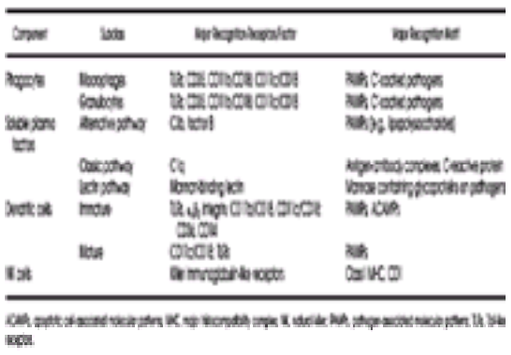

TABLE 1.1. Overview of the Major Components and Receptors of Innate Immunity

ANTIGEN RECOGNITION: IMPORTANCE OF INNATE RECEPTORS

Proper antigen recognition and handling comprise the crux of a normal immune system. Failure to recognize invading pathogens efficiently results in potentially lethal infections, and, conversely, unwarranted recognition of host-derived antigens may lead to autoimmune disease. The innate immune system ensures proper responses based on highly evolved cell-surface receptors and serum proteins that are specific for foreign structures and for self-structures. Many of the system's proteins actually recognize both foreign and host-derived cells and antigens. Because of the inherent risks in this dual recognition, the ability to reconcile mechanisms involved in innate recognition of cells and antigens may lead to novel strategies for both vaccine development and treatment of autoimmune disorders.

Components of the innate response recognize pathogen-associated molecular patterns (referred to as PAMPs) (2). The concept of pattern recognition is a relatively novel formulation of immune recognition. PAMPs include diverse moieties such as lipopolysaccharides (LPS) of gram-negative bacteria, peptidoglycans and lipoteichoic acid of gram-positive bacteria, and mannans of bacteria and fungi (1,3,4). PAMP recognition receptors (PRRs) are similarly diverse. For example, mannan-binding lectin (MBL) is a multimeric serum protein with six carbohydrate recognition domains that bind mannan with relatively high avidity (5). Binding of MBL to pathogen surfaces can activate the complement cascade, resulting in both microbial opsonization to facilitate uptake by phagocytic cells and microbial lysis through complement's membrane attack complex. The mannan receptor is a membrane form of MBL expressed on the surface of mammalian macrophages. Engagement of this receptor directly promotes phagocytosis of the pathogen and subsequent release of proinflammatory chemical mediators (5).

Toll-like receptors (TLRs) are another class of protective PRRs that were described initially in the fruit fly *Drosophila melanogaster* (6). Conserved through evolution, this complex system of receptors responding to distinct ligands includes at least seven *Tlr*-related genes in *Drosophila* and six in humans (7). TLRs are found on mammalian phagocytic cells such as macrophages and on accessory cells such as dendritic cells (DCs) that are important links to adaptive immunity (8). TLRs can bind polypeptide products of proteolytic cascades such as the kinin system, which are often activated during bacterial infection. In addition, TLRs can be activated by secondary innate receptors. For example, mammalian TLR4 is activated indirectly by bacterial LPS after LPS binds the cell-surface receptor CD14 (9). TLR4 activation then triggers activation and translocation of nuclear factor-kB (NF-kB) from the cytoplasm to the nucleus and results in expression of inflammatory cytokines such as tumor necrosis factor-a (TNF-a) and interleukin-1 (IL-1) (9). Currently, intense research is under way to characterize other TLRs and ligands.

The protective power of innate immunity is amplified by a large collection of antimicrobial serum proteins and their cognate cell-surface receptors such as the complement system. When activated, the complement cascade of sequential proteolytic events generates many bioactive peptide fragments (10,11). The C3 component, for example, is enzymatically degraded in a stepwise manner resulting in distinct products identified according to molecular size: C3a, C3b, iC3b, and C3d. For each distinct split product there are one or more cell-surface receptors whose engagement can induce diverse effects on cells of both the innate and adaptive immune systems. Indeed, at least two of these receptors, CD21 and CD35, are discussed later as important links between innate and adaptive immunity (12,13).

IMMUNE SURVEILLANCE

Host cells protect against viral infection or neoplastic transformation by random and continuous sampling of local microenvironments. NK cells are important participants in this immune surveillance (14,15). Technically a subfamily of T lymphocytes, NK cells use “hard wired” recognition receptors rather than somatically rearranged antigen receptors and therefore are considered components of the innate immune system. Both inhibitory and activating receptors, collectively referred to as killer immunoglobulin-like receptors (KIRs), are differentially expressed on NK cells (16,17). NK cell inhibitory receptors recognize conserved regions of the major histocompatibility complex (MHC) class I proteins that are expressed on nearly all host cells (16,18). Host cells expressing these heterodimeric glycoproteins repress NK cell activity. Viral infection or neoplastic transformation can disrupt normal MHC class I expression, and the absence of recognizable MHC class I molecules on host cell surfaces releases the baseline NK cell inhibitory signals, thus permitting NK cell activation. Activating receptors on NK cells include CD2, CD16, and CD69. Coordinate signaling through these receptors allows recognition and potentiates killing of tumor cells or virally infected cells either by direct cytotoxicity or by antibody-dependent cellular cytotoxicity (ADCC) . ADCC is yet another link between innate and adaptive responses during which NK cell cytotoxicity is triggered by the stimulatory Fc receptor FcgRIIIA and by the complement receptor CR3 (CD11b/CD18) after recognition of abnormal cells that are coated with antibody and complement fragments.

The task of continuous immune surveillance by the innate immune system is shared with the alternative pathway of serum complement. Although there are some specific activators of complement, the system exists in a state of perpetual low-level activation through the spontaneous conformational changes or “tickover” of C3 molecules (19). Activated C3 can bind covalently to nearly any surface in its vicinity. C3 attachment to acceptor sites on pathogens triggers rapid amplification of the complement cascade and elimination of those invaders. Host tissues cells are protected from spontaneous complement-mediated injury because host cells express C3 inhibitors. This family of receptors and serum proteins, referred to as regulators of complement activation (RCA) (20), bind activated C3 (C3b) and either block propagation of the complement cascade or cooperate with factor I to degrade the C3 moiety. These regulators include membrane cofactor (CD46), decay-activating factor (CD55), and the Crry receptor (20). Mice lacking the Crry receptor are not viable (21), a finding implying that inadequate inhibition of the complement cascade induces spontaneous injury and death to the fetus.

INFLAMMATION

Inflammation is a major consequence of activating the innate immune system. Classically identified by the four symptoms of heat, rash, edema, and pain, inflammation is the rapid response to an infectious organism that can lead to direct lysis or uptake of pathogens by phagocytic cells within minutes to hours. Serum and cellular components together mediate the phenotype. For example, local activation of the complement system can stimulate mast cell release of proinflammatory cytokines such as TNF-a, chemical mediators such as histamine and a variety of proteases (22). Together, these agents promote dilation and increase permeability of local blood vessels. By upregulating selectins on local endothelial cells, histamine can initiate margination and rolling of circulating leukocytes (23). Additional mediators such as the leukotrienes and platelet-activating factor further enhance the inflammatory response by upregulating integrins and leukocyte influx into the local tissues (24).

Complete characterization of inflammation is not the intent of this introductory chapter. Instead, two animal models of inflammatory processes are presented as specific examples of how inflammation can be both protective and pathogenic to the host. The first example is cecal ligation and puncture (CLP), a model for acute septic peritonitis that includes the combined interaction of serum and cellular components in clearing a bacterial infection. The second example, ischemia reperfusion (IR) injury, is a condition in which the host's innate immune system is provoked to attack self-tissue and can result in death depending on the severity of the inflammatory response.

Acute Septic Peritonitis as a Model for Host Protection

CLP is a mast cell–dependent model of acute septic peritonitis that can progress to fulminant sepsis (25,26). In this surgical model, the cecum is ligated, it is punctured to release bacteria from the intestine, and then the peritoneum is reclosed. Within minutes, bacteria in the peritoneum activate the innate response beginning with mast cell degranulation that, in turn, promotes massive infiltration of neutrophils similar to a ruptured appendix. The innate immune system is essential for host protection because the adaptive response is too slow to be protective in this acute infection model. Nonetheless, mice deficient in serum immunoglobulin M (IgM) have more fulminant sepsis than normal mice undergoing CLP. Reconstitution of IgM-deficient animals with natural IgM from naive unimmunized donors affords some protection against the sepsis syndrome (27). This observation suggests that spontaneously produced natural antibody may be considered a soluble component that is shared between the innate and adaptive immune systems (see later, in the discussion of innate immunity-mediated control of adaptive responses).

Because of its pentameric structure, IgM is effective at binding to pathogens and activating the classical pathway of complement (28,29). Antigen binding induces a conformational change in the antibody that allows C1q binding and initiates the classical complement pathway cascade, with sequential activation of complement components (see chapter 26 for detail on complement pathways). Deficiency in C3 or C4 or in their receptors CD21/CD35 dramatically increases morbidity and mortality in the CLP model (30). The impaired activation of the classical pathway reduces survival by blocking bacteriolysis by the C5-C9 membrane attack complex and by diminishing activation of peritoneal mast cells. In the absence of complement activation, peritoneal mast cells do not recruit neutrophils to the peritoneum, thereby permitting bacteria to escape opsonophagocytosis.

In summary, the CLP model identifies some of the cellular and serum components of innate immunity that are required in protection from severe bacterial infection. Although mast cells express PRRs, costimulatory interactions from IgM natural antibody and the classical pathway of complement are also required for complete mast cell activation. In the absence of IgM, complement or complement receptors (CD21/CD35), neutrophil infiltration and clearance of bacteria from the peritoneum are impaired.

Ischemia Reperfusion Injury: A Model of Pathogenesis

Brief periods of ischemia, which alone do not induce the irreversible cell damage of an infarct, can nonetheless result in severe necrosis after restoration of blood flow. Ischemia appears to alter the expression of surface antigens on local endothelium. These newly exposed antigens can become targets of a vigorous inflammatory response that induces the so-called IR injury. Studies in animal models reveal that IR injury is mediated by many of the same components used in host protection from bacterial infection. Complement proteins, natural IgM, and neutrophils all contribute to inflammation and injury (31,32). Because mice deficient in complement C4 or in IgM are partially protected in a hindlimb model of IR injury (33,34 and 35), this model demonstrates that the protective responses of the innate immune system are also potentially pathogenic.

INNATE IMMUNITY-MEDIATED CONTROL OF ADAPTIVE RESPONSES

One important advance in immunology has been the understanding that the innate immune system regulates adaptive responses. As introduced earlier, the innate system includes “hard-wired” receptors that facilitate either direct or indirect identification of invading pathogens. One example of this phenomenon is the uptake of opsonized microorganisms by phagocytes such as macrophages and DCs, which then process and present microbe-derived peptides to T lymphocytes (36). These antigen-presenting cells further modulate the adaptive response by cytokine release (37). In the absence of costimulation from an antigen-presenting cell, the T-cell response to pathogens would be ineffective and potentially could even lead to anergy (38).

The innate immune system also regulates the development and differentiation of B lymphocytes. Complement, for example, is a positive regulator of B-lymphocyte responses to thymus (T)-dependent antigens (39). Complement-mediated regulation of humoral responses was first noted in 1970, when B lymphocytes were found to bind activated products of the third component of complement (C3) (40). Shortly thereafter, Pepys discovered that mice depleted of serum C3 by treatment with cobra venom factor have diminished antibody responses to T-dependent antigens (41). Building on the Pepys study, investigators subsequently discovered that antibody responses are diminished in animals with naturally occurring deficiencies in complement components C3 as well as C4 and C2 (42,43,44,45,46 and 47) (Fig. 1.1). Humans with deficiencies in C3 and C4 also have diminished responses to T-dependent protein antigens (48). The impaired responsiveness is comparable between animals deficient in classical pathway activators (C4, C2) and C3-deficient animals, a finding suggesting that the effect is mediated through the classical pathway of the complement system. Moreover, the evolutionary conservation of similar phenotypes in species as diverse as guinea pigs, dogs, and humans clearly emphasizes the importance of the classical pathway complement in regulating humoral responses.

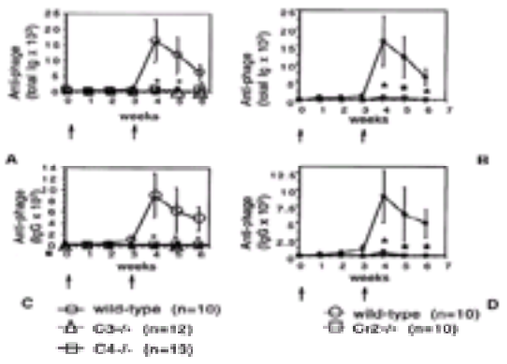

Figure 1.1. Humoral immune responses are impaired in mice deficient in complement C3 or C4 or complement receptors CD21/CD35. Mice (complement-sufficient (WT) or complement-deficient) were immunized at days 0 and 21 with a thymus (T)-dependent antigen (2 × 109 plaque-forming unit bacteriophage) intravenously and total immunoglobulin (Ig) (**A** and **C**) or IgG (**B** and **D**) titers were determined by plaque assay.

Complement's effects on humoral responses are mediated principally through complement receptors CD21 and CD35 found on B lymphocytes and on follicular DCs (FDCs) (49). CD35 is also found on polymorphonuclear cells, macrophages, mast cells, and DCs (49). In mice, the *Cr2* locus encodes both CD35 (CR1) and CD21

(CR2), whereas in humans CD35 and CD21 are encoded by distinct, but closely linked, genes. CD35 and CD21 bind overlapping subsets of proteolytic fragments derived from activated C4 and C3 (see Chapter 26 on the complement system for more details). The C3d and C4d peptide fragments generated during the proteolytic cascade of the classical pathway can covalently attach to antigen (50,51). Complement-coated antigen is more immunogenic than antigen alone. This “adjuvant effect” was demonstrated by two types of experiments. First, by immunizing mice with fusion proteins of hen egg lysozyme (HEL) coupled to multimers of C3d fragments, Dempsey et al. found that addition of three C3d moities were 10,000 times more potent than HEL alone in stimulating an immune response (52).

A second set of experiments used either antibodies directed against CD21/CD35 or a soluble form of the CD21 receptor (sCR2) to compete for uptake of C3d-coupled antigen (53,54,55 and 56). In both examples, humoral responses to T-dependent antigens were impaired. In addition, blocking antibodies against CD21/CD35 were more effective than anti-CD35 alone, a finding suggesting that CD21 may be more important for regulating humoral responses (53).

The finding that CD21 associates with the CD19 and CD81 coreceptors on the surface of human B lymphocytes helped to explain how complement-coupled antigen is more immunogenic than antigen alone (57,58). By engaging the BCR and CD21 simultaneously, the antigen-C3d complex delivers a stronger stimulus than antigen alone (59). Accordingly, because naive B lymphocytes bear low-affinity receptors for antigen, concomitant coreceptor signaling would augment the BCR signal and would thereby lower the threshold of response. Complement receptors may also exert their adjuvant effect by increasing the efficiency of antigen trapping by FDCs (60,61,62 and 63) (Fig. 1.2).

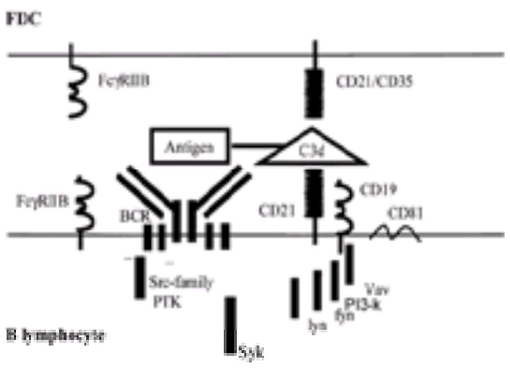

Figure 1.2. Complement recptors CD21 and CD35 are coexpressed primarily on B lymphocytes and follicular dendritic cells (FDCs) in mice. On B lymphocytes, CD21/CD35 form a coreceptor with CD19 and TAPA-1 (CD81). Binding of antigens coupled to C3d coligates the coreceptor with the B-cell antigen receptor (BCR) and results in a lowered threshold of B-lymphocyte activation. CD21/CD35 on FDCs allows efficient antigen trapping within lymphoid follicles.

The availability of *Cr2*$^{-/-}$ mice, deficient in both CD21 and CD35, provides an opportunity to differentiate between the independent contributions of CD21/CD35 expression by B lymphocytes and by FDCs (64,65). Based on the observation that FDCs are resistant to irradiation and are not regenerated from adult bone marrow, Ahearn et al. designed chimeric mice that contained *Cr2*$^{+/+}$ B lymphocytes and *Cr2*$^{-/-}$ FDCs (64). Initially, these chimeric mice respond normally to immunization with T-dependent antigens; however, their long-term memory responses are poor. Therefore, it appears that CD21/CD35 on B lymphocytes is sufficient for generating near-normal antibody titers, but the absence of efficient antigen retention by CD21/CD35 on FDCs may compromise long-term B-lymphocyte memory.

Complement-Regulated B-Lymphocyte Responses

B-lymphocyte maturation and differentiation proceed through an ordered sequence of events that depends on interactions with other cell types and the local microenvironment (66). Moreover, B-lymphocyte responses to antigen vary in each stage of development. For example, cross-linking of the BCR during the immature stage leads to death or anergy (67,68,69,70,71 and 72). By contrast, BCR stimulation of mature B lymphocytes leads to activation. B lymphocytes are tightly regulated at multiple stages, or checkpoints, of development and maturation. The complement system appears to be involved in at least five of these stages (summarized in Fig. 1.3), and complement's influence at these checkpoints further exemplifies the linkage between innate and adaptive immunity.

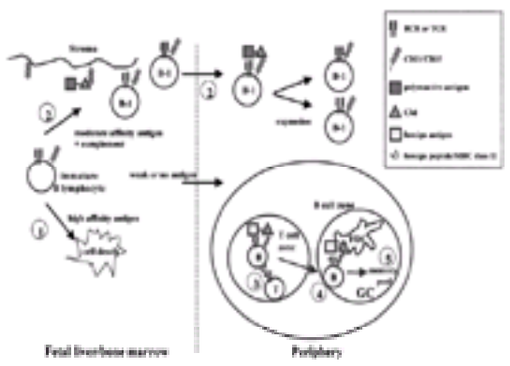

Figure 1.3. Checkpoints in B-lymphocyte development and differentiation in which complement is likely important. At checkpoint 1, immature B lymphocytes recognizing antigen with high affinity are triggered to apoptose. Immature B lymphocytes recognizing antigen with moderate affinity in addition to receiving a signal through CD21/CD35 undergo differentiation into B-1 cells (checkpoint 2). Similarly, signals through CD21/CD35 in the periphery may lead to expansion of B-1 cells during checkpoint 2. Immature B lymphocytes not recognizing antigen or recognizing antigen with low affinity are released into the periphery as B-2 cells, where they survey secondary lymphoid tissues in search of antigen. Their survival after contact with moderate-affinity antigen depends on coreceptor signals through CD21/CD35 during checkpoint 3. Lymphocytes receiving requisite signals continue to differentiate within germinal centers (GCs), where CD21/CD35 is again important for checkpoint 4. B lymphocytes not receiving complement-ligand interactions in GCs die. Successful survival during selection and differentiation in GCs leads to production of long-lived memory B lymphocytes and plasma cells. The life span of these lymphocytes may also depend on continued interaction of antigen deposited on follicular dendritic cells (FDCs) with CD21/CD35 (checkpoint 5)

CHECKPOINT 1: NEGATIVE SELECTION OF IMMATURE SELF-REACTIVE B LYMPHOCYTES

B lymphocytes are regulated during development so those bearing self-reactive antigen receptors are either eliminated or rendered anergic before reaching maturity (73,74). Insight into this negative selection process derives primarily from studies of mice possessing autoreactive Ig transgenes (71,73,74). However, even in these experimental model systems, it remains unclear how self-antigens are presented to the developing lymphocytes. Growing evidence supports a role for the innate immune system in directing negative selection by enhancing interactions between immature lymphocytes and highly conserved self-antigens such as nuclear proteins and DNA (75). This stage can be referred to as the first checkpoint and is discussed further later in this chapter.

CHECKPOINT 2: POSITIVE SELECTION AND EXPANSION OF B-1 CELLS

Natural antibody, in contrast to antibody secreted in response to active immunization, is continuously released by the B-1 subpopulation of lymphocytes (76). Predominantly IgM, natural antibodies tend to be polyreactive with low-affinity binding for antigens such as nuclear proteins, DNA, and phosphatidyl choline that are common structures among both pathogens and host tissues (77,78,79,80 and 81).

Unlike conventional B lymphocytes (i.e., B-2 cells), B-1 cells are found primarily in the peritoneal cavity and reside only at low frequencies in traditional lymphoid tissues (82,83). They rarely undergo class switching or somatic hypermutation in response to antigenic stimulation, a finding suggesting that they do not require germinal centers for further maturation and expansion (84,85 and 86). As a result, antibodies from B-1 cells tend to be encoded by germ line Ig variable region genes that may have been selected through evolution for their ability rapidly to recognize pathogens and to activate the complement cascade. Activation of complement then assists recruitment of cellular components of the innate immune system while at the same time enhancing the humoral responses of the adaptive immune system. As discussed at the end of this chapter, natural antibody may also be important for recognition and handling of self-antigens routinely released from apoptotic cells.

In comparison with conventional B lymphocytes, B-1 cells are more sensitive to signaling through the BCR (87,88,89,90 and 91). As a result, genetic defects altering the BCR's signaling capacity have more dramatic effects on B-1 than on conventional B lymphocytes. For example, mice with defects in critical positive regulators of the BCR signaling pathway such as btk, CD19, vav, or phosphatidylinositol-3-kinase have few, if any, B-1 cells, whereas numbers of B-2 lymphocytes are less severely affected (92,93 and 94). Conversely, defects in negative regulators of BCR signaling (e.g. SHP-1, CD72) leads to larger B-1 cell populations (95,96 and 97). These observations indicate that BCR signaling is critical in the initial positive selection, expansion, or maintenance of B-1 cells. Mice deficient in complement receptors CD21/CD35 also have a reduced frequency of B-1 cells (64), consistent with a role for complement in the selection or maintenance of B-1 cells.

CHECKPOINTS 3 AND 4: PERIPHERAL B-LYMPHOCYTE ACTIVATION AND GERMINAL CENTER RESPONSES

Mature B lymphocytes circulate through the spleen and other lymphoid tissues in continuous search for antigen. Antigen encounter by specific B lymphocytes triggers distinct steps of lymphocyte activation, expansion, and differentiation into memory cells and plasma cells (66). Complement's involvement at multiple steps along this pathway offers a complex example of innate regulation of adaptive responses.

Similar to T cells, B lymphocytes require two signals for full activation (i.e., BCR cross-linking and costimulation) (98,99,100,101,102 and 103). By enhancing localization of antigen to the lymphoid compartment (61,62), complement optimizes BCR cross-linking by antigen, and, as a ligand that signals through the CD21/CD35 receptors, complement further augments BCR activation (104). Complement's covalent attachment to antigen engages the CD21/CD19/CD81 coreceptor complex in concert with BCR stimulation by antigen (Fig. 1.2). If this dual binding generates adequate signaling to reach the activation threshold, then the humoral response continues (checkpoint 3), whereas subthreshold signals delivered through the BCR lead to Fas-dependent apoptosis of the B lymphocyte (105). Evidence supporting the threshold hypothesis came from studies of mice with either a functional or a disrupted *Cr2* locus that were also transgenic for Ig heavy and light chains specific for HEL (106). This model system provided an opportunity to measure the contribution of coreceptor signaling in an immune response against lysozyme. When $Cr2^{+/+}$ HEL Ig transgenic B lymphocytes are exposed to lysozyme, they mount a strong immune response. In contrast, CD21/CD35-deficient ($Cr2^{-/-}$) HEL Ig transgenic B lymphocytes generate a weak immune response because most do not survive within the splenic white pulp. Immunization with high-affinity antigen (i.e., a different form of lysozyme) rescues the transgenic CD21/CD35-deficient lymphocytes. These findings suggest that moderate-affinity antigen plus complement can substitute for high-affinity antigen alone. In other words, coreceptor signaling effectively lowers the threshold for activation and survival of B lymphocytes encountering moderate-affinity antigens, thereby substantiating the threshold hypothesis.

The white pulp of the spleen contains T-cell–rich zones where B lymphocytes are first activated and distinct B-lymphocyte zones that are called follicles (107). Activated B lymphocytes receiving above-threshold signals in combination with costimulation from helper T lymphocytes undergo rapid cell division. Some B-lymphocyte progeny differentiate into antibody-forming cells and move into the red pulp, whereas others enter into lymphoid follicles (108). Activated B lymphocytes in follicles initiate germinal center (GC) reactions that are specialized for further B-lymphocyte differentiation (109,110 and 111). GC immigrants initially mutate their Ig receptor genes by somatic hypermutation and are then subjected to antigen selection within the light zones of GCs (112,113 and 114). Selected B lymphocytes undergo additional rounds of proliferation, Ig class switching, and differentiation into long-lived memory and plasma cells (108,115).

Using the HEL Ig transgene model described earlier, it was unexpectedly discovered that complement ligand is critical for effective B-lymphocyte survival within GCs, irrespective of antigen affinity (106). Transgenic B lymphocytes with CD21/CD35 populate 50% of GCs in mice immunized with high-affinity lysozyme, whereas transgenic B lymphocytes without CD21/CD35 are rarely found in GCs under identical experimental conditions. These results imply that coreceptor signaling does much more than simply enhance BCR signaling, and perhaps it provides a unique B-lymphocyte survival signal at what we refer to as checkpoint 4. A requirement for complement at this checkpoint is novel, and the potential mechanisms remain to be elucidated.

CHECKPOINT 5: COMPLEMENT AND B-LYMPHOCYTE MEMORY

High-affinity antigen-specific memory B lymphocytes are generated at the end of GC reactions. Mechanisms of maintaining B-lymphocyte memory over time are not well understood, but they likely involve continued antigen stimulation (116). FDCs that can store antigen may serve as long-term cellular depots (117,118), and complement receptors, important for retention of complement-decorated antigens by FDC (61,62,65), are good candidates for involvement in the maintenance of long-term memory. If so, then the maintenance of long-term memory B lymphocytes can be considered a fifth checkpoint in which innate immunity impinges on the adaptive immune response.

INNATE IMMUNITY AND AUTOREACTIVITY

Not only does innate immunity help to amplify protective immune responses against invading pathogens, but also it may protect against autoreactivity by modulating recognition of autoantigens (75). For example, cell turnover by apoptosis is a continuous process during hematopoiesis and a common response to environmental stresses such as exposure to ultraviolet radiation. The innate immune system seems to participate in the routine clearance of apoptotic debris in part through recognition motifs referred to as apoptotic cell-associated molecular patterns (ACAMPs) (119,120 and 121). Expressed by phagocytic cells of the innate immune system, receptors specific for different ACAMPs include CD36, CD14, and CD11b/CD18. ACAMPs may be the autoantigen equivalent of PAMPs, but unlike the binding of PAMPs by recognition receptors that potentiate immune responses (see section I), ACAMP receptors may participate in a tolerogenic display of self-antigens to autoreactive lymphocytes.

DCs are antigen-presenting cells that express both PAMP and ACAMP receptors. When an immature DC internalizes a PAMP-bearing pathogen, it undergoes activation and maturation, thus becoming a potent stimulator of T lymphocytes (122). In contrast, on internalization of apoptotic debris, presumably through ACAMP receptors, the immature DCs do not mature and do not potentiate lymphocyte activation (123,124). It is tempting to speculate that ACAMPs induce these cells of the innate immune system to communicate tolerogenic signals to cognate T lymphocytes.

Various soluble components of the innate immune system also contribute to the clearance of self-antigens. Antigen can be “labeled” by covalent coupling to C3b and C4b fragments and by noncovalent interactions with other serum proteins. Two such serum proteins are the acute-phase reactants C-reactive protein (CRP) and serum amyloid P component (SAP), which are highly conserved serum pentraxins whose titers rise during infection and inflammation (125,126). SAP is capable of binding to chromatin released from apoptotic cells and can also bind and activate C1q (127,128). This acute-phase reactant may participate in innate mechanisms that clear the circulation of potentially immunogenic autoantigens, thereby protecting against development of autoimmune disease. This notion derives from animal models in which mice genetically deficient in SAP spontaneously produce anti-DNA autoantibodies and have an increased incidence of renal disease (129) (Table 1.2).

TABLE 1.2. Deficiencies in Components of Innate Immunity Associated with Lupuslike Disease in Mice

Complement Deficiency and Systemic Lupus Erythematosus

The striking association of complement deficiency with systemic lupus erythematosus (SLE) is compelling, although circumstantial, correlative evidence that innate immunity has significant effects on the adaptive system. Specifically, humans deficient in either complement C1q or C4 almost always develop SLE or lupuslike disease (130,131). These autoimmune disorders are characterized by high-affinity autoantibodies specific for protein and nucleic antigens that are highly conserved among vertebrates and invertebrates including ribonuclear proteins, histones, and dsDNA (132,133 and 134). Apoptotic cell debris is a potential source of lupus autoantigens (135). *In vitro,* experimental induction of apoptosis promotes the translocation, externalization, and release of nuclear antigens including dsDNA in membrane-bound vesicles referred to as apoptotic bodies (136). The identification of direct binding of complement C1q to the apoptotic bodies may implicate a role for complement in

clearance of the released nuclear material (137).

Two general hypotheses have been proposed to explain the increased incidence of SLE among complement-deficient individuals: the clearance hypothesis (138,139) and the tolerance hypothesis (140,141). The former hypothesis is based on complement's known role of binding to foreign antigens and transporting them to the liver and spleen for degradation, thereby facilitating their removal from the circulation. Mice deficient in C1q develop spontaneous lupuslike autoreactivity characterized by rising titers of autoantibodies with progressive glomerulonephritis (142). Mice deficient in SAP are similarly susceptible to lupuslike disease (129). SAP binds chromatin and may be important for its degradation. In humans, SAP also activates classical pathway complement, a finding further supporting the hypothesis that innate immunity promotes efficient clearance of complex nucleoprotein autoantigens released from apoptotic cells (127).

Natural antibody, which binds many self-antigens that are highly conserved among bacteria, yeasts, and viruses (143,144), also appears to be protective against lupus disease, based on recent characterizations of mutant mice whose B lymphocytes express surface IgM but do not secrete soluble IgM. Essentially devoid of natural IgM ($sIgM^{-/-}$), these mice develop autoantibodies and renal changes analogous to the C1q-deficient and SAP-deficient animal models, a finding suggesting that natural IgM may play a protective role in binding and clearance of lupus autoantigens (145,146). One shortcoming of the clearance hypothesis is that it fails to explain adequately how a breakdown in antigen clearance can lead to development of high-affinity autoantibodies.

The tolerance model proposes that innate immunity protects against SLE by delivering lupus autoantigens to sites where immature B lymphocytes are tolerized. For example, efficient targeting of self-antigens to the bone marrow by components of innate immunity could enhance contact between immature autoreactive B lymphocytes and lupus autoantigens. In addition, coreceptor signaling by complement receptors can augment the strength of BCR signaling so self-antigens coated with complement ligand may be more potent tolerogens for immature B lymphocytes than self-antigen alone. Where and how autoreactive B lymphocytes actually encounter self-antigens are unknown, however, although presentation of self-antigens may involve the innate immune system.

One prediction of the tolerance hypothesis is that defects in the induction of B-lymphocyte tolerance will lead to spontaneous development of autoreactivity. For example, mice deficient in proteins involved in the BCR signaling pathway (e.g., CD22, Lyn or SHP-1) spontaneously develop lupuslike disease, presumably because dysregulation of BCR signaling allows self-reactive B lymphocytes to escape tolerance (147,148 and 149). Transgenic mice in which most of their B lymphocytes express an antibody transgene specific for self-antigens, such as dsDNA or MHC glycoprotein, have been instrumental in identifying the distinct stages of B-lymphocyte development and regulation of autoreactivity (70,71). Breeding of the transgenic mice with strains deficient in BCR signaling proteins has demonstrated that the strength of antigen-associated signal transduction dictates whether self-reactive B lymphocytes are eliminated, are anergized, or develop to maturity. For example, by breeding the previously discussed HEL Ig transgenic mouse strain to another strain transgenic for soluble HEL (sHEL), Goodnow et al. (1988) generated a novel animal model of autoreactivity in which HEL Ig transgenic B lymphocytes exist in a nonreactive, or anergic, state (150).

Compared with the HEL Ig single transgenic mice, the life span of mature HEL-specific B lymphocytes in sHEL/HEL Ig double transgenic mice is markedly diminished, a finding suggesting that anergy pares the autoreactive population considerably. Experimental overexpression of the BCR-associated signaling protein CD19 leads to increased signaling on BCR engagement (151). In sHEL/HEL Ig double transgenic mice that overexpress CD19, more HEL Ig transgenic B lymphocytes are eliminated while still immature and those that escape to the periphery are no longer tolerant (152). These findings suggest that enhanced BCR signaling in immature autoreactive cells promotes deletion, whereas enhanced BCR signaling in mature autoreactive cells promotes activation. Similarly, loss of BCR coreceptor proteins CD21/CD35 also disrupts normal tolerizing mechanisms. When the sHEL/HEL Ig double transgenic mice are bred with CD21/CD35-deficient ($Cr2^{-/-}$) mice, increased numbers of mature, nonanergic autoreactive B lymphocytes escape tolerance regulation (75). Not only do these results support the idea that decreased signal transduction through CD21/CD35 permits escape of immature B lymphocytes from central tolerance in the bone marrow, but also they implicate a specific role for complement ligands in normal induction or maintenance of B-lymphocyte tolerance to autoantigens.

In all likelihood, the complement ligands that bind CD21 and CD35 in the induction of anti-HEL tolerance derive from the classical complement pathway because similar autoreactive phenotypes also arise in the absence of C4, but not C3 (75). After bone marrow transplantation from anti-HEL donors into sHEL hosts, anti-HEL B lymphocytes are tolerized reasonably well even when the recipients are deficient in C3. In contrast, the HEL Ig transgenic B lymphocytes that develop in C4-deficient recipients are not properly anergized. Much like in the CD21/CD35-deficient double transgenics, these HEL Ig transgenic B lymphocytes are present at increased frequency and retain the ability to respond to antigen *ex vivo* (75). These observations suggest that the classical pathway mediates CD21/CD35-based signaling for tolerance induction, possibly in the immature B lymphocyte, whereas C3 fragment-mediated signaling is reserved for the activation of mature B lymphocytes.

SUMMARY

The innate immune system includes a diverse and broad range of serum and cellular recognition proteins that, on activation, carry out various effector functions. Not only does the innate system respond immediately to pathogenic infection, but also it initiates and propagates adaptive responses. For example, the classical pathway of complement is likely involved in at least five checkpoints in B-lymphocyte development and differentiation, ranging from negative selection to maintenance of long-term memory. The appreciation that innate immunity protects against autoimmune diseases such as SLE offers further insight into the pathogenesis of this potentially fatal disorder. Continued elucidation of the mechanisms linking innate and adaptive immunity hold promise for more effective vaccine strategies and treatment of autoimmune disorders as well as for a provocative field of research.

2 ARCHITECTURE OF THE IMMUNE SYSTEM

Garnett Kelsoe, D.Sc., and Laura P. Hale, Ph.D.

Coincident with the development of specific immunity, a series of organs and tissues appeared in jawed vertebrates to provide distinct cellular environments for lymphopoiesis and sites for lymphocyte interaction and response against antigen (1,2 and 3). Thus, the immune system has compartmentalized the generative and response phases of immunity into discrete organs and tissues and interconnected these elements by the blood vasculature and lymphatic channels.

The lymphatic organs are commonly divided into primary, or generative, lymphoid organs and secondary, or peripheral, organs. In the primary lymphoid tissues, organized sets of specialized cells and molecular cues support and direct T- and B-lymphocyte development from hematopoietic stem cell progenitors. This cellular ontogeny includes the generation of antigen-specific receptor molecules, developmental checkpoints to ensure the production of functional receptor molecules, and the removal or functional inactivation of cells bearing receptors that avidly react to self-antigens (4). Secondary lymphoid organs are rich in mature, functional lymphocytes and their accessory cell partners; in secondary lymphoid tissues, lymphocytes, accessory cells, and antigen are brought together to maximize the efficiency of immune responses. The placement of secondary lymphoid tissues in the body and their vascularization direct antigen and antigen-transporting cells through regions of concentrated lymphocyte populations. This parade of antigen and antigen-bearing cells maximizes the numbers of lymphocytes that can respond to infection or immunization and accelerates protective immunity (5,6 and 7).

In humans and rodents, the primary lymphoid organs comprise the bone marrow, the site of B-cell lymphopoiesis, and the thymus, the site of T-cell lymphopoiesis. The major secondary lymphoid tissues include the spleen, the lymph nodes, and Peyer patches. Nonetheless, the tissues of lymphocyte generation vary substantially from species to species. For example, the Peyer patches function in humans and rodents as secondary lymphoid tissues, whereas in sheep, they play a major role in B-cell generation (8). Other species, such as birds, have specialized organs for lymphopoiesis. The bursa of Fabricius is a primary site of B-cell development in all avian species (9,10), and similar developmental activity is present in the rabbit appendix and sacculus rotundus (11,12).

PRIMARY LYMPHOID TISSUES

The generation of mature lymphocytes depends on a common, self-renewing hematopoietic *stem cell* that is present in the bone marrow (13,14). The progeny of this cell undergoes regulated differentiation steps and rounds of proliferation to establish populations of committed precursors and developing lymphocyte forms. This pattern of development is characteristic for both T and B lymphocytes, and the establishment and regulation of precursor cell pools depend on the cellular environments present in the thymus and bone marrow (15,16). The stromal and epithelial cells present in bone marrow and thymus do not merely function as mechanical supports for the hematopoietic cells they surround; rather, they provide essential developmental signals that guide lymphopoiesis.

SECONDARY LYMPHOID TISSUES

As tissues specialized for immune response, most *secondary lymphoid tissues* possess collection systems for antigen and antigen-transporting cells that drain associated nonlymphoid tissue. These collection channels transport antigen into highly organized populations of antigen-presenting cells and T and B lymphocytes (17,18 and 19). All secondary lymphoid tissues make use of specialized vascular structures that enable them to recruit lymphocytes, particularly naive lymphocytes, from the blood (20,21). The secondary lymphoid tissues also contain distinct lymphoid microenvironments, principally zones rich in either T or B lymphocytes (5,6,17,18). These zones also contain accessory cells specific for the appropriate lymphocyte type. Interdigitating dendritic cells (DCs) present in the T-cell–rich areas of secondary lymphoid tissues are specialized for antigen-processing and major histocompatibility complex (MHC)–restricted antigen presentation (22). In contrast, the follicular DCs (FDCs) present in B-cell regions are unable to process antigen but retain it in native form by binding antibody-antigen and complement-antigen complexes by cell surface complement and Fc receptors (23,24).

In various forms, these common elements, collection channels for antigen, specialized blood vasculature, and organized populations of lymphocytes and accessory cells, define types of secondary lymphoid tissues. Lymph nodes are the termini of efferent lymphatic channels that drain the interstitial space of most tissues; lymph nodes collect and localize immune responses to antigen recovered by its associated lymphatics (5,18,19). The spleen filters blood, collecting antigens that have been introduced into the vascular system (17), whereas mucosal-associated lymphoid tissues, such as Peyer patches, are specialized for the collection of antigen across a mucosal epithelium (19,25).

LYMPHATICS

The *lymphatic network* is a system of thin-walled, specialized vasculature that originates as capillary channels in the extracellular space (26,27). Lymphatic capillaries are widely distributed, but are most numerous beneath the skin and the mucosae of the gastrointestinal, respiratory, and genitourinary tracts (28,29). Lymphatic capillaries collect to form larger lymphatic vessels, the efferent lymphatics, which converge and empty into regional lymph nodes. Each *lymph node,* or cluster of lymph nodes, monitors immunologically the region defined by the efferent lymphatic drainage. The efferent lymphatics continue and converge into larger lymphatic vessels, they pass through increasingly central lymph nodes, and finally meet in a single lymphatic vessel, the *thoracic duct.* The thoracic duct empties into one of the great veins supplying blood to the heart that returns the lymph and its cellular components to the blood circulation (28,29).

TISSUES OF PRIMARY LYMPHOGENESIS

Bone Marrow

The *bone marrow* is the major hematopoietic organ in most mammalian species and is necessary for the production of all formed blood elements. Two types of bone marrow, red and yellow, are present in adults. Red bone marrow derives its color from abundant erythrocytes and hemoglobin-containing precursors, whereas yellow bone marrow is colored by the fat cells, or adipocytes, present within it. In adult humans, the proportion of yellow bone marrow can be as high as 70%; red marrow is actively hematopoietic, whereas yellow marrow does not normally produce blood cells, although it can convert to blood-forming tissue under certain conditions (30,31). In newborns and young humans, the majority of bone marrow is red, but in adults, red marrow is common only in the clavicles, vertebrae, sternum, and bones of the pelvis and skull, where it accounts for about 2% of the body mass (30,31).

In the long bones, red marrow occupies the central cavity of the bone shaft. Protruding ridges and spiculae, collectively known as trabeculae, modify the inner surface of long bones. The trabeculae form interconnecting chambers and passageways lined by a single layer of cells, the endosteum (32). This thin cellular sheath contains distinct populations of cells that continuously remodel the bone: osteoblasts that lay down bone and osteoclasts that resorb it (33). In concert, osteoblasts and osteoclasts reform and repair bone structure. In the long bones, blood is supplied by a central nutrient artery, which enters the marrow at midshaft and branches into central, longitudinal arteries (Fig. 2.1). These longitudinal arteries follow the bone's long axis and send out branches into the marrow's periphery. In turn, these smaller arteries ramify further into arterial capillaries and connect to a network of venous sinuses. Venous blood flow from these sinuses is collected by radial veins and exits

the bone marrow through a central longitudinal vein, which runs parallel to the central longitudinal artery.

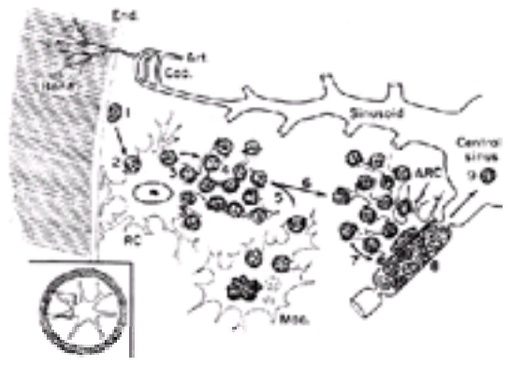

Figure 2.1. The architecture of bone and B lymphopoiesis. **A:** Diagrammatic representation of the vasculature of a long bone showing the pathways of the central (C) and nutrient arteries (N). **B:** Hematopoietic development and differentiation are organized spatially in red bone marrow. Work by D.G. Osmond suggests the placement of early hematopoietic stem cells near the endosteum of the bone marrow *(1).* B-lineage precursors *(2)* differentiate in association with the stromal cell reticulum with individual precursors dividing *(3)* to produce clusters of early B-lineage precursors that retain contact with the stromal cell surface. Successive cell divisions *(4)* of pro-B and pre-B cells result in the central displacement of daughter cells along networks of stromal cell processes. With the rearrangement of the light-chain gene, immature B cells expressing nonfunctional or autoreactive antigen receptors may undergo apoptosis and may be removed by bone marrow macrophages *(5);* maturing B cells bearing membrane immunoglobulin M then follow reticulum cell processes to enter the sinusoids *(6).* After traversing the sinusoid wall *(8)* functional, selected B cells follow along the central sinus to enter the blood vasculature. (From Jacobsen K, Osmond DG. Microenvironmental organization and stromal cell associations of B lymphocyte precursor cells in mouse bone marrow. *Eur J Immunol* 1990;20:2395–2404, with permission.)

The space between the marrow's blood vessels is occupied by irregular cords of tissue containing the bone marrow stroma, a collection of branching, interconnected reticular stromal cells, macrophages, and adipocytes. This reticular framework surrounds the bone's hematopoietic cell populations and functions to support the development of the hematopoietic cell lineages (34,35). In addition to the hematopoietic cells themselves, adipocytes, macrophages, and mast cells are also present in active marrow (34,35). Specific cell lineages and types are generally localized to specific areas within the hematopoietic compartment. Thus, after marrow lympholysis by irradiation (35), B-cell recovery is focused in subosteal areas bearing a distinctive extracellular matrix and rich in reticular stromal cells, megakaryocytes and erythrocytes can be found in approximation to reticular cells within the venous sinuses, and the most mature B lymphocytes are abundant in the centers of the sinusoid lumina (Fig. 2.1).

In mammals, the initial stages of blood formation occur in the hematopoietic tissue, although some of the later stages of cellular maturation may occur within the vasculature (34). To enter the blood circulation, newly formed blood cells pass through the sinus wall. Once there, blood cells, including the lymphocyte precursors, become a part of the blood circulation and may be disseminated by the venous system throughout the body (Fig. 2.1).

Bursa of Fabricius

In all birds, the digestive, urinary, and reproductive tracts open into a common chamber, the cloaca. In the cloaca, a small opening leads to a unique lymphoid follicle, known as the *bursa of Fabricius* (Fig. 2.2). On about the eighth day of embryonic life, lymphocyte precursors migrate from the yoke sack into the bursa, and by the tenth day of development, they extensively proliferate to form mature lymphoid follicles (36,37). The number of lymphocytes in these follicles increases rapidly, partly because of immigration of new lymphocyte precursors, but mainly because of the rapid proliferation of the resident lymphocytes (37).

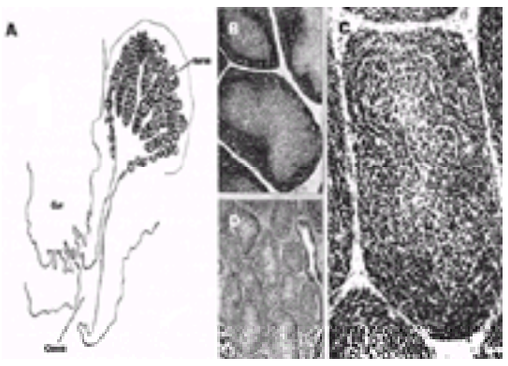

Figure 2.2. The bursa of Fabricius opens into the cloaca **(A)** and contains numerous follicles comprising an associated epithelium and actively dividing B-lymphocytes. Development of the bursa and its lymphoid compartments begins *in ovo* but appears to be driven by microbial flora after hatching. Bursal follicles reach their peak size just prior to sexual maturity and then involute; bursal follicles are virtually absent in mature birds. Within bursal follicles **(B,C)**, B cell–rich areas include peripheral dark zones of dividing lymphocytes that surround a central light zone containing non-dividing cells. Each follicle is delimited by a lacework of connective tissue; after irradiation or administration of nortesterone **(D)**, the follicular capsules become dramatically less cellular due to massive apoptosis. In contrast to the germinal center-like structures of appendix (Fig. 3) or Peyer's patch (Fig. 9), few if any T-lymphocytes (T) are present in the follicles of the bursa of Fabricius even in hatchling or maturing birds. (Original magnification ×100. From Weiss L. *The cells and tissues of the immune system. Structure, functions, interactions*. Englewood Cliffs, NJ: Prentice-Hall, 1972.)

During their residence in the bursa of Fabricius, precursor B cells develop into mature, functional B lymphocytes and acquire novel antigen receptors by a process of gene conversion (9,10,36). These bursal-derived B lymphocytes emigrate from their follicular niches, enter the circulation, and are carried to the peripheral lymphoid organs, primarily the spleen. As the bird becomes sexually mature, the bursa of Fabricius undergoes physiologic involution. In the domestic fowl, bursal activity begins to decline at 7 to 13 weeks after hatching, but bursal involution can be induced by injecting androgenic hormones. Significantly, the injection of such hormones into the eggs during embryonic life arrests bursal development almost completely and results in hatchling birds that are completely deficient of B lymphocytes (37).

Organs that appear to serve homologous functions occur in certain mammalian species, namely, rabbits and sheep. In rabbits, the appendix (Fig. 2.3) and sacculus rotundus have a similar although not absolute role in the development and diversification of mature B cells (38,39). Lymphocyte precursors that enter the fetal and neonatal appendix proliferate, are diversified by immunoglobulin gene conversion or mutation, and mature into responsive, peripheral B lymphocytes (11,12). In the fetal lamb, many of the developmental processes active in the bursa of Fabricius have been observed in Peyer patches, foci of lymphoid tissue that become established along the gut of fetal mammals (8,11,12,39,40 and 41). Within ovine Peyer patches, B-lymphocyte development and genetic diversification by immunoglobulin hypermutation are supported in follicular environments that are strikingly similar (42) to the follicles present in the avian bursa (Fig. 2.2) and rabbit appendix (Fig. 2.3). Mature B cells from Peyer patches emigrate by means of the lymph and blood throughout the fetal lamb and become disseminated into secondary lymphoid tissues.

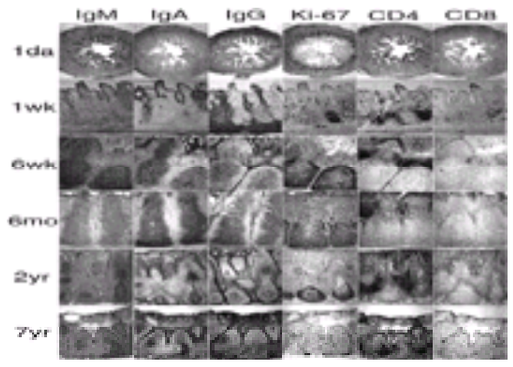

Figure 2.3. The rabbit appendix at various times after birth. The basic structure of the appendix is similar to that of the bursa of Fabricius (Fig. 2.2), with numerous ovoid or trapezoidal follicles containing B lymphocytes (B) in apposition to a supporting follicular epithelium. The development of follicular structure begins after birth and depends on the presence of a gut flora. With time, the follicles enlarge, reaching a maximum in young adult animals and then regressing with advancing age. The appendix contains well-described perifollicular T-cell zones, and $CD4^+$T lymphocytes (T) are scattered about in secondary follicles or germinal centers (GC). These germinal centers contain light and dark zones (LZ, DZ) (original magnification ×100). (From Dasso JF, Obiakor H, Bach H, et al. A morphological and immunohistochemical study of the human and rabbit appendix for comparison with the avian bursa. *Dev Comp Immunol* 2000;24:797–814, with permission.) (See Color Figure 2.3.)

Thymus

During embryonic development, the endoderm of the third and fourth pharyngeal pouches, the ectoderm of the corresponding brachial clefts, and mesenchymal cells from the associated pharyngeal arch develop into the *thymic anlage* (43). Interaction among all three cell types is necessary for complete thymic development, and mutations that block these interactions result in athymia (44). Similarly, ablation of the embryonic neural crest that provides the mesenchymal cells of the pharyngeal arch interferes with thymic development and results in defects similar to those of DiGeorge syndrome (45,46).

In mice and birds precursor cells begin to infiltrate the thymic anlage even before the organ becomes vascularized, and this cell immigration proceeds in ordered waves until early neonatal life (47,48,49 and 50). These immigrants derive from the hematopoietic centers of the embryo, the yolk sac, and the liver. After birth, immigration continues from the bone marrow (51,52). The lymphocyte precursors that enter the nascent thymus interact with the epithelial cells present in the thymic rudiment and induce mutual and specific differentiation. Obvious consequences of these interactions are the organization of the uniformly distributed lymphocyte precursors into specific zones that become the cortex and medulla of the definitive thymus and the induction of vascularization (53). This organization is also associated with the elaboration of specific factors by the thymic epithelium that promote differentiation in the thymic lymphoid population (53,54).

The *human thymus* consists of two lobes, joined at their apex, that extend from the upper end of the sternum to the pericardium (Fig. 2.4). This structure is common in most mammals. Interestingly, in guinea pigs and birds, the thymus consists of reiterated nodules of thymic tissue that follow along the jugular veins of the neck.

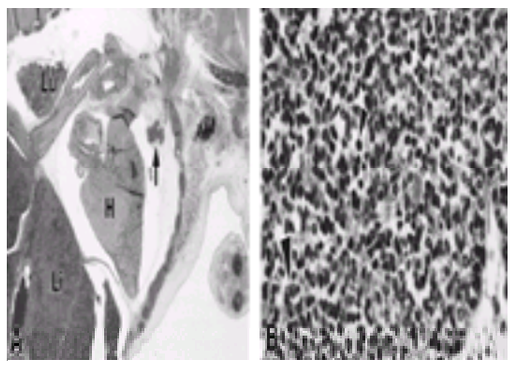

Figure 2.4. Human thymus at 8 weeks, gestation. **A:** The developing thymus is located in the anterior mediastinum overlying the heart (H). The position of the lung (Lu) and liver (Li) are also shown. **B:** At this stage of development, both lymphocyte precursors *(small arrowhead)* and epithelial cells *(large arrowhead)* are present; however, a distinction between cortex and medulla will not become apparent until week 14 of gestation (hematoxylin and eosin stain; original magnification ×3 in **A** and ×132 in **B**). (See Color Figure 2.4.)

The thymus achieves its greatest relative weight at birth; however, the thymus continues to grow until sexual maturation, and it reaches its greatest size just before the onset of puberty. Afterward, the thymus progressively declines in size to less than half of its peak volume. This age-associated decrease in thymic weight is referred to as *physiologic involution.* Involution is accompanied by changes in thymic structure that include large expansions of adipose tissue, diminished thymocyte proliferation, and a lower capacity to produce new T cells. Physiologic involution is controlled hormonally, because castration delays thymic involution, whereas the injection of corticosteroids accelerates it (55,56). Occasionally, transient thymic involution follows acute stress or infection.

The fully developed human thymus is divided into lobules by septa that extend from the thymic capsule into the interior of the organ. Thymic tissue can be divided into two main compartments or spaces: the thymic epithelial space and the perivascular space. The thymic epithelial space can be further subdivided into the subcapsular zone, the cortex, and the medulla. The first of these, the subcapsular zone, contains the most primitive lymphocyte progenitors that arrive from the bone marrow and the least developed populations of thymic lymphoblasts. The thymic cortex lies immediately below the subcapsular zone and is packed with small lymphocytes actively engaged in the generation, expression, and selection of functional T-cell antigen receptor molecules. Finally, the central medulla of the thymus contains lymphocytes undergoing the final stages of thymic selection and maturation. From the medulla, mature T lymphocytes pass through the circulation into the secondary lymphoid tissues and lymphatics.

In children, the cortex is located directly beneath the thymic capsule and contains immature developing lymphocytes (thymocytes) are that densely packed into a lacy meshwork of thymic epithelial cells. These epithelial cells are often obscured by dense masses of thymocytes using conventional histologic stains, but they can be easily detected using labels that are specific for epithelial cells (Fig. 2.5). Most thymocytes, usually at least 90%, are located in the thymic cortex. The medulla is located internal to the cortex and contains a less dense arrangement of more mature thymocytes and thymic epithelium, including characteristic clusters of terminally differentiated thymic epithelial cells called *Hassall bodies* (57,58) (Fig. 2.5). Epithelial cells are more tightly aggregated in the medulla, as compared with the cortex, in which they form stellate figures connected by long cytoplasmic processes (Fig. 2.5). These epithelial components create a reticulum or meshwork that surrounds and supports the thymocytes. The distinction between cortex and medulla becomes evident at week 14 of development in humans, with Hassall bodies first detectable at 15 weeks. The human thymus is considered fully developed by weeks 16 to 20 of gestation.

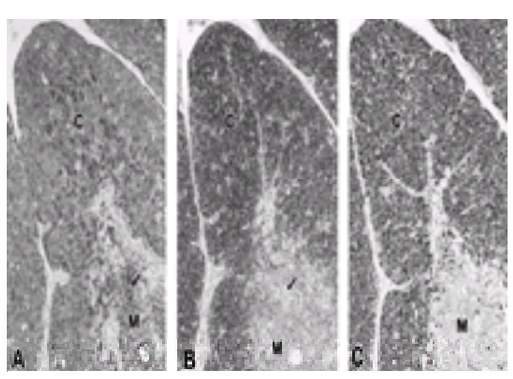

Figure 2.5. Architecture of the pediatric human thymus. Immunoperoxidase staining highlights cell types present in thymic cortex (C) and medulla (M). *Arrows* point to Hassall bodies. Cytokeratin antibodies highlight the meshwork of thymic epithelium **(A),** which is more attenuated in the cortex as compared with the medulla. The immature thymocytes present in the cortex can be uniquely identified as those cells reactive with antibodies specific for CD1a **(B)** and for the Ki-67 nuclear proliferation antigen **(C).** *Brown* indicates positive reaction (original magnification ×33). (See Color Figure 2.5.)

The perivascular space is defined as the area within the thymic capsule that is separated from the thymic epithelial space by a basement membrane and does not contain developing thymocytes (56,57). In human infants, the perivascular space is primarily a potential space, containing blood vessels and small numbers of stromal cells. Branches of the subclavian artery penetrate the thymic capsule and travel within the perivascular space to the medulla, where they subdivide into smaller arteries and arterioles that progressively supply the corticomedullary junction, cortex, and subcapsular region. Venules run parallel to the arterioles in the perivascular space. Eventually, these venules join into medullary veins, which, in turn, empty into the innominate vein.

The thymus exhibits marked changes in architecture and cellular composition with aging. In mice, the thymus appears to grow until sexual maturation, then it progressively decreases in size to less that half of its peak volume. In humans, the thymus size remains approximately the same throughout life; however, thymic output decreases progressively with age (55,56). The decrease in thymic output parallels a decrease in the thymic epithelial space in which thymocyte development occurs. To maintain organ size, the perivascular space increases in the human thymus correspondingly, filling up with adipose tissue and variable numbers of peripheral lymphocytes (Fig. 2.6). However, despite this thymic atrophy, foci of immature thymocytes and molecular evidence for ongoing thymocyte development have been observed in humans in the eighth decade of life (59,60,61 and 62).

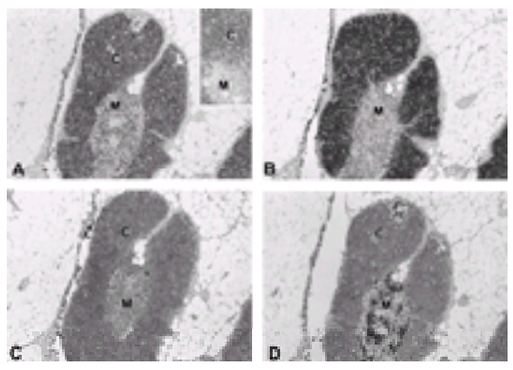

Figure 2.6. Architecture of the adult human thymus. Age-related thymic atrophy results in an increase in adipose tissue within the perivascular space (seen on the **left** and the **right** of each panel) concomitant with a decrease in the thymic epithelial space that is involved in production of new thymocytes. The architecture of the remaining cortex (C) and medulla (M) is relatively unaltered. Immunoperoxidase staining identifies the phenotype of cells present in the cortex and medulla. **A:** CD3 stain (T cells); the **inset** shows $CD8^+$ cells (immature cortical and a subset of medullary thymocytes). **B:** CD1a (immature cortical thymocytes and medullary dendritic cells).**C:** CD68 (macrophages). **D:** CD20 (B cells). *Brown* indicates positive reaction (original magnification ×16; ×40 for the **inset**). (See Color Figure 2.6.)

In addition to age-related thymic involution, the thymus may also undergo involution from hormonal or other factors. Castration delays thymic involution in rodents, whereas injection of corticosteroids accelerates it (63,64). Occasionally, thymic involution follows acute stress or infection (65,66). This acute involution is transient, and normal thymic architecture is restored on recovery.

Thymectomies of neonatal mice by J.F.A.P. Miller demonstrated that the thymus is the primary site for the development of mature T lymphocytes (67). The thymus houses early committed T-cell progenitors and functions to develop this pool of cells into functional, mature T lymphocytes.

ORGANS OF THE IMMUNE RESPONSE

Spleen

The largest definitive lymphoid tissue of higher vertebrates is the *spleen;* it contains some 25% of the body's lymphocytes (17,68). The spleen is not supplied with efferent lymphatic channels but is joined to the vasculature by a single splenic artery and vein. These blood vessels enter the smooth capsule of the spleen at an indentation known as the *hilum.* Blood percolating through the splenic sinuses is filtered through a complex reticulum of phagocytic cells that remove immune complexes, particulate matter, and damaged erythrocytes (17,68,69). This blood flow represents some 5% of cardiac output in humans (70), and it effectively supplies the spleen with antigen and antigen-transporting cells.

Structurally, the spleen is divided into three distinct compartments: the red pulp, the white pulp, and a marginal zone that separates the two (Fig. 2.7). The immunologic compartment of the spleen is predominately located within the white pulp, which accounts for 15% to 20% of the splenic parenchyma (17,69). The white pulp is the secondary lymphoid tissue of the spleen, and like all other secondary lymphoid tissues, it is segregated into T- and B-cell zones that are organized around the vasculature that supplies antigen, accessory cells, and lymphocytes.

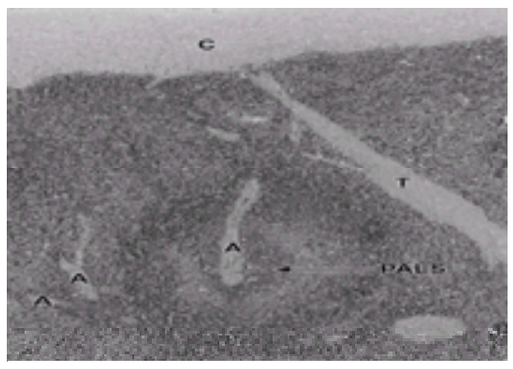

Figure 2.7. Architecture of the human spleen. The spleen is surrounded by a fibrous capsule (C) that invaginates to form trabeculae (T). The white pulp is arranged concentrically around arterioles (A) to form the periarteriolar lymphoid sheath (PALS) (hematoxylin and eosin stain; original magnification ×16). (See Color Figure 2.7.)

After the splenic artery penetrates the spleen's capsule at the hilum, it ramifies into numerous branches that run along invaginations of the splenic capsule, called *trabeculae* (Fig. 2.7). The trabecular arteries further branch to produce central arterioles, which finally give off still finer vessels, the penicillary tufts that end in arterial capillaries. Blood is discharged from the arterial capillaries into the venous sinuses of the red pulp, which expand or contract in response to the volume of blood passing through them. The walls of these sinuses are perforated with the openings of venous capillaries that eventually coalesce into veins of the splenic pulp. These merge into trabecular veins and return filtered blood to the circulation through the splenic vein (17,69,70 and 71).

Lymphatic vessels do not drain into the spleen. However, the spleen contains efferent lymphatic vessels that carry lymph out of the organ. These efferent lymphatics originate in the white pulp, where they lie in approximation to the central arterioles and near the trabeculae.

The red pulp contains extensive blood sinuses that are lined with macrophages; these sinuses are organized into tissue cords (68,70). The red pulp contains most of

the erythrocytes present in the spleen as well as the other formed elements of the blood, and it also contains large numbers of plasmacytes.

The white pulp is arranged concentrically around the central arteries and arterioles (Fig. 2.7). The innermost cylinder of lymphocytes that surrounds the central arteriole is the *periarteriolar lymphoid sheath* (PALS). The PALS contains mostly T lymphocytes, DCs, and small populations of macrophages (71). Lymphoid follicles, areas rich in B lymphocytes, are joined to the PALS, either surrounding it or forming eccentric columns to one side. Whereas most follicular cells are B lymphocytes, the lymphoid follicle also contains characteristic clusters of FDCs and scattered populations of macrophages. In naive animals, the white pulp constitutes approximately 15% of the splenic volume; however, infection or repeated immunizations can double the white pulp volume. This increase is largely due to expansion of the B-cell–rich lymphoid follicles and the development of intense areas of antigen-driven B-cell proliferation and differentiation, known as *germinal centers*. Follicles containing active germinal centers are known as *secondary follicles* (71).

A marginal sinus surrounds the PALS and follicle and separates the splenic white pulp from the red pulp (Fig. 2.7). The area between the white and red pulps is referred to as the *marginal zone;* it constitutes a distinct microenvironment that is populated by distinct macrophage and lymphocyte populations and is important for humoral responses to certain thymus-independent antigens (72,73).

Lymph Nodes

The structure of *lymph nodes* is (Fig. 2.8) similar to that of the spleen in that each lymph node is contained by connective tissue capsule that sends many trabecular projections into the node's interior (5,18,19,74). The intratrabecular areas are occupied by a network of reticular cells and by free cells, mostly lymphocytes that are lodged in the mesh. The external regions of the lymph node, or cortex, contain more lymphocytes than its interior or central medulla. Within the lymph node's cortex, lymphocytes are organized into B-cell–rich follicles and perifollicular zones of T cells. T cells also extend in approximation to the B-cell zones to form pericortical regions.

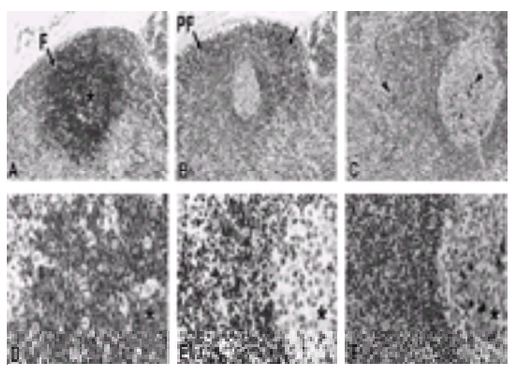

Figure 2.8. A–F: Architecture of the human lymph node. Lymphocytes within lymph nodes are organized into B-cell–rich follicles (F in **A**) and T-cell–rich perifollicular zones (PF in **B**). *Arrowheads* point out representative macrophages in **C.** Germinal centers are denoted by an *asterisk* in **A** and **D–F.** Immunoperoxidase stains identify specific cell types present in various lymph node regions. **A, D:** CD20 (B cells); **B, E:** CD3 (T cells); **C, F:** CD68 (macrophages). *Brown* indicates a positive reaction (original magnification ×33 for **A–B,** ×66 for **C,** and ×132 for **D–F.**) (See Color Figure 2.8.)

The interior of the lymph node contains channels or sinuses with walls made of reticular cells. In contrast to the blood sinuses of the spleen, the sinuses of lymph nodes contain lymph rather than blood. These sinuses are formed by the channels of afferent and efferent lymphatic vessels that enter and drain the lymph node. Afferent lymphatic vessels bring lymph and lymph cells into the large subcapsular sinus of lymph nodes. This drains into many cortical or trabecular sinuses that often are formed parallel to the penetrating trabeculae of the capsule. These merge into lymphatic cords that are drained by the efferent lymphatic vessels that exit the lymph node at the lymph node hilum. Thus, lymph nodes act as cellular filters for the lymph that flow through them, entering through the afferent vessels and leaving through the efferent vessels (18,19,28,29,74).

Characteristically, multiple afferent lymphatic vessels empty into the lymph node at a site opposite the hilum. The hilum serves as the entry point for lymph node arteries and the exit for lymph node veins and the efferent lymphatics.

Blood supply to the lymph node is similar to that of the spleen. Arterial blood penetrates each lymph node at a hilum, ramifies into trabecular projections and forms baskets of capillary loops within the region of the follicular cortex. In the lymph node, the capillary baskets surround the B-cell areas, and the postcapillary venules are lined by a unique high cuboidal endothelium; venules lined with an endothelium having this special morphology are known as *high-endothelium venules* (HEVs) (20,21). Postcapillary blood is collected by veins, which return to the hilus alongside the penetrating arterial blood supply.

Within the lymph node, afferent lymphatics open into the *subcapsular or marginal sinus,* an opening that separates the fibrous capsule of the lymph node from the underlying organized lymphoid tissue (Fig. 2.8). Lymphocytes may be found in the subcapsular sinus, but macrophages, DCs, and the reticular stromal cells of the lymph node are the most common cell types present. The lymph and its cellular components that enter the subcapsular sinus then pass through the densely packed lymphocytes present in the lymph node cortex by way of radial sinuses before reaching the central part of the lymph node or medulla. The medulla contains branching partitions or cords of stromal cells and fibers, separated by medullary sinuses rich in macrophages and plasma cells. The sinus coalesces to form the efferent lymphatic channel that drains the lymph node. Thus, lymph-born antigens derived from distant sites filter through the lymph node cortex and medulla. Lymphocytes, particularly naive lymphocytes, are also continuously passing through the cortex. Naive lymphocytes enter lymph nodes through the HEVs that form basketlike structures interposed between the B- and T-cell zones of the cortex. HEVs display particular adhesion molecules that interact with the homing receptors on lymphocyte surfaces and serve to recruit circulating lymphocytes (20,21).

The lymph node cortex can be broadly divided into two structural and functional regions populated by T- or B-lymphocytes. The B-cell zones, or follicles, not only contain B-lymphocytes but also FDCs, specialized macrophages, and oftentimes small numbers of $CD4^+$ T lymphocytes. As in the spleen, follicles present in lymph nodes are divided histologically into two categories: primary- and secondary follicles. Primary lymphoid follicles are composed of small resting B-cells and an associated network of sparse FDC processes, whereas secondary follicles contain an inner region of rapidly proliferating B-cells associated with a dense FDC reticulum. This germinal center is surrounded by a compressed rim of resting B-cells known as the mantle zone. The number of follicles present in a lymph node and the ratio of primary and secondary follicles define immunologic activity in the lymph node (5,18,19). Resting lymph nodes, those with little or no active immunity, often contain few primary follicles, whereas lymph nodes that house active immune responses may be nearly filled with secondary follicles (71,75). The pericortical regions of lymph nodes contain T lymphocytes and large numbers of DCs that are specialized for the effective presentation of antigen T cells (5,18,19,22,75). This T-cell–rich pericortex extends into the lymph node and separates the individual B-cell follicles.

Peyer Patches: Gut-Associated Lymphoid Tissue

Secondary lymphoid tissues within mucosal organs are usually situated within the *lamina propria,* a well-vascularized sheath of connective tissue immediately below the mucosal epithelium (19,25,76). These *gut-associated lymphoid tissues* (GALT) contain B-cell follicles that are surrounded by a region of T cells much like the pericortex of lymph nodes (Fig. 2.9). Vascular trees containing HEVs enter this T-cell zone and provide a mechanism for lymphocyte recruitment. In the absence of efferent lymphatics, antigen enters the Peyer patches through an overlying mucosal epithelium that is specialized for the uptake and transport of antigen (77). These specialized epithelial cells, M cells, are capable of transporting antigens ranging in size from soluble proteins to intact microorganisms from the mucosal lumen to the underlying GALT (77,78). Plexuses of lymphatic capillaries surround Peyer patches and serve to transport lymphocytes, accessory cells, and antigen to draining lymph nodes (19,25,76,77 and 78).

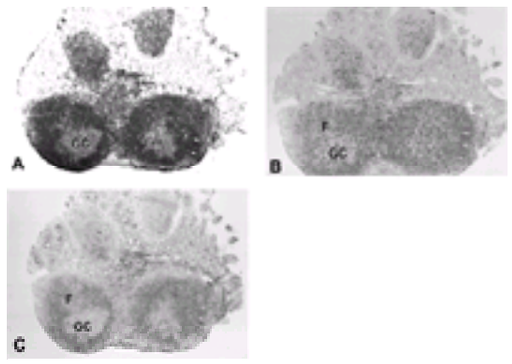

Figure 2.9. A–C: Architecture of Peyer patch. Peyer patches consist of organized aggregates of B-cell follicles (F) with germinal centers (GC) and intrafollicular zones of T cells that are present within the lamina propria of small bowel. Immunoperoxidase stains identify the locations of B cells (**A,** CD45RAB/B220 stain), helper-T cells (**B,** CD4/GK1.5 stain), and macrophages (**C,** F4/80 stain) (original magnification ×16). (See Color Figure 2.9.)

B and T lymphocytes are distributed with the Peyer patches as they would be within a lymph node that is undergoing an active immune response; that is, B cells are organized into active, secondary follicles that are separated by interfollicular zones of T lymphocytes. In contrast to lymph nodes, in normal mice Peyer patches do not exhibit a resting structure; germinal centers are always present because of incessant activation by antigens of the gut flora (19,25,76).

Like the lymph nodes that punctuate the lymphatic vasculature, Peyer patches form late in fetal development by a process that depends on lymphotoxin-a (LT-a) (79,80 and 81). During the formation of the Peyer patch GALT, invagination of lymphatic vessels is followed by the ordered immigration of DCs and lymphocytes and their subsequent resolution into follicular and interfollicular zones (80,81). This organogenesis is remarkable in that it relies on signals that are later used to effect immunity (5,80,81).

Structural Organizers of Secondary Lymphoid Tissues

The detailed architectures of the spleen, lymph nodes, and Peyer patches are unique, but they all share fundamental features that characterize secondary lymphoid tissues. Generally, T and B lymphocytes are segregated, with areas of T-cell predominance containing few B cells and substantial numbers of DCs. B-cell areas of secondary lymphoid tissues contain primary follicles that represent the sites where antigen-activated B cells that have received T-cell help expand, mature, and initiate the germinal center reaction before becoming antibody-forming cells and entering the memory cell pool.

Organizing immunocytes within the secondary lymphoid tissues is thought to increase the efficiency of immune responses by organizing B and T lymphocytes in association with their accessory cells and by providing a framework that permits the rapid circulation of naive cells through a space where antigen become concentrated. Indeed, the efficiency of organized secondary lymphoid tissue structure has been demonstrated experimentally (5).

What are the signals that organize T and B lymphocytes into discrete zones within the secondary lymphoid tissues? The membrane form of LT-a is now recognized as providing crucial signals required for the biogenesis of secondary lymphoid tissues and the organization of primary B-cell follicles and T-cell zones within these structures (5,82,83,84 and 85). Tumor necrosis factor (TNF) mediates independent signals for primary B-cell follicle structure and can cooperate with membrane-associated LT contributing to other aspects of secondary lymphoid tissue development (84,85). Some of the developmental actions of LT become fixed in the architecture of secondary lymphoid tissues, whereas others require continuing expression of LT to be sustained. For example, once formed, the lymphatic modifications that house the lymph nodes are stable, whereas withdrawal of LT-expressing B lymphocytes results in the loss of FDC networks and primary B-cell follicles over a period of days to weeks (86,87). Significantly, B cells have been identified as the lineage that delivers the LT signal for the formation and maintenance of the FDC network (5,84,85). Thus, B cells use LT as an inductive signal for the formation of lymphoid tissue, structures that, in turn, are required for the B cell to express its immune function most clearly (5). The actions of LT and TNF in signaling the formation of secondary lymphoid tissues are mediated primarily through the LT receptor LT-bR and the TNF receptor TNFR-I, but participation by additional receptors is likely (86,87 and 88). Experiments in which mixtures of lymphoid cells, purified cell populations, or bone marrow are transferred from one strain of mice to another have defined rules that govern the compartmentalization of lymphocytes within the spleen (5,79,86,87 and 88).

TRANSIENT STRUCTURES OF THE IMMUNE RESPONSE

Germinal Center

The *germinal center reaction* (Fig. 2.10) is prominent in primary and secondary responses to thymus-dependant antigen and represents cellular processes leading to the generation of high-affinity memory B cells and long-lived plasmacytes. (71,75,90,91 and 92). It is within germinal centers that antigen-specific B cells acquire mutations in the V(D)J region of rearranged immunoglobulin genes (91,92). In conjunction with affinity-dependent selection, this process of somatic hypermutation is necessary for the affinity maturation of serum antibody (90,92,93).

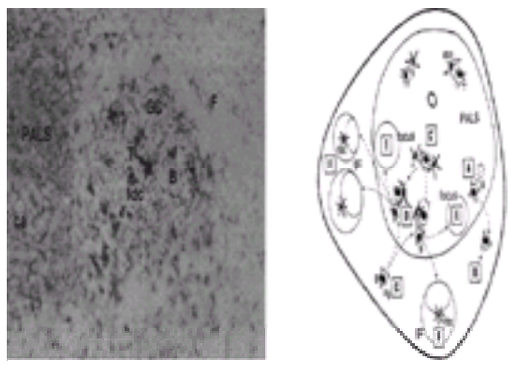

Figure 2.10. Germinal center reaction in murine spleen. Immunization with most thymus-dependent antigens initiates the germinal center (GC) reaction. GCs form within the B-cell follicle (F) by the expansion of antigen-specific T- and B-cell immigrants (T, B) from the periarteriolar lymphoid sheath (PALS). Both lymphocyte types proliferate in the reticulum of follicular dendritic cells (fdc) forming a distinct histologic structure containing light and dark zones (LZ, DZ). Original magnification ×200. Thus, the primary humoral immune response begins with antigen-dependent activation of lymphocytes [C, C']. Activated T- and B-lymphocytes then meet along the border of the PALS and follicle [D] where cognate interactions drive proliferation in both lymphocyte compartments. Some daughter B-lymphocytes remain adjacent to the T-cell area and differentiate into foci of antibody-secreting plasmacytes [E]. Other, clonally related, B-cells migrate along with specific T-cells back into the follicle and lodge in the processes of fdc where the GC reaction begins. Modified from ref. 71. (See left panel of figure in Color Figure 2.10.)

Germinal centers form within the primary follicles of secondary lymphoid tissues, creating secondary follicles (71,75,89); similar histologic structures also form at sites of chronic inflammation, such as in the synovium of patients with rheumatoid arthritis (94,95). In primary immune responses, activated T lymphocytes appear in T-cell–rich areas shortly after immunization and are subsequently met by antigen-specific B cells that migrate from the follicle to the edge of the T-cell zone (96,97). Interaction between these antigen-specific lymphocytes leads to CD154-dependent B-cell proliferation and the subsequent migration of both T and B lymphocytes back into the follicle (71,75,96). In mice, antigen-specific lymphoblasts begin to fill the FDC reticulum within 3 to 5 days after primary immunization (71,75,96,97,98,99 and 100). These dividing cells displace small, nondividing follicular B-cells to create a zone of compressed cells, the follicular mantle zone (75,96). Once established, the nascent germinal center polarizes to form two distinct zones: a dark zone that is adjacent to the T-cell region and contains rapidly dividing centroblasts and a light zone that contains nondividing centrocytes, FDCs, and virtually all the $CD4^+$ cells present in the germinal center (71,75,96,97 and 98).

Hypermutation in germinal center B cells is initiated approximately 1 week after the primary response begins (91,92,101), generally coincident with the polarization of germinal centers into light and dark zones (71,75). Mutations accumulate at a steady rate for at least 2 to 3 weeks by the incorporation of frequent nucleotide substitutions and, less commonly, short deletions or insertions (91,100,101). This process results in clonal genealogies that recapitulate repeated rounds of mutation,

selection, and proliferation (91). The mechanism of V(D)J hypermutation is unknown, but it introduces a distinctive pattern of nucleotide misincorporations. Characteristically, hypermutation favors transition mutations and exhibits biased nucleotide exchanges that reflect both antigen-driven selection and the intrinsic properties of the hypermutation process (102,103).

The germinal center reaction is normally dependent on the presence and activity of $CD4^+$ helper-T cells (96,97,99); however, surprisingly low numbers of helper cells can support the formation of histologically typical germinal centers (104,105). Indeed, reconstitution experiments in congenitally athymic nude mice demonstrate that fewer T cells are necessary to reconstitute the germinal center reaction than to generate foci of antibody-forming cells (105) present in the bridging channels of the spleen (75,96). The nearly normal kinetics and magnitude of the germinal center reaction in the presence of limiting numbers of T lymphocytes suggest that cognate T-B interactions may not be required to sustain follicular activation or proliferation. This germinal center–like reaction may even generate increased numbers of immunoglobulin M (IgM)-positive antigen-specific precursor cells and may prime for enhanced IgM responses on subsequent rechallenge (104,105). However, IgM®IgG isotype switching is poorly supported by limited numbers of T cells, and the extent of immunoglobulin V(D)J hypermutation is directly proportional to the numbers of helper-T cells available during the response (105).

The cellular and molecular signals that direct and control germinal center formation are not well understood. Genetic defects and the administration of antibodies or fusion proteins that disrupt collaboration between antigen-specific T and B lymphocytes block or reduce antibody production and the germinal center reaction (91,93,99,106,107 and 108). Mice that cannot express MHC class II molecules exhibit no or few germinal centers in response to protein antigens, presumably because they cannot support the generation of $CD4^+$ T lymphocytes that drive B-cell activation (96,98 and 99). In the absence of complement, germinal center responses are strongly suppressed by diminishing the ability of FDC to trap antigen-antibody complexes on their surface or diminishing signals necessary for B-cell survival in the germinal center (109,110 and 111). Administration of passive antibody specific for CD154 or CD86 at the initiation of the germinal center reaction has little or no effect on early serum antibody titers but significantly alters the germinal center response (93). Treatment with anti-CD154 antibody abrogates the germinal center reaction within 48 hours, a finding demonstrating that the germinal center reaction is maintained by CD154-dependent processes. This disruption does not result in the death of germinal center B cells, but it causes their migration from the follicles (93,99). In contrast to the disruption of germinal centers by anti-CD154 antibody, administration of antibody specific for CD86 does not disrupt germinal center architecture. Instead, transient blockades of CD86 function impair germinal center development by retarding local B-cell proliferation, diminishing frequencies of V(D)J point mutations, and impairing humoral immune memory (15,93,112). These effects are specific to the germinal center B-cell compartment, because passive anti-CD86 antibody has no effect on early antibody levels or T-cell priming (93,112).

Although the germinal center reaction is thymus dependent, several thymus-independent antigens (113,114 and 115) elicit the formation of germinal centers or germinal center–like reactions within splenic follicles. The kinetics of the germinal center–like reaction that is induced by thymus-independent antigens is initially similar to that seen in primary, thymus-dependent responses but ends sooner (114,115). In the case of the germinal center–like structures formed in response to haptenated lipopolysaccharide, the follicular reaction was not judged to be as intense as that observed in carrier-primed animals (114). However, responses to thymus-independent bacterial vaccines are often substantial, with some 60% to 100% of follicles containing antigen-specific germinal centers (105). Studies demonstrate that some inflammatory signals elicit the emigration of lymphocyte populations from the bone marrow into secondary lymphoid tissues (116,117 and 118). Immature B-cell emigrants share many phenotypic characteristics of germinal center B cells and may be capable of organizing into histologic structures resembling germinal centers.

Extrafollicular Plasmacytic Foci

In many (71,75,96), but not all (119), primary antibody responses, discrete collections, or foci, of antigen-specific *lymphoblasts* and *plasmacytes* form in secondary lymphoid tissues (Fig. 2.11). When present, plasmacyte foci represent the initial site of antibody production and the major source of early serum antibody. In murine spleen, plasmacytic foci are located adjacent to the PALS, in extrafollicular bridging channels that communicate directly to the marginal sinus and red pulp (75,119). These foci are formed before the nascent germinal center, and genetic analysis of B lymphocytes in neighboring foci and germinal centers indicates that both populations are founded by common precursors (120,121). Plasmacyte foci are transient and generally lost by the second week of primary responses (71,75,120,121,122); in secondary responses, foci are uncommon, and plasmacytes are most abundant in the splenic red pulp and medullary cords of lymph nodes (71,75,119). The formation of plasmacytic foci can be blocked by the administration of passive antibodies that inhibit cognate interaction between T and B lymphocytes; however; once formed, these foci are resistant to such inhibition, a finding suggesting independence from continuing T-cell help (93,122). Despite this independence, IgM®IgG class switching occurs in plasmacytic foci (121,123,124) although V(D)J hypermutation does not (91,121,122).

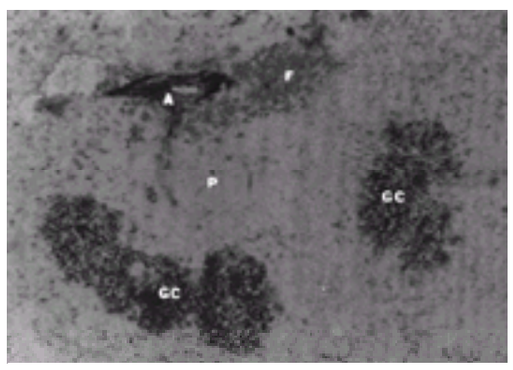

Figure 2.11. Plasmacytic foci and germinal centers in murine spleen. Following a period of proliferation near the periphery of the splenic T-cell zone, the periarteriolar lymphoid sheath (P), antigen-specific B lymphocytes differentiate into plasmacytes (F) and remain in close approximation to the T-cell zone. These large foci of AFC produce the earliest serum antibody and the plasmacytes within them may undergo IgM®IgG class switching but do not support V(D)J hypermutation. Original magnification ×200. From ref. 119. (See Color Figure 2.11.)

Inflammatory Lymphoid Tissue

Chronic inflammation is frequently associated with the development of lymphocytic follicles at sites that do not normally support secondary lymphoid tissue, including the thyroid and salivary gland, nasal sinus mucosa, eustachian tube, and joint synovium (94,95,125,126). The development of MALT (mucosa-associated lymphoid tissue) lymphomas offers the best studied example of naturally acquired, ectopic lymphoid tissue. The stomach is the most common site for these MALT lymphomas, even though normal gastric mucosa has no associated lymphoid tissue (127). However, chronic inflammation from gastric pathogens can induce MALT *de novo,* a process almost pathognomonic for *Helicobacter pylori* infection (127,128). This so-called acquired MALT histologically resembles normal Peyer patch with active germinal centers, a perifollicular T-cell zone, and vascularization by HEVs. Remarkably, T- and B-cell populations present in MALT associated with *H. pylori* gastritis are specifically activated by *Helicobacter* antigens, and the elimination of infection by antibiotics commonly results in the eventual loss of the acquired MALT (127,128 and 129).

The triggering signal for the neogenesis of lymphoid tissue is mediated by LT-a. Tissue-specific expression of transgenic LT-a modulates the local induction of adhesion molecules and chemokines, which, in turn, direct immunocyte recruitment and vascularization (130,132).

Infection and chronic inflammation can elicit the formation of lymphoid tissue and active germinal centers at sites where such tissues are not normally present (94,95,125,126,127 and 128). It is plausible that this process of tissue neogenesis is analogous to the developmentally regulated formation of lymph nodes and Peyer patches (79,80 and 81). The genetic instability that is typical of germinal center B cells (133) may initiate the oncogenic changes that result in MALT lymphoma (134,135,136 and 137).

CURRENT ISSUES IN LYMPHOID ARCHITECTURE

The immune system is an evolutionary adaptation that has radiated to all jawed vertebrates. Remarkably, signals that determine immune effector function also seem to be responsible for the organogenesis of many peripheral lymphoid tissues, especially lymph nodes and Peyer's patches. It is now generally thought that developmentally regulated inflammatory signals initiate the formation and organization of these organs, just as environmentally induced inflammation can generate acquired lymphoid structures. Kratz et al. have called this process *lymphoid neogenesis* (132). Identification and an understanding of the redundant signals that both organize immune structure and mediate immunity represent remarkable possibilities for the integration of molecular and cellular biology.

3 MAJOR HISTOCOMPATIBILITY GENE COMPLEX: STRUCTURE AND FUNCTION

Hidde Ploegh, Ph.D.

MAJOR HISTOCOMPATIBILITY COMPLEX AS A GENETIC REGION

The *major histocompatibility complex* major histocompatibility gene complex (MHC) is a genetic region that encodes a set of glycoproteins essential for immune recognition. Initially discovered in mice as the genetic locus that controls the rejection or acceptance of grafts from a genetically distinct individual of the same species, the products encoded by the MHC are now known to serve as essential intermediaries in conveying antigenic information to antigen-specific receptors on T lymphocytes.

The discovery of the MHC in mice was followed by the definition of a similar genetic complex in humans, followed in short order by the characterization of homologous gene clusters in other mammals, birds, amphibians and fish. The complete nucleotide sequence of a 2.3-Mb region encompassing the entire human MHC has now been published, as has that of the chicken. The sequence of the mouse is close to completion, and it is only a matter of time before the genomic sequence of model organisms such as *Rerio danio* (zebrafish) will have been added to the list. The comparative analysis of vertebrate MHCs illustrates both structural conservation of MHC genes, indicative of conserved function, and extreme divergence and evolutionary plasticity in the number of genes contained within it: whereas the human MHC encompasses some 200 genes, that of the chicken is a minimalist version possessing only 17 functional genes. The range of products encoded by the human MHC not only includes the structural genes for the MHC product *sensu stricto,* but also provides the information for proteins that function as accessories to MHC products. Not all the MHC-encoded genes have obvious immunologic functions, but many of them do. Specifically examples of such accessory genes found in the MHC include the following: genes that encode subunits of the proteasome, the proteolytic organelle involved in cytosolic proteolysis; genes that encode the transporter required for delivery of peptides to MHC molecules; a gene that encodes a chaperone involved in providing class I molecules with antigenic peptide; and a gene that encodes a chaperone involved in providing class II molecules with its peptide cargo.

The increase in information on the genetics of the MHC was made possible by large-scale population and family studies. In addition, the detailed analysis of inbred strains of mice and their suitability for *in vivo* experimentation made essential contributions to the understanding of both MHC structure and function. The introduction of modern molecular biologic tools allowed the definition of the extremely high degree of polymorphism of the genes encoded in the MHC. This polymorphism is at the heart of the immune system's ability to confront many different pathogens: each polymorph variant of an MHC product is capable of presenting a unique set of antigens to specific receptors on T lymphocytes. The genetics of MHC products is straightforward: these products are expressed codominantly and are inherited in strictly mendelian fashion. Notwithstanding their extensive polymorphism, no unusual mechanisms appear to give rise to new allelic variants. The fixation of the large number of MHC alleles in the population must surely relate to the biologic function of the products they encode, a function that, to a first approximation, is strictly immunologic.

The identity of the polymorph variants expressed in a given individual is conveniently determined using antibody-based methods, and for routine human leukocyte antigen (HLA) typing, such methods continue to be used (Table 3.1). A more refined analysis relies on the use of the polymerase chain reaction, which allows definition of MHC polymorphisms with single nucleotide precision. The complete coding sequences of the most commonly occurring MHC alleles are now a matter of record. An international database maintains and expands on the available sequences and ensures adherence to a rational nomenclature for newly identified alleles. As far as the HLA system is concerned, the immunologically relevant loci are the so-called class I and class II loci. The structure of the class I products is described later; for class I molecules, the so-called heavy chain is encoded in the MHC. The human MHC contains the following class I loci (Fig. 3.1): HLA-A (195 alleles known), HLA-B locus (399 alleles), HLA-C locus (94 alleles), HLA-E (5 alleles), HLA-F (1 allele), and HLA-G (14 alleles). Class II loci encode two subunit proteins, in which the genes for both subunits are MHC encoded. These genes are as follows: DRa (2 alleles), DRb1 (269 alleles), and DRb2 (63 alleles); DQa1 (20 alleles) and DQb1 (45 alleles); and DPa1(19 alleles) and DPb1 (92 alleles).

Protein	Residues	Peptide Sequence
HTLV Tax	(11–19)	LLFGYPVYV
HIV Pol	(476–484)	ILKEPVHGV
Flu matrix	(58–66)	GILGFVFTL
TRP2	(288–296)	SLDDYNHLV
TRP2	(180–188)	SVYDFFVWL
HCMV pp65	(495–503)	NLVPMVATV
p53	(65–73)	RMPEAAPPV
MART-1	(27–35)	AAGIGILTV
gp100	(280–288)	YLEPGPVTA
HIV Gag	(77–85)	SLYNTVATL

[a] Alignment of ten cellular and virus-derived nonamer peptides presented by HLA-A2 reveals anchor binding motifs. Small hydrophobic amino acids are preferred by this allele at at the second and ninth residues.

TABLE 3.1. Definition of Anchor Residues for the HLA-A2 Molecule as Inferred from an Alignment of Ten Peptide Sequences that Bind to HLA-A2[a]

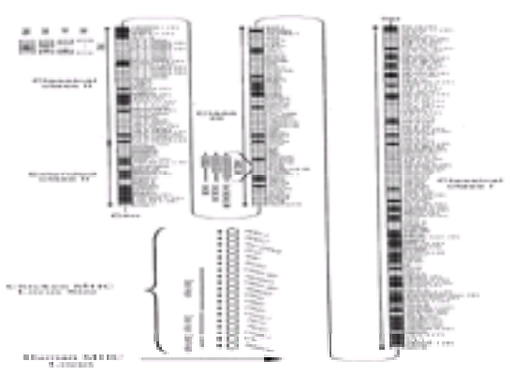

Figure 3.1. Structure and gene content of the human and chicken major histocompatibility complex (MHC). (*Nature* 1999;401:923–925, with permission.)

The DO and DM genes encode proteins that assist the class II products in their function, as described in Chapter 6. They are themselves MHC genes and are structurally related to class II products. Their polymorphism is limited: eight alleles for DOa and b, and four and six allelic forms, respectively, for DMa and DMb. In addition to these MHC-encoded membrane glycoproteins, the MHC contains the genes for components of the complement system, also referred to as class III MHC genes. A database of all HLA alleles whose nomenclature has been approved may be found on *http://www.ebi.ac.uk/imgt/hla/index.html.* The sequence for chromosome 6 itself may be found at *http://www.sanger.ac.uk/HGP/Chr6//.* The complement system is discussed in Chapter 2.

FUNCTION OF MAJOR HISTOCOMPATIBILITY COMPLEX PRODUCTS

Pathogens such as viruses usurp the cellular synthetic apparatus for the synthesis of their nucleic acids and use the host protein synthetic apparatus to produce viral polypeptides. These reactions are confined to the cytoplasmic compartment. As long as the viral genome and the products encoded by it are not displayed at the cell surface, the infected cell remains invisible to the immune system. By the same token, bacterial pathogens that are specialized to invade the mammalian cell and to multiply intracellularly are not immediately accessible to cells and molecules of the immune system. The cytoplasm—the inside of the cell—and endocytic compartments—topologically equivalent to the outside of the cell—represent two topologically distinct sites that can sustain survival and multiplication of pathogens. A successful defense against these pathogens demands that both types of compartment can be sampled. It is now clear that the MHC products evolved to perform such surveillance. The function of MHC products, in essence, is the conversion of antigenic proteins into entities recognizable by T lymphocytes. This is perhaps the most remarkable aspect of the function of MHC products: their ability to present short fragments of proteins to antigen-specific receptors on T lymphocytes. Whereas surface immunoglobulins on B lymphocytes can recognize antigen without the intervention of any third-party molecules, the antigen-specific receptors of T cells generally do not recognize intact antigen, but rather short peptides, generated by proteolysis from proteins in both the cytoplasmic and extracellular compartments. The antigen receptors on CD4 and CD8 T lymphocytes, for the most part, obligately require the engagement of MHC-encoded products loaded with fragments derived from antigenic proteins. The conversion of an intact protein into an entity that can be recognized by T lymphocytes is called *antigen processing,* and the combined result of this proteolytic conversion together with display of the resultant MHC peptide combination at the cell surface is referred to as *antigen presentation.* In the following discussion, the structure of MHC products is described, as are the cell biologic processes that underlie the conversion of an intact protein into a peptide suitable for display by MHC products.

STRUCTURE OF THE MAJOR HISTOCOMPATIBILITY COMPLEX–ENCODED PRODUCTS

MHC products are generally classified as class I and class II. Both types of protein are membrane glycoproteins (Fig. 3.2 and Fig. 3.3). Class I molecules are composed of an MHC-encoded heavy chain of approximately 45 kd. The heavy chain associates noncovalently with the light chain, b_2-microglobulin. MHC class I products are encoded by the HLA-A, HLA-B, and HLA-C loci in humans and by the H-2K, H-D, and H-L loci in the mouse. These class I molecules are also referred to as classic class I products. This classification distinguishes them from the so-called nonclassic or class Ib products. MHC class II products are composed of two MHC-encoded subunits, the a and b chain, of approximately 35 and 30 kd, respectively. In humans, class II products are encoded by the HLA-DR, HLA-DQ, and HLA-DP loci, and in the mouse, they are encoded by the I-A and I-E loci. MHC products consist of a large extracellular domain, transmembrane segments that anchor the MHC products in the lipid bilayer, and a short cytoplasmic tail. The cytoplasmic tails contain information that may allow these products to be delivered to distinct intracellular sites as well as allow retrieval from the cell surface. The most important portion of the MHC product is its extracellular domain, through which antigen is presented and the T-cell receptor is engaged. The three-dimensional structure of the luminal domain of numerous MHC class I and class II products has now been determined, and it shows their structures to be remarkably similar. The membrane-proximal domains of the luminal portion are immunoglobulin G (Ig)–like domains that occur in paired fashion. The Ig-like domains support a platform of an eight-stranded b sheet on top of which two long a-helical segments are found. The combination of the b sheet (“floor”) and the helices forms the peptide binding crevice. The mode of peptide binding is such that a contiguous surface is formed, composed of residues contributed by both peptide and MHC product. The T-cell receptor for antigen recognizes this surface and interacts with side chains of the MHC product as well as with residues contributed by bound peptide. The MHC-encoded subunits display polymorphism: residues that show allelic variation are found in and around the peptide binding pocket. Thus, polymorphisms directly affect the architecture of the peptide binding cleft and determine which peptides are bound by a particular MHC product. At the same time, polymorphic residues—the amino acid substitutions that distinguish the different allelic products—outside the peptide binding area proper also contact the T-cell receptor for antigen. The manner in which T lymphocytes are selected (Chapter 5) and the structure of the T-cell receptor itself (Chapter 4) ensure that only the host's own MHC products can be used in a productive manner for antigen presentation to T cells, a phenomenon known as *MHC restriction.* The ability of T-cell receptors to recognize antigenic peptides only when presented in the context of an appropriate MHC molecule explains the central position occupied by MHC products not only in the recognition and elimination by cytotoxic T lymphocytes of cells infected with a virus, but also the ability of T lymphocytes to interact with B lymphocytes to provide the help essential for B cell activation and differentiation.

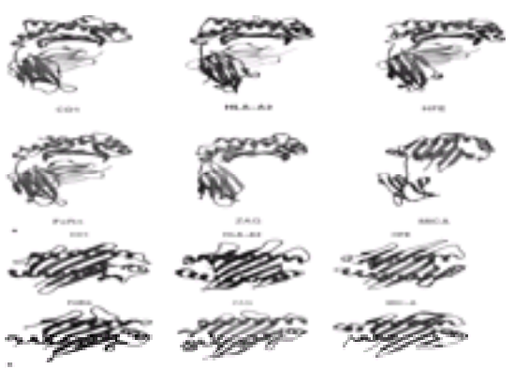

Figure 3.2. A: Structure of major histocompatibility complex (MHC) class I products and related structures. The HLA-A2 structure is representative of the so-called classic class I products, involved in presentation of peptide to T-cell receptors. The CD1 molecule presents lipid antigens. The HFE product interacts with and modifies internalization of the transferrin receptor. The neonatal Fc receptor (FcRn) is involved in transepithelial transport of immunoglobulins in the gut of the newborn. The ZAG protein is a zinc-binding serum protein. The MIC-A product is encoded by a gene linked to the MHC (Fig. 3.1) and is probably involved in antitumor immunity and eradication of cells subjected to stress. Note the presence of the common light chain, b_2-microglobulin, in CD1, HLA-A2, HFE, and FcRn. **B**: As in **A,** but structures viewed from above. Note the presence of the peptide in the cleft of the HLA-A2 molecule. (See Color Figure 3.2.)

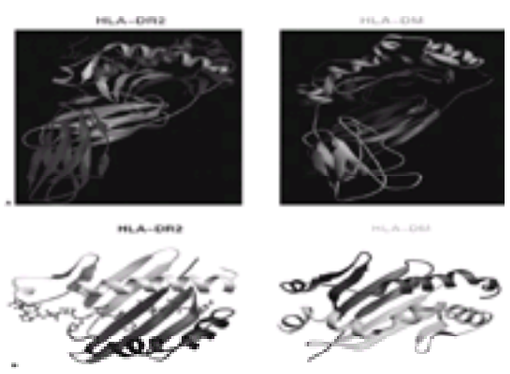

Figure 3.3. A: Comparison of the structure of the class II molecule HLA-DR2 and of the DM molecule, a catalyst involved in the peptide loading of major histocompatibility complex (MHC) class II molecules. **B**: As in **A,** viewed from above. (See Color Figure 3.3.)

MODE OF PEPTIDE INTERACTION WITH MAJOR HISTOCOMPATIBILITY COMPLEX PRODUCTS

The atomic structure of MHC products has allowed a detailed description of the interactions with their peptide cargo. Class I molecules possess a peptide binding groove that accommodates peptides in the size range of eight to ten residues. Exceptionally, slightly longer peptides may be accommodated. The architecture of the class I peptide binding groove provides for conserved features that accommodate the N and C terminus of the peptide. Accommodation of the peptide termini is essential to confer stable binding. Occlusions at either end of the peptide binding pocket and the need to accommodate the peptide termini explain the strict limits imposed on peptide size by the class I peptide binding cleft. In addition, several pockets provide docking sites for amino acid side chain in the peptide. The structure of

these pockets indicates a pronounced preference for particular amino acids, such that only peptides possessing that particular amino acid can occupy this pocket and provide the interactions required for stable binding. These positions are referred to as *anchor residues.* Usually, class I molecules require at least one so-called primary anchor residue, which is nearly invariant. In addition, secondary anchor positions may be defined, at which several amino acid side chains can be accommodated with equal efficiency.

Often, the nature of the C-terminal residue is that of an anchor residue: murine class I molecules invariably require an aliphatic amino acid (Leu, Ile, Met, Val) at the C terminus. This mode of interaction results in so-called peptide binding motifs that are unique for the different allelic class I products. In the mouse, the H-2Kb locus product prefers a Tyr or Phe residue at position 5, whereas the H-2Db product prefers an Asn residue at position 5. For many human class I molecules, the preferred binding motif is known and is a useful parameter to predict which peptides from a given polypeptide chain may be presented by that MHC class I product. These motifs may be determined experimentally by extracting peptides from purified MHC class I molecules and by subjecting the eluted peptides to sequence analysis by Edman degradation. At the so-called anchor positions, most class I–bound peptides possess the preferred anchor residue, whereas the other positions are either entirely variable or show only some restriction in the side chains allowed at that position, a trait that manifests itself as the occurrence of many different amino acids at a given cycle of Edman degradation.

More recent studies employ tandem mass spectrometry to acquire sequence information for MHC bound peptides. By demanding only a few truly fixed parameters to allow stable binding, a single MHC class I allelic product can accommodate a substantial number of different peptides. For an individual heterozygous at the HLA-A, HLA-B, and HLA-C loci, six different class I products are expressed, and this number apparently suffices to cover the spectrum of antigenic peptides that must be displayed in the defense against the wide range of pathogens that confronts the species. The interaction of peptides with MHC class I products is dominated by contacts between the peptide side chains and the MHC product.

MHC class II products have an overall structure similar to that of class I molecules. Their peptide binding groove operates on different principles, however. First, there is no requirement for tight binding of the peptide termini, and the architecture of the cleft is such that it lacks the occlusions found at both ends of the class I peptide binding cleft. This means that no fixed length characterizes a class II ligand. Furthermore, whereas anchor residues can be defined for class II molecules much like for class I molecules, many of the contacts between MHC class II products and peptide involve main chain atoms of the peptide that are contacted by amino acid side chains of the MHC product. Chapter 6 provides a detailed account of class II–peptide interactions. The website *http://wehih.wehi.edu.au/mhcpep//* maintains a current database of MHC-bound peptides for both class I and class II products.

ANTIGEN PROCESSING AND PRESENTATION

An obvious prerequisite for class I–restricted antigen presentation is the presence of the MHC class I molecules themselves. The class I molecules follow a biosynthetic pathway typical of a type I transmembrane protein: signal sequence-dependent insertion into the endoplasmic reticulum (ER), cotranslational attachment of the N-linked glycans, and delivery to the cell surface by the secretory pathway. All nucleated cells can synthesize MHC class I molecules, but wide ranges in the levels of expression are seen. Professional antigen-presenting cells and lymphocytes are strongly positive for class I molecules. Hepatocytes and fibroblasts express modest levels, and cells of the central nervous system have few, if any, MHC class I products. Exposure to the appropriate cytokines such as interferon-g (IFN-g) can dramatically increase expression of MHC class I molecules on cells that would otherwise express only modest levels of MHC class I molecules.

It is useful to divide antigen processing and presentation into a series of discrete steps that are reasonably well defined biochemically and cell biologically. This classification applies to the pathways used by class I and class II molecules alike. The basic concept is the conversion of a protein antigen into a MHC-bound peptide. This conversion requires (a) tagging of the protein antigen for degradation, (b) proteolysis, (c) delivery of the resultant peptides to the compartment of peptide loading, (d) delivery of peptide to the MHC product, (e) peptide binding, and (f) display of the peptide-MHC complex at the cell surface.

MHC Class I–Restricted Antigen Presentation: Acquisition of Antigen and Tagging the Antigen for Destruction

Antigens destined for presentation by MHC class I molecules reside predominantly in the cytoplasm, where protein synthesis occurs. Cytoplasmic proteins are tagged for destruction through the ubiquitin-proteasome pathway. This pathway comprises the activation of ubiquitin, a conserved 76-residue polypeptide, and its transfer to the protein to be destroyed. Ubiquitin is attached through its C terminus in isopeptide linkage to an appropriate lysine residue in the target protein. The signals that invite ubiquitin conjugation are not completely understood, but they may include defective translation (premature termination, misincorporation of amino acids), oxidative or proteolytic damage, and more specific modifications such as phosphorylation.

The initial attachment of a single ubiquitin moiety is followed by the addition of further ubiquitin moieties, again in isopeptide linkage to the preceding ubiquitin. A minimum of four ubiquitin molecules is required to allow the tagged protein to dock with the proteasome, the main protease responsible for cytosolic proteolysis. To date, no specific inhibitors that allow intervention in the ubiquitin conjugation reaction have been identified.

Proteolysis

Proteolysis of ubiquitin-tagged proteins is carried out by the proteasome. This complex consists of a catalytically active core particle, built from four rings of seven subunits each. The outermost rings contain seven distinct a subunits; the innermost rings of b subunits contain seven distinct subunits, only three of which are catalytically active. The core particle is equipped at either end with a so-called cap complex or a 19S particle.

The cap complex contains some 20-odd polypeptides, required for ubiquitin recognition, ubiquitin removal, and adenosine triphosphate (ATP)–dependent polypeptide unfolding to allow entry of the substrate into the catalytically active region of the core particle. Proteasomal proteolysis is usually highly processive: the degradation of a 400-residue protein may take as little as 3 to 4 minutes, with release of few or no intermediates.

The final hydrolysis products are short peptides in the range of three to ten residues. Remarkably, in cells exposed to IFN-g, the three catalytically active subunits are replaced by three IFN-g–inducible b subunits: LMP2 and LMP7, both of which are encoded in the MHC, and the MECL1 subunit. These three subunits, having replaced the constitutively expressed X, Y, and Z subunits, convert the proteasome into the so-called *immunoproteasome.* Furthermore, the 11S or PA28 regulator complex is likewise IFN-g inducible. These combined replacements rearrange the proteasome such that the products generated are better suited for presentation by class I MHC products. Whether the b subunit replacements result in altered cleavage specificity remains controversial. Investigators agree, however, that these replacements improve overall class I–restricted antigen presentation. Crystallographic evidence suggests that the regulator may promote the release of partial digestion products from the proteasome, thus favoring the generation of peptides in the size range appropriate for binding to class I molecules.

The catalytic mechanism employed by the proteasome is unusual, in that the active site nucleophile is an N-terminal Thr residue. Proteasome inhibitors of pronounced specificity have been described, among which are the natural products lactacystin and epoxomycin. Furthermore, modified tripeptides have been described that are potent proteasome inhibitors. These compounds can be used on living cells and are often used to implicate the proteasome in the proteolytic process under study. Sensitivity of T-cell recognition to treatment of the antigen-presenting cell with a proteasome inhibitor is used as a criterion to implicate the proteasome in the process, although the usefulness of these inhibitors is no better than the extent to which their specificity has been characterized. Peptides generated by proteasomal proteolysis may be further processed, both in the cytosol itself and after translocation into the ER. Most of this trimming appears to be restricted to the N terminus of the peptide. The enzyme leucine aminopeptidase is yet another example of an IFN-g–inducible protease implicated in further processing of proteasomally generated peptides.

Delivery of Peptides to the Compartment of Peptide Loading

Peptides generated by proteasomal proteolysis still reside in the cytosol. The biosynthesis of type I membrane proteins such as MHC class I molecules involves their cotranslational insertion into the lumen of the ER. Nascent class I heavy chains are directed to the ER in a conventional signal sequence-dependent manner. As the nascent chain is elongated, its signal sequence is removed by signal peptidase, and the N-linked glycans are attached on emergence of the consensus N-linked glycan attachment site (residue 86 in human class I molecules) in the ER. For a limited number of class I molecules, these signal peptides can provide peptide ligands for MHC class I molecules. This mode of presentation is of particular relevance for the display of the nonclassic class I molecule HLA-E, which is a potent ligand for receptors on natural killer (NK) cells. Folding of the class I heavy chain is assisted by ER-resident chaperones such as calnexin and calreticulin, both of which exploit the N-linked glycan on the class I heavy chain for recognition. Assembly with the light chain b_2-microglobulin occurs shortly after completion of the heavy chain. These reactions complete the construction of the folded class I molecule. How do the class I molecules acquire peptides? The MHC encodes two genes that specify an ATP binding cassette containing transporter, the TAP1 and TAP2 genes. The TAP1 and TAP2 polypeptides associate and form an ATP-dependent peptide transporter. This transporter translocates peptides into the lumen of the ER at the expense of ATP hydrolysis. The substrate preference of the peptide transporter is well matched with that of the binding specificity of the class I molecules it serves. In particular in the mouse, the TAP complex prefers peptides with the same C termini as those preferred by the class I molecules themselves: Leu, Ile, Val, Met. The human TAP complex, like the class I molecules it serves, is more relaxed in its substrate preference, as far as the C terminus is concerned. The length preference of the TAP complex is likewise well matched with that of the class I molecules: TAP preferentially translocates peptides in the 5- to 15-residue size range. Cells deficient in the TAP complex are defective in the assembly of stable class I molecules and fail to display class I molecules at the cell surface in normal amounts: their level of expression is approximately 5% of that seen in wild-type cells. On delivery of peptides to the lumen of the

ER, further proteolysis may trim the newly translocated peptides. The available evidence favors trimming predominantly at the N terminus, whereas the C-terminal cleavage appears dictated predominantly by the proteasome.

Delivery of Peptide to the MHC Product

The TAP complex is associated with a polypeptide called tapasin, a polypeptide that can also be coimmunoprecipitated with the MHC class I molecules themselves. The gene that encodes tapasin maps to the MHC. Although it was first assumed that the tapasin would simply promote close proximity of the class I molecule awaiting peptide to the TAP complex that delivers peptides, it now appears that tapasin retains “empty” MHC class I molecules in the ER. The possibility exists that the proximity of the class I molecule to the TAP complex, as brought about by the tapasin linker protein, promotes delivery of peptides to the class I molecule. A special case is peptides derived from signal sequences: after removal by signal peptidase of the signal sequence itself, further cleavage of the signal sequence is catalyzed by signal peptide peptidase. Usually, the N-terminal cleavage fragment is released toward the cytosol. Presentation of such fragments requires reimport into the ER through TAP. The C-terminal fragment of the signal peptide is probably released into the lumen of the ER.

Peptide Binding

No further accessory proteins appear to be required to achieve peptide loading of the class I molecule. Although the “empty” class I molecule bound to tapasin is assumed to have a conformation subtly distinct from that of a peptide-occupied class I molecule, no crystal structure of an “empty” class I molecule confirms this notion. Class I molecules not occupied with peptide show increased thermolability and have a strong tendency to dissociate even before they leave the ER. These molecules are destroyed by the normal pathway of ER quality control.

Display of the Peptide-MHC Complex at the Cell Surface

Peptide-loaded class I molecules are released from the ER and enter the constitutive secretory pathway. The so-called high mannose-type oligosaccharide, transferred onto the nascent chain, is converted into so-called complex type oligosaccharides by Golgi-resident glycosyl transferases. Mature class I molecules contain the typical complex-type oligosaccharides, including sialic acids. Once present at the cell surface, the class I peptide complex is available for recognition by $CD8^+$ T cells or for the delivery of inhibitory signals to NK cells. Once the synthesis of a pathogen-derived polypeptide ceases, the half-life of class I molecules at the cell surface determines the persistence of the relevant peptide-MHC complex.

MHC CLASS II–RESTRICTED ANTIGEN PRESENTATION

At this juncture, it is instructive briefly to compare the class I and class II pathways of MHC-restricted antigen presentation and to analyze the same key steps used to dissect class I–restricted presentation. More details on the class II pathway may be found in Chapter 6. MHC class II molecules follow an early biosynthetic sequence conceptually similar to that of class I molecules, with several important distinctions. Assembly of the class II heterodimer in the ER involves a third, non–MHC-encoded polypeptide referred to as invariant chain, because there appears to be only a single gene that encodes this nonpolymorphic protein. The invariant chain fulfills several important roles. First, it trimerizes to generate a scaffold onto which the class II molecules assemble (Table 3.2). Second, the invariant chain (Ii) contains a segment that occupies the class I peptide binding cleft. Because the association of Ii occurs early in the biosynthetic pathway of class II molecules, Ii temporarily occupies the peptide binding cleft of the class II molecule and thus prevents confusion about whether TAP-delivered peptides must choose between class I and class II molecules: the class II peptide binding pocket is not available to ER-resident peptides. The invariant chain, finally, contains in its cytoplasmic tail targeting information that directs the Ii–class II complex from the Golgi apparatus into the secretory pathway. Although most class II molecules are delivered directly into the endocytic pathway, the small numbers of class II–Ii complexes that escape sorting and move directly to the cell surface are internalized from the cell surface by internalization signals, again contained in the cytoplasmic tail of Ii. The delivery of class II molecules to the endocytic pathway is the major departure in the biosynthetic pathway that distinguishes class II molecules from the route followed by class I molecules. This distinction determines the sets of proteins sampled by either MHC product for presentation to T-cell receptors.

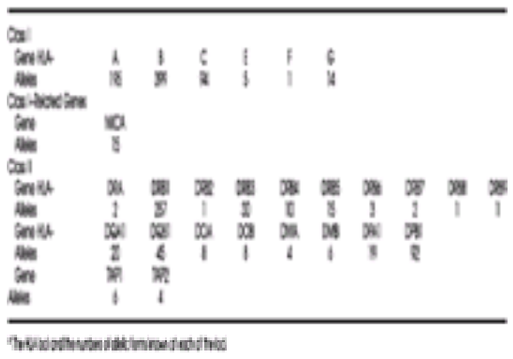

TABLE 3.2. Human Leukocyte Antigen (HLA) Genes and Their Extent of Polymorphism[a]

Class II: Acquisition of Antigen and Tagging Antigen for Destruction

Proteins destined for class II–restricted presentation are acquired by endocytosis, either in receptor-mediated fashion or by less specific processes such as pinocytosis or phagocytosis. The conditions that prevail in the endocytic pathway expose internalized proteins to an increasingly harsh regimen of low pH, reducing conditions, and high concentrations of proteolytic enzymes. No specific event appears to tag proteins for destruction. Unless they are specifically designed to survive in the endocytic pathway, most proteins are destroyed by lysosomal proteolysis.

Class II: Proteolyis

Proteolysis itself is carried out by the abundant proteases that reside throughout the endocytic pathway. Large collections of aspartyl and cysteinyl proteases degrade polypeptides into smaller peptides, including the size range appropriate for binding to class II molecules. The invariant chain itself is likewise attacked by proteases in the endocytic pathway. What remains once proteolysis of Ii is complete is a small remnant, referred to as CLIP (class II–associated invariant peptide), which remains firmly wedged in the peptide binding cleft of the class II molecule.

Delivery of Peptides to the Compartment of Peptide Loading and Delivery of Peptide to MHC Class II Molecules

The binding portion of class II molecules is located in the same topologic compartment as are the internalized proteins. In addition, the machinery required for degradation (proteases, reducing agents, low pH environment) is in the same compartment as the class II molecules themselves. Therefore, no specialized delivery functions are required to allow the class II molecules to meet peptides that can bind to them. There appear to be no specialized functions required for delivery of peptides to the MHC product itself.

Peptide Binding

The act of peptide binding to class II molecules require dislodging the Ii remnant, CLIP, from the peptide binding cleft. This is accomplished through interaction of the class II CLIP complex with the DM molecule. DM exerts true catalytic function, in that it promotes the exchange of CLIP for antigenic peptide. DM has no role in detaining class II molecules that are not occupied with peptide, because cells deficient in DM continue to display class II molecules at the cell surface. However, because of their inability to exchange the Ii remnant for antigenic peptide, such DM-deficient cells cannot present antigen effectively through class II molecules.

Display of Class II–Peptide Molecules at the Cell Surface

Unlike class I molecules, the delivery of class Ii peptide complexes to the cell surface appears to be a tightly regulated process, especially in professional antigen-presenting cells such as dendritic cells. Externalization of class II peptide complexes is poorly understood, but it is likely to be controlled by exposure of class II positive cells to the appropriate cytokine milieu. Again, this appears to be different from the situation encountered for class I molecules. Although it is regulated, class

I–restricted presentation encompasses more of a constitutive element than seen for class II–restricted presentation. This brief synopsis, expanded on in Chapter 6, highlights the similarities and differences between the two major pathways of antigen processing.

CD1 MOLECULES

One aspect of antigen presentation involves gene products not encoded by the MHC, yet their function and properties are best considered along with MHC class I and class II presentation pathways. Humans have a family of class I–related proteins collectively referred to as CD1 antigens (Fig. 3.4). Four subtly distinct forms of CD1 exist: CD1a, CD1b, CD1c, and CD1d. The genes that encode these products are not located in the MHC, yet the structure of the protein products is similar to that of a class I product. The CD1 molecules, like their classic MHC encoded counterparts, present antigen to T cells. However, both the nature of the antigen and the mode of antigen acquisition set them apart: CD1 products present lipid antigens to T cells. The CD1d product appears capable of presenting classes of lipids structurally distinct from those presented by the CD1a, CD1b, and CD1c molecules. The CD1 protein is a two-chain structure, the light chain being identical to b_2-microglobulin. The peptide binding pocket prominently present in classic class I molecules has been modified such that the CD1 molecules accommodate the hydrophobic acyl chains of lipids and their derivatives, with hydrophilic head groups protruding from the lipid binding cleft to engage T-cell receptors. Prominent classes of lipids presented are glycosylceramides, inositides, and mycobacterially derived lipids. These lipids are acquired in endocytic compartments where microbes are exposed to all manner of hydrolases, some of which must be capable of liberating the lipid antigens. The mechanism of transfer of these lipid molecules onto the CD1 products has not been clarified.

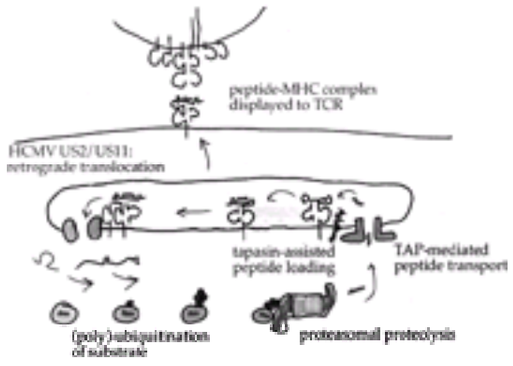

Figure 3.4. Overview of the major histocompatibility complex (MHC) class I–restricted pathway of antigen presentation. For details, see the text. For a detailed discussion of the various strategies used by viral pathogens for immune evasion, see Tortorella et al.

Three distinct routes of antigen presentation have been defined: the class I pathway focused predominantly on peptides generated in the cytosol; the class II pathway, which samples predominantly endocytic compartments for peptides; and the CD1 pathway, which is responsible for presenting lipidlike molecules generated in endocytic compartments. The different isoforms of CD1 appear to target selectively to different stations of the endocytic pathway, mostly through signals carried in their cytoplasmic tail. In this manner, the different endocytic compartments can be examined for the presence of microbially derived lipid antigens.

REGULATION OF ANTIGEN PRESENTATION

Most of the components of the antigen-processing machinery are active constitutively in the cell types that express them. The class II pathway and the CD1 pathway are restricted mostly to professional antigen-presenting cells; the class I pathway is found on most, if not all, nucleated cells. This machinery can be tuned on exposure to cytokines. The T-helper cell (Th1)–type cytokine IFN-g is one of the most potent inducers of both class I and class II pathways. Not only is the level of MHC products and their accessories stimulated in IFN-g–exposed cells, but also it appears that the details of class II trafficking, in particular in dendritic cells, are subject to drastic changes, coincident with differentiation or maturation of the antigen-presenting cell. Generally, immature dendritic cells are more prone to internalize antigen as well as class II molecules than are mature dendritic cells. This aspect is further explored in Chapter 6. Antiinflammatory cytokines such as interleukin-10 have the opposite effect on class II trafficking: interleukin-10 tends to counteract the effects of IFN-g. Although it is outside the scope of this chapter, the antigen presentation pathways have been targeted by pathogens. Because antigen presentation is among the earliest processes that alert the organism to the presence of a pathogen, these pathogens have acquired countermeasures that allow them effectively to elude many aspects of the pathways described earlier. The large DNA viruses (poxviruses, herpesviruses) are notorious for the diverse array of gene products that interfere with cytokine signaling and antigen presentation, respectively.

In the case of autoimmune disease, or predisposition to infectious disease, the antigen presentation–MHC axis occupies a central place. No T cell can recognize an antigen unless it is properly presented by an MHC product. For many autoimmune diseases described elsewhere in this volume, the association of disease with certain alleles of the MHC (particularly for class II products) is evident. In many cases, it is not known which antigens are presented, although a plausible case has been made for myelin basic protein and other myelin-derived peptides in the case of multiple sclerosis. Such peptides must be presented efficiently for an autoimmune T cell to be able to mount an attack. At the same time, the involvement of MHC products in the earliest stages of T-cell development helps to explain both the positively shaping forces exerted by MHC proteins complexed with self-peptides and the elimination of potentially self-reactive T cells from the newly generated repertoire (Chapter 5). Clearly, these selective events impinge on the available repertoire of T cells within a given individual and must be taken into account in all considerations of autoimmunity, whether arising spontaneously or precipitated by an infectious event.

4 T-CELL ANTIGEN RECEPTORS

Mark M. Davis, Ph.D., and Yueh-Hsiu Chien, Ph.D.

In the last decade and a half there has been tremendous progress in identifying the molecules and genes that govern T-cell recognition, and more recently, we have seen the first concrete information on their biochemistry and structure. Although T-cell receptors for antigen (TCRs) share many similarities, both structural and genetic, with B-cell antigen receptors (immunoglobulins), they also possess a number of unique features related to the roles that particular types of T cells play in the immune system.

For classically defined helper and cytotoxic T cells, the most important of these differences was first suggested by the experiments of Zinkernagel and Doherty (1,2), who showed that viral antigen recognition by cytotoxic T cells was possible only with a certain major histocompatibility complex (MHC) haplotype on the infected cell. Evidence for this phenomenon of “MHC-restricted recognition” also was demonstrated for helper T cells (3,4). We now know that this type of T-cell recognition involves the recognition of fragments of antigens (e.g., peptides) bound to specific MHC molecules (see Introduction and Chapter 20). Because all antigens must eventually be degraded, this form of T-cell recognition seems very complementary to that of B cells, as pathogens can escape recognition by obscuring an antibody-binding site or using “decoy” molecules.

TCRs occur as either of two distinct heterodimers, ab or gd, both of which are expressed with the nonpolymorphic CD3 polypeptides g, d, e, z, and in some cases, the RNA splicing variant of z, h, or Fe chains. The CD3 polypeptides, especially z and its variants, are critical for intracellular signaling (5). The ab TCR heterodimer–expressing cells predominate in most lymphoid compartments (90% to 95%) of humans and mice, and they are responsible for the classic helper or cytotoxic T-cell responses. In most cases, the ab TCR ligand is a peptide antigen bound to a class I or class II MHC molecule. T cells bearing gd TCR are less numerous than the ab type in most cellular compartments of humans and mice. However, they make up a substantial fraction of T lymphocytes in cows, sheep, and chickens (6). Recent work on the structural characteristics and specificity if gd TCRs suggests that they may be much more like immunoglobulins than like ab TCRs in their antigen-recognition properties. In particular, they do not seem to require MHCs or other molecules to present antigens, but instead appear to recognize antigens directly (6). Although it is not yet clear what role they play in the immune response, this is a very active area of current research, and many interesting leads are being pursued.

T-CELL RECEPTOR/CD3 POLYPEPTIDES

The search for the molecules responsible for T-cell recognition first focused on deriving antisera or monoclonal antibodies (mAbs) specific for molecules on T-cell surfaces. Ultimately, a number of groups identified “clonotypic” sera (7) or mAbs (8,9,10,11 and 12). Most of these antibodies were able to block antigen-specific responses by the T cells they were raised against or, when coated on a surface, could activate the T cells they are specific for. They immunoprecipitate 85,000 to 90,000 MW disulfide-bonded heterodimers consisting of two 40,000 to 50,000 MW glycosylated subunits (a and b). Peptide-mapping studies showed that there was a striking degree of polymorphism between heterodimers isolated from T cells with different specificities, thus indicating an antigen-specific polymorphism akin to that of immunoglobulins (13,14).

Work in parallel to these serologic studies exploited the small differences (~2%) observed between B- and T-cell gene expression (15) and isolated both a mouse (16,17) and a human (18) T-cell–specific gene that had antibody-like V-, J-, and C-region sequences and could rearrange in T lymphocytes (16). This molecule was then identified as TCRb by partial sequence analysis of immunoprecipitated materials (19). Subsequent work rapidly identified two other candidate TCR cDNAs identified as TCRa (20,21) and TCRg (22). It was quickly established that all antigen-specific helper or cytotoxic T-cells expressed TCRab heterodimers. Where the TCRg fit in remained a puzzle until work by Brenner et al. (23) showed that it was expressed on a small (5% to 10%) subset of peripheral T cells together with another polypeptide, TCRd. The structure of TCRd remained unknown until a new TCR locus was discovered within the TCRa locus, between V_a and J_a (24). Antisera raised against portions of this gene showed that it was TCRd (25,26 and 27). Formal proof that the TCR a and b subunits were sufficient to transfer antigen/MHC recognition from one T cell to another came from gene-transfection experiments (28,29), and equivalent experiments also have been done with gd TCRs (30).

As shown in Fig. 4.1, all TCR polypeptides have a similar primary structure, with distinct variable (V), diversity (D) in the case of TCR b and d, joining (J), and constant (C) regions exactly analogous to their immunoglobulin counterparts. They also share many of the amino acid residues thought to be important for the characteristic variable and constant domains of immunoglobulins (31). The C_b region is particularly homologous, sharing 40% of its amino acid sequences with C_K and C_l (17,18). The TCR polypeptides all contain a single C-region domain (versus up to four for immunoglobulins) followed by a connecting peptide or hinge region, usually containing the cysteine for the disulfide linkage found joining the two chains of the heterodimer [some human TCRgd isoforms lack this cysteine and consequently are not disulfide linked (32)]. *N*-linked glycosylation sites vary from two to four for each polypeptide, and are indicated in the figure. C-terminal to the connecting peptide sequences are the hydrophobic transmembrane regions, which have no similarity to those of *IgH* genes, but instead have one or two positively charged residues that appear to be important for interaction with the CD3 molecules and T-cell signaling (33), perhaps through interaction with the acidic residues found in all CD3 transmembrane regions.

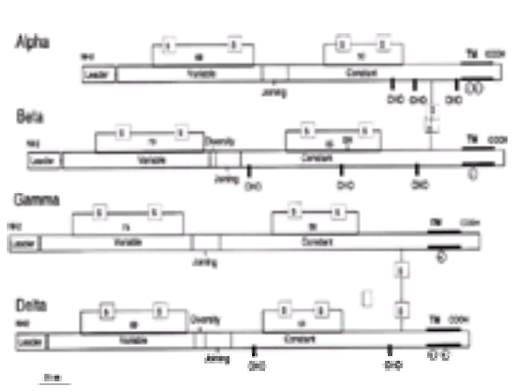

Figure 4.1. T-cell receptor (TCR) polypeptides. Schematic diagram of typical TCR polypeptides. Disulfide bonds, N-linked carbohydrate attachment sites (CHO), and transmembrane charges are indicated for TCRa, -b, -g, and -d.

T-CELL RECEPTOR STRUCTURE

Similarities to and Differences from Immunologlobins

As discussed earlier, the sequences of TCR polypepides show many similarities to those of immunoglobulins and thus it has long been suggested that both heterodimers would be antibody-like in structure (31,34,35). These similarities include the number and spacing of specific cysteine residues within domains, which in antibodies form intrachain disulfide bonds. Also conserved are many of the inter- and intradomain contact residues, and secondary structure predictions are largely consistent with an immunoglobulin (Ig)-like “b barrel” structure. This consists of three to four anti-parallel b strands on one side of the barrel facing a similar number on the other side, with a disulfide bridge (usually) connecting the two b “sheets” (sets of b strands in the same plane). All Ig variable and constant region domains have this structure, with variations in the number of b strands in variable region domains (by convention including V, D, and J sequences) compared with constant domains (34).

Efforts to derive x-ray crystal structures of TCR heterodimers and fragments of heterodimers has been very difficult, but in the last 5 years, a number of TCR fragments and heterodimer structures have been solved, particularly from the laboratory of Mariuzza et al. (36,37), who solved the structure of a V_b C_b polypeptide and a V_a fragment. In general, these domains all are very Ig-like, with the classic b-barrel structure in evidence in all three domains. At each end of the barrel in each V-region domain, there are four loops between the b sheets, three of which form the complementary determining regions (CDRs) of immunoglobulins. The fourth loop, between the D and E strands, has been implicated in superantigen binding. The six CDR loops from the two variable domains form the antigen-binding surface of immunoglobulins, and as we discuss shortly, TCRs as well. Whereas the V_b domain depicted in Fig. 4.2 follows the canonic V-domain b sheet structure, V_a differs significantly in that one of the sheets has been translocated to the other half of the barrel (as schematized in Fig. 4.2). This acts to remove a bulge in the side of the V_a domain, and it has been suggested that this would allow dimers of TCRs or perhaps higher-order structures to assemble (38). More recently, Garcia et al. (39) were able to solve the structure of the C_a in the context of a complete heterodimer, and it has a remarkable variation of the classic Ig-like domain (39). Here there is only one half of the classic b barrel, that is, one set (or “sheet”) of b strands, whereas the rest of the somewhat truncated domain exhibits random coils. This type of structure is unprecedented in the Ig superfamily and seems likely that it will be true for C_d as well, as it has many sequence similarities to C_a (24). The functional significance of such a variant structure in unknown, but it has been suggested that this incompletely formed Ig-like domain may be responsible for the observed lability of TCRa, and this may allow greater flexibility in the regulation of its expression. Another possible explanation is that this alteration may be designed to accommodate one or more of the CD3 molecules (39). Interestingly, the recently solved structure of a V_d domain (40) shows a somewhat more V_H-like pattern, consistent with CDR3 length analyses and its apparent ligand-recognition properties (see later).

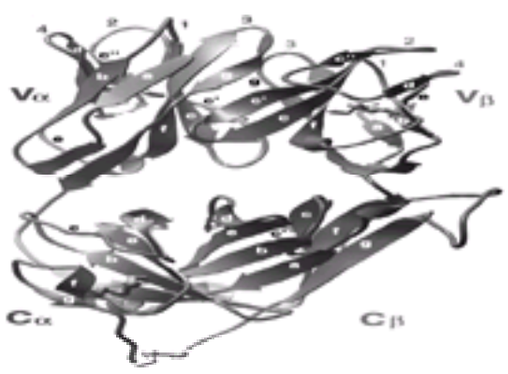

Figure 4.2. T-cell receptor (TCR) structure. Ribbon diagram of the structure of an ab TCR heterodimer (extracellular portion). b Strands are indicated in *letters*, and complementarity-determining region (CDR) loops in *numbers*. The *yellow spheres* depict disulfide bonds within the V and C domains and joining the a and b chains. (From Garcia KC, Decagon M, Stanfield RL, et al. An ab T-cell receptor at 2.5Å and its orientation in the TCR-MHC complex. *Science* 1996;274:209–219, with permission). (See Color Figure 4.2.)

With respect to complete heterodimer structures, there are now data from five ab heterodimers (39,41,42,43 and 44), and they largely resemble an Fab fragment of an antibody. Whereas many features of these structures are shared with their antibody counterparts, several unusual features are emerging that may be significant. These include

1. In one structure (39), four of seven *N*-linked sugars diffracted to high resolution, indicating that they are not free to move very much and thus are likely to play a structural role, particularly in C_a/C_b interactions.
2. There is much more contact between V_b and somewhat more between V_a and C_a than in the equivalent regions of antibodies.
3. The geometry of the interaction of V_a and V_b more closely resembles that of the C_H3 domains of antibodies than .... V_HV_L.
4. Between the CDR3 loops of V_a and V_b, there is a pocket that can [and does in at least one case (41)] accommodate a large side chain from the peptide bound to an MHC.

Another key question is whether any conformational change occurs in the TCR on ligand binding. Conformational changes in the TCR or in the CD3 polypeptides in particular may hold important clues as to the mechanism of signal transduction across the membrane after TCR engagement. Recent studies also have indicated that TCR/peptide/MHC complexes have an inherent ability to self-associate (46), and thus it would be very interesting to know the structure of such a cluster and how it may relate to early signaling events.

Also associated with both ab and gd TCR heterodimers are the CD3 polypeptides, which are not covalently linked but coprecipitate with TCRs under certain conditions (as reviewed in 5,47). These are CD3g, -d, -e, and -z. The z chain is usually disulfide-bond homodimer; but certain other forms are also found, such as z-h or z-FceRI (5).

With respect to overall stoichiometry, current evidence favors at least two TCR heterodimers per CD3 cluster. This is based on a number of findings, particularly the work of Terhorst et al. (as reviewed in ref. 5) and more recently that of Fernandez-Miguel et al. (45), who showed that in T cells that have two transgenic TCRb chains, antibodies to one V_b can immunoprecipitate the other. It also was found that they are often close enough to allow fluorescence energy transfer, meaning that the two TCRb chains in a cluster are within 50 Å of each other (45).

T-CELL RECEPTOR GENES

As shown in Fig. 4.3, *TCR* gene segment organization is similar to that of immunoglobulins, and the same recombination machinery seems responsible for joining separate *V* and *D* segments to a particular *J* and *C*. This was initially indicated by the fact that the characteristic seven- and nine-nucleotide conserved sequences adjacent to the V, D, and J regions with the 12- or 23-nucleotide spacing between them, first described for immunoglobulin genes, also are present in *TCR*s (48,49). The most conclusive evidence of this common rearrangement mechanism has been shown recently by the fact that both a naturally occurring recombination-deficient mouse strain [severe combined immune deficiency, SCID (50)] and mice engineered to lack recombinase activating genes (RAGs) 1 (51) or 2 (52) are unable to rearrange either *TCR* or immunoglobulin gene segments properly. As with immunoglobulins, if the V-region and J-region gene segments are in the same transcriptional orientation, the intervening DNA is deleted during recombination. DNA circles of such material can be observed in the thymus (53,54), the principal site of TCR recombination (see later). In the case of *TCR*b (55) and *TCR*d (56), there is a single V region 3' to the C in the opposite transcriptional orientation to J and C. Thus rearrangement to these gene segments occurs through an inversion. Variable points of joining are seen along the *V, D,* and *J* gene segments as well as random nucleotide addition (N regions) in postnatal TCRs (57). The addition of several nucleotides in an inverted repeat pattern, referred to a P element insertion, at the V/J junction of the TCRg chains, also has been observed (58).

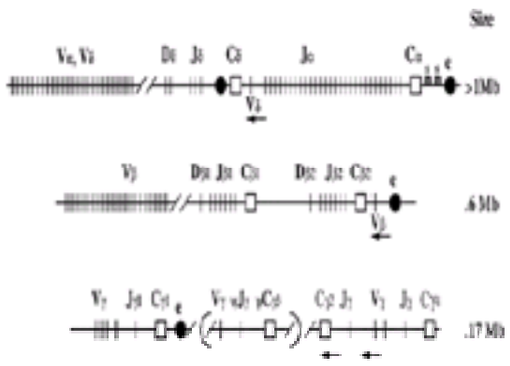

Figure 4.3. T-cell receptor (TCR) genes. Outline of murine TCR loci.

Organization of the T-cell Receptor Loci

In humans and in mice, there is a single a-chain C-region gene composed of four exons encoding (a) the constant region domain, (b) 16 amino acids including the cysteine that forms the interchain disulfide bond, (c) the transmembrane and intracytoplasmic domains, and (d) the 3' untranslated region (Fig. 4.3) (59,60 and 61). The entire ad locus in humans has now been mapped (62) and spans about 1.1 MB. The mouse TCR locus appears to be similar in size. There are 50 different J-region gene segments upstream of the C region (Fig. 4.3) in the murine locus (63). At least eight of the J-region gene elements are nonfunctional because of in-frame stop codons or rearrangement and splicing signals that are likely to be defective. A similar number of a-chain J regions are present in the human locus (61,62). This very large number of a-chain J regions compared with the immunoglobulin loci may indicate that the functional diversity contributed by the J segment of the TCR (which constitutes a major portion of the CDR3 loop) makes a special contribution to antigen recognition (see later).

Both the murine and human C_d, J_d, and two D_d gene segments are located between the V_a and J_a gene segments (24,64,65,66 and 67). In the murine system, there are two J_d and two D_d gene segments on the 5' side of C_d (24,64), and the C_d gene is approximately 75 kb upstream of the C_d gene, but only approximately 8 kb upstream of the most 5' known J_a gene segments. The human organization is similar, with three D_a gene segments and two J_d (67). Surprisingly, in both species, all of the D elements can be used in one rearranged gene rather than alternating, as is the case with TCRb or IgH. That is, in mice one frequently finds V_d, D_1, D_2, J_d rearrangements (57), and in humans, V_d, D_1, D_2, D_3, and J_d (67). This greatly increases the junctional or CDR3 diversity that is available, especially because of the potential for N-region addition in between each gene segment. This property makes TCRd the most diverse of any of the antigens receptors known, with approximately 10^{12} to 10^{13} different amino acid sequences in a relatively small (10 to 15aa) region (57).

The location of D_d, J_d, and C_d genes between V_a and J_a gene segments raises the possibility that TCRd and a could share the same pool of V-gene segments. Although there is some overlap in V-gene use, in the murine system, four of the commonly used V_d genes (V_d1, V_d2, V_d4, V_d5) are very different from known V_a sequences, and they have not been found to associate with C_a (68). The other four V_d gene families overlap with or are identical to V_a subfamilies (V_d3, V_d6, V_d7, and V_d8 with V_a6, V_a7, V_a4, and V_a11, respectively).

The mechanisms that account for the preferential use of certain gene segments to produce d versus a chain are not known. Whereas some V_d genes are located closer to the D_d and J_d fragments than V_a genes (such as V_d1), other V_d genes (such as V_d6) are rarely deleted by V_a J_a rearrangements and thus seem likely to be located 5' of many V_a gene segments (57).

An implicit characteristic of the a/d gene locus is that a rearrangement of V_a to J_a deletes the entire D/J/C core of the d-chain locus. In many ab T cells, the a-chain locus is rearranged on both chromosomes, and thus no TCRd could be made. In most cases this is due to V_a®J_a rearrangement, but evidence suggesting an intermediate step in the deletion of TCRd has been reported (69). This involves rearrangements of an element termed TEA to a pseudo-J_a 3' of C_d. The rearrangement of TEA to this pseudo J_a would eliminate the d-chain locus in ab T cells. Recent gene targeting of the TEA element resulted in normal levels of ab and gd T cells, but use of the most J_a cells was severely restricted (70), suggesting that its function has more to do with governing the accessibility of the most 5'$_{Ja}$ cells for recombination.

The entire human 685-kb b-chain gene locus has been completely sequenced (71), and the organization is shown in Fig. 4.3. One interesting feature is the tandem nature of J_b-C_b in the *TCR*$_b$ locus (). This arrangement is preserved in all higher vertebrate species that have been characterized (mouse, human, chicken, frog). The two C_b coding sequences are identical in the mouse and nearly so in humans and other species. Thus it is unlikely that they represent two functionally distinct forms of C_b. However, the J_b clusters have unique sequences and thus this may be a mechanism for increasing the number of J_b gene segments. Together with the large number of J_a gene segments, there is far more combinatorial diversity ($J_a \times J_b = 50 \times 12 = 600$) provided by J regions in ab TCRs than in immunoglobulins.

Most of the V regions are located upstream of the joining and constant regions, and in the same transcriptional orientation as the D and J gene element and rearrange to D_bJ_b gene by deletion. Similar to the case of V_d5, a single V_b gene, V_b14, is located 3' to C regions and in the opposite transcriptional orientation; thus rearrangements involving V_b14 occur through inversion (55).

The organization of the mouse and human g-chain loci have been thoroughly defined (72,73,74,75,76,77 and 78). The human g genes span about 150 kb (77) and are organized in a fashion similar to that of the b-chain locus with two J_gC_g regions. An array of V_g regions in which at least six of the V regions are pseudogenes (filled in), are located 5' to these J_gC_g clusters, and each of the V genes is potentially capable of rearranging to any of the five J regions. The sequences of the two human C_g regions are very similar overall and differ significantly in only the second exon. In C_g2 this exon is duplicated 2 to 3 times, and the cysteine that forms in the interchain disulfide bond is absent. Thus C_g2-bearing human T cells have an extra large g chain (55,000 MW) that is not disulfide bonded to its d-chain partner (74).

The organization of the murine g-chain genes (Fig. 4.3) is very different from that of the human genes, in that there are three separate rearranging loci (73,74) and spans about 205 kb (78). Of four murine C_g genes, C_g3 is apparently a pseudogene in BALB/c mice, and the J_g3 C_g3 region is deleted in several mouse strains including C57 Bl/10. C_g1 and C_g2 are very similar in coding sequences. The major difference between these two genes is in the five-amino acid deletion in the C_g2 gene, which is located in the C II exon at the amino acid terminal of the cysteine residue used for the disulfide formation with the d chain. The C_g4 gene differs significantly in sequences from the other C_g genes (in 66% overall amino acid identity). In addition, the C_g4 sequences contains a 17-amino acid insertion (compared with C_g1) in the C II exon located at similar position to the five-amino acid deletion of the C_g2 gene (G. Kershard, S.M. Hedrick, unpublished results).

Each of the C_g genes is associated with a single J_g gene segment. The sequences of J_g1 and J_g2 are identical at the amino acid level, whereas J_g4 differs from J_g1 and J_g2 at nine of 19 amino acid residues.

Chromosomal Locations of T-cell Receptor Genes and Translocations Associated with Disease

The chromosomal locations of the different *TCR* loci have been delineated in both mouse and humans, and the results are summarized in Table 4.1 (as reviewed in ref. 79). One significant factor in cancers of hematopoietic cells is chromosomal translocations, which result in the activation of genes that are normally turned off or the inactivation of genes that are normally turned on. Thus B- or T-lymphocyte neoplasia is frequently associated with inter- or intrachromosomal rearrangements of Ig or TCR loci, and in some cases, both (80,81).

	Mouse Chromosome	Human Chromosome
TCR-α	14	14(q11-q12
TCR-δ	14	14(q11-q12
IgH	12	14(qter)
TCR-β	6	7(q35)
CD4	6	12
CD8	6	2(p11)
Thx	6	2(p12)
TCR-γ	13	7(p14)
CD3-γ	9	11(q23)
CD3-δ	9	11(q23)
CD3-ε	9	11(q23)
CD3-ζ	1	1
Thy-1	9	11(q23)
Igλ	16	22(q11.2)
MHC	17	6(p21)
Pre-T-α	17	6

TCR, T-cell receptor; Ig, immunoglobulin; MHC, major histocompatibility complex.

TABLE 4.1. Locations of Receptors

These translocations seemed to mediated by the V(D)J recombinase machinery, indicating the inherent danger and need for tight regulation of this pathway. Such rearrangements are particularly common in the a/d locus, perhaps because this locus spans the longest developmental window in terms of gene expression, with *TCR*d being the first and *TCR*a the last gene to rearrange during T-cell ontogeny (as discussed in more detail later). In addition, the a/d locus is in excess of 1 Mb in size, and this provides a larger target, for rearrangement than does either TCRb or TCRg. Interestingly, in humans, *TCR*a/d is on the same chromosome as the *IgH* locus, and V_H®J_a rearrangements (by inversion) have been observed in some human tumor material (82,83). The functional significance of this is not known.

Particularly frequent is the chromosome 8–14 translocation [t(8;14) (q24;q11)], which joins the a/d locus to the c-*myc* gene, analogous to the C-*myc*®IgH translocation in many mouse myeloma tumors and in Burkitt lymphomas in humans (80,81). In one cell line, a rearrangement occurs between the J_a-region coding sequences, and a region 3' of c-*myc* (84). In both B- and T-cell malignancies, the translocation of c-*myc* into IgH or TCRa/b appears to increase the expression of c-*myc*, and may be a major factor in the unregulated cell growth that characterizes cancerous cells. Other putative protooncogenes that have been found translocated into the TCRa/b locus are the LIM domain containing transcription factors Ttg-1 (85), and Ttg-2 (86,87), which are involved in neural development; the helix/loop/helix proteins Lyl-1 (88,89) and Scl (90,91), which are involved in early hematopoietic development; and the homeobox gene Hox 11 (92), which is normally active in the liver. How these particular translocations contribute to malignancy is unknown, but it presumably causes aberrations in gene expression that contribute to cell growth or escape from normal regulation. In T-cell leukemia patients infected with the human T-cell lymphoma virus (HTLV)-I, there are large numbers of similar translocations, and here it is thought that HTLV-I itself is not directly leukemogenic, but acts by causing aberrant rearrangements in the T cell it infects, some of which become malignant.

Another disorder that exhibits frequent TCR and Ig locus translocations is ataxia telangiectasia (AT), an autosomal recessive disorder characterized by ataxia, vascular telangiectasis, immunodeficiency, increased incidence of neoplasia, and an increased sensitivity to ionizing radiation. Peripheral blood lymphocytes (PBL) cells from patients with AT have an especially high frequency of translocations involving chromosomes 7 and 14 (93). These sites correspond to the TCRg, -b, and -a loci, and the Ig heavy-chain locus (94,95). Thus it appears as though one of the characteristics of AT patients is a relatively error-prone rearrangement process that indiscriminately recombines genes that have the TCR and Ig rearrangement signals.

BIOCHEMISTRY OF ab T-CELL RECEPTOR/LIGAND INTERACTIONS

Although it has long been established that T cells recognize a peptide in association with an MHC molecule, it was many years before a formal biochemical demonstration was possible that this was due to TCR binding to a peptide/MHC complex. Part of the difficulty in obtaining measurements of this type has been the intrinsically membrane-bound nature of MHC and TCR molecules. Another major problem is that the affinities are relatively low, with K_d values of 10^{-4} to 10^{-7} *M*, too unstable to measure by conventional means.

Ultimately these technical problems were resolved, and the first measurements of TCR affinities for peptide/MHC complexes were made by Matsui et al. (95) and Weber et al. (96). They obtained K_d values of ~50 μ*M* and ~10 μ*M*, respectively. Subsequent work, particularly using surface plasmon resonance instruments with their remarkable sensitivity to weak macromolecular interactions (97,98,99,100,101,102,103 and 104), has allowed rapid progress in this area and extended the range of affinities observed to 300- 0.1 μ*M*. This has thus far been the method of choice for measuring the kinetics of TCR binding to its ligands [excepting the very highest affinity TCRs (105)]. Kinetic measurements show that while the on-rates of TCR binding to peptide/MHC molecules vary from very slow (1,000 msec) to moderately fast (200,000 msec), their off-rates fall in a relatively narrow range (0.5 to 0.01 per second) or a t½ of 12 to 30 seconds at 25°C, similar to other membrane-bound receptors that recognize membrane molecules on other cells (106,107). In the case of the class I MHC–restricted TCR, 2C, this relatively fast off-rate is significantly stabilized if soluble CD8 is introduced (108). This same effect of CD8 stabilization had previously been seen by Luescher et al. (109) in their unique cell-based TCR-labeling assay. Similar BIAcore experiments using soluble CD4 have not produced comparable results (J. Hampl, J. Boniface, unpublished data) Whereas all of the BIAcore measurements cited earlier were performed at 25°C because of instrument limitations, the off-rates are generally much faster (from 10 to 20 times) at 37°C (110,111).

Altered Peptide Ligands

To what extent are we now able to predict a T-cell response based on the binding characteristic of its TCR to a ligand? One of the most intriguing discoveries concerning T-cell reactivity in recent years has been the phenomenon of altered peptide ligands. These are single amino acid variants of antigenic peptides that either change the nature or degree of the T-cell response (partial agonists) or prevent a response to a normally stimulating ligand (antagonists) (112,113). Discussions concerning the mechanism of these “altered peptide” responses have centered around whether they are due to some conformational phenomenon involving TCRs and/or CD3 molecules or to affinity or kinetic characteristics. With the data in hand, we can now say that most, but not all (see especially ref. 104), T-cell responses correlate very well with the binding characteristics of their TCRs (as reviewed in ref. 114).

How might the relatively small differences in the binding characteristics of the ligands cause such different T-cell signaling outcomes as agonism or antagonism? As McKeithan (115) and Rabinowitz et al. (116) noted, any multistep system such as T-cell recognition has an inherent ability to amplify small differences in signals that are received on the cell surface to much larger differences at the end of the pathway, in this case gene transcription in the nucleus. Thus antagonism may occur at one threshold and an agonist response at another. Alternatively, an antagonist ligand may traverse the activation pathway just far enough to use up some critical substrate, as proposed by Lyons et al. (102). Yet another possibility also suggested is that some antagonists may act even earlier, by blocking TCR clustering at the cell surface (46).

Role of CD4 and CD8

What is the role of CD4 and CD8 with respect to the T-cell response to agonist and antagonist peptides? In the case of a T-helper cell response, the presence of CD4 greatly augments the amount of cytokine produced and, in some cases, determines whether there is a response at all (as reviewed in ref. 117). Much of the effect of CD4 seems to come from the recruitment of lck to the TCR/CD3 complexes. In addition there is a significant positive effect even with CD4 molecules that are unable to bind lck, and thus there appears to be an affect on TCR/ligand interaction as well. CD8 also greatly augments the response of class I MHC–specific T cells (113), and, as discussed earlier, CD8 stabilizes TCR/peptide/MHC complexes. Overall it seems likely that each of these coreceptor molecules has two roles: to stabilize TCR/ligand interactions physically and to aid in signaling by recruiting lck. Data show, consistent with this, that the presence of CD4 can convert an antagonist peptide into a weak agonist (118,119). Work by Hampl et al. (120) puts a new twist on this by showing that whereas weak agonist peptides are made almost as potent as the best peptides by the presence of CD4, little or no effect is seen on antagonism.

These results suggest that CD4 engagement is not automatic and simultaneous with TCR binding, but rather is recruited later into preexisting TCR/peptide/MHC complexes (or oligomers), as suggested by Germain (121,122). In some cases, antagonist/MHC complexes will be stable long enough for CD4 to have an effect, in which case, the T cell could be stimulated, but in the antagonism experiments of Hampl et al. (120), the TCR/ligand association does not last long enough for CD4 to affect the outcome. It also is interesting that subsequent studies of Krummel et al. (123) showed that whereas CD3 and CD4 colocalize at the initiation of T-cell recognition, in most cases, CD4 migrates away soon after the first calcium elevation (e.g., after the initiation of signaling, but long before the T cell is fully committed to action). Thus CD4 seems to play a very transient role in the recognition process.

TOPOLOGY AND CELL BIOLOGY OF T-CELL RECEPTOR/PEPTIDE/MHC INTERACTIONS

An analysis of TCR sequence diversity has shown that the vast majority of amino acid variation resides in the region between the V- and J-region gene segments, which corresponds to the CDR3 regions of antibodies (124). This has led to models in which the CDR3 loops of V_a and V_b make the principal contacts with the

antigenic peptide bound to the MHC (38,124,125). Support for such a model has come from many studies in which it has been shown that the CDR3 sequences of TCRs are important predictors of specificity (as reviewed in ref. 124), as well as the elegant mutagenesis studies of Hedrick et al. (126,127), who showed that a single CDR3 point mutation could alter the specificity of a TCR (126) and also that a CDR3 “transplant” could confer the specificity of the donor TCR onto the recipient (127). In addition, a new approach to TCR/ligand interactions was developed by Jorgensen et al. (128,129), who made single amino acid changes at positions that affect T-cell recognition but not MHC binding in a given peptide. These variant peptides are then used to immunize mice that express either the a or b chain of a TCR that recognizes the original peptide, and the responding T cells are analyzed. The results from this study and work in another system by Sant'Angelo et al. (130) are very similar, in that every mutation at a TCR-sensitive residue triggered a change in the CD3 sequence of V_a, V_b, or both, and in some cases, changed the V_a or V_b gene segment as well. One of the more striking examples of a CDR3/peptide interaction occurred in the cytochrome *c* system, where a Lys®Glu change in the central TCR determinant on the peptide triggered a Glu®Lys charge reversal in the V_a CDR3 loop, arguing for a direct Lys®Glu contact between the two molecules (129).

Structural Analyses

Most definitive is the work of Garcia et al. (39) and Garboczi et al. (41), who nearly simultaneously solved the crystal structures of two different TCR/peptide/class I MHC complexes. As illustrated in Fig. 4.4, these studies show a TCR binding surface much like an antibody fitting down between the two opposite “high points” of the class I MHC a helices, in a roughly diagonal configuration. In these structures and subsequent ones of the CDR3, loops are centrally located over the peptide, but the V_a CDR1 and the V_b CDR1 are also in a position to contact the N-terminal and C-terminal peptide residues, respectively. Such a contact between V_a CDR1 and an N-terminal residue was seen in the Garboczi structure (41), whereas that of Garcia et al. (39) has insufficient resolution at this point. Although more structures are needed, the results are sufficiently consistent with the results of the peptide-immunization and mutation experiments cited previously to indicate that all TCR/peptide/MHC complexes will have roughly the same topology. An extensive mutagenesis/modeling study also arrived at this same orientation (130a). This oriented recognition constitutes a major departure from antibody/antigen interactions and may derive from the need to intercalate CD4/CD8 molecules during activation. The recent structure of a class I MHC/CD8 complex is a first step in understanding how this might be accomplished (131).

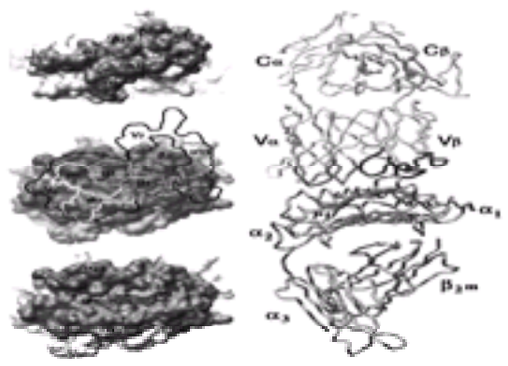

Figure 4.4. T-cell receptor (TCR)/peptide/major histocompatibility complex (MHC). The structure of an ab TCR binding to peptide/MHC. (From Garcia KC, Decagon M, Stanfield RL, et al. An ab T-cell receptor at 2.5Å and its orientation in the TCR-MHC complex. *Science* 1996;274:209–219, with permission.) (See Color Figure 4.4.)

Formation of an “Immunologic Synapse”

Although it has long been known that cross-linking surface immunoglobulin molecules on B lymphocytes or TCR/CD3 molecules on T lymphocytes can trigger activation, it has not been appreciated until recently just how these artificial stimuli relate to the normal process of T-cell activation that begins with TCR engagement of the appropriate ligand. That there is an inherent tendency of TCRs to cluster with peptide/MHC ligands was shown by Reich et al. (46) with pure molecules in solution, and it was soon afterward shown by Kupfer et al. (131a) that the key surface molecules in a T-cell/B-cell couple distributed themselves in a characteristic “bull's-eye” pattern, which they referred to as a supramolecular activation complex, or SMAC, and others have termed an “immunologic synapse.” In these “synapses,” the TCR on the T cell occupies the central region, directly opposite a cluster of the appropriate MHC on the B cell that it is recognizing. The outer ring is composed of leukocyte function–associated antigen (LFA)-1 on the T-cell side and its ligand intercellular adhesion molecule (ICAM)-1 on the B-cell side. Various other surface and signaling molecules distribute themselves into these two areas or segregate into other patterns (A. Kupfer, personal communication). The dynamics of synapse formation have now been directly visualized by using the T cell/artificial membrane systems of Dustin et al. (134) or the green fluorescent protein (GFP)-tagged CD3 system of Krummel et al. (123) involving T-cell/B-cell couples. Figure 4.5 shows a time course of synapse formation from Grakoui et al. (133). This shows a “bulls-eye”-type pattern in which the MHC is gathered into the center, whereas the ICAM-1 (an accessory molecule) tends to be on the outside. Parallel studies on T cells have shown that there is a parallel accumulation of TCR and LFA-1 (the ligand for ICAM-1) at the interface. Another important contributor to synapse formation appears to be costimulatory signals, which, as shown by Wülfing et al. (135) and Viola et al. (136), trigger a membrane cytoskeletal movement towards the T/B interface. This movement may involve membrane rafts (136) and appears dependent on myosin motors (135). It is triggered only by a combination of TCR and costimulates receptor engagement (either CD28 or LFA-1), and it is likely that the resulting movement of cytoskeletally attached membrane molecules, such as TCR/CD3, drive the formation of synapses (C. Wülfing et al., unpublished data). Although the formation of this type of structure is not absolutely necessary for some T-cell stimulation to occur *in vitro*, it may be *in vivo*, especially as antigen stimulation without costimulation generally produces no response or an aborted one in an organism. As to why the different surface molecules segregate into different regions of the synapse, this is not known, but it may enhance signaling reactions or may just reflect the different sizes of the various receptors and their ligands (137,138).

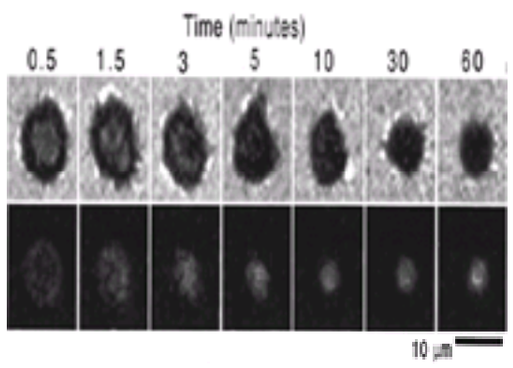

Figure 4.5. Formation of an immunologic synapse. An antigen-specific T cell **(A)** contacts an artificial lipid bilayer containing labeled major histocompatibility complex (MHC; *green*) and intercellular adhesion molecule (ICAM-1; *red*). Within minutes, it has recognized the antigen contained within the MHC and gathered the MHC and ICAM-1 into the distinctive “bulls-eye” pattern. (From Grakoui A, Bromley SK, Sumen C, et al. The immunological synapse: a molecular machine controlling T-cell activation. *Science* 1999;285:221–227, with permission.) (See Color Figure 4.5.)

ab T-CELL RECEPTOR AND SUPERANTIGENS

One of the most interesting and unexpected areas to emerge from the study of ab T-cell reactivities is the discovery of the “superantigen.” Whereas a particular antigenic peptide might be recognized by only one in 100,000 or fewer T cells in a naive organism, a given superantigen might stimulate 1% to 20% of the T cells (as reviewed in ref. 139,140 and 141). As is discussed in more detail later, the physical basis for this is that the superantigen binds to a V_b domain of the TCR on T cells while simultaneously binding to an MHC class II molecule on an antigen-presenting cell (although not in the peptide-binding groove). This allows a single superantigen, such as SEA, to stimulate virtually every murine T cell bearing V_b1, -3, -10, -11, -12, or -17 (~15% of all ab T cells), regardless of what V_a it is paired with or what CDR3 sequence is expressed. Clearly this is a unique class of T-cell stimulatory molecule.

Widespread Use by Pathogens

The first indication of a superantigen effect was the discovery of Kappler et al. (142) of a mouse strain–specific deletion of T cells expressing a specific V_b. This showed

that the effect was due to certain alleles of the minor histocompatibility loci known as mls, which had the abilities to stimulate specific V_b-bearing T cells and caused the elimination of those T cells in mouse strains that carried that particular allele (143,144,145,146 and 147). Intensive efforts to clone these loci revealed that they were endogenous retroviruses of the mouse mammary tumor virus family (148,149,150,151 and 152), and various family members bind different V_b domains. Meanwhile, Janeway et al. (153) showed that *Staphylococcus* enterotoxins could polyclonally activate naive T cells in a V_b-specific manner without a requirement for antigen processing. Unlike the MMTV proteins, which are type II membrane proteins, the enterotoxins are secreted. Subsequently, proteins having superantigenic properties have been isolated from other bacteria [*Yersinia pseudotuberculosis* (154,155), *Streptococcus* (156), and *Mycoplasma* (157,158)]. There also is evidence of superantigen-like activities in other mammalian viruses such as rabies (157), Epstein-Barr virus (160), cytomegalovirus (161), and also in the parasite *Plasmodium falciparum* (malaria) (162) and *Toxoplasma gondii* (163), but the actual molecules have not yet been identified. Because so many pathogenic or parasitic organisms possess these molecules, apparently by convergent evolution, there must be some selective advantage, but in most cases, there is no conclusive evidence as to what this might be. The one exception is the MMTV superantigens, in which it has been shown that polyclonal T-cell stimulation allows the virus to infect much more efficiently the B lymphocytes that are activated by the T cells (164,165). This may be a special case, however, and most authors have suggested that superantigens primarily serve to confuse and occupy the immune system while the pathogen escapes specific targeting and elimination. Large doses of superantigens also have been implicated in various “shock” syndromes, such as food poisoning or “toxic shock” (139), but this is probably not their everyday purpose, as it would violate the general rule that the host and parasite should coexist.

It also has been suggested that superantigens might be involved in triggering autoimmune diseases. Here the hypothesis is that a large number of some V_b-bearing T cells are activated by a pathogenic superantigen, and that subsequently, self-reactive T cells within those activated cells are stimulated by a particular tissue antigen. Although a superantigen-like predominance of particular V_b-bearing cells has been reported in rheumatoid arthritis (166,167) and Kawasaki disease (168), other investigators have not been able to confirm these reports.

The biochemistry of superantigen binding to TCRs and MHC is similar to that of TCR/peptide/MHC interactions (99,169), but the topology is quite different. In particular, it has been found that Mls-1a presentation to T cells is most affected by mutations on the “outside” surface of the V_b domain (amino acids 22, 70, 71), which do not affect peptide/MHC recognition (70,171). In contrast, CDR grafting experiments by Patten et al. (172) have implicated CDR1 and CDR2 of V_b3 in bacterial superantigen reactivity. Similarly, other investigators have found differences in the way different superantigens bind to TCRs, but none has found any involvement of CDR3 sequences.

Recently, the x-ray crystal structures of the superantigens SEC2 and SEC3 complexed with a mouse TCRb chain have been reported (173). Similar to the Patten et al. data (172), these bacterial superantigens bind to CDR1 and CDR2 and somewhat to the outside of the V_b domain. When modeled on the superantigen/MHC structures, the resulting TCR/SAg/MHC complex would displace the TCR somewhat (but not entirely) away from the MHC binding groove (173), thus making the interaction largely insensitive to the TCR/peptide specificity, as suggested by Jorgensen et al. (129). Because this is only the first report of the structure of TCR/SAg complex, it is entirely possible that other molecules will interact differently. Indeed, as the mls antigens are structurally very different from the bacterial SAgs and in their mode of MHC binding. Therefore, their mode of binding to V_b domains is likely to be unique as well.

Why do superantigens only interact with the b chain? One possibility is that the b chain offers the only accessible “face” of the TCR, perhaps because CD4 blocks the V_a side (as suggested by antibody-blocking studies). A second more exotic possibility is that superantigens have usurped a physiologically important mechanism for T-cell activation that is used only rarely. For example, immature thymocytes express only low levels of the TCR and yet are remarkably sensitive to antigen. Perhaps there exists a cellular protein that links the TCRb chain with an MHC molecule as an adjunct to normal binding and recognition (174).

gd T CELLS

Characteristics of gd T Cells

Although ab T cells were originally defined on the basis of functional characteristics, such as providing T-cell “help” or initiating cytotoxicity, gd TCR-bearing cells were not discovered through any biologic assay, but instead first came to light through the accidental discovery of a TCRg cDNA clone. This led to the development of an antiserum with which Brenner et al. (32) discovered a unique subset of T cells, composing 5% to 10% of peripheral T cells in humans and mice. It has been 14 years since this discovery, and we are still trying to understand what these cells recognize and how they function within the immune system. There has been substantial progress, but these questions are still largely unresolved. We review here some of the salient characteristics of these enigmatic cells.

gd T cells are the first to appear in the fetal thymus, fully 2 days before ab T cells in the mouse, but in later weeks, ab T cells quickly predominate. In both mouse and human adults, gd T cells represent only a small fraction of thymocytes (175) and lymphocytes in all of the secondary lymphoid organs. However, they are found in larger numbers in the mucous membranes of a variety of tissues such as the skin (176), small intestine (177), female reproductive tract (178), and lung (179).

One population of gd T cells that has been studied intensively are the $CD4^-CD8^-$ gd T lymphocytes, which have a dendritic morphology and are embedded in the epidermis of the skin (176,180). These cells have been termed dendritic epidermal cells or DECs. Curiously, 90% of these cells express a TCR with identical Vg and Vd sequences (180).

As to what these DEC cells “see,” recent experiments have shown that they can respond to mouse keratinocytes or to an extract of keratinocytes added directly to the DECs (182). The nature of the determinant recognized is unknown, but it is significant that it is a self-protein, albeit one that is made only by “stressed” cells, supporting the proposal that this type of gd cells may serve as a kind of sentinel (184). The gd T cells found in the female reproductive epithelia and tongues of mice preferentially express V_g4 and V_d1 (178). In the BALB/c strain of mice, most of the TCRd sequences are the same (183), but others are diverse, and this phenomenon has not been seen in other strains.

Another population of gd T cells that has been studied extensively is resident in the epithelium of the small intestine (177). The gut intraepithelial lymphocytes (IELs) consist of a population of ab T cells and a population of gd T cells. They are phenotypically $CD4^-CD8^-$ or $CD4^-CD8^+$. Unlike $CD8^+$ab T cells, the CD8 molecules on gd IELs express the CD8a chain and no CD8b (184). IELgd TCRs use different V_g and V_d chains, and the CDR3 regions of both the g and d chains show significant diversity in both length and sequence, suggesting that they can “see” a wide variety of ligands.

Earlier studies showed that gd T cells can secrete a variety of lymphokines and mount cytolytic responses, and therefore have the potential to function as ab T cells. Their preferential localization in the epithelium also suggested that they may be responsible for a “first line of defense” (reviewed in 184). This hypothesis is supported by the increase of gd T lymphocytes seen early in infections by some bacteria and a virulent Sendai virus strain, before ab T-cell responses are observed (185,186). However, in other infection models, gd T cells accumulate within the inflammatory lesions late in the infection after the virus has been cleared (reviewed in 187), suggesting that they may be responding to cells that are damaged and/or stressed by the infection. Consistent with this is the demonstration that some gd T cells can kill virus-infected cells *in vitro* but that the recognition is not virus specific (188).

More recently, mice deficient in ab or gd T cells have been used to dissect the roles of these cells in the immune defense against intracellular pathogens (bacteria, protozoa, and viruses) (189,190,191 and 192). These T-cell deficiencies were induced either by the administration of an mAb against ab or gd T lymphocytes or by disruption of a TCR gene through homologous recombination. It was found the role(s) that gd T cells play is dependent on the types of infection. In models such as bacille Calmette-Guérin (BCG) and *Salmonella* infections, ab but not gd T cells are essential in controlling the infection. In other cases such as *Mycobacterium tuberculosis* and *Listeria monocytogenes*, gd T cells are able to compensate for the absence of ab T cells. Interestingly, in *Listeria* and *Vermiformis* infections, a lack of gd T cells does not change the pathogen load but instead results in a different pathology in the infected tissue (189,190,191 and 192). This has led to the suggestion that gd T cells may somehow regulate immune and nonimmune cells to maintain host tissue integrity (193). This possibility is supported by data showing that certain gd T cells can produce keratinocyte growth factor and chemokines (182), as well as regulate the development of epithelial cells (194) and influence ab T-cell responses (195,196,197 and 198). It also is compatible with the analysis of gd T-cell recognition requirements, in that these cells can mediate cellular immune functions without a requirement for antigen-processing and specialized antigen-presenting cells (reviewed in ref. 6). Therefore they have the capacity to initiate immune responses by recognizing other lymphoid cells or damaged cell/tissues directly. Whereas all these experiments point to a unique role for gd T cells in the immune system, gd T-cell specificity and their exact effector functions in any pathologic situation remains undefined. It is interesting to note that the function of gd T cells has been studied mainly in mouse and humans, yet they are significantly more abundant in birds and artiodactyls (175). This may be because they encompass other functions in these organisms or that species of this type have a greater need for gd T cells.

Antigen Recognition by gd T Cells Does Not Require Antigen Processing

During the past few years, a number of studies have shown that gd T cells have profound differences in their antigen-recognition requirements compared with ab T cells. Some gd T cells also seem to recognize entirely different types of antigens. More specifically, these experiments show that the many gd T cells do not recognize processed and presented proteins but rather intact ones, and that in some cases, they can recognize nonprotein entities (as reviewed in ref. 6). Examples of intact

protein recognition include the mouse class II MHC molecules IE^k by the T-cell clone LBK5 (199); the recognition of the mouse nonclassic MHC class I molecules T10 and T22 by the T cell clone G8 (204,205); and the recognition of a herpes simplex virus glycoprotein, gI, by the T-cell clone TgI4.4 (201). It is noteworthy that only the last of these is a foreign antigen. It also may be significant that epitope mapping with mutant IE molecules shows that amino acid residues in the a helices of the IEa and IEb chains that affect ab T-cell recognition do not affect gd stimulation (199).

Interestingly, T10 and the closely related T22 molecule (94% identity) were identified as the ligand of another gd KN6 (202,203). Whereas G8 was generated by immunizing BALB/c nude mice with B10.BR spleen cells, KN6 was derived from a double-negative C57BL/6 thymocyte. Thus these nonclassic class I molecules can be considered to be “natural” ligands for gd T cells. Neither is capable of binding peptides, as indicated by early biochemical studies (205) and most definitively by x-ray crystallographic analysis (206). It also was found recently that T10/T22 is inducibly expressed on activated lymphocytes (204), suggesting that gd T cells specific for it may serve autoregulatory or even suppressive functions (204).

gd T Cells Also Can Be Stimulated by Nonpeptide Antigens

gd T cells from healthy human peripheral blood and from patients with tuberculoid leprosy or rheumatoid arthritis were found to respond to heat-killed *Mycobacteria*. The major T-cell stimulatory components in the former are not the mycobacterial heat shock proteins, but instead have been identified to be phosphate-containing, nonpeptide molecules (207,208,209 and 210). Although the consensus is that “phosphate” is a necessary component, compounds identified from various laboratories with different mycobacteria-responsive clones appear to be distinctive in their structures (211). The nonphosphate moieties include unusual carbohydrate and phosphate moieties; a 5'-triphosphorylated thymidine or uridine substituted at its g-phosphate by an as yet to be characterized low-molecular-weight structure; isopentenyl pyrophosphate and related prenyl pyrophosphate derivatives, synthetic alkenyl and prenyl derivatives of phosphate, pyrophosphate as well as g-monoethyl derivatives of nucleoside, and deoxynucleoside triphosphates (210). Although the relative biologic importance of these compounds remains to be determined, it is clear that a major class of stimulants are phosphate-containing nonpeptides. It also is clear that multiple phosphate-containing compounds are able to stimulate different clones with different efficacies.

An important finding is that all of these compounds can be found in both microbial and mammalian cells. Constant et al. (208) proposed that the mammalian TTP-X and UTP-X conjugate may be involved in a “salvage pathway” in DNA and RNA synthesis, and thus could be involved in a metabolic pathway related to DNA or RNA synthesis, such as cell proliferation. Such a molecule would fit with the stress antigen or “conserved primitive stimulus” expected for gd T-cell ligands (184,211). Tanaka et al. (210) proposed that a link in the recognition of both microbial pathogens and hematopoietic tumor cells by these gd T cells is provided by the common set of prenyl pyrophosphate intermediates, isopentenyl and related prenyl pyrophosphate derivatives. These compounds are present in normal mammalian cells as precursors in lipid metabolism for the synthesis of farnesyl pyrophosphate. In mammalian cells, farnesyl addition has been proposed to be a critical modification for the membrane association of the ras protein and is required for its transforming activity. gd T-cells with this specificity accumulate in lesions caused by mycobacterial infections in humans (212,213) and are able to respond to virally and bacterially infected cells. Together with the data cited previously, the original sentinel hypothesis of Allison and Havren (211) may well be generalizable to all or most of the T cells carrying this receptor, and thus it may have a unique function with respect to recognizing gd cells response to a class of antigens shared by a number of pathogens and transformed, damaged, or stressed cells.

5 T-CELL BIOLOGY AND THE THYMUS

Jonathan Sprent, M.D., Ph.D., and Charles D. Surh, Ph.D.

Like B cells, T cells are mobile cells that patrol the body in a highly disciplined fashion. In the absence of exogenous antigen, naive T cells remain in interphase and percolate through defined regions of the lymphoid tissues. They move constantly from blood to the spleen and lymph nodes and then back to blood through the lymphatic vessels. In the presence of exogenous antigen, however, antigen-reactive T cells cease their blood to lymph recirculation and become temporarily trapped in the lymphoid tissues, where they undergo extensive proliferation and differentiation into activated effector cells. These cells then move back into the circulation and disseminate throughout the body and mediate their various effector functions to eliminate the antigen. Most newly generated effector cells die rapidly, but a few of the responding cells survive to become long-lived memory cells.

This chapter provides a brief overview of the normal patterns of T-cell migration and the changes in migration that occur when T cells encounter antigen and differentiate into effector and memory cells. The decisive influence of the major histocompatibility complex (MHC) in controlling T-cell specificity and function is discussed, followed by a description of how the T-cell repertoire is selected in the thymus during early ontogeny.

SUBSETS OF T CELLS

T cells can be divided into subsets based on the expression of surface markers and antigen-specific receptors.

Lineages of T Cells

Typical T cells express antigen-specific heterodimers composed of a and b chains, each chain containing variable (V) and constant (C) regions (1,2,3,4 and 5). In the extrathymic environment, these ab T-cell receptors (TCRs) are found on two broad subsets of T cells distinguished by their mutually exclusive expression of CD4 and CD8 molecules (6,7 and 8). $CD4^+8^-$ (CD4) T cells generally outnumber $CD4^-8^+$ (CD8) cells by 2:1. In most species, ab TCR-bearing CD4 and CD8 T cells comprise more than 90% of the T cells found in the lymphoid tissues and in blood and lymph. The specificity of typical ab T cells is not directed to native antigens but to peptides bound to cell-associated MHC molecules (4,5). As discussed later, CD8 T cells recognize peptides bound to MHC class I (MHC I) molecules, whereas CD4 T cells bind peptide-MHC II complexes.

A few ab T cells show features of natural killer (NK) cells (9). These NK T cells have highly restricted TCR specificity and preferentially recognize lipids and glycolipids bound to MHC I–like CD1 molecules (10,11). Another small subset of T cells expresses gd TCR heterodimers (12,13); gd T cells tend to accumulate in nonlymphoid tissues and are mostly $CD4^-8^-$. Whereas ab T cells recognize “processed” antigens, the specificity of gd TCR molecules resembles that of immunoglobulin G (Ig) and is directed to a spectrum of native antigens. The biologic functions of ab NK T cells and gd T cells are still unclear and are not covered in this chapter.

Naive and Memory T Cells

Most ab T cells are small resting cells (8,14,15). These cells can remain in interphase for prolonged periods and do not require constant replenishment from the thymus. Typical naive resting T cells characteristically express high-molecular-weight isoforms of the CD45 molecule (e.g., CD45RA) (16,17,18 and 19). Resting T cells also express high levels of the lymph node homing receptor, CD62L (see later); certain other surface molecules, such as CD44, are expressed at low levels (14,15). Activated T cells have a different phenotype. These cells show diminished expression of high-molecular-weight CD45 molecules and instead express a low-molecular-weight isoform termed CD45RO. Activated T cells downregulate expression of CD62L but upregulate CD44 expression. Activated T cells also show upregulation of other markers. Many of the markers on activated T cells are also expressed on memory T cells, that is, the cells controlling responses to recall antigens (16,19,20). As implied by their phenotype, memory T cells appear to remain in a state of chronic or partial activation and undergo a much faster turnover than typical naive T cells (15,21). However, some memory cells eventually revert to resting cells and reacquire some of the phenotypic characteristics of naive T cells.

Although naive T cells rarely divide, survival of these cells requires continuous TCR contact with self-MHC–peptide complexes (8,22). TCR signaling is less important for the survival of memory T cells (23,24 and 25). For these cells, their persistence and rapid turnover may be controlled largely by cytokines.

Other Subsets of T Cells

Some T cells are known to suppress the functions of other T cells, and there are many claims that “suppressor” T cells represent a separate lineage (26,27). Unequivocal evidence on this issue is lacking, however, and the current tendency is to explain T-cell suppression in terms of the activity of cytotoxic lymphocytes or the release of inhibitory lymphokines. With regard to lymphokines, accumulating evidence indicates that ab T cells display considerable heterogeneity in terms of their patterns of lymphokine release (28,29). As discussed later, the conditions of T-cell priming can have a decisive influence on the subsequent patterns of lymphokine production by primed T cells.

TISSUE DISTRIBUTION AND MIGRATORY PROPERTIES OF T CELLS

Typical CD4 and CD8 ab T cells are found at their highest concentration in the circulation (blood and lymph) and in the spleen and lymph nodes (14,21,30,31). These T cells also accumulate in certain other lymphoid organs, such as Peyer patches and tonsils. In each tissue, T cells are situated in clearly defined microenvironments, termed T-dependent areas. As discussed later, T-cell migration to spleen and lymph nodes is different (Fig. 5.1 and Fig. 5.2).

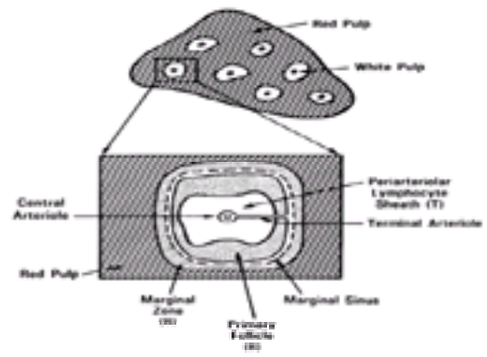

Figure 5.1. Microanatomy of the spleen. T cells are concentrated in periarteriolar sheaths (PALS) in the white pulp. T cells reach this region from the marginal sinus, which receives T and B cells as well as other blood components from the terminal arterioles that branch from the central arterioles. B cells also move from the marginal sinus to the PALS but then localize in the outer portions of the white pulp, that is, in primary follicles and germinal centers (the latter are not shown). B cells also localize in the marginal zone (which forms a layer of cells between the marginal sinus and the red pulp). After passing through the white pulp, T and B cells leave the spleen by percolating through the loose network of sinusoids in the red pulp to reach the tributaries of the splenic vein. Exit through lymphatic channels is limited in most species. (From J Sprent. T lymphocytes and the thymus. In: WE Paul, ed. *Fundamental immunology,* 3rd ed. New York: Raven, 1993:75–109, with permission.)

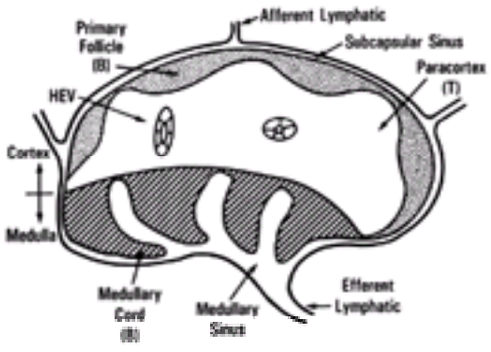

Figure 5.2. Microanatomy of a lymph node (131). T and B cells enter the lymph node (LN) by penetrating the walls of HEV to reach the paracortex. B cells pass through the paracortex to reach primary follicles and germinal centers (not shown) in the outer cortex. In the medulla the medullary cords are packed with plasma cells (i.e., the differentiated progeny of small B lymphocytes). T and B cells leave the LN by moving from the cortex to the medulla to enter the medullary sinus and then the efferent lymphatic vessel. Afferent lymphatic vessels contain macrophages (Mf) and dendritic cells (DC) but few T and B cells (except when the afferent lymphatics receive cells from efferent lymphatics of other LN). (From J Sprent. T lymphocytes and the thymus. In: WE Paul, ed. *Fundamental immunology,* 3rd ed. New York: Raven, 1993:75–109, with permission.)

Spleen

The spleen is partitioned into two distinct types of tissue: red pulp and white pulp. The red pulp contains a full spectrum of lymphohemopoietic cells, including neutrophils and erythrocytes, and the white pulp consists predominantly of lymphocytes. T cells (including both CD4 and CD8 cells) are concentrated in the central regions of the white pulp and form a sheath around arterioles. These periarteriolar lymphocyte sheaths (PALSs) constitute the T-dependent region of the spleen and contain a dense network of interdigitating dendritic cells. As discussed later, dendritic cells play a vital role in presenting antigen to T cells during immune responses.

T-cell entry to the spleen is largely nonspecific. There are no direct anastomoses between the arterial and venous systems in the spleen, and all blood-borne cells enter the spleen at the same site, namely, the marginal sinuses at the junction between the red and white pulp. Whereas most cells are carried directly to the red pulp for eventual exit through the splenic vein, lymphocytes move from the marginal sinuses into the white pulp. B cells migrate to the peripheral regions of the white pulp, and T cells accumulate in the PALSs. After several hours, T cells move back into the red pulp and leave the spleen through the splenic vein.

Lymph Nodes

In marked contrast to the spleen, the arteries and veins of lymph nodes are directly connected through capillaries. Most blood-borne cells are swept rapidly through lymph nodes through capillaries and fail to enter the lymphoid tissue itself. Lymphocytes are the exception. As a reflection of their expression of specific “homing” receptors, lymphocytes can bind to a unique type of venule characterized by a lining of plump endothelial cells; these high endothelial venules (HEVs) are also found in certain other lymphoid organs (e.g., Peyer patches) but are not present in the spleen or in nonlymphoid organs. Through CD62L and other homing receptors, T cells make contact with complementary molecules on the luminal surface of HEVs and then squeeze between the endothelial cells to enter the central region of lymph nodes, the paracortex. B cells move rapidly to follicles under the capsule, whereas T cells remain in the paracortex. This region, the T-dependent area of lymph nodes, resembles the PALS of the splenic white pulp in that it contains a dense network of interdigitating dendritic cells. T cells remain in the paracortex for several hours and then make their way out of lymph nodes by migrating to the large efferent lymphatic vessel in the medulla; in contrast to the spleen, T-cell exit from lymph nodes through the venous system is minimal. Efferent lymphatic vessels drain into the thoracic duct. This vessel terminates in the left subclavian vein in the neck and thus allows lymph-borne cells to reenter the circulation.

Whereas efferent lymphatic vessels contain large numbers of T cells (and B cells), afferent lymphatics contain few lymphocytes (unless these afferent lymphatics are tributaries of efferent lymphatics draining from other lymph nodes). Afferent lymph draining the skin, muscle, and so on is almost devoid of the typical ab CD4 and CD8 resting T cells that predominate in efferent lymph. Most of the few T cells found in afferent lymph are a mixture of gd T cells and memory ab T cells. Afferent lymph also contains immature dendritic cells; these cells lodge in the paracortex and are important for transporting antigen into lymph nodes from nonlymphoid tissues (32,33).

Recirculation of T Cells

The capacity of lymphocytes to migrate from blood to efferent lymph through HEVs is termed recirculation (30,34,35). In animal models, blood to lymph recirculation can be demonstrated by injecting lymphocytes intravenously and by monitoring the appearance of these cells in a cannula placed in the thoracic duct. Typical T cells begin to appear in thoracic duct lymph at about 6 hours after intravenous injection and reach peak levels at 18 hours. This prolonged transit time (which is even longer for B cells) is partly a reflection of slow blood-to-blood migration of T cells through the spleen. Because the spleen has a rich blood supply, a high proportion (about 40%) of T cells injected intravenously lodge initially in the spleen before reaching lymph nodes. These cells leave the spleen after about 6 hours and then gradually accumulate in lymph nodes through arterial blood.

By allowing lymphocytes to penetrate the walls of HEVs, the homing receptors on T cells play a critical role in recirculation. Resting T cells express at least two types of HEV homing receptor (14,36,37). In the mouse, the first receptor is CD62L, which has binding specificity for a complementary molecule on HEVs termed peripheral lymph node addressin (PNAd). The second homing receptor is the integrin a_4b_7, which binds to a different ligand on HEV called mucosal addressin cell adhesion molecule-1 (MAdCAM-1). Homing of T cells into peripheral lymph nodes is mainly mediated by binding of CD62L to PNAd. Migration of T cells into mesenteric lymph nodes and Peyer patches, by contrast, occurs through interactions of either CD62L or a_4b_7 with their respective ligands on HEV; entry into Peyer patches is more efficient with a_4b_7 than CD62L.

Recirculation of T cells is also controlled by a class of small soluble proteins termed chemokines (CCs) (38,39 and 40). CCs are chemoattractive molecules released by endothelial and stromal cells and direct movement of all types of hemopoetic cells by forming a gradient to which the cells respond using their chemokine receptors (CCRs) on the cell surface. For HEV, these vessels release a specific CC, termed secondary lymphoid tissue chemokine (SLC), which attracts lymphocytes and facilitates migration of these cells through HEV. Within lymphoid tissues, CCs also direct movement of lymphocytes to specific microenvironments. Thus, T cells find their way to the T-cell zone with the aid of CCR7 receptors that bind SLC and also another CC, Epstein-Barr virus–induced chemokine (ELC), released by resident stromal cells. CCR7 is also expressed on dendritic cells, and, through SLC and ELC, this receptor allows dendritic cells to enter the T-cell zone. Other CCs enable B

cells to move from the T-cell zone into primary follicles.

After contact with antigen, T cells downregulate CD62L and alter their pattern of CCR expression. As a result, activated T cells lose the capacity to enter peripheral lymph nodes through HEVs. Entry to Peyer patches is retained, presumably through the use of a_4b_7, which allows activated T cells to continue to recirculate. Activated T cells also appear to recirculate by an indirect pathway that involves migration through nonlymphoid tissues followed by entry into afferent lymphatics (36,41); the cells then pass through lymph nodes to reach efferent lymph.

Much less is known about the migratory properties of gd T cells. These cells do recirculate from blood to lymph through lymph nodes but, like activated ab T cells, entry to lymph nodes seems to be predominantly through afferent lymphatic vessels rather than through HEV (36,41). The homing receptors on gd cells have yet to be characterized.

RESPONSE OF MATURE T CELLS TO ANTIGEN

In discussing how typical T cells respond to antigen, it is essential to emphasize that ab T-cell specificity and function are under the strict control of MHC molecules (31,42,43). As mentioned earlier, the specificity of ab T cells is directed to small fragments (peptides) of protein antigens held in a groove on cell-bound MHC molecules (4,5).

Cell-surface MHC molecules normally express a variety of self-peptides derived from breakdown of intracellular proteins. As the result of selective events governing their initial formation in the thymus, mature T cells are unresponsive to these MHC–self-peptide complexes and thus display self-tolerance. When self-peptides are replaced by foreign peptides, however, a few T cells bind to these foreign peptide-MHC complexes with high affinity and are triggered.

At the level of naive resting T cells, triggering of T cells by foreign peptides requires contact with MHC-peptide complexes expressed on the surface of specialized antigen-presenting cells (APCs), particularly dendritic cells and macrophages (33,44,45). As discussed in other chapters, these and other APCs degrade antigens into peptides intracellularly and load these peptides onto MHC I and II molecules. MHC molecules plus bound peptides are then transported to the cell surface. Loading of peptides on to MHC I and II molecules involves different mechanisms (44,46,47,48,49,50 and 51). Peptide binding to class II molecules generally involves an “external” pathway of antigen processing whereby exogenous antigens are ingested and then are degraded into peptides in endosomes; these peptides are then bound by the class II molecules in endosomes and are ferried to the cell surface for recognition by $CD4^+$ T cells. For binding of peptides to MHC I molecules, most of the peptides are generated by an “internal” pathway whereby intracellular antigens (e.g., antigens synthesized by infectious viruses) are conveyed to the endoplasmic reticulum and the Golgi network. Here, peptides are bound to class I molecules, which are then transported to the cell surface and are recognized by CD8 T cells. One subset of APC has the ability to process and present exogenous antigens on class I molecules and to activate $CD8^+$ cells. This process of “cross-priming” is well documented, but the identity of the APC and the exact mechanisms of antigen processing involved are still unclear (52).

Distribution of Antigen-Presenting Cells *In Vivo*

Although antigen processing and peptide loading of MHC molecules has been studied extensively *in vitro,* much less is known about antigen processing *in vivo.* In particular, the relative contributions of macrophages and dendritic cells to APC function *in vivo* are still debated. Dendritic cells are found in the T-dependent areas of the lymphoid tissues and are thus strategically positioned to present antigen to recirculating T cells (32,33,53). Nevertheless, typical dendritic cells are poorly phagocytic and are therefore unsuited to degrading exogenous native antigens into peptides. How then do dendritic cells present antigen? The resolution to this problem seems to be that, at least in lymph nodes, the dendritic cells found in the T-dependent areas arise from a precursor population in the skin and other nonlymphoid tissues. These immature dendritic cells, termed Langerhans cells in the skin, are actively phagocytic but are not capable of stimulating T cells. Uptake of microbial antigens and exposure to inflammatory products, however, induce migration of immature dendritic cells to lymph nodes through afferent lymphatics; en route, the cells differentiate into mature dendritic cells. During this stage, the ingested antigens are degraded into immunogenic MHC-bound peptides, and the cells become potent stimulators of naive T cells by upregulating the expression of “costimulatory” molecules such as B7 and also by acquiring the ability to synthesize certain cytokines.

Whether this situation is applicable to other lymphoid organs, such as the spleen, is still unclear. In addition to mature dendritic cells in the white pulp, the spleen has a dense network of macrophages in the marginal sinuses, and it is likely that these cells, which are strongly phagocytic, play a major role in degrading large particulate antigens for presentation to T cells (44,54). Macrophages are found in other lymphoid organs, such as in the subcapsular sinus of lymph nodes, and are also scattered throughout nonlymphoid tissues. The role of macrophages and blood monocytes in antigen presentation to T cells is controversial. When tested directly *ex vivo,* macrophages generally display poor APC function for naive T cells. However, after ingestion of particulate antigens *in vitro* and subcutaneous injection *in vivo,* monocytes migrate into the T-cell areas of the draining lymph nodes and express dendritic cell markers (55). Hence, some monocytes behave functionally as dendritic cell precursors. Indeed, many of the cells typed as macrophages in the marginal zone of the spleen can migrate to the white pulp after exposure to inflammatory stimuli and differentiate rapidly into mature dendritic cells (56). These and other data suggest that macrophage-monocytes and dendritic cell precursors are closely related and perhaps synonymous.

The wide distribution of dendritic cells throughout the body is often taken to signify that T cells can be stimulated by antigen in nonlymphoid tissues. For naive T cells, this possibility is unlikely because, as discussed earlier, typical unprimed T cells remain strictly within the confines of the recirculating lymphocyte pool. Moreover, only mature dendritic cells, that is, the cells found in the T-cell zones of lymphoid tissues, are strongly immunogenic for naive T cells.

T-Cell Recognition of Antigen: Receptor-Ligand Interactions

The receptor-ligand interactions involved in T-cell recognition of antigen are discussed in detail in other chapters. In brief, MHC-peptide complexes on APCs are recognized by two molecules on T cells: the ab TCR and either CD4 or CD8 molecules (7,8,31). The latter molecules act as coreceptors and have binding specificity for nonpolymorphic, class-specific epitopes on the membrane proximal domains of MHC molecules: CD4 molecules bind to class II MHC molecules, whereas CD8 molecules bind to class I molecules. T cells need to make contact with costimulatory molecules, notably B7 (B7-1, B7-2), and various adhesion molecules, such as intercellular adhesion molecule-1 (ICAM-1), on APCs (57). These molecules are recognized by complementary molecules on T cells, that is, CD28 for B7 and LFA-1 for ICAM-1. These interactions stabilize TCR-peptide-MHC binding and intensify T-cell triggering. For CD28/B7 interaction, ligation of CD28 delivers a “costimulatory” signal to T cells that is crucial for synthesis of cytokines, notably interleukin-2 (IL-2).

T-Cell Triggering

Although T-cell triggering is initiated by cross-linking of TCR molecules, the intracytoplasmic regions of the TCR are too short to mediate signal transduction. Triggering appears to depend on the formation of complexes between at least four sets of cell-surface molecules: (a) TCR, (b) CD4 or CD8, (c) heterodimers formed from the three chains (gde) of the CD3 family, and (d) heterodimers or homodimers of zh or zz chains (58,59 and 60). Triggering involves the actions of several protein tyrosine kinases (PTKs) that activate proximal signaling molecules through phosphorylation; this process subsequently leads to activation of multiple downstream pathways through key adapter proteins. The proximal signal after TCR cross-linking is initiated by $p56^{lck}$, a Src-family PTK that associates with CD4 and CD8 molecules and phosphorylates CD3z chains. ZAP-70, a Syk-family PTK, then binds to CD3z chains and phosphorylates key adapter proteins, LAT and SLP-76, which, in turn, recruit several other crucial signaling molecules and initiate a cascade of signaling events that ultimately turn on multiple downstream events including phosphoinositide hydrolysis, calcium mobilization, and activation of Ras signaling pathways; T-cell triggering is also influenced by a tyrosine phosphatase associated with the CD45 molecule. Downstream signals are then transmitted to the nucleus to initiate gene transcription, which leads to cell division and synthesis of various cytokines and receptors for these cytokines.

T-cell–derived cytokines, also termed lymphokines or interleukins, play a vital role in promoting and controlling T-cell proliferation and, for CD8 cells, differentiation into cytotoxic cells (28,29,61,62,63 and 64). IL-2 is of particular importance and is synthesized rapidly when naive T cells respond to antigen. IL-2 production is conspicuous for CD4 cells but is less prominent for CD8 cells. With strong TCR stimulation, CD8 T cells can produce their own IL-2 and are termed helper-independent cells; with weaker stimulation, CD8 cells produce little IL-2, and these helper-dependent cells proliferate only in the presence of exogenous IL-2 produced by other cells, notably CD4 cells.

In addition to IL-2, triggering of naive T cells causes synthesis of a variety of other lymphokines, such as interferon-g (IFN-g), IL-4, and IL-10. CD4 T cells use these and other lymphokines to mediate numerous effector functions, such as delayed-type hypersensitivity and interaction with B cells leading to antibody production. Cytokines, notably IFN-g, also augment the capacity of CD8 cells to destroy target cells, such as virus-infected cells. The precise spectrum of lymphokines produced by T cells appears to depend on their stage of differentiation and the conditions encountered during interaction with APC. Naive T cells have the potential to produce many different lymphokines, but primed or memory T cells often show a restricted pattern of lymphokine release. Thus, with APCs releasing IL-12 and IFN-g, activation of CD4 cells leads to generation of type 1 T-helper (Th1) cells producing large amounts of IL-2 and IFN-g but little IL-4 or IL-10. Conversely, exposure to IL-4 by neighboring T cells favors the production of Th2 cells, which are cells showing a reciprocal pattern of lymphokine release. Although the precise factors controlling the differentiation of T cells into Th1 and Th2 cells are still not clearly defined, the changes induced in T cells are often irreversible and reflect expression of unique

transcription factors and loss of certain cytokine receptors.

T-Cell Responses to Antigen *In Vivo*

As discussed earlier, unprimed T cells reside in the recirculating lymphocyte pool and move continuously from one lymphoid organ to another. When foreign antigen enters the body, confrontation with MHC-peptide complexes displayed on APCs in the T-dependent areas of the lymphoid tissues causes antigen-specific T cells to be withdrawn from the recirculating pool (30,65). T cells bind to APCs and are triggered to proliferate. After 2 to 3 days, the progeny of the proliferating cells leaves the lymphoid tissues through efferent lymphatics (for lymph nodes) or venous blood (for spleen) and reenters the circulation as effector cells.

This process of antigen-specific trapping of T cells followed by clonal expansion and reentry into the circulation is most easily visualized when the precursor frequency of T cells is high. For conventional antigens and peptides, the precursor frequency of naive T cells for antigen is low, less than 1×10^4. A different situation applies to MHC alloantigens. Whereas T cells display self-tolerance to autologous MHC molecules (plus the endogenous self-peptides on these molecules), T cells are strongly reactive to foreign MHC molecules. Thus, when T cells are exposed to APCs from an MHC-different individual, as many as 5% to 10% of unprimed T cells display overt reactivity to these alloantigens and enter cell division (30). Under *in vitro* conditions, this response constitutes a mixed-lymphocyte reaction and generates large numbers of blast cells. Similar findings apply *in vivo* (30,35,66) (Table 5.1).

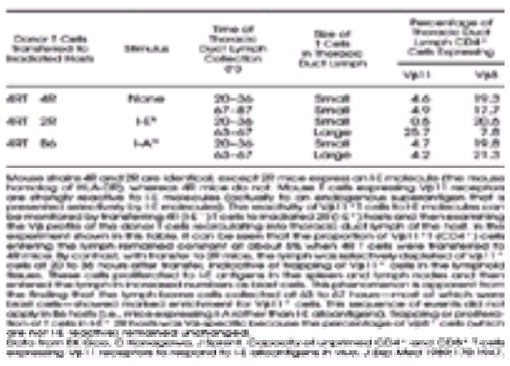

TABLE 5.1. Trapping and Proliferation of Alloreactive T Cells in Vivo Revealed with Vb-Specific Antibody

Hence if T cells from a mouse of MHC^a genotype are injected into an MHC^b mouse, the donor T cells with MHC^b specificity mount a vigorous immune response to the MHC^b-bearing APCs of the host. In this graft-versus-host reaction, the responding T cells, which include both CD4 and CD8 cells, are initially trapped in the T-dependent areas and begin to proliferate extensively. During this period of trapping, the donor-derived T cells recirculating into thoracic duct lymph are selectively depleted of host MHC^b-reactive T cells. After about 3 days, host-specific T cells appear in the lymph as blast cells, and by 4 to 5 days, these blast cells constitute a high proportion of the lymph-borne cells. Indeed, when the host is exposed to irradiation before T-cell injection (which destroys host T cells but spares host APCs), donor-derived host-specific blast cells can account for more than 90% of total lymph-borne cells.

Essentially similar findings apply when T cells respond to conventional antigens, such as to a virus infecting the respiratory system. In this situation, dendritic cell precursors transport viral antigens from the site of infection to the draining lymph nodes. Recirculating T cells encounter viral peptides on mature dendritic cells in the T-cell zones of lymph nodes and then proliferate extensively before reentering the circulation through efferent lymphatics. Because the precursor frequency of naive T cells for viral antigens is low, it is difficult to trace the distribution of the responding T cells in the early stages of the primary response. After clonal expansion of the responding cells, however, tracing the cells is relatively easy, especially with the development of the tetramer approach for detecting individual antigen-specific T cells (67,68 and 69); with this technique, specific T cells can be detected on the basis of their capacity to bind tetramers of recombinant MHC molecules loaded with defined peptides. The tetramer approach has shown that, during viral infections, specific $CD8^+$ T cells divide rapidly (every 4 to 6 hours) and can undergo a 10^4-fold expansion during the first week of infection (69). As the result of this massive proliferation, the precursor frequency of the responding cells increases from undetectable levels to 50% or more of total T cells. These cells enter the circulation as effector blast cells.

The entry of blast cells into the circulation after trapping and proliferation in the lymphoid tissues serves to disseminate effector T cells throughout the body. These cells migrate from the circulation to the original sites of infection, and there the cells destroy infected target cells. Because nonlymphoid tissues are outside the confines of the recirculating lymphocyte pool, entry of effector cells into these sites necessitates a radical change in their migratory properties. Although the mechanism of homing of activated T cells to nonlymphoid tissues is not fully understood, this process appears to involve downregulation of lymph node homing receptors and upregulation of a series of other receptors, which allow T cells to penetrate the walls of typical small capillaries and to percolate through the extracellular matrix to make contact with stromal cells such as epithelial cells (37,40,70).

Elimination of viruses (and other pathogenic organisms) also involves specific antibody. Production of antivirus antibody is initiated by contact of CD4 cells with APCs expressing viral peptides bound to class II MHC molecules. After activation and proliferation in the draining lymph nodes, virus-specific CD4 cells move from the T-dependent areas and make contact with antigen-specific B cells in adjacent germinal centers. Describing the complex events involved in T-cell–B-cell collaboration (71,72,73 and 74) is beyond the scope of this chapter. In brief, B cells bind native protein molecules (e.g., viral proteins) through their specific immunoglobulin receptors. After internalization, the protein is degraded into peptides, some of which associate with class II MHC molecules in endosomes. These peptide-MHC complexes then move to the cell surface. Some of these peptides correspond to the peptides seen by CD4 cells on APCs during initial T-cell activation. Recognition of these peptides on the surface of B cells by CD4 cells results in the delivery of a “helper” signal to the B cells. Under the influence of T-cell–derived lymphokines such as IL-4 and T-cell expression of CD40L, a receptor for B-cell CD40 molecules, B cells then differentiate into antibody-forming cells. The haptenic determinants on the native protein antigen recognized by antibody molecules (and the immunoglobulin receptor on the precursor B cells) are unrelated to the particular breakdown product (peptide) seen by the Th cell. Nevertheless, T-cell–B-cell collaboration depends critically on physical linking of the two epitopes before degradation in the B cell.

Most typical immune responses involve the simultaneous production of CD4 and CD8 effector T cells and the release of specific antibody (31,42). Such combined cellular and humoral immunity is the most effective method for eliminating pathogens. Although the manifestations of cellular immunity by CD4 and CD8 effector cells are often highly complex, virtually all forms of cellular immunity involve the generation of effector cells at sites of antigen concentration, usually the draining lymph nodes, followed by migration of effector cells to the site of infection. Effector cells then destroy pathogen-infected cells by a combination of direct cell-mediated lympholysis and local release of lymphokines. Although the effector functions of CD4 and CD8 cells are broadly overlapping, CD8 cells typically mediate cell-mediated lympholysis, whereas CD4 cells control lymphokine release. In the case of CD4 cells, cellular immunity is principally under the control of Th1 effector cells (29,64,75,76). These cells produce delayed-type hypersensitivity reactions and typically release large quantities of IFN-g.

The ratio of Th1 to Th2 cells can have a major influence on the efficiency of the destruction of pathogen-infected cells. In particular, an excess of Th2 cells can severely inhibit cellular immunity, presumably because IL-10 production by Th2 cells is suppressive for Th1 cells. This situation is illustrated by experimental leishmaniasis, in which, in certain strains of mice, an overabundance of Th2 cells prevents a delayed-type hypersensitivity reaction to *Leishmania*-infected cells.

Although effector T cells can elicit nonspecific (“bystander”) damage through release of lymphokines, the interaction of effector T cells with antigen-bearing target cells is MHC restricted. In fact the MHC-restricted specificity of T cells applies throughout the life history of these cells, even during the stage of initial T-cell formation in the thymus (see later).

T-CELL MEMORY

A characteristic feature of the primary immune response is that, after the infectious agent is cleared, most effector T cells are destroyed by apoptosis (77,78 and 79). Elimination of effector cells involves several mechanisms, including loss of contact with life-sustaining cytokines and delivery of death signals, such as by ligation of cell-surface Fas by a receptor, FasL expressed on other cells (78,80,81). Teleologically, destroying effector cells at the end of the immune response makes sense: the cells are no longer useful, and their long-term survival would clutter the lymphoid tissues.

Despite the widescale death of T cells at the end of the primary response, some of the responding T cells survive as long-term memory cells (16,19,20,82). Immunologic memory is often lifelong, and secondary contact with the pathogen concerned leads to a much more intense T-cell response than is seen during primary infection. The intensity of the secondary response reflects both a higher precursor frequency of T cells and the fact that primed (memory) T cells are more sensitive to

antigen than naive T cells.

The factors controlling the long-term survival of memory cells are controversial (16,19,20,82). Some workers argue that memory cells need to be maintained in a state of chronic activation through contact with residual depots of the primary antigen or by cross-reactive specificity for environmental antigens. However, in animal models, it is now apparent that memory cells survive well in MHC^{-} hosts, that is, where TCR ligation is precluded. As discussed earlier, another possibility is that memory cells receive life-sustaining signals through contact with certain cytokines.

T-CELL SELECTION IN THE THYMUS

Most mature ab (and gd) T cells arise in the thymus (7,83,84,85 and 86), as is apparent from the finding that congenitally athymic (nude) rodents and patients with congenital thymic aplasia (Digeorge syndrome) are almost devoid of mature T cells. Likewise, T cells fail to develop when the thymus is removed early during ontogeny.

The release of T cells from the thymus is maximal during young life and then decreases markedly after the onset of puberty (87,88). T-cell production by the thymus is roughly proportional to the size of the thymus. Although during young life the thymus is a massive organ, after puberty it shrinks progressively through the action of sex hormones. At least in rodents, however, the thymus remains functional until late adult life, as evidenced by the effects of exposing mice to whole-body irradiation, which destroys T cells and other lymphohemopoietic cells. When irradiation is followed by reconstitution with stem cells (bone marrow or fetal liver cells), young adult mice show full restoration in T-cell numbers within 2 months. With old mice, the replenishment of T cells occurs much more slowly but is eventually substantial, provided the mouse has a thymus. When the thymus is removed before irradiation and stem cell reconstitution, the T-cell pool remains severely depleted almost indefinitely.

Removing the thymus in adults without irradiation does not cause a rapid decrease in T-cell numbers. Such a finding is sometimes taken to indicate that T cells in adults arise primarily by an extrathymic pathway. This possibility belies the effects of thymectomy discussed earlier. In rodents, most researchers accept that extrathymic differentiation of T cells, although significant, is limited. The most likely explanation for the persistence of T cells after thymectomy in adults is that, once formed, the mature T-cell pool in largely self-sufficient, and most T cells at a population level are extremely long-lived. The mature T-cell pool is also regulated by poorly understood homeostatic mechanisms that maintain the total size at a near constant level.

In humans, the thymus is functional well before birth. Removing the thymus after birth (e.g., during cardiac surgery in infants) has surprisingly little effect on T-cell numbers and function, presumably because the thymus has already generated large numbers of mature T cells. The same finding applies in mice. In this species, the thymus does not begin to export T cells until around the day of birth. Removing the thymus at this time results in marked and permanent T lymphocytopenia. Thymectomy at 1 week after birth, however, generally causes only minimal T lymphocytopenia, a finding reflecting the substantial output of T cells from the thymus during the first week of life followed by homeostatic expansion of these cells.

Although the rate of production of T cells in the thymus is enormous, relatively small numbers of these cells are released to the extrathymic environment (87,88). In mice, the young thymus produces approximately 4×10^7 T cells per day. Yet the maximal release of T cells from the thymus is fewer than 2×10^6 cells per day. One is thus confronted with the paradox that the thymus produces huge numbers of young T cells and then destroys most of them, apparently *in situ.* At face value, then, T-cell production in the thymus seems to be inefficient. It is now clear, however, that the wide-scale destruction of T cells in the thymus is a reflection of a rigorous process of positive and negative selection whereby only those T cells with the requisite fine specificity to function in the extrathymic environment are allowed to exit to the periphery. Few T cells meet this criterion. The rest are destroyed *in situ.*

To understand T-cell selection in the thymus, it is important to reconsider the specificity of mature T cells. As discussed earlier, T-cell specificity is directed to foreign antigens (peptides) bound to MHC molecules. MHC molecules are highly polymorphic, and in an outbred population each individual generally displays a unique set of these molecules (the chance that any two individuals will express an identical set of MHC molecules is slight). The key point is that the particular MHC molecules expressed in the individual play a decisive role in shaping the T-cell repertoire (42,65,89). Thus, in each individual, the specificity of mature T cells is directed to recognition of foreign antigens presented by the particular self-MHC molecules expressed in the individual. Presentation of antigen by nonself-MHC molecules is much less effective.

Given the enormous polymorphism of MHC molecules, how does the thymus selectively export a T-cell repertoire that is skewed toward recognition of antigen presented by self-MHC molecules rather than by nonself-MHC molecules? Based on studies with bone marrow chimeras and TCR transgenic mice (31,90), the answer seems to be that T-cell confrontation with polymorphic residues on MHC molecules (plus bound endogenous self-peptides) on thymic epithelial cells selects for T cells displaying low but significant reactivity for these ligands (84,90,91,92,93,94 and 95). The level of “physiologic” specificity for self-MHC molecules is delicately balanced. After export from the thymus, T cells are unresponsive to self-MHC molecules (plus bound self-peptides) in the absence of exogenous antigen and thus display self-tolerance. Nevertheless, despite this lack of overt reactivity to self-MHC molecules, postthymic T cells retain *covert* reactivity to these molecules. This specificity is manifested by the strong reactivity of mature T cells to slight perturbations of self-MHC molecules (“altered self” determinants); these epitopes are created when self-peptides are displaced by foreign peptides. As discussed earlier, covert reactivity of T cells for self-MHC–self-peptide complexes is also important for maintaining T-cell survival, presumably by induction of continuous low-level TCR signaling.

As discussed later, T-cell selection in the thymus involves three distinct steps. The first step entails generation of large numbers of immature T cells with potential reactivity for all the various MHC molecules expressed in the species as a whole; this early stage of thymocyte differentiation is independent of MHC. The second step, positive selection, involves screening the immature T-cell repertoire for cells expressing some degree of reactivity for the self-MHC–peptide complexes displayed in the thymus. Positively selected T cells are then subjected to negative selection. This step involves self-tolerance induction and results in the destruction of T cells expressing overt reactivity for self-MHC–peptide ligands. To avoid confusion, it should be stressed that most (more than 95%) T cells differentiating in the thymus are ab T cells; thymic selection of gd T cells is still poorly understood and is not discussed here.

Early Differentiation of Thymocytes

The thymus is divided into two broad areas, the cortex and the medulla (84,85,96,97 and 98). Mature T cells occupy the medulla, whereas immature T cells (which comprise 85% to 90% of thymocytes) reside in the cortex. All thymocytes arise from a minority population of stem cells lacking CD4 and CD8 expression. These $CD4^{-}8^{-}$ cells are the descendants of blood-borne stem cells and form a thin rim under the thymic capsule. Differentiation of $CD4^{-}8^{-}$ cells is controlled by the rearrangement of TCR genes. Rearrangement of the TCR b chain allows $CD4^{-}8^{-}$ cells to undergo extensive proliferation and expression of the pre-TCR, a dimer of the TCR b chain and a surrogate TCR a chain that is expressed without gene rearrangement. Replacing the surrogate a chain with a rearranged conventional TCR a chain causes the cells to express both CD4 and CD8 molecules and to cease to proliferate. These “double-positive” ($CD4^{+}8^{+}$) thymocytes express low levels of mature ab TCR heterodimers on the cell surface but live for only 3 to 4 days unless they are rescued by positive selection.

Positive Selection

Positive selection involves TCR-mediated interaction of $CD4^{+}8^{+}$ thymocytes with self-MHC–peptide complexes expressed on cortical epithelial cells (7,84,85,99,100,101 and 102); these cells, which form a dense network throughout the cortex, express both MHC I and II molecules. When the affinity of TCR-MHC interaction is higher than a certain threshold, $CD4^{+}8^{+}$ T cells receive a protective signal that enables the cell to survive and to differentiate into mature T cells; this process allows the selective survival of T cells displaying physiologic specificity for self-MHC–peptide complexes. Positive selection reflects significant, but probably low-level, TCR signaling and is directed largely to weak (antagonist) peptides. Most thymocytes have negligible specificity for the particular MHC-peptide complexes expressed in the thymus. These T cells fail to receive a protective signal from cortical epithelium and die rapidly by apoptosis; this process is viewed as death by neglect (Fig. 5.3).

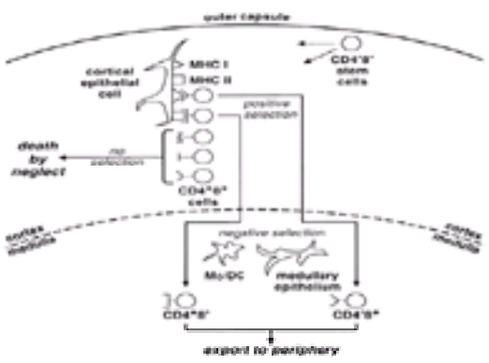

Figure 5.3. Model for positive and negative selection of T cells in the thymus. As discussed in the text, small numbers of $CD4^{-}8^{-}$ stem cells under the outer capsule of the cortex proliferate extensively and generate large numbers of immature $CD4^{+}8^{8+}$ cortical thymocytes. These cells are screened for reactivity to self-MHC loaded with self-peptides through exposure to the class I and class II molecules expressed on cortical epithelium. T-cell receptor (TCR) recognition of polymorphic epitopes of class I and class II molecules loaded with self-peptides is aided by CD8 and CD4 molecules, respectively; these molecules act as coreceptors. T cells able to bind to MHC-peptide complexes on epithelial cells receive a protective signal that enables the cells to survive and move to the medulla. These positively selected T cells downregulate the unwanted coreceptor (CD4 or CD8) and upregulate TCR expression to become typical single-positive $CD4^{+}8^{8-}$ and $CD4^{-}8^{+}$ cells. In the medulla and the corticomedullary junction, $CD4^{+}8^{-}$ and $CD4^{-}8^{+}$ cells are screened for overt reactivity to MHC-peptide complexes expressed on bone-marrow-derived macrophages (Mf), dendritic cells (DCs), and medullary epithelial cells; strong interactions with these cells causes T cells to die by apoptosis. Cells surviving negative selection are exported to the periphery by veins and lymphatics. Positive and negative selection of T cells applies to only a small proportion (< 5%) of thymocytes. Most $CD4^{+}8^{+}$ thymocytes do not have significant reactivity for the particular MHC-peptide complexes expressed in the thymus, and these cells die within a few days by an unknown process.

The CD4 and CD8 molecules on double-positive thymocytes determine the MHC class specificity of positive selection. Thus, when T cells undergo positive selection to peptides bound to MHC class I molecules, TCR binding to MHC class I epitopes plus peptides is strengthened by simultaneous binding of CD8 molecules to MHC class I molecules; as mentioned earlier, CD8 molecules bind to a nonpolymorphic site on the membrane-proximal region of MHC class I molecules, and this interaction strengthens the affinity of TCR-MHC class I interaction. Combined TCR-CD8 binding of T cells to MHC class I molecules is followed by downregulation of CD4 molecules and differentiation into mature CD8 ($CD4^{-}8^{+}$) cells expressing a high TCR density. Conversely, positive selection in response to MHC class II molecules is controlled by CD4 molecules. Here, combined TCR-CD4 binding of T cells to MHC class II molecules results in downregulation of CD8 molecules and differentiation into mature CD4 ($CD4^{+}8^{-}$) cells.

Negative Selection (Tolerance Induction)

Of the T cells undergoing positive selection, many of the cells have the appropriate covert physiologic specificity for self-MHC–peptide complexes required by postthymic T cells; after maturation in the medulla, this subset of thymocytes is released into the periphery by veins and lymphatics and feeds into the recirculating lymphocyte pool. Other thymocytes have stronger reactivity for self-MHC–peptide complexes, and these potentially autoaggressive T cells must be destroyed *in situ.* Negative selection of these T cells involves clonal deletion (apoptosis) and appears to take place largely in the medulla through contact with bone-marrow–derived APCs, especially dendritic cells (103,104,105,106,107,108,109,110,111 and 112).

Because dendritic cells are restricted to the medulla, most T cells undergoing negative selection are presumed to have passed through a prior stage of positive selection. However, although negative selection generally occurs later than positive selection, this is not invariably the case. Thus, in certain experimental models, negative selection can occur in the cortex in parallel with positive selection.

Given the enormous range of self-antigens (and the peptides derived from these antigens), how are T cells rendered self-tolerant to these diverse antigens? When considering this question, one must distinguish between circulating and noncirculating self-antigens. Many self-components, such as serum proteins and the surface molecules of lymphohemopoietic cells, readily enter the circulation. These circulating self-antigens have access to the medullary region of the thymus and are presumably degraded there into peptides by thymic APCs for presentation to newly formed T cells. T cells reactive to these peptides are then deleted *in situ.* Intrathymic deletion of T cells specific for circulating self-antigens is extremely efficient, requiring only minute doses (10^{-8} to 10^{-9} M) of antigen, a finding that explains why these antigens are rarely, if ever, the targets of (T-cell–mediated) autoimmune disease.

A different situation applies to tissue-specific self-antigens (e.g., antigens unique to the brain). These antigens are presumed to enter the circulation in negligible quantities, with the result that T cells generally display little or no tolerance to tissue-specific antigens. This situation is exemplified by the relative ease of inducing experimental organ-specific autoimmune disease to these antigens (e.g., by injecting rodents with myelin basic protein) (113).

Although it is well accepted that tissue-specific antigens are the main targets for autoimmune disease (experimentally induced or spontaneous), one must account for the relative rarity of autoimmune disease. Thus, if T cells are nontolerant to tissue-specific antigens, one could expect T cells to enter tissues such as the brain and to mount autoimmune reactions there. Yet such reactions are uncommon. The simplest explanation for this paradox is that tissues such as the brain are not accessible to normal resting T cells. As discussed earlier, resting T cells remain in the recirculating lymphocyte pool and are excluded from entering nonlymphoid tissues. Accordingly, tolerance to tissue-specific antigens may be largely a reflection of “ignorance.” It is also possible that tolerance to tissue-specific antigens is partly a reflection of central tolerance, that is, as the result of trace levels of these antigens that reach the thymus from the circulation or are synthesized *in situ* (114,115 and 116). Such intrathymic expression could be sufficient to delete high-affinity T cells and could leave only less dangerous low-affinity cells to escape to the periphery. This model could explain why autoimmune disease is relatively uncommon. Despite the foregoing possibilities, many workers believe that tolerance to tissue-specific antigens involves postthymic mechanisms (117). This topic is discussed in the next section.

Postthymic Tolerance

As a supplement to clonal deletion in the thymus, induction of T-cell anergy is currently the most popular backup mechanism for self-tolerance. Anergy is postulated to be the result of mature, unprimed T cells that encounter antigen on “nonprofessional” APCs (i.e., on cells other than macrophages or dendritic cells) (118,119 and 120). In this situation, T cells recognize antigen in the absence of the second signals required for T-cell stimulation. As a result, T cells undergo a form of partial triggering in which the cells are refractory to subsequent stimulation by “professional” APCs.

Although T-cell anergy is well documented *in vitro,* whether anergy plays an important role in inducing or maintaining tolerance *in vivo* is controversial. There are many examples of T-cell stimulation *in vivo* that lead to a refractory state (121), but whether this form of anergy is attributable to T-cell contact with antigen on nonprofessional APCs is unclear. The alternative possibility (for which evidence is clear) is that T cells can transiently enter an anergic state even after optimal stimulation (see later). The key issue is whether induction of anergy can explain the rarity of organ-specific autoimmune disease.

This question has been addressed by preparing transgenic mice in which foreign MHC molecules or viral antigens are displayed selectively in organs such as the pancreas, for example by placing the transgene under the insulin promoter (122). In this situation, the foreign antigens are expressed on nonprofessional APCs (i.e., on pancreatic b cells). Unfortunately, the results of this ingenious experiment are variable (122,123,124,125,126,127 and 128). The general finding is that the transgenic mice fail to develop spontaneous autoimmune disease, a finding indicating operational tolerance. The mechanism of tolerance, however, is still unclear. Some groups find little or no tolerance at the T-cell level but observe strong induction of autoimmune disease when the antigen is injected in immunogenic form, for example, as part of a live virus. Under these conditions, contact with antigen expressed on professional APCs in the lymphoid tissues breaks tolerance; the T cells proliferate and express new homing molecules, and this allows the cells to enter nonlymphoid tissues, such as the pancreas, and thus elicit autoimmune disease. These observations imply that tolerance to tissue-specific antigens is largely a reflection of ignorance. However, other studies with this model have shown significant tolerance at the level of peripheral T cells. In some situations, tolerance at the T-cell level may reflect minor expression of the transgene in the thymus, thus inducing central tolerance. In other situations, tolerance seems to reflect an abortive immune response directed to leakage of antigen from the pancreas that reaches the draining lymph nodes; perhaps because of inadequate expression of costimulatory molecules on APC, the responding T cells are rapidly eliminated or are rendered anergic.

Although inconclusive, the foregoing data indicate that T-cell tolerance to tissue-specific antigens can involve various different mechanisms, including clonal deletion in the thymus, ignorance, and postthymic induction of anergy and clonal deletion. In addition, autoimmune reactions are often subject to immunoregulation, such as by subsets of T cells that produce inhibitory cytokines (129). Collectively, these various mechanisms usually ensure that T-cell responses to self-antigens are minimal or undetectable. Therefore, the implication is that, when it occurs, the development of overt autoimmune disease reflects breakdown of one or more of the mechanisms that normally hold nontolerant T cells in check. As typified by extensive studies on the nonobese diabetic mouse, however, the origin of autoimmune disease is highly complex and is still largely obscure (130).

6 ANTIGEN PROCESSING AND PRESENTATION

Emil R. Unanue, M.D.

A fundamental step in immune induction is *antigen presentation,* the process whereby an *antigen-presenting cell* (APC) takes up protein antigens, processes them, and presents fragments to the T cell. The reason that this process is of central importance in immune induction is that T cells do not recognize antigens directly, but only fragments or peptides bound to molecules of the major histocompatibility gene complex (MHC). MHC molecules are peptide binding proteins that rescue protein fragments from intracellular catabolism and select peptides that are then presented to the T cells (1). The T-cell receptor for antigen (TCR) is a molecule that recognizes the peptide fragments and at the same time contacts the MHC molecules (2). Thus, it is a receptor that has dual specificity: recognition of the peptide and recognition of the self-MHC molecule. The two major sets of T cells, CD4 and CD8, recognize peptides, but on the two major classes of MHC molecules: CD8 T cells on class I MHC molecules and CD4 T cells on class II MHC molecules (Chapter 3). Class I and II molecules of the APC interact with peptides derived primarily from cytosolic proteins, whereas class II molecules interact with those peptides derived primarily from the vesicular endocytic compartments. In this way, MHC molecules alert the T-cell system of the composition of its intracellular environment. Because the APCs are phagocytic cells that sample the extracellular milieu, any disruption of their intracellular environment, such as by the uptake of viruses or bacteria or extracellular toxins, is rapidly flagged to the T-cell system by way of MHC molecules.

Finally, to generalize, the molecular basis for the two major types of antigens, the thymus-dependent antigens, which are proteins and glycoproteins, and the thymus-independent antigens, which are the polysaccharides, is based on their capacity to associate with the two major sets of MHC molecules. The thymus-dependent antigens are capable of donating peptides to MHC molecules and therefore can form the epitope that engages the specific T cells. In contrast, thymus-independent antigens do not bind to MHC class I and II molecules (3), and they do not bring T cells to the reactions. (Polysaccharides can directly trigger some B cells.) Table 6.1 compares the response to these two sets of antigens and underscores the importance of antigen presentation in inducing a full immune response.

	Pure Polysaccharide	Globular Protein
Recognition by BCR	Yes	Yes
Recognition by TCR	No	Yes, after processing
Binding to MHC	No	Only after processing by antigen-presenting cells
Involvement of CD4 T cells	No	Yes
Memory	Poor	Strong
Affinity maturation	Poor	Strong

[a] The B-cell receptor (BCR), a membrane-bound antibody molecule, can interact with either pure polysaccharides or proteins. However, pure polysaccharides do not bind to MHC molecules, so the ligand for the T-cell receptor (TCR) cannot be formed. Consequently, responses to polysaccharides are not influenced by the helper function of CD4 T cells that takes place during antigen presentation.

TABLE 6.1. Comparison of the Response to Carbohydrates and Proteins[a]

Besides the classic MHC class I and II molecules, other nonconventional MHC or MHC-like molecules appear to have a role against special sets of molecules represented in microbes. Thus, H-2 M3 is a murine nonpolymorphic class I molecule that binds short peptide sequences having a formylmethionine at the amino-terminal (4). The CD1 family of molecules binds lipids and presents glycolipids to T cells, including mycolic acid from the tubercle bacillus (5,6). The role of these presenting molecules in now being evaluated and compared with the classic class I and II MHC proteins (Table 6.2). Although comparisons are made in this chapter between the features of class I and class II presentation, the major emphasis is to review primarily the basis of antigen presentation by the class II MHC system (Chapter 18 discusses the effector role of CD8 T cells.)

	MHC-I	MHC-II
Expression	Most cells	Primarily in antigen-presenting cells and in some specialized epithelial
Structure	A heavy transmembrane chain (~44 kd) together with β2-microglobulin (12 kd)	Two transmembrane chains α and β of ~30 kd
Peptide binding	Usually 8–10 residues in length	Normally large peptides, >15 residues
Peptide loading	In endoplasmic reticulum	In vesicles
Site of catabolism of the protein	Cytosol: proteasome	Vesicles: lysosomal
Auxiliary molecules	Tapasin, calreticulin	Invariant chain, DM
Biology	Antiviral and tumor immunity	Immunity to intracellular pathogenesis and foreign proteins
	Interaction with CD8 T cells	Interaction with CD4 T cells

TABLE 6.2. Comparison of Class I and II Major Histocompatibility Complex (MHC) Molecules

The APC interaction with T cells is an indication of the strong relationship between the cellular elements of the innate system of defense and the adaptive immune system. The innate system, represented by monocytes and macrophages, the family of dendritic cells (DCs), the natural killer (NK) cells, and the polymorphonuclear leukocytes, constitutes an early system of defense against a variety of microbes and foreign material (7,8). The innate system is the cellular system first identified by Eli Metchnikoff, a discovery that led to the first major controversy in immunology, centering on how immune reactions operated. Recognition of the microbe by the innate system is followed by a cascade of intracellular events leading to activation of the cells and the release of inflammatory molecules, including cytokines. These molecules produce inflammation and partially control the growth of the microbe. Probably the best example of the innate system operating alone can be found in mice with genetic abnormalities that result in their lack of development of lymphocytes. Such mice challenged with bacteria and viruses show partial resistance to the pathogens resulting from a variety of reactions that include phagocytosis, activation of leukocytes by cytokines, particularly interferon-g, activation of the complement system, and mobilization of leukocytes and sequestration of the pathogen (9).

In contrast to the innate system is the adaptive or lymphocyte system, represented by B and T cells with their antigen-specific receptors. We now recognize that both systems depend on each other and operate in a symbiotic manner (10). The APCs of the innate system by way of antigen presentation (and also by the release of cytokines) select, engage, and activate the T-cell adaptive system. The molecular basis of communication between both cell systems is through the MHC molecules during antigen presentation. Once activated after antigen presentation, the T cells release a plethora of cytokines that mobilize and activate the cells of the innate system, thus making the elimination of the pathogen a highly effective process, hence the term *symbiosis* to describe the interactions of the two cellular systems.

ANTIGEN PRESENTATION IN TISSUES AND IN THE THYMUS

Antigen presentation takes place at two stages in the natural history of a T cell. Mature T cells encounter APCs that have taken up antigen to which their TCR has specificity. This encounter can take place in lymphoid or in nonlymphoid environments, that is, in the extracellular spaces of many tissues: APCs, particularly DCs, and monocyte-macrophages, are found in all tissues and are constantly sampling their extracellular milieu. This encounter of APCs with antigen and the presentation of the peptide-MHC complex results in the selection of the T-cell clones, and with it, their expansion and activation. This encounter may take place between monocyte-macrophages or DCs, as APCs, and CD4 T cells or between B cells and CD4 T cells. The result is the reciprocal activation of both cells. In the case of macrophages and DCs, their activation is characterized by the release of cytokines and inflammatory radicals, and particularly with macrophages, in microbicidal activity. In the case of B cells, the result is B-cell expansion and differentiation with antibody formation.

However, T cells also encounter the peptide-MHC complex during the process of differentiation that takes place in the thymus gland (Chapter 5). There, the immature T cells bearing both CD4 and CD8—the double positive thymocytes—can interact with cells bearing MHC molecules. This interaction depends on the specificity of their TCR, which is expressed during differentiation as a result of rearrangements of the various gene segments that encode for it. The cells that bear MHC molecules are the epithelial cells of the cortex and the monocytes and DCs of the medulla. In the case of the thymus, their APCs are presenting peptides derived from the processing of autologous proteins. Foreign antigens enter the thymus in only limited amounts, if at all. Thus, the function of presentation in the thymus is to control the repertoire of immature T cells, whereas that of antigen presentation in the periphery is to select and activate the mature T cells (11,12). A thymocyte that expresses a TCR that does not have any degree of complementarity to the MHC-peptide complex eventually dies in the gland and does not peripheralize. Moreover, a thymocyte that expresses a receptor that matches perfectly with the ligand likewise is eliminated by a process now termed *negative selection,* identical to the central tolerance described in the classic experiments since Medawar's original work. The T cells that are selected are mainly those with TCRs that have affinities to self-MHC, but weakly for one of the self-peptides. However, such receptors have higher affinity for, but strongly against, a foreign peptide. These T cells mature and circulate among tissues and lymphoid organs, and they express a TCR that has affinity for self-MHC and against a peptide of a foreign protein.

These features of differentiation of thymocytes lead to the phenomenon of *MHC restriction* during antigen presentation; that is, the MHC, a gene complex with a high degree of allelic polymorphism, *restricts* the T cells that recognize the foreign peptides. This phenomenon was discovered in the early 1970s when either CD8 T cells or CD4 T cells were found to recognize only antigens presented by their own APCs (by their own MHC molecules) and not by APCs from another genetically disparate individual containing an unrelated allelic MHC molecule. MHC restriction was discovered in the experiments of Zinkernagel and Doherty when they tested cytolytic T cells against viral antigens (13). At about the same time, the same phenomenon was found for interactions of macrophages and T cells (14), as well as for B and T cells during antibody formation (15,16). The experiments of Rosenthal and Shevach, the first to show MHC restriction with macrophages, are presented in Table 6.3.

Macrophages		T lymphocytes (cpm × 10^{-3})		
Strain	PPD	Strain 2	Strain 13	Strain (2 × 13) F1
2	–	0.9	5.7	1.6
2	+	26.4	8.6	7.0
13	–	4.6	1.7	1.8
13	+	3.1	19.9	7.8
(2 × 13) F1	–	1.9	4.3	1.7
(2 × 13) F1	+	12.4	11.8	12.6

[a] The inbred strains of guinea pigs, which differ at their class II MHC gene locus, were immunized with complete Freund adjuvant. Their T cells were isolated and cultured with macrophages from normal guinea pigs in the absence or presence of PPD of *Mycobacterium tuberculosis*. Strain 2 lymphocytes responded only to PPD presented by macrophages of strain 2, and the same applied to lymphocytes from strain 13. Note the mild mixed lymphocytic reaction when lymphocytes from strain 2 or 13 are incubated with macrophages of strain 13 or 2, respectively.
Modified from Rosenthal AS, Shevach EM. Function of macrophages in antigen recognition by guinea pig T lymphocytes. *J Exp Med* 1973; 138:1194, with permission.

TABLE 6.3. Rosenthal-Shevach Experiment Showing Major Histocompatibility Complex (MHC) Restriction for the Presentation of Purified Protein Derivative (PPD)[a]

ANTIGEN-PRESENTING CELLS

For a cell to present antigen, it needs to (a) be able to take up the foreign molecule, (b) process the foreign proteins, (c) express histocompatibility molecules, and (d) express auxiliary molecules that foster the interaction with the T cell. The last requirement falls into three sets: adhesion molecules, costimulatory molecules, and cytokines that regulate T-cell function. We briefly comment on the APCs involved in physiologic interactions with T cells, which are the DCs, the monocyte-macrophages, and the B cells.

DCs have been the center of much attention (17,18). Derived from the blood monocytes, DCs are found in many tissues. Particularly important is their localization in lymphoid organs, where they form an antigen-trapping network in the deep cortex of the lymph nodes and in the periarteriolar lymphoid sheath of the spleen. DCs also circulate in small numbers. In the skin, an immature form of DC is found among epidermal cells, the Langerhans cell. Langerhans cells are the cells responsible for contact sensitivity: they take up antigen that enters through the skin, and they migrate through the local lymphatics into draining nodes, to localize to the deep cortex, where they present antigen to T cells (19). In the thymus, DCs are found in the medulla, where they present self-antigens, as described earlier. When they are isolated from tissues, DCs are heterogeneous and bear different surface markers. DCs have been divided into two major sets, myeloid and lymphoid, depending on the presence primarily of the CD8 a chain in the latter. Their interrelationship is the subject of much attention at this time (20).

DCs are the most effective cells in presenting antigen among the APC family, and they are responsible for the initial recruitment and activation of the T cells. DCs are particularly effective in interacting with T cells by favoring contacts by way of thin cytoplasmic extensions, called veils or dendrites: DCs express high levels of MHC molecules, as well as adhesion and costimulatory molecules, and they release early cytokines that modulate T-cell activity. In culture, DCs have proven to be highly effective in stimulating both CD4 and CD8 T cells (17,18). In fact, DCs are also effective in stimulating allogeneic T cells and are thought to be the central cell in sensitizing against organ allografts in transplantation reactions.

Monocytes can be made to differentiate *ex vivo* as well as *in vivo* into DCs, by specific cytokines, particularly granulocyte-macrophage colony-stimulating factor (GM-CSF) (21). The easiest procedure for isolating DCs is to generate them from cultures of monocytes or bone marrow stem cells by the addition of GM-CSF together with IL-4 (22). Other cytokines that favor their survival include TRANCE, a member of the tumor necrosis factor (TNF) family (23). Evidence indicates that monocytes differentiate to DCs as they cross endothelial beds (24).

DCs pass through different stages of maturation in their antigen-presenting function. The “immature” DCs are actively phagocytic but are less effective in processing (25). The “mature” DCs result from their stimulation by cytokines such as interleukin-1 (IL-1) and TNF-a, endotoxins, double-stranded RNA, apoptotic cells, or gram-positive or gram-negative bacteria (22,23,25,26 and 27), or even by T cells through interaction with their CD40 ligand (28,29). Mature DCs are less phagocytic, but yet they are highly effective in presenting antigen. Thus, in DCs, the two stages of presentation, uptake and presentation, can be dissociated.

DCs are mobilized during antigen presentation and represent the cells responsible for the recruitment and early activation of the naive T cell (30,31 and 32). The mobilization of T cells and DCs involves complex interaction among chemokines produced by various cells in the lymphoid organs. Some features of this complexity are now being identified. For, example, as DCs mature, they upregulate the chemokine receptor CCR7 that directs their migration to T-dependent areas of lymph nodes and where the two ligands SLC and ELC are being generated. As mature DCs accumulate, they themselves produce these two chemokines that, in turn, bring in more activated T cells (30,31 and 32).

Macrophages also serve as presenting cells. In fact, the first cells to be studied as APCs were peritoneal macrophages from mice (10). As with DCs, macrophages also derive from blood monocytes (33). The major cytokine that favors the monocyte differentiation to macrophages is macrophage colony-stimulating factor (M-CSF). Thus, the cytokine milieu is the key element in regulating the differentiation of monocyte to either DCs or to macrophages. In tissues, macrophages differentiate further, to express particular functions, such as happens in bone, with the osteoclast, or in lung, with the alveolar macrophages. Macrophages have other functions besides antigen presentation in that they are actively involved in uptake and degradation of particulate material, in tissue remodeling, and in cytocidal activity. Macrophages are also highly secretory cells, releasing cytokines such as IL-12, IL-1, and TNF that regulate lymphocyte function. Macrophages bear a large array of surface molecules that allow them to interact with many different microbes. Macrophages, like DCs, are also mobilized to sites of infectious foci where they can be activated by T-cell cytokines. Highly responsive to interferon-g, macrophages become cytocidal to intracellular microbes by way of release of reactive oxygen and nitrate intermediates. Indeed, the activated macrophage is the central cell in bringing about resistance to intracellular pathogens. Thus, macrophages form the cells of delayed hypersensitivity reactions and of infectious granulomas. Macrophages express class I and II MHC molecules. Their expression is also highly regulated by interferon-g,

which increases it by severalfold (10).

B cells express constitutively both sets of MHC molecules and can present antigen, particularly B cells that bind to their surface-bound antibody molecules (34,35). Bound to surface immunoglobulin (Ig), the complex is effectively internalized and can be processed so peptides can be selected and bound to class II MHC molecules.

Concerning B cells, the function of presenting antigen is the first step in the interaction between B and T cells that results in antibody formation: in a two-step process, the B cell first binds, internalizes, and processes the antigen and, in a second step, presents the peptide-MHC complexes to the CD4 T cells. The end result is reciprocal activation: the T cell proliferates and differentiates, and the B cell undergoes clonal expansion and differentiation to an antibody-forming cell. This two-stage interaction explains the classic results of immunization with globular proteins. Immunization with globular proteins induced mostly antibodies that recognized conformational determinants of the protein; that is, the protein was recognized before it was handled by the normal catabolic processes, whereas the T cell recognized linear determinants, after intracellular processing, as we now understand during antigen presentation (10). Indeed, the native antigen selected those B cells with high-affinity antibody molecules that interacted with the antigen molecule in its unfolded form. Once it was processed, the T cell then recognized a linear segment of the molecule in the form of a peptide bound to class II molecules.

B cells vary in their presenting activity depending on their stage of differentiation. Immature B cells tend to be poor APCs, but their activation improves this function, most likely because of their increased expression of adhesion and costimulatory molecules. In lymphoid tissue, the situation that is favored is of a first interaction of antigen molecules with the DCs of the deep cortex leading to activation of CD4 T cells, followed by the interaction between B cells and T cells, as described earlier (36). The B cells may capture the antigen draining into the deep cortex of the lymph nodes (or into the periarteriolar lymphoid sheath in case of the spleen). Investigators have also suggested that macrophages or DCs can present unprocessed antigen to the B cell (37). Regardless, the first interaction of B cells with the activated T cell takes place outside the B-cell follicle (38,39). Once the B cell presents to the CD4 T cells, it becomes competent to translocate into the follicles, where subsequent activation takes place, with differentiation and class switching. The interaction in the follicles involve the B cells with follicular DCs that capture antigen by way of complexes with antibody and complement proteins, in a process independent of MHC presentation (39). Some T cells have been found in the follicles, but their precise role at that site is not clear.

Aside from the three sets of APCs described earlier (i.e., the “professional” APCs), other cells may have the potential to present antigen. Under normal conditions, most epithelial and mesenchymal cells do not express class II MHC molecules, and their levels of class I molecules are low. In humans in particular, class II proteins expression is found in some endothelia and some epithelia. For example, some of the cells of the renal proximal tubules or the gastrointestinal mucosa express a small level. This lack or low level of expression of class II and the lack of adhesion or costimulatory molecules ensure that most cells in tissues do not present antigens, therefore avoiding autoimmunization (40). Investigators have speculated that abnormal tissue conditions that result in inflammation and interferon-g production may make these cells effective in presentation and could be an element in autoreactivity. Whether this is the case has yet to be determined.

STEPS IN ANTIGEN PRESENTATION

Antigen presentation is made up of several steps. At the level of the APC, the process starts with the internalization of the protein antigen, its traffic through intracellular vesicles, and its processing. At some point during the intracellular sojourn of the protein, the products of processing meet with the class II MHC molecule, and the assembly of the peptide with class II MHC takes place. Eventually, the MHC-peptide complex is transported to the plasma membrane. Once the peptide-MHC complex—the TCR ligand—is displayed, the issue becomes one of selection for a T-cell clone with a TCR that has complementarity to the ligand. The issue of how in a clonal system such encounters take place has not been settled, and it probably involves complex changes at the level of the tissue environment by cytokines and chemokines that may regulate the flow of T cells through networks of APCs (see the previous section).

For antigen presentation to be effective in activating T cells, several molecular interactions need to take place at the surface of both interacting cells. The essential one that gives specificity to the interaction is, of course, that of CD4 T cells recognizing through their TCR the peptide-MHC complex. In this initial interaction, the CD4 molecule plays an important role because it interacts with class II MHC molecules and fosters the binding of the two cells. (CD4 molecules are also involved in the intracellular scaffolding of molecules around the TCR, and this leads to signaling of the cell to proliferate and express different cytokine genes.) Other interactions that are required for optimal T-cell activation include those among adhesion molecules and among costimulator molecules. Adhesion molecules most prominently involved are those involving the b_2 integrin molecules. Costimulators consist of membrane molecules that regulate the final fate of the T-cell–APC interaction. Finally, during the APC–T-cell interaction, cytokines are released that influence each of the interacting cells.

Uptake and Processing

Peptides that bind to class II MHC molecules are generated from proteins that enter the APC as soluble proteins, as part of large macromolecules, or as constituents of microbes. Processing requires the internalization of the protein antigen. No pathway of entry of the protein antigen in the APC is unique in the sense of donating or not donating peptides for complexing with class II MHC molecules, although the efficiency may vary (10,35,41,42). Antigens can enter the cell by fluid-phase endocytosis or by binding to cell-surface receptors that include the Fc and C3 receptors (which bind to antigen-antibody complexes, containing Ig or C3, respectively), or to a variety of surface ligands, such as scavenging receptors or mannose receptors. In the case of the B cell, binding to the extracellular protein by its surface-bound antibody molecule markedly increases the amount taken into the cell and improves the degree of presentation (35). Generally, the higher the amount of antigen entering the APC, the more peptide-MHC complex is generated.

Processing is a fast event. For most protein antigens, the peptide-MHC complexes are detected on the membrane of the APC, within the first hour after its uptake (10,43,44 and 45). The biochemical steps that take place leading to the peptide fragment bound to the MHC molecule may depend on the structural and chemical features of the protein antigen: they could involve partial fragmentation of the protein before or after a step of denaturation of the protein. The protein antigens travel through vesicular compartments that are progressively acidic and that contain cathepsins or acid hydrolases, many of broad specificity (41). Inhibition of lysosomal catabolism usually translates into a reduction in the amount of peptide-MHC complex that is generated (41,46). A substantial amount of the protein processing takes place in a deep vesicular compartment in the APC. A situation favored by some investigators is that the protein first unfolds, acquiring more conformational flexibility, and the MHC then binds to segments that contain a sequence favored for binding (47). Subsequently, the portions of the protein that extend beyond the combining site of the MHC molecules can be trimmed by amino and carboxy peptidases.

Peptides bound to MHC molecule are highly protected from intracellular catabolism. Indeed, although most peptides or denatured proteins are extensively catabolized to the level of amino acids, an MHC-bound peptide for the most part survives the sojourn through highly acidic, proteolytic vesicles and reaches plasma membrane. Overall, the efficiency of processing tends to be low; most internalized proteins are catabolized, and only a few of those internalized associate with MHC molecules (43).

The possibility that protein processing by APC involves a first step of internalization of the protein followed by its release from the APC to the extracellular milieu does not appear to take place with most antigens. However, cellular antigens from an nonpresenting cell can be presented by APCs, in what is termed *cross-priming.* Cross-priming is a term first used by Michael Bevan when testing responses to minor histocompatibility antigens: the antigens from one cell could be transferred to a presenting cell (48). Cross-priming has been studied extensively in the response of peptides presented by the class I MHC system and also takes place in the class II system (49). (Cross-priming may be particularly important in the presentation of allogeneic cellular antigens in transplantation reactions.) How the transfer takes place may vary and is not entirely clear. The antigen from the donating cell may be released as a macromolecule or as part of a fragment taken up by the APC, or the whole cell may be phagocytosed by the APC and the antigens processed (27,50). Indeed, necrotic or apoptotic cells or their fragments can be internalized by APCs, and their antigens can be processed and presented.

Role of the Major Histocompatibility Complex

The role of the MHC molecules is to bind peptides creating the structure, the peptide-MHC complex, that engages the TCR. Class II MHC molecules are made up of two chains, the a and b chains (of about 30 and 25 kd, respectively), that are assembled in the endoplasmic reticulum (ER) and are transported after a sojourn through the Golgi complex and the trans-Golgi network into endocytic compartments. Involved in the transport of the ab dimer is the invariant chain (Ii), so called because in contrast to the a and b chains, it exhibits no genetic polymorphism. (The b chains are highly polymorphic; the a chain has limited polymorphism in humans, but it does show allelic differences in the mouse. The selective pressure for the high degree of allelism is peptide binding; indeed, the amino acids responsible for the allelic differences are represented in the areas of the molecule that form the combining site for peptides.) Ii expresses various physical forms brought about by differential splicing of the gene, as well as by posttranslational changes (51). However, most of the protein is represented in a 33-kd single chain. In the ER, Ii forms a complex with the ab dimers with three chains associating with three dimers (52). A segment of the Ii actually folds over the combining site of the dimer. This segment is termed CLIP, for class II–associated invariant peptide, and encompasses residues 83 to 109 (51,53). The interaction of Ii with the ab dimer takes place through various sites in the Ii proximal and distal to the CLIP segment. During transport through ER-Golgi complex, the CLIP segment inhibits binding of peptides and therefore protects the combining site until it reaches an endocytic compartment (53). Ii, a type II transmembrane molecule, contains cytoplasmic motifs that target most of the complexes to endocytic compartments, this being one of its important functions (41,52,54). (There is a minor traffic route by which the I-ab is transported to plasma membrane and is rapidly internalized.) Ii is degraded in endocytic compartments through the actions of various cathepsins, the acidic proteolytic enzymes typical of lysosomal vesicles (41,55,56). Although several cathepsins are involved in a stepwise process of degradation, cathepsin S, and, in some APCs, cathepsin F and L are major enzymes in

the final process of degradation of Ii (55,56,57 and 58). In thymus, cathepsin L plays a role in Ii degradation (58). Degradation of Ii allows for the ab dimer to become competent to bind peptides.

Other proteins help in the assembly of the peptides with the ab dimer of class II. Most prominent is the HLA-DM or, in the mouse, H-2DM molecule. From here on, we refer to both as DM (59,60 and 61). The gene encoding the a and b chains of DM are found in the large MHC gene complex (62,63). DM has a general structure similar to a class II MHC molecule. However, structural analysis shows that the combining site does not contain peptides because the two helices come near each other to close the groove (64,65). In the APC, DM is localized to the same vesicular compartment as class II molecules. DM assembles with the CLIP–class II dimer in ways that are unclear at this time: nonetheless, this association results in the faster release of the CLIP peptide (66). The CLIP peptide has relatively weak binding for the ab dimer of class II, but its spontaneous rate of dissociation depends on particular class II alleles. By DM's favoring the release of CLIP at a faster rate, the dimer becomes competent to bind to polypeptides in the vesicular compartment (66,67 and 68). Thus, DM can be viewed as a catalytic protein that favors the dissociation or off rate of peptides bound to class II molecules (69). The stronger the peptide interaction with class II, the lesser is the effect of DM on the complex. Thus, the effect of DM is to edit the peptides selected by class II molecules. In the absence of DM, the class II molecules are restricted in the diversity of peptides they contain, because they are mostly occupied by CLIP peptides. Another protein, DO, has also been identified (70); it associates with DM and perhaps regulates the effective free concentration of DM available for peptide exchange (71).

The vesicular compartment in which Ii proteolysis takes place and the proteins are processed has been the subject of much analysis (72,73 and 74). In general, class II molecules are found in various vesicular compartments, including vesicles involved in the recycling of membrane proteins. At each of the various sites, class II molecules have the potential to bind peptides. Peptides or unfolded proteins can bind to MHC molecules in early endocytic vesicles where class II recycling may be taking place. However, deep vesicular compartments or prelysosomal vesicles containing lysosomal enzymes contain class II molecules with Ii and DM. It is believed that in these compartments, termed MIICs, Ii is degraded and much of the peptide assembly takes place. MIICs are characterized by containing multilamellar profiles (75).

The class II molecules bind peptides by their combining site found in the membrane distal domains of both their a and b chains (Fig. 6.1). The combining site has features in common with those of the class I MHC molecule (76,77,78,79 and 80). It is made up of a platform of b-pleated sheets surrounded by two a helices. The peptide sits stretched between the two helices. Most of the amino acids of MHC molecules responsible for allelic polymorphisms are located either in the b sheets or in the a helices. The fine ultrastructure noted by x-ray crystallography has identified the main features responsible for the binding of the peptide. The class II–bound peptides are found in an extended polyproline-type helix in which some side chains are contacting the residues in the helix or the b-pleated sheets while some residues are solvent exposed to contact the TCR. Peptides bind to class II MHC molecules through several chemical interactions. A large network of hydrogen bonding involves the peptide backbone with conserved amino acid residues along the combining site. In general, the extent of contribution to binding energy of the hydrogen bond network depends on the length of the peptide. In contrast to peptides bound to the class I MHC combining site, peptides bound to class II MHC are usually long, 14 residues or more. A key factor in binding peptides is the interaction between side chains and sites or pockets in the combining site that are formed by the polymorphic residues. These side chain interactions determine the degree of binding and the sequence motif of the peptides that class II molecules select. For many class II molecules, a single side chain from the peptide can be responsible for the binding and selection of peptides. This has been shown to happen with HLA-DR1 (81) and I-A^k (82), in which a single residue at the P1 pocket can be responsible for the binding (a tyrosine or an aspartic acid, respectively) (47). Although other peptide side chains may not contribute to binding energy, they will or will not permit the peptide chain to fold properly in the combining site (83).

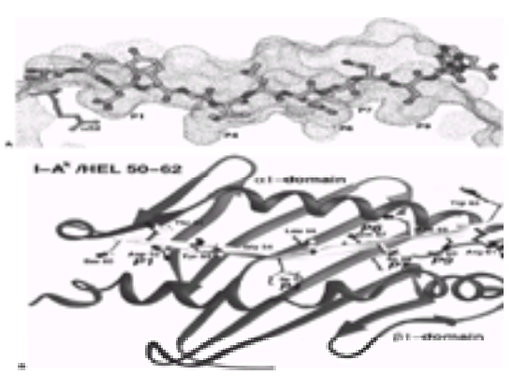

Figure 6.1. Peptide 52-61 of hen egg white lysozyme binds to I-A^k. **A:** Side view of the peptide. **B:** Ribbon diagram of the peptide as it is found on the I-A^k protein. The sequence of 52-61 is DYGILQINSR. The Asp52 residue is responsible for the selection of the peptide from HEL as well as in the binding affinity. Asp52 forms a salt-bridge with Arga52 situated at the base of the P1 pocket. Mutation of Asp52 to Ala52 reduces binding affinity severalfold. (Fremont DH, Monnaie D, Nelson CA, et al. Crystal structure of I-A^k in complex with a dominant epitope of lysozyme. *Immunity* 1998;8:305–317, with permission.) (See Color Figure 6.1A.)

The interactions between the TCR and the peptide-MHC complex have been examined at the structural level by x-ray crystallography using TCR complexed to either class I or class II peptide-MHC complexes (2,84,85,86 and 87). Some structures show the TCR in a diagonal position relative to the peptide, whereas in other cases, the position is orthogonal to it. The TCR contacts residues of the peptide that are solvent exposed mainly through the complementary determining regions that show most variability, the CDR3a and b. The important feature is that regions of the TCR contact the peptide, whereas others contact the MHC; indeed, both MHC and peptide form part of the interacting face with the TCR, an explanation for the phenomenon of MHC restriction mentioned earlier (2).

Class II Major Histocompatibility Complex Binding

The assembly of peptides with MHC induces changes in the macromolecular complex that depends on the binding features of the peptide. With strong binding peptides, the complex becomes highly stable (88,89 and 90) and resistant to proteolytic enzymes (91,92). In contrast, weak peptides form more labile complexes in which the dimer becomes more sensitive to proteolysis. These features are of biologic importance in that they determine the extent to which the complex survives in the APC, that is, its half-life, which, in turn, reflects in the immunogenicity of the complex in the APC surface (47).

The binding of peptides to class II MHC molecules can be studied in free solution using purified proteins and peptides (1,93,94). The combining site of the MHC molecule can accommodate only a single peptide. This finding implies that for these molecules to have biologic significance, they must bind to a wide diversity of them. This is the case because the specificity for peptides of any MHC molecule is broad (47,94,95,96 and 97). The binding affinities depend on the peptide, usually in the range of nM to mM. Some peptides do not bind. Binding can have slow on rates but extremely slow off rates. Indeed, for some MHC-peptide combinations, the reactions are practically irreversible. By using peptides in which amino acids are changed at each position, usually with alanines, the identification of the key residues responsible for the binding can be made (47).

The biologic significance of peptide binding is clear. From complex proteins, several epitopes are usually selected (see later), and this selection establishes the degree of immunogenicity of the protein. Historically, it is interesting to mention how this physiologic role of MHC was identified. Early observations made primarily by McDevitt, Sela, and Benacerraf indicated that some peptides of limited heterogeneity did or did not induce responsiveness, and this property was linked genetically to the MHC class II genes (98,99 and 100). McDevitt and Chintz went on to identify the genes locus responsible for the control as that encoding for class II MHC molecules (101). These results were subsequently explained by the interaction between peptides and MHC molecules, that is, by the formation, or lack thereof, of the peptide-MHC complex (93). These studies led to the discovery of the role of MHC in normal immune responses to proteins, a function distinct from its role in transplantation reactions where this gene locus was first identified.

Class II Major Histocompatibility Complex Selection of Peptides

From a protein that is taken by APC, many peptides can be generated that become associated with a class II MHC molecule. The MHC alleles determine the composition of the peptides that are selected. This “determinant selection” was first indicated in the now classic studies of Barcinski and Rosenthal when they evaluated the response to insulin by guinea pig macrophages: each allelic form of the guinea pig class II system presented different segments of the molecule (102). These observations were later confirmed by other investigators and were extended noticeably as the various peptides reactive with T cells could be identified. Thus, from a single protein, various segments are selected for processing and are found expressed as peptides bound to MHC (47,103,104). A peptide that is not selected by one allele may be selected by others (105). Overall, the most important factor so far identified in peptide selection is the MHC genotype. From a protein, some peptides may be expressed at a high density, and these are chemically dominant, whereas others may be expressed severalfold lower (47). Presumably, those peptides that are strongly represented are those that stimulate more T-cell clones.

MHC molecules have been isolated from APCs, and the peptides bound to them have been released and studied (106,107,108,109 and 110). The method of choice to

examine for MHC-bound peptides is electrospray tandem mass spectrometry, in which peptides, even at the femtomole range, can be identified and sequenced (109,111) (Fig. 6.2). The procedure consists of isolating APCs, releasing by detergents the MHC molecules, and purifying them by immunoaffinity chromatography with anti-MHC antibodies bound to insoluble matrices. When these purified MHC molecules are denatured, the peptides are released and can then be fractionated, usually by reverse-phase high liquid pressure chromatography, and identified by mass spectrometry combined with bioassays. This technical approach has identified hundreds of self-peptides bound to MHC molecules. Many peptides are represented extensively, and these usually have binding motifs that favor the interaction. However, many peptides are at low density of a few per APC. In our own experience studying the I-A^k molecules, about 60% of the peptides are found in few numbers per APC, whereas the remaining range up to a few thousand molecules (47). In essence, the MHC molecules do not discriminate between foreign peptides and self-peptides. Both self-peptides and foreign peptides share the same binding properties (and, in fact, compete among each other). For example, the major dominant epitope of chicken lysozyme antigen for the murine I-A^k binds strongly, and so does the murine equivalent peptide. The final self-nonself discrimination of a peptide therefore is made by the T cell.

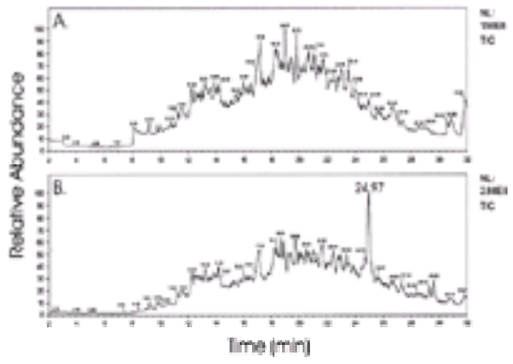

Figure 6.2. Chromatogram of peptides isolated from antigen-presenting cells (APCs) bearing I-A^k molecules. **A:** The line C3.F6 (a B-cell line) was cultured, the cells were lysed, and the I-A^k molecules were isolated. Shown are the profiles of the most abundant peptides. Many of these autologous peptides bear Asp or Asn at the fourth or fifth residue from the amino terminus. **B:** The cell was cultured with lysozyme. At 24.97 minutes, there is a large peak represented by HEL (48,49,50,51,52,53,54,55,56,57,58,59,60,61 and 62) (Fig. 6.1). (From Gugasyan R, Vidavsky I, Nelson CA, et al. Isolation and quantitation of a minor determinant of hen egg white lysozyme bound to I-A^k by using peptide-specific immunoaffinity. *J Immunol* 1998;161:6074–6083, with permission.)

In the class II system, in contrast to the class I, peptides are usually selected as families (47,107,108,109,111). A family can be made up of up to 30 members and consists of peptides having a “core” segment and “flanks.” The core portion is about 9 residues in length and binds to the MHC combining site, from the P1 to the P9 pockets that constitute the allele specific sites. Flanks in the amino-terminal and carboxy-terminal are of variable lengths, and this variation determines the number of peptides in a family. Structurally, the binding sites of the class II MHC molecules are more open at their ends, so peptides can extend beyond the end pockets. Although the core segment is responsible for the selection, the extensions or flanks are of considerable importance: the flanks contribute to binding affinity of peptides (82), specificity of the TCR (112), and to the persistence of the peptide-MHC complex in the APC (113).

The peptides bound to class II MHC derive from three sources of proteins: those from the media where the APCs are cultured, those that are constituents of the vesicular system of the APCs, and, perhaps surprisingly, those normally residing in the cytosol. The cytosolic peptides found associated with class II MHC molecules are long, like those derived from exogenous proteins. Clearly, the pathway from cytosol into the class II MHC system is distinct from that taken by peptides that bind to the class I MHC molecules. These peptides are of limited size—eight to ten residues—and are processed from cytosolic proteins in proteasomes and transported to the ER by way of the transporters of antigen processing (TAP) transporters.

Binding of Autologous Peptides

The presence of self-peptides bound normally to MHC proteins is, of course, of major importance in the context of antigen presentation and the cause of autoimmune diseases. The current thinking is that autoimmune diseases develop as T cells that escape deletion in the thymus recognize the self-peptides expressed by the MHC molecules of APCs located in the tissues. Depending on the particular MHC genotype, some self-peptides may be preferentially displayed over others, and these may be the target of recognition because of their amounts bound to MHC, or because of other factors, such as local tissue conditions induced by inflammation and cytokines. Indeed, autoimmune diseases have an association with a particular MHC allele, that is, individuals with a particular allele will have a higher relative risk in developing the disease (114). A most thoroughly discussed example is autoimmune or type I insulin-dependent diabetes mellitus (IDDM). The MHC gene complex is most strongly linked to susceptibility to IDDM. Persons bearing the DR3 and DR4 alleles show a relatively higher risk of developing IDDM. Genetic studies have shown that this linkage is most strong with DQ alleles that show changes in one or two key residues of the b chain (115). Similar changes are found in the I-A^{g7} class II molecule of the mouse NOD, a strain of mice that spontaneously develops IDDM (116). The diabetes-susceptible class II molecules are distinguished by having a serine instead of an aspartic acid at residue 57 of the b chain; Asp57 found in most other alleles forms a salt bridge with Arg76 in the a chain. These two residues help to form part of the P9 pocket in the combining site for peptides (117,118). Although the identification of the peptides responsible for triggering IDDM remains unidentified, the spectrum of self-peptides displayed by the non-Asp 57 alleles (i.e., those with a propensity for IDDM) is markedly different from the wild type. The non-Asp prefers peptides in which an acidic residue is present to interact at the P9 site and ion pair with the unpaired Arg 76 residue.

Continuing to take autoimmune diabetes as a representative example, the situation for presentation would be as follows: the b cells do not express class II MHC molecules and therefore cannot be the presenting cell: however, the antigen passes from b cells to those APCs found in the draining peripancreatic nodes or in the islets. The nature of this antigen passage is unclear, but the presentation that activates the autoreactive diabetogenic T cell takes place in the APCs at the local sites (119). Of course, many events have to come together not only to activate the T cell but also to bring about the effector side of the reaction. Presentation of the self-b cell antigen is only the initiating event.

ANTIGEN-PRESENTING CELL–T-CELL INTERACTION: CELLULAR EVENTS

Adhesion and Synapse Formation

During presentation, close contact exists between the T cell and the APC (120,121 and 122). T cells remain associated with the APC for several hours, during which time the intracellular events that lead to their activation and expression of different gene programs are taking place. The T cell eventually leaves the APC and enters DNA cell cycle and undergoes differentiation. Investigators believe that during the time of contact there are repeated interactions of the TCR with the peptide-MHC complex (122). Certainly, TCRs are lost from the T-cell surface in amounts unrelated to that of peptide-MHC complex displayed on the APC.

The amounts of peptide-MHC complex required to trigger the T cells depend on the biology of the T cells, indeed, on their state of differentiation and their past experience, that is, whether naive or memory T cells. The immature T cells in the thymus gland, those expressing both coreceptors CD4 and CD8, are unusually sensitive to peptide-MHC complexes and can undergo apoptosis by engagement of as few as ten or fewer. In our own studies using hen egg-white lysozyme, we directly calculated as few as three MHC-peptide complex per APC (123,124). This sensitivity is expected if antigen presentation in the thymus is the means to eliminate T cells that are autoreactive to circulating proteins, if one takes into account the blood–thymus barrier and the relatively inefficiency of processing.

In contrast, the mature T cell that has not encountered antigen requires a few hundred complexes to be stimulated; however, activated T cells require many fewer. So although 3 complexes per APC induced death of double-positive thymocytes, a mature T cell required about 300 complexes, whereas an activated T cell required about 30 to 50 per APC (125,126) (Fig. 6.3).

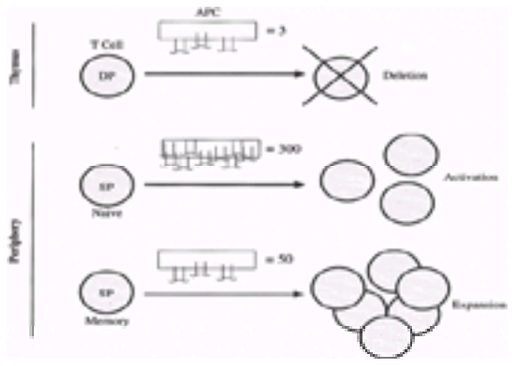

Figure 6.3. The amount of peptide–major histocompatibility complex (MHC) required to activate T cells depends on the state of the T cell. In the thymus, the amounts of complexes that delete double-positive ($CD4^+$ $CD8^+$) T cells is extremely low. This amount is about 100-fold more for stimulating mature T cells. Thus, a biochemical margin of safety protects the individual from self-immunization against peptides expressed in peripheral lymphoid tissues. An activated T cell requires fewer complexes. (Data from Peterson DA, DiPaolo RJ, Kanagawa O, et al. Negative selection of immature thymocytes by a few peptide-MHC complexes: differential sensitivity of immature and mature T cells. *J Immunol* 1999;162:3117–3120; and Peterson DA, DiPaolo RJ, Kanagawa O, et al. Quantitative aspects of the T cell repertoire that escapes negative selection. *Immunity* 1999;11:453–462.)

The interaction of the T cell with the APC results in a rapid reorganization of the molecules in both interacting cell surfaces, in what is termed the *immunologic synapse* (127). During the contact between the two cells, the TCR needs to interact with the few peptide-MHC complexes among plasma membrane proteins of different sizes and structures. Shortly after the cells come together, the center of the contact area of the T cell is occupied by the TCR forming an extensive cluster or aggregate that is surrounded by other molecules on the outer side (128,129,130,131 and 132). On the APC side, the center is occupied by the cluster of peptide-MHC complex (128). This central cluster also contains CD28 and CD4 molecules and is surrounded by the intercellular adhesion molecules (ICAMs). This reorganization of membrane molecules allows for the segregation of molecules that differ greatly in their dimension and otherwise would have difficulty in associating with their complementary protein. Thus, in the synapse, the small TCR can then associate with the MHC spanning a distance of about 15 nm. In contrast, the ICAM interaction with the integrin lymphocyte function antigen-1 (LFA-1) spans about 40 nm. The same situation develops with the long CD45 molecules. This reorganization of plasma membrane molecules in the synapse allows for more effective contact and takes into account the relatively low density of peptide-MHC complexes as well as the low affinity of a TCR for the complex. Indeed, in solution, TCRs bind to peptide-MHC complexes with affinity constants of about 10^{-4} to 10^{-5} M (129). The clustering of TCRs at the synapse creates a matrix that enhances binding by cooperativity of binding sites. Probably the synapse allows for continuous signaling, as well as for the reorganization of the cytoskeleton and the polarization of the T cell. Evidence indicates that the molecule CD28 is important in the reorganization that constitutes the synapse (122,132).

Costimulation and Cytokines

Important in the interactions between CD4 T cells and the APCs are certain auxiliary molecules that favor and regulate the two interacting cells. Two important features to consider in this discussion are the roles of the various membrane or soluble secreted molecules in the regulation of the two interacting cells and the interrelationships among them, in time and after various stimuli, important for the outcome of antigen presentation. The situation favored by many investigators is that the expression of the peptide-MHC complex as a result of antigen processing and selection by the class II molecules is then followed by the selection and engagement of the appropriate T cell, issues discussed earlier. The interactions that follow require the engagement of the costimulatory or auxiliary molecules that are normally expressed at low levels on either the APC or the T cell. The increased activation of the family of costimulatory molecules can be accomplished by two routes. The first route is a result of the antigen itself (e.g., a microbe), which may have properties that activate the APC to release cytokines and to express costimulatory molecules. The second route is by the interaction of the TCR-peptide-MHC complex, which, depending on amount, stimulates the APC to increase costimulatory molecule expression and to release cytokines. Involved here is the CD40 molecule of the T cell. Thus, the nature of the antigen and its amount become critical for allowing antigen presentation to be productive (Fig. 6.4).

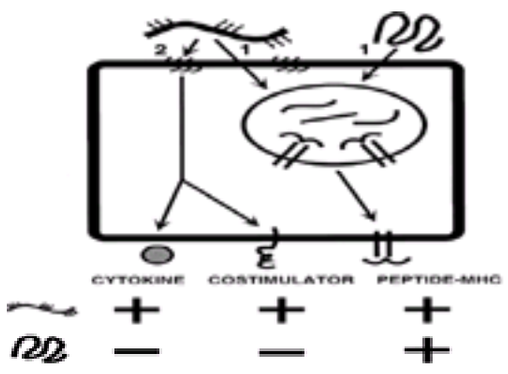

Figure 6.4. Differences in presentation of pure proteins or proteins from microbes. A bacterium **(left)** interacts with Toll-like receptors (TLRs) of the antigen-presenting cell (APC) and stimulates the APC (marked as *2)* to release cytokines and to express costimulators. The protein is processed (indicated as *1)* in vesicles and yields peptides bound to class II major histocompatibility complex (MHC) molecules. In one example, a protein **(right)** enters the APC by fluid-phase endocytosis: it is catabolized to yield peptides, but by itself the protein does not stimulate the APC. In the latter case, interaction with the T cell CD40L is required to activate the APC to express costimulators and cytokines.

Costimulator molecules stimulate T cells once the TCR-MHC interaction has taken place. Although several costimulator systems exist, we mainly consider the CD28 molecules on the T cell, which interact with the B7-1 and B7-2 molecules on the APC. We also review the interactions between another pair of critical molecules, the CD40 ligand (CD40L), which is found on T cells, and CD40 on the APC membrane.

Interactions of CD4 T cells with APCs under situations in which costimulator molecules are absent or their function is blocked result in a weaker T-cell response. These results have led to the *two-signal hypothesis,* which states that the T cell requires two fundamental interactions for activation, one involving the TCR with the peptide-MHC complex and the other involving costimulatory molecules (133). In culture, T cells that are exposed to the first signal (usually in the form of antibodies to the TCR or its associated molecules like CD3) do not proliferate well and become unresponsive because of poor production of IL-2 (134). These T cells are thought to be “anergized.” Anergy does not develop when the CD28 molecule of the T cell is engaged, either by antibodies to it or, physiologically, by engaging the B7-1 and B7-2 molecules of the APCs (134). The relationship of anergy as induced in culture to forms of tolerance *in vivo* is not definitively established (135). Indeed, mice with genetic ablation of B7-1 and B7-2 or of CD28 have defects in T-cell responses, but the T cells are usually not anergized. Nevertheless, engagement of CD28 is important and fundamental for T-cell responses that take place during antigen presentation.

B7-1 and B7-2 (i.e., CD80 and CD86, respectively) are two molecules of the Ig superfamily expressed in low amounts on APCs. This low expression is noticeably augmented by interaction of APCs with cytokines or with microbial products (136,137). Their level also increases during interaction with the CD4 T cells during presentation by the class II–peptide complexes, in a reaction that involves two other important pairs of molecules, the CD40L of the CD4 T cell and the CD40 of the APC (28,29,138,139 and 140). Thus, in a resting situation, the APC is in a relatively dormant state regarding its expression of the molecules involved in presentation. The interaction with the antigen or the T cell regulates the APC and, in turn, activates the T cell.

CD28 is a homodimer with a single Ig-like domain capable of interacting at relatively low affinity with the B7-1 and B7-2 molecules. Engagement of CD28 favors certain cellular and metabolic responses, which include fostering the T cell–APC adhesion, regulating the formation of the synapse, as discussed earlier, and transducing intracellular signals by the phosphorylation of intracellular molecules including the tyrosine kinases lck and itk. CD28 can also activate the jun pathway as well as nuclear factor-kB (NF-kB). Thus, CD28 engagement appears to stimulate multiple metabolic pathways in the T cell (141,142 and 143). CD28 engagement also promotes T-cell survival, most likely as a result of induction of the antiapoptotic molecule bcl-xL (144). Finally, B7-1 and B7-2 also engage the CTLA-4 molecules of T cells in an interaction that stops T-cell activation (136,137). CTLA-4 (CD152) is expressed in small amounts for a brief period, late after T-cell stimulation (145). Genetic ablation of its gene results in uncontrolled T-cell proliferation (146).

Other molecules are involved in the regulation of the T-cell response during the interaction with the APC. Included here are the CD2 molecule of the T cell that also confers costimulation similar to CD28 (147). CD2 is a member of the Ig superfamily and interacts with, on the APC side, LFA-3 (in humans) and CD48 (in the mouse).

The CD40 molecule is a member of the TNF receptor family and binds to its ligand the CD40L (or CD154), with homology to TNF and expressed as a trimer. CD40L is expressed in the resting T cells in small amounts, but it increases during antigen presentation (148,149). It interacts with the CD40 molecule expressed on B cells, DCs, or monocytes. This interaction results in important changes on the side of the presenting cell (28,29,138,139,140,150). In the case of the B cells, it results in their activation, involving both proliferation and antibody class switching (151,152). In fact, the important role of the CD40L was discovered from studies of patients with the immunodeficiency termed hyper-IgM syndrome (149). The disease is caused by mutations in the gene encoding for the CD40L that result in nonfunctional proteins. These patients produce few IgG antibodies and consequently suffer infections with extracellular bacteria. The importance of the CD40L-CD40 interaction is found during antigen presentation involving B cells, as well as DCs and monocytes-macrophages. With these APCs, depending on the antigen, as mentioned earlier, the interaction modulates the expression of the B7-1 and B7-2 expression as well as the release of cytokines.

Finally, during the APC–T-cell interaction, cytokines are released both by the APC and by the T cell. These cytokines profoundly influence the response to antigen presentation. Particularly critical is IL-12, which prepares the responding T cell to express the interferon-g genes. The extent of release of cytokines by the APCs depends on the nature of the antigen. Interactions of bacteria with membrane receptors on the APC can signal the cell to release IL-1, TNF, and IL-12. The TLR family of receptor molecules has been identified as an important component of this response to microbial stimuli. TLR stands for Toll-like receptors, indicating their homologies to proteins of invertebrates that are involved in innate resistance (7,8). TLR molecules are key proteins that signal the APCs to activate and release the cytokines that will influence the outcome of antigen presentation. With regular protein antigens, the stimulus for the release of early cytokines is the interaction between TCR and the peptide-MHC complex. Important again in this respect is the interaction with the CD40L of the T cell (28,29).

Summary

In conclusion, antigen presentation is one of the seminal steps in immune induction, and it represents an eloquent demonstration of the cooperativity and symbiosis between the cells of the innate system—the phagocytes—and those of the adaptive immune reactions—in this case, the T cells. Careful and extensive analysis of this phenomenon allows us to understand many facets of immune induction and to learn how to manipulate it. We are now in a position to understand immunogenicity and to remove the many empiricisms that have dominated this area: the actual chemistry of the immunogens can be determined and their immunogenicity explained in molecular and quantitative terms. Thus, we should be able to create more meaningful vaccines by knowing the structures of MHC-bound peptides. By identifying the molecules involved in various stages of the interaction and the ways in which they influence outcome, we can proceed to foster or to inhibit the interaction. This is now happening by manipulating the adhesion and costimulator molecules such as those of the CD40 or CD28 group (Chapter 87). Finally, we are starting to understand the molecular basis of autoimmunization, as the identity of self-peptides and the role of the MHC are being disclosed.

7 IMMUNOGENICITY AND ANTIGENICITY

Jay A. Berzofsky, M.D., Ph.D.

This chapter summarizes the basic principles as currently understood on the requirements for immunogenicity and antigenicity of protein and peptide antigens, and to a limited extent carbohydrate and lipid antigens and haptens, for antibodies, $CD4^+$ T cells, and $CD8^+$ T cells. These issues depend strongly on concepts developed in more detail in subsequent chapters in this section, in particular those on immunoglobulin, T-cell receptors (TCRs), T-cell biology, antigen presentation, and major histocompatibility complex (MHC) structure and function. Some of these concepts must of necessity be introduced briefly here, but the reader is referred to Chapter 3,Chapter 4,Chapter 5 and Chapter 6,Chapter 9,Chapter 13 for a more detailed treatment.

IMMUNOGENICITY VERSUS ANTIGENICITY

It is first important to indicate some definitions and to clarify the distinction between immunogenicity and antigenicity, which are so often confused. *Immunogenicity* refers to the ability of a molecule to elicit a new immune response against itself, whereas *antigenicity* signifies only the ability to be recognized by the product of a preexisting immune response, be it antibody or T cell. Both concepts also imply that the response is specific for the molecule in question. Specificity, of course, does not preclude some degree of cross-reactivity with other related molecules, but it implies only that the response is limited to chemical structures in some way resembling the molecule in question. Thus, for example, a mitogen such as lipopolysaccharide (LPS or endotoxin) that stimulates a polyclonal B-cell response would not be considered immunogenic unless that response includes antibodies specific for the LPS itself. Similarly, a superantigen such staphylococcal enterotoxin B would not be considered immunogenic because it acts as a mitogen for a subset of T cells with a certain family of receptors, but it does not elicit an immune response directly specifically to itself.

It should be apparent from these definitions, and from clonal selection theory, that antigenicity is a prerequisite for immunogenicity. The theory of clonal selection, as proposed by Burnet (1), states that immune cells preexist in a organism with a broad repertoire of receptors, each specific for a limited number of molecular structures, before a foreign antigen is ever encountered. The foreign antigen then merely selects from this preexisting repertoire to expand those cells with receptors specific for itself. Implicit in this theory, then, is the notion that for a molecule to be immunogenic, that is, able to elicit an immune response, it must also be antigenic, that is, able to be recognized by the specific receptors on preexisting immune cells. When this theory was first proposed, the distinction between T and B lymphocytes had not yet been made, but the theory and this corollary to it apply equally well to B cells with surface immunoglobulins and to T cells with surface antigen-specific receptors.

However, the converse is not necessarily true: that is, it is possible for a molecule to be antigenic without being immunogenic. For example, small organic molecules may be bound by antibodies, but they may not be able to elicit an immune response unless they are attached to a larger molecule, called a carrier. Such molecules that can bind antibodies but not by themselves elicit them are called haptens. Similarly, some short peptides may be antigenic for antibodies or T cells without being immunogenic. Thus, binding to an existing receptor on an immune cell is necessary for immunogenicity but is not sufficient. In the case of polysaccharide antigens, sufficient multivalency to obtain extensive cross-linking of receptors may be the only other requirement, but in the case of protein antigens, the additional requirement is usually the induction of help from a helper T cell to activate either a B cell or a cytotoxic T cell (CTL). The provision of antigenic sites eliciting T-cell help is probably the major contribution of the carrier, although it can also provide some degree of multivalency.

Finally, it is worth clarifying the use of the terms antigenic determinant, antigenic site, and epitope, from the beginning. As originally understood for antibodies, these terms have been generally used as synonymous, applying to the portion of a molecule interacting with the antibody combining site. However, as applied to T cells, the term epitope has been given a narrower meaning in the nomenclature proposed by Heber-Katz et al. (2), to refer only to that portion of the antigenic determinant interacting with the TCR, in contrast to the portion that interacts with an MHC molecule. Antigenic site remains approximately synonymous with antigenic determinant, and both imply the whole structure that must simultaneously interact with the TCR and the MHC molecule to trigger a T cell. Although T-cell epitope is often still used to mean the whole antigenic determinant recognized by a T cell, I use the terms T-cell determinant and antigenic site to avoid ambiguity when discussing T cells.

ANTIGENICITY FOR ANTIBODIES

Because antigenicity is a requirement for immunogenicity, it is appropriate to discuss antigenicity first and then to discuss the additional requirements for immunogenicity. In the case of antibodies, all that is required of a molecule for antigenicity is the ability to bind to the antibody combining site with sufficient affinity to be considered specific in some binding assay, that is, an affinity significantly higher than the affinities of random unrelated control molecules. Thus, operationally, antigenicity depends on the threshold for detection of binding in a particular assay, and on the panel of control molecules chosen. However, in most cases, the affinity is sufficiently high that little ambiguity exists.

Surface Exposure

If binding is the *sine qua non* of antigenicity, then it follows that exposure on the surface of a molecule is a necessary condition for a portion of a molecule to be an antigenic site, at least in the native molecule (3). Some would argue that it is the only requirement; that is, any portion of a protein that is exposed can be bound by some antibody. Certainly, it is the only absolute requirement, but other properties of a structure may make it more likely to bind antibodies, that is, to bind a larger proportion of antibodies. Here, the distinction between antigenicity and immunogenicity becomes less clear, because if a substructure of a molecule binds a larger proportion of the antibodies against the molecule than do other substructures, the implication is that this substructure elicited more antibodies in the first place and therefore was more immunogenic.

Exposure on the surface of a macromolecule can be determined in several ways. Experimentally, one can measure exposure by accessibility to reagents that bind to or modify structures on the macromolecule. Indeed, antibodies can be used in other contexts to define exposure, but in the current context, such a result would be considered a tautology. Ideally, one would like a three-dimensional structure of the macromolecule, such as from x-ray crystallography. However, even with a three-dimensional model, exposure is not always obvious by inspection. Because macromolecules are not smooth spheres, but have bumps and crevices, some

portions of the surface may be accessible to small molecules such as water, but not to a large molecule such as an antibody. Different degrees of exposure can be defined by rolling a sphere of defined radius over the van der Waals surface of the macromolecule (4,5 and 6). A sphere the size of a water molecule contacts more surface area than does a sphere the size of an antibody. However, antibodies are not spheres either, so such comparisons represent only gross approximations. From the crystal structures of known antigen-antibody complexes in which the antigen is a protein (7,8 and 9), the buried surface area on each molecule at the contact site is generally around 800 $Å^2$. The contact surface may be relatively flat but may include sections in which bumps on the antibody fit into crevices on the antigen, as well as the reverse. Therefore, the antigen does not necessarily have to fit inside some large, concave pocket of the antibody molecule. From such studies, it is apparent that many structures not accessible to a sphere the size of an immunoglobulin, or even the size of a pair of immunoglobulin variable (V_H + V_L) domains, could still make contact with amino acid side chains of an antibody combining site. The net affinity of the interaction actually corresponds to a small difference between large free energies of attractive and repulsive interactions over this large, buried surface area (3,10). Thus, small changes in the antigen or antibody structure can greatly affect affinity even though most of the contacts remain unchanged.

Exposure can also be measured by the degree of protrusion of parts of a protein, from a known crystal structure, beyond an ellipsoidal solid enveloping the majority of the protein. Such a protrusion index has been shown to correlate with known antigenic sites (11). However, this result may be caused by the use of peptides to identify antigenic sites corresponding to continuous segments of the protein sequence (see the later discussion on assembled topographic sites).

Hydrophilicity

Hydrophilicity, or a preponderance of hydrophilic amino acids, was proposed as an indicator of regions of protein sequence likely to be antigenic (12,13 and 14). Statistically, the correlation appears to be valid. However, some debate exists on the mechanism. Because water-soluble proteins tend to fold in their minimum energy conformation to bury hydrophobic residues in the interior, away from the aqueous solvent, and to expose hydrophilic residues to the water at the surface, one would expect hydrophilic residues to be exposed more frequently than hydrophobic ones, and indeed this is the case (15). Thus, a segment containing a high proportion of hydrophilic residues is more likely to be on the surface of a protein and to be accessible to an antibody. Therefore, hydrophilicity may be an indicator of antigenic sequences in a protein only secondarily, as a locator of surface-exposed sequences, and not an independent contributor to antigenicity. However, because hydrophilic side chains can participate in types of bonding that hydrophobic residues cannot, there is reason to believe that hydrophilic residues may contribute to the specificity of the interaction and may determine the likelihood of binding by specific antibodies beyond their usefulness as predictors of surface exposure. In either case, because crystal structures are not available for most proteins, and surface exposure cannot be determined from amino acid sequence alone, it remains useful to search for hydrophilic regions of a protein sequence in, for instance, deciding what segment to prepare as a synthetic peptide to produce antibodies that are more likely to interact with the whole protein.

Mobility

Mobility was proposed as a factor in antigenicity of protein segments, based on two complementary types of studies. In the first group of studies, antibodies raised against short peptides corresponding to more mobile segments of the protein were more likely to bind to the native protein than those raised against peptides corresponding to more rigid segments (10,16,17 and 18). In the second group of studies, antibodies raised to the native protein and tested for binding to short peptides from the sequence of the protein bound primarily to peptides corresponding to the more mobile segments of the protein (19,20). However, both sets of results deal more with cross-reactivity between peptides and proteins than they do with antigenicity or immunogenicity *per se* (3,20). In the first case, more mobile segments of the protein can more easily assume conformations like those of the short peptides against which the antibodies were raised than can rigid segments of the protein. In the second case, antibodies to more rigid segments of the native protein may not be detected by screening on short peptides because the antibodies are specific for conformations not assumed by the short peptides. Proof of the latter was obtained when longer peptides were used for screening the same antiprotein antisera (21). The longer peptides (about 20 residues) detected antibodies in the serum that bound to more rigid segments of the protein, that were present all the time but had not been detected using extremely short peptides (of only 6 residues). Thus, these rigid segments were immunogenic as well, but to detect them the probes had to be longer peptides. However, antibodies may also prefer to bind to more mobile segments because these have more flexibility to accommodate themselves to the surface of the preexisting antibody combining site, in an induced fit, independent of the question of detection with short peptides.

In any case, prediction of mobility can contribute to the selection of peptide sequences from a protein for raising of antipeptide antibodies as probes of the native protein. Of course, because mobility can best be determined by x-ray crystallography, if enough protein is available to crystallize, there should also be enough to immunize with the intact protein. However, when all one has is a sequence translated from the DNA sequence of a gene, and no purified protein, antibodies made against synthetic peptides corresponding to parts of this sequence may be especially useful for isolating the protein product of that gene. In such cases, prediction of mobility becomes particularly valuable, but it also is the most difficult to accomplish. One approach is based on the finding that interdomain segments tend to be more mobile than segments within globular domains. Because protein domains tend to correspond to exons in the genomic sequence, it is useful to make peptides close to exon boundaries, as well as at the N and C termini of the protein (17).

Glycosylation

Glycosylation appears to be a mechanism by which some organisms shield their protein antigenic determinants from the immune system. For example, the head of the influenza neuraminidase molecule is a target for antibodies, whereas the stem is not, and this finding corresponds to the fact that the stem is almost completely covered with carbohydrate (22). Although *O*-glycosylation sites are not simply predicted, potential *N*-glycosylation sites are identifiable in a sequence as a tripeptide motif, N-X-S or N-X-T (23). Thus, avoiding such segments in selecting peptides for immunization may be useful.

Assembled Topographic Sites

All the approaches based on raising antibodies to synthetic peptides or testing antiprotein antibodies on short peptides apply only to antibodies that bind primarily to a single continuous segment of polypeptide chain. These are called segmental antigenic sites (24). However, many antibodies, sometimes most, raised to native proteins bind to a region of the protein surface that consists of more than one section of polypeptide chain. These sites are called assembled topographic sites because they are assembled from segments of the protein chain that may be far apart in the primary sequence, but they are brought together on the surface of the native protein by the way it folds (3,24). These may also be called discontinuous sites. For example, 30% to 40% of antimyoglobin antibodies in immune sera from several species of animals were found to bind only to the native protein but not to any of the three cyanogen bromide cleavage products of the protein that span the whole sequence (25). Furthermore, crystal structures of protein antigens bound to monoclonal antibodies show that the surface of the antigen in contact with the antibody consists of more than one segment of the protein sequence (6,7 and 8). A likely explanation comes from studies of residues that neighbor each other on the surface of a protein. Investigators have estimated from known crystal structures that the probability that all neighbors within a given distance of a particular residue are from the same continuous segment in the protein sequence becomes vanishingly small when the distance is greater than 10 Å (26). Therefore, because the area covered by an antibody combining site is much larger than this, one would expect that most antibodies would cover more than one continuous segment of polypeptide. An exception may occur when a single loop of polypeptide protrudes from the surface of the protein, and this finding may account for the correlation of segmental antigenic sites with protruding structures, as discussed earlier (11).

IMMUNOGENICITY FOR ANTIBODIES

Mechanisms of T-Cell–B-Cell Cooperation

To understand the requirements for immunogenicity to elicit antibodies, it is first necessary to understand the basic mechanisms of T-cell help for an antibody response. B cells express surface immunoglobulin corresponding to the antibody they will secrete when activated. Thus, a B cell has a high-affinity surface receptor to bind and take up the antigen for which it is specific. However, in contrast to the original notion of a hapten-carrier bridge between the B-cell surface immunoglobulin and the TCR, the surface immunoglobulin does not display the antigen to the T cell, but captures it and facilitates its internalization through receptor-mediated endocytosis. In the resulting endosomes, the internalized antigen is proteolytically degraded into peptide fragments, which bind to class II MHC molecules that are either recycling from the surface or are newly synthesized. The peptide-MHC complexes are then exported to the cell surface, where they serve as a recognition signal for helper T cells specific for the peptide-MHC combination. Investigators have shown that antigen-specific B cells can take up antigen at 1,000-fold lower concentrations than B cells not specific for that antigen, as measured by stimulation of the relevant helper T cell (27,28 and 29). The peptide that binds to the class II MHC molecule is not necessarily related to the antigenic determinant bound by the surface antibody, and indeed, it may be more effective if these are some distance apart. However, the determinant bound by the surface antibody must be physically attached to the peptide that will be presented to the T cell, to take the latter with it into the cell. This explains the requirement for a hapten, that can bind to an antibody but cannot itself bind to an MHC molecule to elicit help, to be attached to a carrier that can be recognized by helper T cells. Such help produced by an attached carrier is called cognate help, in contrast to bystander help, which can be mediated by the secretion of lymphokines in response to a separate stimulus. To elicit such cognate help, the B-cell and T-cell antigenic determinants do not have to be covalently attached, but only physically associated. For example, noncovalent charge complexes of strongly acidic and strongly basic polypeptides also work (30). Moreover, association in a particulate structure, such as a virion, may be sufficient if the whole virion is small enough to be internalized with the surface immunoglobulin. This phenomenon has been called intermolecular intrastructural help (31), and it is exemplified by the ability of helper T cells specific for the core protein of hepatitis B to help B cells specific for the surface protein of the virus (32). It has also been observed with T-cell and B-cell determinant peptides noncovalently associated in liposome membranes (33).

Requirements for Immunogenicity

Antigenicity

Because a B cell from a preexisting repertoire must bind the antigen with its surface immunoglobulin to be activated and to take up the antigen and process it to induce T-cell cognate help, as just discussed, antigenicity is clearly a prerequisite for immunogenicity.

T-Cell Help

In the case of T-dependent antigens, such as most proteins, T-cell help is also required. This means that the B-cell determinant must be physically attached to a helper T-cell determinant, as discussed earlier, to bring the latter into the cell where it can become bound to class II MHC molecules and presented to T cells. However, because the class II MHC molecules are polymorphic in many of the residues in their peptide-binding groove (34,35), the class II MHC molecules expressed on a particular B cell determine which peptide fragments of the protein antigen or carrier protein can bind to those MHC molecules and can be presented by that B cell. These requirements are discussed further in the later section on helper T cells and in Chapter 3 and Chapter 6. The peptide binding specificity of MHC molecules thus accounts for MHC-linked *Ir* gene control of immune responses, in which the same antibody determinant or hapten may be immunogenic or not, depending on the helper determinants to which it is attached and the MHC molecules of the animal being immunized (36,37).

Difference from Self

A structure may be antigenic in that it can bind to antibodies raised in another animal, but it may not be immunogenic in a particular animal because it resembles some autologous protein to which the animal is tolerant. Self-tolerance and the regulation of the repertoire are discussed in detail in Chapter 9. Here, it is worth pointing out that when one examines the antigenic structure of a mammalian protein used to immunize another mammal, the regions of difference from the homologous self-protein are the primary targets of antibodies (24). This has been clearly shown for cytochrome *c* (24,38) and for myoglobin (39). Even a single amino acid difference is sufficient to permit recognition as nonself (24,38).

Influence of T-Cell Help on Antibody Specificity

Two types of influence have been described. First, helper T cells specific for some antigenic determinants may more efficiently provide help for some B-cell antigenic determinants on the same protein than others. This has been observed by using defined populations of helper T cells to help an antibody response, by noting the differences in antibodies produced (40,41,42 and 43), and by using B cells with defined surface antibody to stimulate T-cell clones specific for different determinants on the same protein (44). Investigators have also observed that macrophages taking up immune complexes consisting of the same antigen bound to different antibodies preferentially stimulate different helper T cells (45). The mechanism thus proposed is that what an antigen-specific B cell takes up to process is not just free antigen, as in the case of a macrophage or dendritic cell; rather, it is an immune complex of the antigen with a monoclonal antibody, namely, the B cell's own surface immunoglobulin, and the bound immunoglobulin influences the way the antigen is proteolytically processed (46). Many antigen-antibody complexes are stable at the pH of the endosome (in the range of pH 5 to 6). Furthermore, *in vitro,* antibody has been shown to protect its antigenic determinant from proteolysis sufficiently to allow mapping of an antigenic determinant by analysis of the proteolytic fragments produced in the presence and absence of antibody (47). Finally, direct proof of this hypothesis has been obtained by the demonstration that the products of antigen processing by B cells depend on the epitope specificity of the surface immunoglobulin of the monoclonal Epstein-Barr virus–transformed B cells used (48). Moreover, the same surface immunoglobulin can enhance presentation of one determinant and can hinder presentation of an adjacent determinant, both within the footprint of the antibody (49). This mechanism may explain how MHC-linked *Ir* genes, which control T-cell specificity, can also control the fine specificity of an antibody response (46,50,51). It also has practical implications for the use of specifically designed immune complexes as immunogens to steer the immune response and to enhance responses to subdominant epitopes. This influence may also contribute to epitope spreading (52), in which the response to one antigenic site facilitates induction of responses to other sites.

The second type of influence has to do with the way short peptides are attached to carrier proteins to make them immunogenic. Investigators have observed that the antibodies raised against these complexes are predominantly specific for the end of the peptide that is not tethered to the carrier protein (53). Thus, attaching a peptide through its carboxy-terminal favors antibodies to the amino-terminal, and *vice versa.* Attaching a slightly longer peptide by both ends favors antibodies to the middle. This observation can be useful in designing appropriate coupling methods for particular peptide-carrier complexes.

Immunogenicity of Polysaccharides

Unlike proteins, polysaccharides have not been found to bind to and be presented by MHC molecules to T cells, and in general, T cells do not recognize carbohydrate (54). Therefore, for a polysaccharide to be immunogenic, it has to be either sufficiently polyvalent to elicit a T-independent response or attached to a protein as a carrier. Polysaccharides are the prototypical antigen for a T-independent response, probably because they tend to have multiple copies of the same structure to allow sufficient cross-linking of the B-cell surface immunoglobulin to trigger such a response. However, more than cross-linking is involved. Some studies have shown that T-independent responses are primarily mediated by a specialized subset of B cells bearing specific surface markers such as Lyb 5 (55,56). Because such B cells appear late in ontogeny, they are absent from human umbilical cord blood and from newborns during the first few months of life, and thus newborns are defective in their response to polysaccharide antigens (57,58). This situation has serious practical implications for the development of polysaccharide vaccines against bacterial pathogens in newborns, and it has forced vaccine designers to use bacterial polysaccharides attached to a protein carrier to create a T-dependent vaccine that is effective in newborn children (57).

IMMUNOGENICITY AND ANTIGENICITY FOR $CD4^+$ HELPER T CELLS

Because immunogenicity of protein antigens for B cells generally requires induction of helper T cells as well, immunogenicity for such $CD4^+$ helper T cells is necessary for the protein antigen to be immunogenic for both B-cell and T-cell responses. Immunogenicity for $CD4^+$ T cells, which generally recognize complexes of peptide fragments of proteins bound to class II MHC molecules, requires a segment of the protein that can survive proteolytic processing of the protein into fragments, generally in endosomes, and can bind to both a class II MHC molecule and a TCR of a helper T cell that has not been deleted or anergized by self-tolerance. Each of these requirements is addressed in turn.

Role of Antigen Processing

The pathways of antigen processing are discussed in detail in Chapter 6. Here, the focus is the impact of processing on T-cell recognition. The apparent purpose of proteolytic processing of antigens is to produce a structure that can interact with the peptide-binding groove of an MHC molecule and to have relevant portions accessible to interaction with a TCR (59,60 and 61). Most globular proteins or domains of proteins are too bulky, and if a polypeptide segment on one exposed surface of the protein could interact with the MHC molecule, the other side of this segment would likely be buried in the interior of the protein and would be inaccessible to a TCR. Thus, if exposure of all sides of a polypeptide segment is the critical requirement, it is conceivable that simply unfolding a small protein or protein domain may be sufficient to accomplish this goal. Indeed, several early studies indicated that unfolding a protein was sufficient without proteolysis (60,62,63 and 64). Moreover, even a short peptide that was constrained by disulfide bonds required reduction and unfolding to allow T-cell recognition (65), so short length is not sufficient in the absence of unfolding. The ability of longer, unfolded polypeptides to bind to class II MHC molecules with the ends hanging out of the peptide-binding groove has been confirmed by x-ray crystallography (66,67,68,69 and 70).

However, in most cases, unfolding is accomplished by proteolytic digestion of the protein into smaller fragments. The exact size of these fragments has not been determined in most cases, but because peptides eluted from class II MHC molecules generally range from 13 to 18 residues, with some much longer (71,72), it is unlikely that these fragments correspond exactly to the synthetic peptides widely used to study T-cell recognition. Indeed, the naturally processed fragments may be considerably larger than the actual T-cell antigenic determinant. A crystal structure study of a TCR-peptide-MHC class II molecular complex shows that the length of the peptide contained within the MHC II groove and interacting with the TCR is about 9 residues, as in the case of class I molecules, but additional peptide may extend from both ends of the groove. These additional residues may not be merely extraneous, but they may actually interfere sterically with binding of the peptide to the MHC molecule or to the TCR (73,74 and 75). In one such case, the hindrance was MHC specific, so the naturally processed fragment of a protein was presented by one class II MHC molecule but not by another, even though a synthetic peptide corresponding to the antigenic determinant contained within the natural fragment could be presented by both MHC molecules (73). In a second example, a 10-residue peptide was presented, but a 15-residue peptide containing this was not (74). Mutations in the additional 5-residue extension, or within the original 10-residue sequence, could restore function. This result suggests that interaction between residues in the extension and the original peptide led to obstruction of interaction between the antigenic determinant and either the MHC molecule or the TCR. Another situation in which the structure of the naturally processed fragment can influence recognition is the competition among antigenic determinants on the same fragment for binding to the same or different MHC molecules (61,75,76). High-affinity binding of one determinant to one MHC molecule may prevent binding of a different determinant on the antigen fragment to a different MHC molecule. Thus, the location at which a peptide is cleaved during processing can profoundly affect both antigenicity and

immunogenicity of a determinant for T-cell recognition, and that effect may be different in individuals of different MHC types, even if the processing is the same.

Finally, the determinant must not be destroyed by processing. Thus, otherwise potentially recognizable determinants, if they contain a cleavage site for a protease involved in processing, may be immunologically silent. For this reason, it may be important that many proteins are processed in endosomes in which proteolysis is not complete and the antigens are not exposed to the full proteolytic capacity of the cell in lysosomes, although cases may also occur in which the more vigorous proteolysis of lysosomes is required (77,78 and 79). In addition, for both antigenicity *in vitro* and immunogenicity *in vivo,* proteases in serum may mediate extracellular processing that can lead to degradation of the antigenic determinant (80,81), or in some cases even activation of the determinant by appropriate processing (81,82).

For all these reasons, a more complete characterization of the enzymes involved in processing, and of their sequence specificity, would greatly aid in predicting the availability of sequences for presentation, and their susceptibility to degradation. Cathepsins B, D, L, and E have been implicated in processing different proteins (83,84,85,86 and 87). Cathepsin S has been implicated primarily in cleavage and degradation of the MHC class II invariant chain in both murine and human antigen-presenting cells, and so it affects presentation of peptides by class II molecules by contributing to the removal of invariant chain that protects the peptide-binding pocket (88,89). Thus, protease inhibitors that inhibit antigen presentation may be affecting either the degradation of the antigen itself or the processing of invariant chain to allow peptide binding. Unfortunately, the specificity of these cathepsins is not as sharply defined as that of restriction endonucleases, or even that of trypsin.

Binding to Class II MHC Molecules

As discussed in Chapter 3, both class I and class II MHC molecules are polymorphic within most mammalian species, and in particular are so in humans. Moreover, the structural differences among such MHC molecules have been found to occur primarily within the groove identified by x-ray crystallography as the likely site for peptide binding (66,67,68,69,70,90,91,92,93,94,95,96,97 and 98). This variability in the peptide binding site in large measure accounts for the phenomenon of immune response *(Ir)* genes (37,99), which are defined as genes that determine in an antigen-specific fashion whether an individual or inbred strain of animals will respond to a particular antigen. Many of these genes, defined functionally by the magnitude of antibody or T-cell responses to specific antigens, were mapped to the MHC and, for antibody and $CD4^+$ T-cell responses, were mapped to the region encoding the class II MHC molecules (36,37). Indeed, the original name of the class II molecules, Ia antigens, stands for *Ir*-associated antigens. However, it was only by use of structural mutations in the class II MHC molecules, and by production of class II transgenic mice, that investigators finally proved that the *Ir* genes were the structural genes for class II MHC molecules, and not merely genes mapping nearby (37). Indeed, studies of single residue mutations in the peptide binding groove of class II MHC molecules show that structural changes in the groove affect not only whether a peptide binds, but also how it binds, that is, in what conformation or orientation (100,101). Similar findings have been made for class I MHC molecules (102). These differences in conformation or orientation of the peptide induced by the structural differences in the MHC groove also affect T-cell recognition of the peptide.

The important functional result of the class II MHC polymorphism is that each MHC molecule binds a different (although possibly overlapping) set of peptide fragments from a given protein. If few or no peptide fragments from a protein bind to any of the class II molecules of an individual, then that individual is a low or nonresponder to that protein. Therefore, immunogenicity of a protein varies among individuals of a species, depending on their MHC type. In this context, immunogenicity is not the inherent property of a structure, but it depends on the recipient of the immunization.

For this reason, attempts have been made to identify sequence motifs that are predictive of binding to specific MHC molecules (103,104,105,106,107,108 and 109). Several such motifs have been defined for a few murine and human class II molecules (103,104,106,108,109,110,111,112,113 and 114), but they are much less clear-cut and consistent than motifs defined for peptides binding to class I MHC molecules (see later). This may in part relate to the variability in length of peptide binding class II MHC molecules. As noted earlier, in contrast to peptides naturally bound to class I MHC molecules (8 to 10 residues; see later), naturally bound peptides eluted from class II molecules appear to be much longer, ranging from 13 to 18 residues (71,72). The reasons for this greater permissivity in length are that both ends of the class II molecule's peptide-binding groove are more open than those of class I molecules, and the peptide thus can extend from both ends (66,67,68,69 and 70,96,98). The nonpolymorphic peptide-binding residues of MHC class II molecules interact with the peptide main chain backbone, rather than with the amino-terminal and carboxyl-terminal, as in the case of the class I MHC molecule, so the ends of the peptide do not have to be buried. The result, however, is that it is more difficult to define precise binding motifs, because the key peptide anchor residues that fit in pockets of the MHC class II molecule may occur at any random distance from the amino-terminal of the peptide, in contrast to peptides binding to class I molecules in which the anchor residues occur at fixed distances from the ends. Thus, sequencing of unseparated eluted peptides from class II molecules is less likely to reveal clear patterns (see later). Furthermore, in the $I\text{-}A^d$ molecule, specific high-affinity binding occurs without any large anchor residues fitting into pockets in the class II MHC molecule (98). The groove of the class II molecule may also be more flexible, because it is assembled from two separate polypeptide chains, rather than from two domains on the same polypeptide chain as in the case of class I molecules. Nevertheless, motifs for certain MHC class II molecules have been reported (108,110,111,112,113 and 114), as reviewed in (109,115,116 and 117), and have proved useful for prediction of antigenic determinants of medically relevant proteins (112,118,119,120 and 121).

Even before motifs were found for peptides binding to specific MHC molecules, sequence patterns were observed that occurred more commonly in peptides recognized by T cells than those that were not (103,122,123,124,125,126,127 and 128). As pointed out by DeLisi and Berzofsky (122) and Cornette et al. (125,126), all these patterns tend to represent periodicities in hydrophobicity of amino acid residues consistent with sequences that fold as amphipathic helices. An amphipathic structure is one that can be separated into hydrophilic and hydrophobic regions. Thus, an amphipathic helix is one in which the hydrophilic residues are aligned preferentially on one side of the helix, and the hydrophobic residues are aligned on the other. Such helices are found in native proteins, especially among helices in which one face of the helix is buried in the protein and the other is exposed to aqueous solvent (15). Amino acid sequences that would be amphipathic if folded as a helix were found to be statistically significantly more frequent among known T-cell antigenic sites than among random segments of the same proteins in which the T-cell sites had been identified, by several different statistical comparisons (123,124,129). A computer program was developed to search protein sequences for such sites (124). As the number of known antigenic sites for helper T cells has increased exponentially, the statistical significance of the correlation has remained high ($p < .001$) (125,126,129). Thus, the statistical correlation has remained robust, a finding suggesting that this property reflects something important about the chemistry of T-cell recognition.

However, the crystal structures of class I and class II MHC molecules have revealed extended peptides in the MHC grooves, not helices (66,67,68,69,70,91,92,93,94,95,96,97,98,130,131,132,133,134,135,136 and 137). How, then, can one explain the statistical correlation with periodicity of hydrophobicity? Two explanations have been suggested. First, in class II molecule crystal structures, the peptides have been found to lie in the groove with a 130-degree twist, like that of a type II polyproline helix (67,69), and the hydrophobicity of these sequences shows a 130-degree periodicity (129). Although not identical to an a helix (100-degree periodicity) or a 3^{10} helix (120-degree periodicity), this 130-degree twist is close enough that computer algorithms designed to detect such periodicity of hydrophobicity would detect them (129). Second, the spacing of the anchor residues that bind to pockets in the MHC molecule (92,132,135,136,138,139) tends to be consistent with the spacing between residues on the same side of an a helix. The anchor residues of class I MHC–binding peptides (that are best defined) are most commonly at positions 2, 5, and 9 (for different MHC molecules 2 and 9 or 5 and 9), and the spacing between these approximates the distance between one or two turns of an a helix (3.6 or 7.2 residues). Because most anchor residues are hydrophobic, if other residues are more random, such spacing often results in a periodicity of hydrophobicity like that of an amphipathic a helix even though the peptide is bound in an extended conformation (129). Effectively, the spacing of pockets in the MHC groove enforces a spacing of hydrophobic anchor residues that, in turn, creates the observed periodicity in hydrophobicity. Thus, these hydrophobicity sequence patterns represent the first sequence motifs detected to T-cell antigenic determinants, and they define an overall pattern that encompasses most of the motifs known for peptides binding murine and human MHC molecules and that may continue to be useful.

Recognition by a T-Cell Receptor

Once bound to a class II MHC molecule, the peptide must still be recognized by a TCR. Although the potential repertoire of TCRs is enormous, probably comparable to that of antibodies despite the lack of somatic mutation, it is not infinite. Holes in the repertoire have been reported (140). However, such holes are rare (141). There is considerable plasticity in the repertoire, so if one family of TCR genes is deleted that normally predominates in a response to a given antigen, a response to the same antigen can be made using other families of TCR genes (142,143). For this reason, although some cases have been reported of limited use of particular a or b chain TCR variable regions in the response to particular antigens (144,145,146,147,148,149,150 and 151), such constraints do not appear to have a major impact on immunogenicity. Indeed, the repertoires of murine and human TCRs are sufficiently broad that peptide binding to MHC molecules tends to be the limiting factor, so in the case of CTL responses to peptides presented by class I MHC molecules, CTL responses in human leukocyte antigen A2.1 (HLA-A2.1) transgenic mice have been found to predict antigenic determinants recognized by human CTLs in association with HLA-A2.1 (152).

A much greater limitation than holes in the potential TCR structural repertoire imposed by the availability of TCR genes and by chemical constraints on the structure is the narrowing of that potential repertoire by self-tolerance, as well as possibly by positive selection for recognition of peptides bound to particular MHC molecules (so-called self-MHC restriction). These functionally imposed holes in the repertoire must be sizable to exclude reactivity to a host of normal self-proteins. Thus, a protein identical to a normal protein of the animal or person being immunized would not be expected to be immunogenic. Moreover, a related protein that differs only in one or two amino acid residues from a self-protein would be expected to be immunogenic only if those amino acid substitutions occur in peptide fragments that can bind to and be presented by class II MHC molecules of the responding person or animal. Thus, some differences from self may be detected in individuals of some MHC types but not in individuals of other MHC types. This MHC-linked difference in the ability to break tolerance by particular mutations may play a role in the MHC-linked propensities to particular autoimmune diseases.

This last point is related to the notion that self-tolerance is MHC restricted (153,154 and 155). By this, I mean that one can be tolerant to only those peptide fragments of self-proteins that bind to self-MHC molecules and thus lead to tolerance. Peptides of self-proteins that do not bind to any self-MHC molecule would be

immunologically silent. However, they may be recognized as part of an alloantigen, because the complex of a self-peptide with an allo-MHC molecule to which it can bind is a different antigen from the complex of the same peptide with a self-MHC molecule, given that the MHC molecule contributes to the total structure bound by the TCR. It is conceivable that a mutation could arise in a self-protein that affected only the ability of a peptide fragment to bind to a self-MHC molecule, so a formerly silent peptide, to which one was not tolerant, could now become immunogenic. Such events could also therefore contribute to autoimmune disease.

Immunogenicity of Peptides, Haptens, and Carbohydrates

The immunogenicity of short peptides for $CD4^+$ T cells depends on the same considerations as that of whole proteins, except the short peptide may not need processing. However, it still must survive the processing enzymes, and even extracellularly, it may be susceptible to degradation by proteases in serum (80,81 and 82). Most peptides that bind to class II MHC molecules can elicit a $CD4^+$ T cell-response. However, some peptides bind to a class II MHC molecule, but the complex produced fails to activate a T cell, and it serves as an inhibitor of T cells specific for a structurally related peptide-MHC complex. Such peptides are called antagonist peptides or altered peptide ligands and are reviewed in detail elsewhere (156). In between fully agonist peptide-MHC complexes and antagonists are some peptide-MHC complexes that are partial agonists, that can induce only a partial signal, and thus produce a subset of the responses of which the T cell is capable (156,157,158,159,160,161,162,163,164 and 165). One potential mechanism for such partial responses is a reduced dwell time of the peptide-MHC complex on the TCR, insufficient to permit transduction of the complete signaling process (166,167,168,169,170 and 171). Thus, this phenomenon is at least partly related to the affinity of the peptide-MHC complex for the TCR. If such antagonist or partial agonist peptides are produced by pathogens, they could contribute to induction of anergy in T cells that could otherwise contribute to protection. They may also skew the cytokine phenotype and thus alter the outcome of the immune response produced.

Haptens, which are small molecules that themselves are not immunogenic, but require attachment to a carrier, almost by definition are not molecules that can bind directly to MHC molecules and be presented to T-cells. How then can one account for apparent cases of hapten-specific T cells (172)? At least one explanation has come to light, by the demonstration that MHC-restricted trinitrophenyl (TNP)-specific T cells are actually recognizing a TNP group attached to an amino acid residue of a peptide that does bind to the MHC molecule in question (173,174). Furthermore, apparent differences in T-cell specificity in this system appear to relate to the position along the length of the peptide at which the TNP group is attached. Thus, in this case, the hapten-specific TCR is binding to a conventional peptide-MHC complex, and the TNP group is serving merely as a modified side chain of one of the peptide amino acids. Similarly, T cells can be specific for carbohydrate moieties (175,176,177 and 178) or even metal ions (179,180,181 and 182) bound to peptides (or proteins that can be processed into peptides) in analogous fashion.

IMMUNOGENICITY AND ANTIGENICITY FOR $CD8^+$ CYTOTOXIC T LYMPHOCYTES

Many of the same considerations apply to $CD8^+$ CTL recognition that applied to $CD4^+$ helper T cell-recognition (183,184). The main differences arise because the class of MHC molecule presenting to $CD8^+$ cells is usually class I rather than class II, with their different binding constraints, and because the pathway for processing of antigens to be associated with class I MHC molecules is different from that for class II. In addition, a fourth step influencing specificity, between antigen processing and MHC binding, applies in the case of $CD8^+$ T cells, because a specific active transport mechanism translocates processed peptides from the cytosol to the endoplasmic reticulum, where they are loaded onto nascent class I MHC molecules. The transport is mediated by the transporter associated with antigen processing (TAP) 1 and 2 proteins, which shows preferences for peptides of certain size and sequence.

Antigen Processing

In general, class I MHC molecules bind peptide fragments of proteins synthesized within the cytoplasm of the cell or introduced there in some other way, rather than proteins taken up from outside the cell, as in the case of class II MHC molecules (185,186,187,188 and 189). This difference arises from the finding that peptide fragments produced in the cytoplasm are transported by a specific transporter mechanism into the endoplasmic reticulum (190,191,192,193,194,195 and 196), where they encounter nascent class I MHC molecules that actually require bound peptide to be stabilized in their native conformation and to be transported out to the surface of the cell efficiently (189,197,198,199 and 200). In contrast, class II molecules in the endoplasmic reticulum cannot bind peptide because they are complexed to an invariant chain, which is not dissociated until the class II molecule reaches an endosome, where fragments of exogenous antigens are produced (201,202,203,204 and 205). This mechanism, which is described in more detail in Chapter 6, helps to segregate the two pathways to allow class I molecules to sample primarily the proteins in the cytoplasm of the cell and class II molecules to sample the proteins taken up from outside into endosomes. The functional importance of this segregation is that class I molecules present their peptides to $CD8^+$ CTLs, which provide immune surveillance to destroy cells producing inappropriate proteins, such as viral proteins in a virally infected cell, or mutant proteins in a cancer cell, whereas class II molecules present their peptides to helper T cells that activate the presenting cell, be it a B cell to make immunoglobulin or a macrophage to trigger its cytolytic or oxidative machinery. Clearly, one would not want a B cell that had finally encountered the antigen for which it was specific to present it to a $CD8^+$ T cell and be destroyed instead of positively selected and expanded. Conversely, one would not want a virally infected cell to present viral antigen to a helper T cell and be activated to produce more virus, rather than being destroyed. Thus, a clear rationale exists for the segregation of the two pathways.

From our perspective in terms of immunogenicity, this segregation of processing pathways implies that immunization with an intact protein that suffices for induction of $CD4^+$ helper T cells and for antibody production may not be sufficient for induction of $CD8^+$ CTLs. The most effective general method for inducing a class I MHC–restricted response to an antigen is to have the antigen expressed by a virus with which one can infect the recipient, so the antigen in question is expressed in the cytoplasm of the infected cells. For this purpose, many recombinant viral vectors have been prepared, such as the many recombinant vaccinia viruses now in use (206,207). More recently developed DNA vaccines accomplish the same goal by expressing the relevant antigen in the cytosol of professional antigen-presenting cells (208,209,210,211,212,213,214,215,216,217,218,219,220,221,222,223,224,225,226,227,228 and 229), such as dendritic cells or macrophages (217,221,230). Townsend and coworkers opened up new approaches in 1986 by showing that short synthetic peptides could bind directly to class I MHC molecules on the surface of cells without entering the class I processing pathway (231). This approach was initially applicable to antigenicity, rather than immunogenicity, because most early attempts to use such short peptides to immunize failed. However, the approach was extremely valuable for mapping epitopes with short synthetic peptides. Subsequently, methods of immunizing with peptides to induce $CD8^+$ CTLs were reported, using either free peptides in adjuvant (232,233,234 and 235), peptides attached to a lipid tail (236,237), or peptides coated onto cells that were then injected (238,239,240,241,242,243,244 and 245). In some of these cases, the peptide immunization actually led to protective immunity (234,238,240,241,242 and 243).

The limitation on using whole native purified proteins can be circumvented as well. For example, incorporation of the whole protein into ISCOMs, which are immunostimulatory complexes consisting of 35-nm particles containing the protein with cholesterol and Quil A, a mixture of natural plant saponins (246), could induce $CD8^+$ CTLs to human immunodeficiency virus type 1 (HIV-1) envelope protein or influenza hemagglutinin, whereas whole protein in saline or complete or incomplete Freund's adjuvant did not (247). Although it was originally supposed that the detergent-like properties of the ISCOM allowed the antigen to enter the cytoplasm of the cell and thus the class I processing pathway, the difficulty in using ISCOMs to sensitize targets for recognition by CTLs *in vitro* has hampered the elucidation of the mechanism (unpublished data). However, investigators were able to show that ISCOMs containing whole measles fusion protein could deliver the protein to the endogenous processing pathway for recognition by class I–restricted CTLs (248). In any case, protein in ISCOMs consistently induces CTLs that are specific for the same antigenic determinants that are dominant in the response induced by live viral vectors (247). QS21, a less toxic component of Quil A that retains adjuvant activity, can also facilitate induction of $CD8^+$ CTLs with soluble whole proteins (249,250) and peptides (251,252). Similarly, proteins in liposomes can be used to immunize to elicit $CD8^+$ CTLs. Particulate antigens can also escape from endosomes into the cytosolic class I processing pathway (253,254 and 255). Viruslike particles are especially useful in this regard (256,257 and 258). Finally, whole proteins coated onto the surface murine spleen cells and injected intravenously can induce $CD8^+$ CTLs (259,260 and 261). It appears that the cells, or the antigen they carry, are processed and are represented by some cell in the recipient, because parental spleen cells bearing antigen injected into an F_1 hybrid recipient induce CTLs restricted to both MHC types of the F_1, not just the one of the injected cells (260). The mechanism likely involves uptake of apoptotic bodies of the injected cells by dendritic cells of the recipient (262). This method induces CTLs that have the same epitope specificity and same MHC restriction as those induced by live viral immunization (261).

As in the case of $CD4^+$ helper T cells, recognition of a determinant with a class I molecule requires that it not be destroyed by the processing mechanism and that it be made accessible to both the class I MHC molecule and to the TCR. In this regard, investigators observed in one case that flanking residues adjacent to the minimal determinant inserted into the sequence of a fusion protein expressed by a recombinant viral vector influenced whether the minimal determinant was recognized (263). However, a similar study with another protein found no effect of flanking residues (264), so it is not clear how often this effect is a problem.

Studies with specific inhibitors of proteasomes indicated that these large proteolytic complexes are the primary machinery for cytosolic proteolytic processing of proteins to produce peptides for the class I pathway (265,266,267 and 268). The relative efficiency of proteasomes to cleave cytosolic proteins at different sites can significantly influence the relative dominance of different antigenic determinants of a protein for CTL recognition (183,184,269). In particular, the MHC-encoded LMP-2 and LMP-7 subunits of the proteasome can influence the site of cleavage (266,270,271 and 272), thus affecting the relative amount of cleavage after hydrophobic or basic amino acids versus acidic ones. Because class I MHC–binding motifs of peptides typically involve hydrophobic or basic, not acidic, residues at the C terminus (see later), these subunits can enhance the production of peptides that can potentially bind to class I MHC molecules. The production of these subunits is induced by interferon-g (270), so interferon-g can enhance processing of relevant peptides for CTL recognition. Another interferon-g–inducible protein called PA28, which is associated with the proteasome, may influence the length of the peptide produced and thus may also affect the repertoire of peptides available for binding to class I MHC molecules (273,274). Another study using purified proteasomes for digestion of well-characterized antigens showed a predominant length of peptide produced in the 7- to 10-residue range, and a distribution of terminal residues corresponding to that for class I MHC binding (275,276). Furthermore, the production of a

immunodominant epitope far exceeded that of a subdominant epitope, a finding suggesting a role for proteasome specificity in determining immunodominance (276). This proteasome specificity preceded the evolution of the MHC and the vertebrate immune system, consistent with the possibility that the MHC evolved taking advantage of the preexisting proteasomal system (277). A more recent analysis of naturally processed peptides indicated that the cleavage depends most heavily on the residues on either side of the cleavage site, but this is especially notable at the C terminus, presumably because the N terminus is subject to further trimming in the endoplasmic reticulum (278). Thus, the specificity of the proteasome, which can be altered by components such as LMP-2, LMP-7, and PA28, which are induced by interferon-g, is a key factor in the first step of the multistep pathway for selection of antigenic determinants recognized by $CD8^+$ T cells. It is relevant, therefore, that the size of the peptides produced and the nature of the C-terminal residues are compatible with those of peptides binding to class I MHC molecules.

Finally, when peptides are used exogenously to bind to MHC molecules on the surface of target cells, peptides longer than appropriate for binding to the class I MHC groove (see later) may be effective in serum, but not without serum, because proteases in serum process the peptides down to a functional size (81,82,279). Examining presentation by purified MHC molecules in the absence of presenting cells allowed the identification of one serum protease that processes antigenic peptides as the angiotensin-converting enzyme, inhibitable by angiotensin-converting enzyme inhibitors such a captopril (81). However, if the minimal length peptide is used in serum, it may actually be less potent than in the absence of serum, because serum proteases can further divide it into smaller peptides (80,81). Thus, for example, the minimal 10-residue peptide of the HIV-1 envelope, RGPGRAFVTI, presented by $H\text{-}2D^d$, is about 10-fold more potent on a molar basis than the 15-residue peptide RIQRGPGRAFVTIGK in the presence of serum, but it is more than a millionfold more potent in the absence of serum (81).

Transport into the Endoplasmic Reticulum

The second selective step influencing which potentially antigenic determinants are available for recognition by $CD8^+$ T cells is transport of peptides from the cytosol to the endoplasmic reticulum (ER) by an active transport mechanism mediated by the transporter associated with antigen processing (TAP) 1 and 2 complex of proteins. TAP 1 and 2 are 70-kd proteins of the adenosine triphosphate–binding cassette family of transporters, such as multidrug resistance protein and the cystic fibrosis transporter (280,281 and 282). The observed association of class I MHC heavy chain–b_2-microglobulin complexes (but not free heavy chains) with TAP in both murine and human cells suggested that TAP may facilitate peptide loading of class I MHC molecules in the endoplasmic reticulum by transferring peptides it transports directly to bound empty class I MHC molecules (283,284 and 285). This process may be facilitated by a third molecule, tapasin, which appears to mediate the association between class I MHC molecules and TAP and may facilitate peptide loading, although it may not be essential (286,287 and 288).

Relevant to the issue of antigenicity and immunogenicity, the TAP molecules appear to bind and transport some peptides more effectively than others, and they contribute a second step during which potential antigenic peptides are selectively winnowed (183). The functional significance of this was demonstrated by the observation that a polymorphism in TAP in the rat that affected binding of peptides with different C-terminal residues led to MHC-linked histoincompatibility in strains of rats that had identical MHC molecule sequences (289). TAP selectively transports peptides of 9 residues or longer in the mouse (290), and in the human TAP preferentially transports peptides of 8 to 11 residues and rarely transports peptides shorter than 7 residues or longer than 24 residues (291). Using glycosylation of an indicator peptide as a marker of transport into the endoplasmic reticulum, and using competition with other peptides, investigators showed that the sequence specificity of the TAP complex is much broader than the binding specificity of MHC class I molecules (291), as could be expected because the same TAP molecules must function with multiple class I MHC molecules. Nevertheless, selection against peptides with Pro at positions 2, 6, or 9 was found in the rat (292), and an assay measuring binding of peptides to human TAP showed some specificity for peptides, especially involving residues 2, 3, and 9 (293,294). Another study using combinatorial peptide libraries for measuring binding to TAP indicated that the three N-terminal residues and the C-terminal residue were the most critical in determining TAP binding (295). It may not be coincidental that these residues are often the key anchor residues in peptide binding to class I MHC molecules and that the lengths of peptides preferentially transported by TAP correspond to the lengths that bind to class I MHC molecules (see later). At the C-terminal position, TAP appears to select against Glu, which is also not generally a C-terminal anchor residue for class I MHC molecules. Human TAP appears to transport peptides with Arg at position 2 and Phe, Tyr, Leu, Arg, or Lys at position 9, consistent with the residues involved in peptide binding to HLA-B27, whereas it disfavors peptides with Pro at position 2, such as those that bind to HLA-B7 (293,294,296). Therefore, the specificity of TAP transport could favor the loading of some HLA molecules more than others. Thus, the peptide specificity of TAP, although not as limiting as that of the MHC molecules themselves, contributes to the selective process determining which antigenic determinants dominate the $CD8^+$ T-lymphocyte response.

MHC Binding

Major advances have been made in defining the structural requirements for peptide binding to class I MHC molecules. The most striking finding is a severe length limitation, apparently imposed by the closure of both ends of the peptide-binding groove in the case of class I MHC molecules, apparent from the crystal structure (91,93), as is not the case for the class II MHC molecule based on the class II crystal structure (66,67,68,70,95,96,97 and 98). Investigators first found that small, truncated peptides contaminating the major population of synthesized longer peptide could be the active species, so for example, a 9-residue fragment may be responsible for all the activity, even though it is but a minor contaminant in a 12-residue peptide that is actually inactive (297). A similar length constraint was found by the independent approach of eluting natural peptides from class I MHC molecules on cells and sequencing them (105,298,299). The natural peptides bound to class I molecules were mostly nonamers, with a few octamers. Subsequent studies also identified decamers (300). In contrast, elution of peptides from class II MHC molecules gave exclusively longer peptides with a broader range of lengths, from 13 to 17 residues (71,72). The latter are consistent with the observation that the ends of the class II molecule peptide binding groove are open, thus allowing varying lengths of peptide to extend from both ends (66,67,68,70). In support of the length restrictions on peptide binding to class I MHC molecules, a study of the effect of length of a nested series of peptides from influenza nucleoprotein on binding to $H\text{-}2D^b$ revealed a strong dependence of affinity on length (301). The highest affinity peptide was 9 residues long, and increases in length resulted in a lower affinity and shorter half-time for stability of the complex. Furthermore, the study cited earlier in which a 15-residue peptide appeared to be active in serum, but was not active in the absence of serum, whereas a 10-residue peptide contained within it was active even without serum (81), illustrates the point that even when using purified MHC molecules without cells, the apparent activity of a longer peptide can depend on protease contaminating the system.

However, one should not conclude that only peptides of 8 to 10 residues can be used for immunization. Most of the cases in which peptide immunization was successful (referenced earlier) used longer peptides. Therefore, longer peptides can be just as effective, and in some cases they are more immunogenic because they stimulate helper cells as well (see later), provided they can be processed appropriately by cellular or serum proteases to a size that can bind to class I MHC molecules.

Besides the length limitations, the next most striking finding is the presence of well-defined sequence motifs for specific binding to a particular MHC class I molecule. Many of these were found by sequencing the mixtures of peptides eluted from a class I molecule and by finding that, at certain positions in the sequence, a single amino acid occurred predominantly, whereas at other positions, many amino acids were found (105). This method would work only if the peptides had a strict length limitation on the N-terminal side of the motif. Otherwise, among peptides all sharing the same motif, the motif would not always start at the same position in the peptide. Other motifs were found by eluting peptides from class I MHC molecules, by purifying the major peptides in the mixture, and sequencing these individually (298,299), or by analyzing the residues required for presentation of a particular antigenic peptide (302). When a motif was found using two different methods, such as in the case of $H\text{-}2K^d$, the same motif was found by both methods, a finding providing independent support for the motif (105,302). Further support for this motif concept was provided by the prospective prediction of an antigenic site, in which 1 of 16 peptides synthesized on the basis of this motif for K^d was found to be antigenic (303).

Most of these motifs involve only 2 or, at most, 3 residues within the peptide, usually at positions 2 and 8 or 9, or sometimes at positions 5 and 9. These key residues have been called anchor residues because it is thought that they anchor the peptide by binding in specific pockets in the floor of the peptide-binding groove, thus leaving more flexibility in the other residues in between, some of which must interact with the TCR. This concept of anchor residues binding in pockets has been confirmed by x-ray crystallography (92,93,131,132,133,134,135,136,137,304,305). The presence of more sharply defined motifs for peptides binding class I molecules than for those binding class II molecules may result from the greater length restrictions, which force all peptides binding to a given MHC molecule to line up in a similar position and therefore to have similar side chains to fit into pockets in the MHC groove at defined positions. These motifs may prove extremely useful in locating within protein sequences peptides that should be presented by a given class I MHC molecule. A correlation has been found between the affinity of peptide-binding to class I MHC molecules and the ability to raise CTLs to that peptide, that is, the immunogenicity of the peptide (306).

However, the predictive success rate of only about 30% for such motifs, based on primary anchor residues (303,307,308), can probably be improved by taking into account the role of other peptide residues that serve as secondary anchor residues, as defined for HLA-2.1, for example (309). This approach has been expanded to take into account a weighted value for each peptide residue in a matrix approach for predicting binding (120,310,311 and 312), and it has been applied to class II MHC molecules as well (114,313,314). It is also useful that MHC molecules have been found to fall into families that bind similar peptides containing what has been called a supermotif (117,315,316 and 317). A detailed structural analysis of each of the class I MHC binding pockets that shows how the class I MHC molecules fall into families that can be defined independently for each pocket, as if similar pockets have been resorted among different alleles, allows prediction of anchor motifs for other class I MHC molecules for which empiric data are lacking or are too limited (139). Motifs for peptides binding to class I and class II MHC molecules have been summarized by Rammensee et al. (109).

Although in all the published cases in which a peptide could be clearly discerned within the groove of a class I MHC molecule by x-ray diffraction the peptide appeared to be in an extended conformation (93,94,131,132,133,134,135,136,137,304,305), the spacing of the anchor residues 7 residues apart or 4 residues apart in most motifs would place them exactly 2 turns or 1 turn of an a helix apart if the peptides folded as helices, because each turn of an a helix has 3.6 residues. Moreover, in the case of class I MHC molecules, although fewer peptide binding sequences are known than for class II, 33 of 51 or 65% could fold as amphipathic helices, and the correlation was significant compared with other sequences from the same proteins (129). Similarly, 7 of the 11 natural peptides eluted from HLA-B27 by Jardetzky et al.

(298) would be amphipathic if they were folded as a helix (126). For comparison, 2 control sets of 11 control peptides were selected at random from the protein sequence database, with the only constraint besides similar length being that they shared the Arg at position 2 shared by all the B27-binding peptides, and only 2 of 11 and 3 of 11 were helically amphipathic ($p < .02$). Thus, even though the conformation adopted by the peptide when bound by the class I MHC molecule is not helical, the periodicity in hydrophobicity that resembles that of an a helix is imposed by the spacing of the pockets in the MHC groove that, in turn, enforce a spacing of peptide anchor residues similar to the spacing of residues of like hydrophobicity on one side of a helix (129), considering that most class I anchor residues are hydrophobic (109). Thus, this periodicity of hydrophobicity is predictive of MHC-binding peptides in a relatively allele-independent fashion, thus creating perhaps the broadest of supermotifs (129).

Finally, the polymorphism of class I MHC molecules within the peptide binding groove, like that of class II MHC molecules, leads to the phenomenon of *Ir* gene control of responses. For example, response of female mice to the H-Y male antigen occurs in mice expressing D^b because this is the class I molecule that presents the H-Y peptide (318,319 and 320). Strains of mice lacking D^b generally do not respond to H-Y antigen.

Recognition by a T-Cell Receptor

The same issues apply here as for $CD4^+$ T cells discussed earlier. The potential TCR repertoire is enormous, and absolute holes in the repertoire are probably rare (321). For example, the subset of peptides from hepatitis C virus (HCV) containing a motif for HLA-A2.1 binding that actually elicited CTLs in HLA-A2.1–transgenic mice were predictive of the subset recognized by CTLs from HCV-infected human patients, despite the differences in murine and human T cell-repertoire (152). However, holes created by self-tolerance may be significant, and they certainly would be expected to affect recognition of determinants that resemble self.

Requirement for Help

Like a B-cell, a CTL requires some form of T-cell help to be activated. Not all antigenic determinants presented by class I MHC molecules necessarily induce help as well. Although the existence of $CD8^+$ cells that can secrete interleukin-2 (IL-2) and provide help for other $CD8^+$ cells has been demonstrated (322), most $CD8^+$ CTL responses seem to be at least partially dependent on help from $CD4^+$ cells. Thus, an antigenic determinant that can be presented by class II MHC molecules may contribute to the immunogenicity of a peptide for induction of $CD8^+$ CTLs. Studies indicate that adding a helper site to a peptide presented by a class I MHC molecule can contribute to its immunogenicity, as, for example, in the case of determinants from the HIV-1 envelope protein or from HCV (235,251,323,324 and 325). Without attachment of a helper determinant, a peptide containing only a CTL determinant was not immunogenic (251). Similarly, a peptide containing an intrinsic helper determinant as well as a CTL determinant did not require attachment of an extrinsic helper determinant, whereas one that lacked an intrinsic helper determinant required an extrinsic one to be attached to induce CTLs (325). Moreover, improving the level of $CD4^+$ T-cell help can greatly enhance the immunogenicity of a peptide for eliciting $CD8^+$ CTLs (326). The concepts in this section should be applicable to the systematic development of peptide immunogens that are capable of eliciting strong CTL responses.

ENHANCING IMMUNOGENICITY THROUGH IMMUNOPOTENTIATION AND EPITOPE ENHANCEMENT

Given what we know about the mechanisms of antigen recognition by T and B lymphocytes and about antigen processing, what maneuvers can be used to attempt to enhance or potentiate the immune response to a particular antigen, that is, to enhance its immunogenicity? Attaching a small peptide or hapten to a large carrier protein could be considered immunopotentiation and is discussed earlier in this chapter. Here the focus is on three types of approaches in which covalent modifications of the antigen or admixtures to the adjuvant could significantly enhance the response.

Targeting the Antigen to Antigen-Presenting Cells

Investigators have shown, both with antiimmunoglobulin as antigen (327,328) and with antigen-specific B cells that bind antigen through the combining site of their surface immunoglobulin (27,28,29,329), that antigens that bind to surface immunoglobulin of a B cell are presented more efficiently to antigen-specific T cells, often at several orders of magnitude lower concentration. However, most antigens bind only to relatively rare B cells specific for them *in vivo,* and these few antigen-specific B cells are not sufficient to enhance immunogenicity, unless, perhaps, they have already been greatly expanded by prior immunization. To make any antigen more immunogenic by targeting it to such antigen-presenting cells, Kawamura and Berzofsky coupled antigen to antiimmunoglobulin antibodies that would bind specifically to B cells as antigen-presenting cells (328). Both antilight-chain and anti-IgM heavy-chain antibodies enhanced potency of the antigen for presentation by spleen cells to specific T-cell clones *in vitro,* whereas anti-IgA heavy-chain antibodies of the same isotype did not, a finding indicating that this was not a conventional carrier effect or simply binding to Fc receptors. Rather, only antibodies that could bind to B-cell surface immunoglobulin worked. The radiosensitivity of the presenting cell was consistent with B-cell presentation of the antigen. More strikingly, despite the presence of serum immunoglobulin that could potentially compete, these same antigen-antiimmunoglobulin constructs were also much more immunogenic *in vivo,* and they could elicit a detectable antibody response at 50- to 100-fold lower immunization doses (328). Again, the control construct in which the antigen was coupled to anti-IgA heavy-chain–specific antibodies did not enhance immunogenicity, so the immunopotentiation was not simply a conventional carrier effect. As a carrier to elicit immunoglobulin-specific T-cell help, the anti-IgA construct should have functioned equivalently to the antilight chain or the anti-IgM. Therefore, this *in vivo* immunopotentiation must be caused by targeting of antigen to B cells as antigen-presenting cells, which then enhance induction of antigen-specific T-cell help and so increase the antibody response (328). This same immunopotentiation was subsequently shown to occur with antigen coupled to anti-IgD antibodies, even without adjuvant (330). The anti-IgD antibodies have the potential advantage that there is little circulating IgD to compete with the B-cell surface IgD for binding the antigen–anti-IgD complex. Furthermore, this method of immunopotentiation is not unique to antibodies to B-cell surface immunoglobulin. For example, Carayanniotis and Barber found that coupling of antigen to antibodies specific for other surface molecules on antigen-presenting cells, such as class II MHC molecules, can also greatly increase their immunogenicity, even without the use of an adjuvant (331). This approach may therefore be useful in vaccine development, because the same antiimmunoglobulin or anti-MHC molecule can serve not only as a conventional carrier, but also as a specific targeting agent to produce high-affinity binding of antigens to antigen-presenting cells and therefore can reduce the concentration necessary to elicit a response. Moreover, the response would not be just an antibody response using T-cell help to the carrier, but it would also be a helper T-cell response to the targeted antigen presented more efficiently by the target presenting cell.

Incorporation of Cytokines in the Adjuvant

One of the limiting factors in immunogenicity for induction of an antibody response is the ability of the antigen to elicit T-cell help. Failure to elicit help because of failure to bind to a class II MHC molecule is the basis for many cases of *Ir* gene low responsiveness, as discussed earlier (37). Although cognate help, elicited, for example, by coupling the antigen to a carrier containing structures that can be presented by the class II MHC molecules of the animal in question, may be more efficient than noncognate help, it may nevertheless be possible to compensate for inadequate help by the addition of IL-2. IL-2 can help to expand the suboptimal number of T-helper cells present, and it can mimic noncognate help by a direct effect on the B cell (332,333 and 334). Therefore, the question was raised whether incorporation of IL-2 in the adjuvant emulsion would enhance the immunogenicity of a protein in an *Ir* gene low-responder strain of mice (335). Indeed, low responders to myoglobin made antimyoglobin antibodies at nearly the same level as high responders after a single immunization when recombinant IL-2 was incorporated in the adjuvant (335). No increase was noted in the response of high responders above this level, a finding consistent with the interpretation that IL-2 increased or substituted for help in the low responders and that help was not limiting in the high responders. Similar enhancement of immunogenicity was seen for short peptides from the malaria circumsporozoite protein when IL-2 was included with the antigen in the adjuvant (336). In this case, the effect was shown not to simply result from noncognate help specific for the human IL-2 molecule as a carrier, because a mutant of IL-2 that was equally immunogenic but lacked lymphokine activity had no effect (336). An attempt to take advantage of this method by incorporating the gene for IL-2 along with antigen in a recombinant vaccinia virus did not result in increased immunogenicity for the antigen expressed, but it did greatly attenuate the viral infectivity, perhaps by increasing the T-cell response to the virus (337). The use of an emulsion or perhaps other slow-release formulation seems to be important to keep the IL-2 in the same local area as the antigen, because simply injecting IL-2 intravenously multiple times during 3 days after immunization was not sufficient to produce any significant enhancement of antibody response (336; H. Kawamura, S.A. Rosenberg, and J.A. Berzofsky, unpublished data).

The success of this type of approach led to the question whether other cytokines, such as IL-4, IL-12, or granulocyte-macrophage colony-stimulating factor (GM-CSF), could also be incorporated into the adjuvant emulsion not only to enhance immunogenicity but also to steer the immune response in a desired direction, such as toward T-helper cell subtype (Th1 or Th2) cytokine responses or toward CTL induction, or particular antibody isotypes (338). In a comprehensive comparison of eight different cytokines emulsified in incomplete Freund's adjuvant with either of two different HIV-1 peptide vaccine constructs, and tested in mice of different strains, seven different immune responses were analyzed (338). GM-CSF was found to increase most responses without tipping the balance between Th1 and Th2 phenotypes (338), similar to the enhancement of responses observed with this cytokine by other investigators (339,340). In contrast, IL-4 in the adjuvant enhanced Th2 responses, whereas IL-12 in the adjuvant enhanced Th1 and CTL responses (338). The cytokines could also influence the antibody isotypes produced. Strikingly, a synergy was observed between GM-CSF and IL-12 in increasing CTL responses (338), which we now know to result from their action through different mechanisms in which the GM-CSF increases functional antigen presentation, whereas IL-12 increases interferon-g production (340a). A similar synergy for CTL induction was seen between IL-12 and tumor necrosis factor-a (TNF-a), which also synergize to markedly increase the production of interferon-g (338). Triple synergy of IL-12, TNF-a, and GM-CSF was shown to be more effective than any combination of two of these cytokines in inducing CTLs and also in protecting against challenge of mice with a recombinant vaccinia virus expressing the HIV-1 envelope protein (340a, in preparation). A similar enhancement of immunogenicity and steering of the response could be achieved with DNA vaccines by incorporating cytokine genes in the plasmid or an associated plasmid (216,341,342 and 343). Indeed, IL-12 and GM-CSF seem to synergize in DNA vaccines as well (216). IL-12 can also been incorporated in mucosal vaccines to alter cytokine production (344) or to enhance mucosal and systemic CTL

induction (345,346,346a).

Besides cytokines, other molecules can be incorporated into a vaccine to enhance immunogenicity. These include costimulatory molecules (216,347,348), immunostimulatory DNA sequences or oligonucleotides containing CpG motifs (349,350,351,352 and 353), and chemokine molecules (354). Thus, a host of immunomodulatory molecules can be used as needed not only to increase immunogenicity, but also to steer or manipulate the immune system to achieve a particular type of response.

Epitope Enhancement: Modification of the Structure of the Antigen to Increase Immunogenicity

If the immune system exerts natural selection on the evolution of pathogens, one would expect that pathogens evolve to evade the immune system. Thus, the sequences of viral or bacterial proteins would not be expected to be optimally immunogenic. In principle, one should be able to make vaccines that are more immunogenic than the pathogens themselves. One approach to accomplish this is based on the idea that some amino acid side chains that are not involved in interaction with the TCR can adversely affect binding to the MHC molecule, so altering these may lead to improved antigen presentation without loss of T-cell specificity (111,346,355,356,357 and 358). Boehncke et al. observed that removal of a negative charge by replacement of a Glu with an Ala or Gln residue increased the affinity of an HIV envelope helper peptide, T1, for binding to the murine class II molecule, I-E^k, and increased potency for stimulating T1-specific T cells (355). Ahlers et al. therefore tested whether this same modification would increase immunogenicity, and indeed it did, not only for T-cell proliferation, but also for providing help for induction of a CTL response to another epitope attached to this helper epitope (326). A genetic experiment showed that the enhancement of induction of MHC class I–restricted $CD8^+$ CTLs mapped to the class II MHC molecule, a finding indicating that it was indeed caused by increased help from the modified helper epitope. This result provides strong evidence for the importance of $CD4^+$ MHC class II–restricted helper T cells in optimal induction of a $CD8^+$ MHC class I–restricted CTL response. It also serves as proof of principle for the process of epitope enhancement, in which one can modify an amino acid sequence to make a peptide epitope more efficacious. This approach was extended to a human HLA class I molecule, HLA-A2.1, in the case of an HCV core peptide (359). Modification of the sequence of this epitope increased its potency for sensitizing targets for lysis by core-specific human CTLs and increased its immunogenicity for inducing an HCV core-specific CTL response in HLA-A2.1–transgenic mice. Similar findings were made for a peptide epitope from the HIV-1 reverse transcriptase (360), as well as a peptide from the human melanoma tumor antigen, gp100, which, when modified, was more effective at eliciting a $CD8^+$ T cell-response in patients with melanoma (361,362). Thus, the approach of epitope enhancement by sequence modification may turn out to be a useful tool to make second-generation vaccines that are more effective than the pathogens themselves.

A less specific approach to improved immunogenicity of proteins is cationization of the proteins, that is, making them positively charged, by converting carboxyl groups to aminoethyl amide groups. This alteration has been shown to reduce the concentration required to stimulate T cells *in vitro* by several orders of magnitude, as well as to increase immunogenicity *in vivo* even without adjuvant (363,364 and 365). The antibodies and T cells elicited appear to crosss-react with the native protein. Although the exact mechanism of the immunopotentiation is not clear, the finding that the concentration required for activation of T cells *in vitro* is markedly reduced suggests that the cationized proteins are more efficiently taken up or processed by antigen-presenting cells. It seems less likely that the affinity for specific MHC molecules is increased, because the effect is not limited to certain MHC molecules. Moreover, the positive charges would be introduced in different places in the protein, not in the same location with respect to each antigenic determinant. Therefore, some more global effect on uptake or processing seems to be a more likely mechanism. Regardless of the mechanism, cationization appears to be a potentially widely applicable method for enhancing immunogenicity.

CONCLUSION

The selective use of cytokines and the modification of antigens to enhance uptake, processing, and presentation provide new methods of potentiating and steering an immune response that complement the more traditional adjuvants. As we learn to identify the minimal antigenic determinants required for antigenicity, to improve on them by epitope enhancement, and to combine these in a way to make them more immunogenic, for instance, by providing cognate help from T cells specific for the same antigen, we can hope to make artificial vaccines that are more selective for particular responses than would be whole proteins. Other modifications may take advantage of new knowledge on the specificity of proteases performing antigen processing, on the specificity of TAP transport into the endoplasmic reticulum, or on the conformational specificity of antibodies. These engineered constructs, combined with new methods of immunopotentiation such as those discussed earlier, may allow a new generation of vaccines designed to elicit desired immune responses selectively.

8 LYMPHOCYTE SIGNALING

Lyse A. Norian, Ph.D., and Gary A. Koretzky, M.D., Ph.D.

T and B lymphocytes are the effectors of adaptive immune responses. Recognition of specific antigens occurs through engagement of either T-cell antigen receptors (TCRs) or B-cell antigen receptors (BCRs), and it leads to clonal proliferation, differentiation, and activation of effector functions in lymphocytes. These events are directed by a complex network of intracellular signal transduction events that is initiated on ligation of either the TCR or BCR. Lymphocyte signaling encompasses a wide array of biochemical reactions that translate alterations in the status of cell surface receptors into the production of activation-induced gene products and the rearrangement of the cytoskeleton. This chapter focuses on the biochemical events generated as a result of either TCR or BCR ligation.

The TCR and BCR are expressed on the surface of lymphocytes as part of multimeric protein complexes that contain both antigen recognition and signal transduction components (1,2,3 and 4) (Fig. 8.1). In both T and B cells, antigen recognition occurs through a polymorphic protein structure that is composed of disulfide-linked subunits. The TCR is heterodimeric, and it can be composed of either a and b chains or, in a minority of cells, g and d polypeptides. The BCR consists of membrane-bound immunoglobulin made of two heavy- and light-chain heterodimers. Random recombination events between multiple gene segments encoding these polypeptides give rise to their polymorphic nature and enable these receptors to recognize a tremendous array of antigens. However, the TCR and BCR do not possess any intrinsic enzymatic activity, and they must therefore rely on associations with other molecules to transduce signals within the cytosol. The signal transducing component of the antigen-receptor complex differs structurally between T and B lymphocytes. In T cells, signal transduction is mediated by six invariant CD3 polypeptide chains that associate with the TCR noncovalently. The CD3 chains are organized into de and ge heterodimers, and zz homodimers (5). Each d, e, and g chain possesses one copy of a motif that is essential for the propagation of signal transduction events arising from the TCR, the immunoreceptor tyrosine-based activation motif (ITAM). In contrast, the z chains each contain three ITAMs (2). Tyrosine residues located within this characteristic YXXL/I-X_{6-8}-YXXL/I motif (where Y designates the amino acid tyrosine, L designates leucine, I designates isoleucine, and X is any amino acid) are rapidly phosphorylated after TCR engagement. Although structurally different, the signal transduction component of the BCR functions in an identical manner. Composed of two separate heterodimers, the invariant Ig-a and Ig-b chains each contain one ITAM that is phosphorylated on BCR ligation (6).

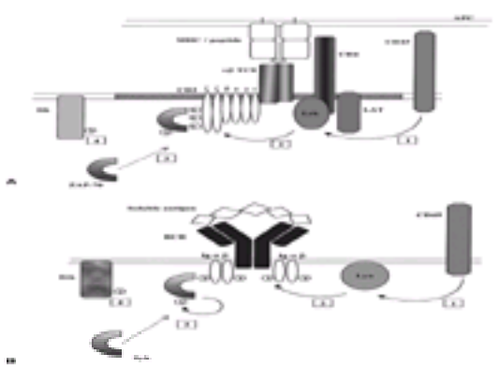

Figure 8.1. A comparison of receptor-proximal protein tyrosine kinase (PTK) activation events in T and B lymphocytes. **A**: Interaction of the T-cell receptor with specific peptide/major histocompatibility complex complexes leads to dephosphorylation of the src PTK, Lck, by CD45 *(1).* Activated Lck then phosphorylates tyrosine residues within immunoreceptor tyrosine-based activation motifs (ITAMs) on CD3 chains *(2).* This induces ZAP-70 translocation to the ITAMs, and allows for its activation by src kinases *(3).* Itk is recruited to the plasma membrane through its PH domain and associations with adapter molecules, and it undergoes phosphorylation-dependent activation by src kinases (4). **B**: Interaction of the BCR with soluble antigen leads to the dephosphorylation of the src PTK, Lyn, by CD45 *(1).* Activated Lyn then phosphorylates tyrosine residues within ITAMs on Ig a and b *(2).* This induces Syk to translocate to the ITAMs and to undergo autophosphorylation *(3).* Btk is recruited to the plasma membrane through its PH domain and associations with adapter molecules, and it undergoes phosphorylation-dependent activation by src kinases such as Lyn *(4).*

Phosphorylation of the ITAM residues is accomplished by members of the src family of protein tyrosine kinases (PTKs). Activation of these kinases is one of the earliest detectable events that follows engagement of either the TCR or BCR (1). Activity of the src kinases is regulated by a balance of phosphorylation and dephosphorylation on key regulatory tyrosine residues. This indicates that phosphatases are also critical mediators of T- and B-cell signal transduction events (7).

After tyrosine phosphorylation of the signal transducing components of TCR or BCR complexes, another family of PTKs is recruited to the complex and is activated. The syk PTKs inducibly associate with CD3 or Ig-a and Ig-b ITAMs by a protein-protein interaction domain referred to as an SH2 (src homology 2) domain (8,9), which mediates binding to phosphorylated tyrosine residues. Once syk PTKs are bound to the ITAMs, they are phosphorylated by src PTKs and become fully active (9). Activated syk PTKs then phosphorylate several important downstream effector molecules and adapter molecules. Adapter molecules are proteins that possess no enzymatic or transcriptional functions, but they coordinate signal transduction by acting as scaffolds around which signaling complexes are formed (10). These complexes effectively bring downstream substrates into contact with their effectors. Therefore, lymphocyte signal transduction is regulated initially by a series of tyrosine phosphorylation events that result in the generation of multimeric clusters of adapter proteins and effector molecules at the site of the engaged antigen receptors.

Although the scheme of signal transduction events initiated by antigen receptors is similar, ligation of the TCR and BCR results in diverse cellular outcomes. These differences are regulated by the specific pattern of kinases, adapter molecules, and downstream effectors, such as transcription factors, that are present and are activated in either T or B cells. To facilitate understanding of lymphocyte signal transduction, this chapter approaches biochemical events in terms of three main categories: activation of PTKs, integration of signal transduction by adapter molecules, and roles of downstream effector molecules. Within each category, both positive and negative regulators of signal transduction are discussed. The major focus is on signaling mediators in T lymphocytes, but throughout the chapter, similarities and differences between T and B cells are discussed.

ACTIVATION OF PROTEIN TYROSINE KINASES

Positive Regulators of Signal Transduction

Src Family Protein Tyrosine Kinases

All downstream biochemical and cellular changes induced by ligation of the TCR or BCR rely on activation of src kinases. Family members Lck and Fyn are thought to be of primary importance in T cells, whereas Lyn and Blk assume prominent roles in B cells (3,4). The src family is characterized by the presence of three functional domains: a kinase domain, an SH2 domain that mediates interactions with phosphorylated tyrosine residues in the context of specific amino acids lying carboxy-terminal to the tyrosine, and an SH3 domain that mediates binding to proline-rich regions on other proteins. In addition, the src kinases possess a myristylated

glycine residue in their amino-terminus that leads to constitutive localization at the plasma membrane (1).

Evidence indicates that src kinases are not randomly distributed across the surface of lymphocytes, but rather are found associated with transmembrane proteins in unique microdomains within the plasma membrane. In resting T cells, Lck is found associated with the cytoplasmic tail of either the CD4 or CD8 co-receptor (Fig. 8.1A). Both CD4 and CD8 are contained within membrane fractions termed glycosphingolipid-enriched microdomains (GEMs) (11). GEMs also possess high concentrations of cholesterol, glycosylphosphatidylinositol (GPI)-anchored proteins, and molecules important for the induction of lymphocyte signal transduction, such as src kinases. It is thought that during the process of TCR ligation, the TCR/CD3 complex, which is normally excluded from the GEMs, rapidly becomes associated with these structures (11). This movement would permit the activated src kinases to phosphorylate ITAM residues. Therefore, the localization of src kinases to GEM regions of the plasma membrane, and their segregation from the TCR/CD3 complex in resting cells, may create another mechanism by which lymphocyte signaling is regulated.

The functional status of src kinases is controlled by a balance of tyrosine phosphorylation and dephosphorylation events. In an inactive state, src kinases are found with a phosphorylated tyrosine residue in their carboxy-terminals. Phosphorylation at this site is predicted to induce an intramolecular association with the SH2 domain, thereby causing a conformational blockade of the kinase domain (12). Therefore, src kinase activation requires dephosphorylation of this negative regulatory residue. In both T and B cells, this is accomplished by the transmembrane phosphatase CD45 (13,14). The importance of CD45 activity has been demonstrated in T-cell clones and variants of the Jurkat T-cell line deficient in CD45 expression. These cells are unable to respond normally to TCR ligation, but they can respond if proximal events, such as src kinase activation, are bypassed by stimulation with pharmacologic agents (13,15). The importance of CD45 function is illustrated in CD45-deficient mice, which display marked abnormalities in thymocyte development and mature T-cell activation (16).

Activation of src kinases may also be influenced by their position in GEMs and their relative proximity to the TCR. Although it is known that CD45 is required to trigger activity of src kinases, the exact mechanisms responsible for this remain unclear. Observations that the phosphatase activity of CD45 does not depend on TCR engagement conflict with evidence that src kinase activity increases significantly only during the process of T-cell activation (17,18).

A possible solution to this dilemma is suggested by work focused on visualizing molecular interactions at the site of contact between T cells and antigen-presenting cells. Several laboratories have shown that cognate engagement of the TCR initiates the dynamic rearrangement of transmembrane surface proteins and intracellular signaling molecules into ordered structures referred to as SMACs (supramolecular activation clusters) (19) or immunologic synapses (20). Results from these studies indicate that Lck and CD45 are repositioned differentially in the plasma membrane, relative to the TCR, after antigen receptor engagement. Further evidence indicates that CD45 may be excluded from GEMs at all times because of limitations in the size of its transmembrane domain (21). Although the exact mechanism of src kinase activation remains unresolved, it seems likely that clues derived from examination of protein localization within the plasma membrane will be essential for understanding these events.

Syk Family Protein Tyosine Kinases

The syk family of PTKs consists of two members: Syk and ZAP-70 (for z-associated protein of 70 kd). Unlike the src kinases, these proteins are cytosolic and possess tandem amino-terminal SH2 domains, multiple phosphorylatable tyrosine residues, and a carboxy-terminal kinase domain. Both ZAP-70 and Syk are expressed in T lymphocytes, whereas only Syk is found in B cells (1).

Phosphorylation of Syk and ZAP-70 modulates not only their enzymatic activity, but also interactions with other proteins. After recruitment to phosphorylated ITAMs, Syk undergoes autophosphorylation and becomes fully active (Fig. 8.1B). In contrast, ZAP-70 requires transphosphorylation by src kinases to become activated (Fig. 8.1A) (2). Many tyrosine residues on Syk and ZAP-70 are phosphorylated after TCR or BCR ligation. Some phosphotyrosines may negatively regulate Syk and ZAP-70 function by allowing an adapter protein known as Cbl to bind through its SH2 domain (22). Models for the role of Cbl as a negative regulator of signal transduction are discussed later in this chapter.

Numerous downstream signal transduction events depend on the activation of Syk and ZAP-70. In T cells, ZAP-70 phosphorylates the adapter molecules LAT (for linker of activated T cells) (23) and SLP-76 (for SH2-domain—containing leukocyte phosphoprotein of 76 kd) (24). These molecules are essential mediators of T-cell signaling (see later). Similarly, in B lymphocytes, Syk phosphorylates a homolog of SLP-76 called B-cell linker protein, or BLNK (25). In addition to these adapter molecules, ZAP-70 and Syk contribute to the phosphorylation and activation of phospholipase C-g (PLC-g) isoforms (2). These enzymes cleave membrane-associated phosphatidylinositol 4,5-bisphosphate (PIP_2) to inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG) (26,27). IP_3 regulates intracellular calcium (Ca^{++}) levels by releasing Ca^{++} sequestered in the endoplasmic reticulum, thereby increasing the cytosolic Ca^{++} concentration. Production of DAG leads to activation of protein kinase C isoforms. The critical nature of ZAP-70 is evidenced in patients with defective expression of this PTK, which is manifested by a loss of T-cell function resulting in a severe combined immunodeficiency phenotype (28). Therefore, syk family PTK function is required for the propagation of signal transduction events initiated by TCR or BCR ligation and src kinase activation.

Tec Family

The third major family of PTKs involved in positively regulating lymphocyte signaling is the Tec family. This family consists of five members: Tec, Btk (or Bruton's tyrosine kinase), Itk (or inducible T-cell tyrosine kinase) also referred to as Emt (expressed in mast and T cells), Rlk or Txk, and Bmx (29). These kinases are cytosolic, but they are rapidly recruited to the plasma membrane after TCR or BCR ligation. For all members except Rlk/Txk (30), this localization is mediated by an amino-terminal pleckstrin homology (PH) domain, which associates with specific lipids produced by the action of another enzyme, phosphatidylinositol-3-kinase (PI3K) (4). Association with the plasma membrane brings Tec PTKs into proximity of the src PTKs, and this activates the Tec kinases by phosphorylating a key tyrosine residue located within the Tec catalytic domain (31) (Fig. 8.1). However, evidence obtained with a ZAP-70–deficient Jurkat T-cell line suggests that ZAP-70 is also indirectly required for Tec family kinase activation (32). In addition to the PH domain, Tec kinases possess one SH2 domain, one SH3 domain, and a carboxy-terminal kinase domain (2). Tec, Itk, and Rlk/Txk are activated in T cells in response to TCR engagement (33,34), and Btk is activated after BCR ligation (29). The requirement for Btk in B-lymphocyte signal transduction is illustrated by loss of function mutations in the protein, which result in X-chromosome–linked agammaglobulinemia (XLA), a disease characterized by profound B-cell immunodeficiency in mice and humans (35). Although early work suggested that mutations in the PH domain of Btk were associated with this disease, a more recent study indicates that mutations in any of the Btk functional domains may cause it (36).

Understanding of the specific contributions of Tec family kinases in both B- and T-cell signal transduction has come from studies using cell lines and mice made deficient for one or more family members. T cells from Itk-deficient mice demonstrate decreased levels of PLC-g1 phosphorylation and IP_3 production after TCR engagement (37). These defects do not substantially alter the amounts of Ca^{++} released from internal stores, but they do impair the opening of calcium channels in the plasma membrane, resulting in a loss of sustained Ca^{++} mobilization in these cells. Examination of activated Itk null T cells shows that z chains are phosphorylated normally, as is ZAP-70 (37). These data suggest that Itk may cooperate with ZAP-70 to bring about PLC-g1 phosphorylation and activation. Similar results have been obtained in a Btk-deficient B-cell line; these cells also demonstrate a decrease in PLC-g phosphorylation and function (38). An inadequate calcium response likely causes the inability of $Itk^{-/-}$ T-helper 0 (Th0) cells to develop into Th2 cells, because a loss of function in the calcium-dependent transcription factor NFAT (for nuclear factor of activated T cells) appears to prohibit interleukin-4 (IL-4) production necessary for the differentiation of Th0 cells into a Th2 phenotype (39). The phenotype of T cells deficient in both Itk and Rlk is more pronounced, and it shows significant losses in the ability of T cells to proliferate and produce cytokines (40), again as a likely result of diminished IP_3 production and calcium responses. Therefore, one role of Tec family kinases is to contribute to the generation of a prolonged rise in intracellular Ca^{++} concentration during the course of T- or B-lymphocyte activation.

The exact mechanism for Tec kinase activation of PLC-g remains unclear. However, studies using mutations in various functional domains of Itk and Btk have suggested potential mechanisms. Loss of the PH domain, for example, prohibits Itk from associating with the plasma membrane after TCR ligation. As expected, this form of Itk is not phosphorylated and remains inactive (41). The SH2 domains of Itk and Btk appear to mediate their interactions with SLP-76 and BLNK, respectively. These associations are not constitutive, but they are observed only after SLP-76 or BLNK become tyrosine phosphorylated in response to antigen receptor ligation (42). Because data indicate that PLC-g isoforms associate with BLNK in B cells (43), this association may provide a mechanism whereby Tec kinases are brought into contact with PLC-g, although such trimolecular complexes have not yet been detected.

Negative Regulators of Signal Transduction

Csk Protein Tyrosine Kinase

Not all PTKs enhance or propagate lymphocyte signaling events. One such example is Csk (or C-src kinase), a cytosolic PTK that opposes the action of CD45 by phosphorylating the negative regulatory tyrosine located in the carboxy-terminals of src kinases (44). By doing so, it negatively regulates T-cell signal transduction.

Csk comprises an amino-terminal SH3 domain, a central SH2 domain, and a carboxy-terminal catalytic domain, much like the src family of kinases. It is ubiquitously expressed, but it is present at higher levels in cells of hematopoietic origin. The critical role of Csk was demonstrated in mice carrying a homozygous deletion of the csk gene, a mutation that results in embryonic lethality (45). To study the effects of Csk on T-cell development, mice carrying a conditional deletion of the csk gene were

generated (46). Thymocytes from these mice mature from the $CD4^-/CD8^-$ double-negative precursor stage through the $CD4^+/CD8^+$ double-positive stage and to the $CD4^+$ single-positive stage without receiving signals from the pre-TCR or TCR. Closer examination of src kinase activity in $Csk^{-/-}$ cells reveals high levels of both Lck and FynT activation, even without TCR ligation. Therefore, without Csk continually to counteract CD45 dephosphorylation of src kinases, even in a resting state, the balance is shifted such that src kinases become constitutively active and initiate inappropriate signal transduction events.

Both the SH2 and SH3 domains of Csk must be present and functional for Csk to phosphorylate src kinases. If either domain is deleted, Csk activity will decrease significantly (47). This finding suggests that associations with other molecules are needed for Csk to function as a negative regulator of src kinase activity. One binding partner that has been identified is a proline-enriched protein tyrosine phosphatase designated PEP (48). The SH3 domain of Csk associates constitutively with PEP, and the formation of a Csk-PEP complex appears to be required for either molecule to inhibit T-cell–signaling events. As part of a Csk-PEP complex, PEP has been shown to dephosphorylate the positive regulatory tyrosine in the src kinase Fyn, thus terminating its activity (49). PEP can also dephosphorylate ZAP-70, at least in a heterologous system using transfections in the COS cell line (49). These results suggest that to understand the regulation of PTK activity in T and B lymphocytes completely, additional work will be required to identify binding partners of PTKs and to determine the functional significance of these interactions.

INTEGRATION OF SIGNAL TRANSDUCTION BY ADAPTER MOLECULES

Positive Regulators of Signal Transduction

LAT

Although PTKs are potent transducers of signal transduction events, their activity is spatially confined to the inner surface of the plasma membrane and the region adjacent to phosphorylated ITAMs within the antigen-receptor signaling complexes. Clearly, additional mechanisms must exist to link these receptor-proximal events to distal effectors that reside in the cytosol and nucleus. It has become evident that the category of proteins known as adapter molecules functions as scaffolds to bring cytosolic proteins into contact with activated PTKs localized at the site of clustered TCRs. In this way, adapter proteins couple TCR-proximal events and downstream signal transduction pathways.

The transmembrane adapter protein LAT illustrates the critical necessity for these molecules in the propagation of signal transduction in T cells. Early studies in the area of T-lymphocyte signaling demonstrated a predominant phosphoprotein of 36 kd that was a substrate of activated PTKs. This phosphoprotein was cloned and was identified as the adapter protein LAT (23). LAT is a small protein that contains multiple cytoplasmic tyrosine residues that are phosphorylated by ZAP-70 after TCR ligation, a feature that makes it an ideal binding partner for proteins with SH2 domains. Although LAT is expressed in natural killer (NK) cells, mast cells, and platelets, it is not present in B lymphocytes.

LAT is targeted constitutively to GEM regions of the plasma membrane by posttranslational palmitoylation on two cysteine residues (50). LAT must be localized within GEMs for it to function as a mediator of T-cell activation (51). Like LAT, other key signaling molecules such as CD4 and CD8-associated Lck are present within GEMs, and LAT associates with these coreceptors (52). This interaction is thought to be important because it presumably enhances the ability of LAT to be phosphorylated by ZAP-70 once the TCR/CD3 complex moves into GEMs after receptor engagement.

Once phosphorylated, LAT associates with several other signaling molecules, both directly and indirectly. Such molecules as PLC-g1 and the p85 subunit of PI3K bind directly to LAT, as does the adapter molecule Grb2, which is discussed later (23). Other molecules, such as the adapter proteins SLP-76 and Cbl, are thought to associate with LAT indirectly. Therefore, LAT appears to assume an essential role as the center of a macromolecular signaling complex that is assembled after the TCR is bound (Fig. 8.2).

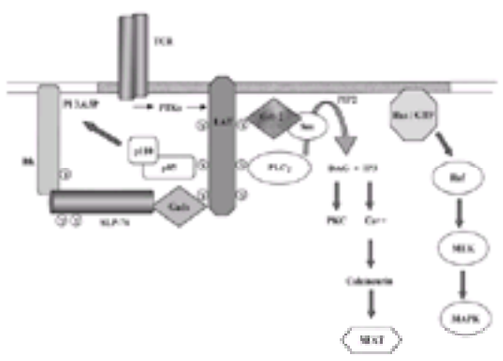

Figure 8.2. LAT (linker of activated T cells)–directed macromolecular complex formation is required for the generation of distal signaling events such as calcium mobilization and induction of the Ras/MAPK cascade in activated T cells. After T-cell receptor ligation, LAT is rapidly phosphorylated by protein tyrosine kinases, a process that allows key signaling molecules such as Grb2, PI3K, and PLC-g to interact with LAT directly. Other proteins, including SLP-76 and Sos, associate indirectly with LAT.

LAT is required for both T-cell activation and development. Mice made deficient for LAT expression illustrate a complete block in thymocyte maturation; thymocytes accumulate at an early $CD4^-/CD8^-$ double-negative stage, and are unable to progress beyond this point to enter circulation in the periphery (53). In response to TCR ligation, two different $LAT^{-/-}$ cell lines show diminished PLC-g1 phosphorylation (54,55), likely from the loss of upstream Itk activation (32). Predictably, subsequent deficiencies in IP_3 production and intracellular calcium mobilization are observed. As a result, transcriptional activity of the calcium-dependent NFAT is lost, and IL-2 promoter activity is absent (54,55). Production of many other cytokines may be deficient as well, because NFAT regulates transcription of numerous genes, although this has not yet been examined. Separate pathways using Ras and its downstream membrane-associated protein (MAP) kinases (MAPKs) are also impaired, leading to a loss of inducible surface expression of CD69. Additionally, SLP-76 phosphorylation is diminished, as is phosphorylation of the SLP-76-associated protein Vav (54,55). Despite these defects, global tyrosine phosphorylation does not appear to be inhibited, a finding indicating that many signaling events proceed in the absence of LAT expression.

LAT is not the only transmembrane adapter protein to be identified in T lymphocytes. Novel proteins such as TRIM (for T-cell receptor interacting molecule), SIT (for SHP-2 interacting transmembrane adapter protein), and KAP 10 also have been described. All three of these molecules are expressed in T cells, and work to elucidate their functions is ongoing. At this time, it is known that TRIM undergoes tyrosine phosphorylation after TCR ligation, and it then associates with the p85 subunit of PI3K (56). KAP 10 also binds to this PI3K subunit, as well as to the adapter protein Grb2 (57). Overexpression studies with SIT indicate that it may negatively affect NFAT activation and perhaps may terminate some T-cell responses (58). As additional transmembrane adapter proteins are identified, it will become increasingly important to understand their functional relevance to each other in terms of competition for binding partners and the effects on downstream cellular responses.

Grb2 Family

Many adapter molecules are cytosolic rather than transmembrane proteins, but they act similarly as scaffolds that recruit signaling molecules to the site of engaged TCRs. Grb2 (for growth factor receptor binding protein 2) is a small, ubiquitously expressed adapter molecule that has been conserved evolutionarily. It consists of an amino-terminal SH3 domain, a central SH2 domain, and a second carboxy-terminal SH3 domain. Grb2 was initially characterized as recruited to phosphorylated PTK receptors (59), and its role in linking growth factor receptors to activation of the Ras pathway is well documented (60). In fibroblasts, Grb2 constitutively associates through its SH3 domains with Sos, a Ras guanine nucleotide exchange factor (61). As Grb2 relocates to the plasma membrane, Sos is brought into contact with Ras. Sos induces Ras to release bound guanosine diphosphate (GDP), thereby promoting interaction with the more abundant guanosine triphosphate (GTP). This process alters the functional state of Ras, which becomes active and initiates a kinase cascade that leads to activation of several transcription factors.

To date, such a definitive relationship between Grb2 and either TCR or BCR complexes has proven more difficult to demonstrate. If Grb2 is recruited to engaged antigen receptors, it may do so indirectly by binding to the adapter molecule Shc (62). Shc is known to associate directly with tyrosine phosphorylated CD3 z chains and ZAP-70 in T cells (63,64). However, the presence of a z/Shc/Grb2/Sos complex has not been demonstrated.

Mounting evidence suggests that in T cells, Sos is not recruited directly or indirectly to the TCR complex. Instead, it may be localized to the plasma membrane as part of a macromolecular complex that forms around LAT (Fig. 8.2). Support for this idea has been provided by several independent studies. For example, it is known that Grb2 interacts inducibly with LAT after TCR ligation (23). Before the identification of LAT, a complex of a 36-kd protein, Grb2, and Sos was implicated in coupling TCR

engagement to activation of the Ras pathway (65). Based on current understanding of T-cell signaling, this early study may have demonstrated a role for LAT in activation of the Ras pathway, an idea that has been substantiated by findings using LAT-deficient T-cell lines (54,55). An equally plausible model is that Sos may be brought into the LAT signaling complex by way of association with a protein related to, but separate from, Grb2.

The proteins Grap (for Grb2-like accessory protein) and Gads (Grb-2 related adapter downstream of Shc) are members of the newly identified Grb2 family of adapter molecules. Like Grb2, both Grap and Gads consist of a central SH2 domain flanked by SH3 domains (66,67 and 68). However, Gads also possesses a proline rich region, and this could facilitate interactions with proteins that would not normally associate with Grb2. Gads was cloned independently by several different laboratories and therefore is also referred to as Grap2, Mona, GrpL, and Grf40 (69,70,71 and 72). Although Gads does not appear to associate with Sos, it does bind to Shc, LAT, and SLP-76 (69,70,71 and 72). Grap does interact with Sos, however, and it also binds to PLC-g1, LAT, and Shc (66,67). Thus, a Grap/Sos complex could be recruited to the plasma membrane through interactions with either Shc or LAT, although this has not been formally demonstrated.

The foregoing discussion has focused on ways in which Sos can translocate to the plasma membrane in T cells. A constitutive association between Grb2 and Sos is observed in B lymphocytes, yet these cells do not express the adapter molecule LAT. Although no homologous transmembrane adapter protein has been identified in B lymphocytes, the novel adapter molecule BLNK may perform an equivalent function.

SLP-76/BLNK

First characterized as an *in vitro* binding partner for Grb2, the adapter molecule SLP-76 is now recognized as an essential mediator of *in vivo* TCR-mediated signal transduction events. SLP-76 is a cytosolic protein consisting of an amino-terminal acidic region that contains multiple tyrosine residues, a central proline-rich region, and a carboxy-terminal SH2 domain (73,74). After ligation of the TCR, SLP-76 is rapidly phosphorylated by ZAP-70 (24), and inducibly associates with other proteins (Fig. 8.3). Although SLP-76 is expressed in a variety of cell types, including NK cells, mast cells, macrophages, and megakaryocytes, it is not present in B cells.

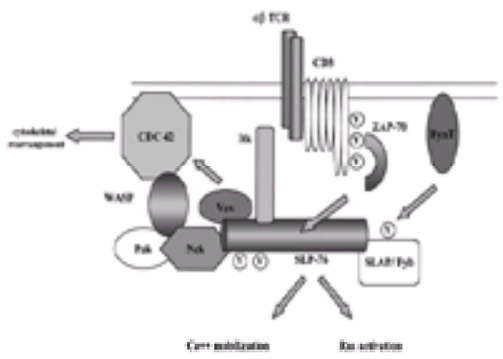

Figure 8.3. The adapter molecule SLP-76 is a central mediator of T-cell receptor (TCR)–induced signal transduction events. After TCR ligation, SLP-76 is tyrosine phosphorylated by ZAP-70. This permits SLP-76 to inducibly associate with such proteins as SLAP-130, and Itk. Binding of Vav and Nck to SLP-76 induces formation of a macromolecular complex that includes Pak and WASP and regulates cytoskeletal rearrangement. The presence of SLP-76 is required as well for downstream events including calcium mobilization and activation of the Ras/MAPK cascade.

The role of SLP-76 as a positive regulator of T-cell signal transduction was suggested from early studies using transient overexpression of SLP-76 in the Jurkat cell line. This work revealed that SLP-76 enhances activity of the MAPK member Erk, as well as transcriptional activity of NFAT and AP-1, resulting in heightened IL-2 promoter function (74,75). Further research showed that phosphorylation of two tyrosines, at positions 113 and 128, mediates the interaction of SLP-76 with the guanine nucleotide exchange factor Vav (76,77 and 78). Unlike Sos, Vav does not modulate Ras function, but acts on members of the related Rho family of GTPases. Overexpression of both SLP-76 and Vav produces a synergistic augmentation of IL-2 promoter activity. However, the interaction between SLP-76 and Vav does not appear to be required for this augmentation to occur, a finding suggesting that the two molecules function in distinct, but overlapping, pathways to enhance NFAT and AP-1 activity (79).

The binding of Vav to SLP-76 does appear to be essential for TCR-induced reorganization of the cytoskeleton. On engagement of the TCR, the cytoskeleton is reoriented and controls antigen receptor capping at the point of contact between the T-cell and stimulatory antigen-presenting cell. SLP-76 and Vav modulate actin polymerization through the formation of a trimolecular complex with another adapter molecule, Nck (80). Nck contains one SH2 domain and three SH3 domains (81). Through its SH2 domain, Nck binds to phosphotyrosine residues 113 and 128 on SLP-76 (82). The Nck/SLP-76 association may be critical, because Nck associates through its SH3 domains with the serine-threonine kinase Pak, and the Wiscott-Aldridge syndrome protein (WASP) (83,84). WASP binds to the activated form of cdc42, a member of the Rho GTPase family, and colocalizes with actin in activated T cells. The loss of WASP prohibits actin polymerization and antigen receptor capping (85). Pak is a serine-threonine kinase that becomes active after binding to GTP-bound cdc42. Studies using specific binding mutants have shown that the trimolecular SLP-76/Vav/Nck complex must be present for actin polymerization and antigen receptor capping to occur (80). Therefore, SLP-76 likely facilitates a cascade in which Vav activation of cdc42 leads to activation of Pak, a process that is possibly caused by the close proximity of substrates and effectors in a multimolecular complex. The results are actin polymerization within the T cell and capping of antigen receptors that may enhance prolonged signal transduction events (Fig. 8.3).

Information about additional functions of SLP-76 was gained by analysis of a Jurkat variant that is deficient in SLP-76 expression. In these cells, phosphorylation of ZAP-70, LAT, and Vav is unaffected by the loss of SLP-76, a finding indicating that these events can occur independently, or upstream, of SLP-76 (86). However, PLC-g1 phosphorylation and activity are entirely blocked. This finding suggests that PLC-g1 binding to LAT is not sufficient to ensure its phosphorylation by PTKs. Events downstream of PLC-g1 activation, including intracellular Ca^{++} mobilization and NFAT activity, are predictably absent in the SLP-$76^{-/-}$ cells. Loss of SLP-76 also negatively affects the Ras pathway, resulting in impaired Erk phosphorylation, decreased AP-1 transcriptional activity, and an inability of TCR ligation to lead to upregulation of the surface marker CD69 (86).

Although much can be learned about SLP-76 function by examining how its absence affects different T-cell responses, identification of molecules that interact with SLP-76 is also revealing. As an example, SLP-76 was initially shown to bind the SH3 domains of Grb2 *in vitro* (73), but this interaction was difficult to observe *in vivo.* An explanation for this discrepancy was provided by the finding that SLP-76 associates with Gads, not Grb2, *in vivo* (71,72,87). Overexpression of both SLP-76 and Gads results in an augmentation of NFAT and IL-2 promoter activity, a finding suggesting that the interaction of these proteins *in vivo* modulates Ca^{++} mobilization and downstream events (71,72,87).

After TCR ligation, SLP-76 inducibly binds through its SH2 domain to another adapter molecule referred to as SLAP-130 (for SLP-76 associated protein of 130 kd) (88) or Fyb (for Fyn-T binding protein) (89). SLAP-130/Fyb is expressed in T and myeloid cells, but it is not found in B lymphocytes. Sequence analysis of SLAP-130/Fyb reveals that it possesses a proline-rich region, multiple tyrosine phosphorylation sites, two nuclear localization motifs, and a carboxy-terminal SH3 domain (88,89). Phosphorylation of key tyrosine residues on SLAP-130/Fyb is accomplished by a T-cell–specific isoform of the PTK Fyn (90). Conflicting evidence has been generated regarding the cellular effects of a SLP-76/SLAP-130 association. Early work performed in the Jurkat T-cell line indicated that overexpression of SLAP-130 inhibited IL-2 promoter activity, a finding that supported a role for SLAP-130/Fyb as a negative regulator of TCR-mediated signal transduction events (88). More recently, however, several studies illustrated positive effects of SLAP-130/Fyb overexpression in Jurkat cells, resulting in augmented IL-2 promoter activity (89). The true nature of SLAP-130 function likely will require use of additional experimental techniques, such as analysis of cell lines or mice made deficient for this adapter molecule.

Although many facets of T-cell activation require the presence of SLP-76, T-cell development in the thymus also depends on SLP-76 expression. This finding was demonstrated through the generation of mice made deficient for SLP-76 by targeted disruption of the gene locus. SLP-$76^{-/-}$ mice possess a complete absence of mature T cells in the periphery (91,92). Thymocyte maturation in these mice is blocked at a $CD4^{-}/CD8^{-}$ double-negative stage during which SLP-76 levels are usually high (93). These data suggest that, as with signaling through the mature TCR, the pre-TCR present on pro-T cells also relies on SLP-76 for propagation of signals. In wild-type mice, the level of SLP-76 expression is downregulated after thymocytes pass through this critical stage of development, and it does not reach equivalently high levels again until T cells become activated in the periphery (93). Therefore, it appears that SLP-76 expression within the T-lymphocyte compartment is tightly regulated as an added means of controlling SLP-76 function.

B lymphocytes express a functional equivalent of SLP-76, BLNK, that also acts as a critical mediator of signal transduction in these cells (25). BLNK, also known as SLP-65 (94) and BASH (95), is a 70-kd protein that is rapidly tyrosine phosphorylated after BCR engagement. Like SLP-76, it consists of a similar functional domain structure: an amino-terminal acidic region containing multiple tyrosine residues, a central proline-rich region, and a carboxy-terminal SH2 domain (25). Homology at the amino acid sequence level, however, is low between the two molecules. BLNK also appears to have a more restricted expression pattern, in that it has been identified

only in B lymphocytes and macrophages.

BLNK shares many functional characteristics with SLP-76, but significant differences between the roles of the two molecules do exist. After BCR ligation, BLNK is phosphorylated on tyrosine residues by the PTK Syk (25). Once this occurs, the SH2 domain of Grb2 mediates binding to BLNK, and data support the presence of a BLNK/Grb2/Sos complex (25). Although Grb2 also binds to Shc in B cells, no evidence has indicated that Shc and BLNK associate indirectly through binding to Grb2. Using a DT40 B-cell line deficient in BLNK expression, it was shown that BLNK is required for activation of PLC-g isoforms (96). Phosphorylated BLNK associates inducibly with the SH2 domain of PLC-g isoforms, and mutations that prevent this interaction lead to a loss of PLC-g phosphorylation and activation (43). Predictably, downstream events, including intracellular Ca^{++} mobilization and NFAT function, are diminished as a result. Because of its structural similarities to SLP-76, and its functional similarities to LAT, it is possible that BLNK acts as a hybrid equivalent of both molecules in B cells.

More recently, it was demonstrated that BLNK is a critical mediator of B-lymphocyte development. Examination of mice made deficient for BLNK expression revealed a block in B-cell maturation at an early pro-B cell stage (97). In contrast to the loss of SLP-76, however, a few B cells are present in the periphery of $BLNK^{-/-}$ mice. These cells possess an altered phenotype from most mature B cells, in that they express increased levels of surface IgM, but do not express IgD. $BLNK^{-/-}$ IgM^{hi} B cells are able to mobilize intracellular calcium and to upregulate B7 expression on the surface after stimulation through the BCR. These findings suggest that other molecules within murine B cells can compensate for the loss of BLNK, albeit only partially. This does not appear to be true for the loss of BLNK in humans. A person with normal numbers of pro-B cells, but a complete loss of mature B cells, was identified as having a splice defect that abrogated processing of BLNK transcripts (98). Therefore, BLNK mRNA and protein were not detectable, and these defects likely were causally related to the absence of B cells in this patient.

Negative Regulators of Signal Transduction

Cbl

Although many adapter molecules function as positive coordinators of signal transduction events in T and B lymphocytes, some act instead to downregulate lymphocyte responses. The Cbl family of adapter molecules comprise perhaps the best-characterized negative regulators of lymphocyte signaling (22). The prototype of the family is a 120-kd cytosolic protein known as Cbl. Cbl is the cellular homolog of the viral, or v-cbl, gene product that has been shown to transform B lymphocytes. It is also a homolog of the *Caenorhabditis elegans* protein Sli-1, a finding indicating that the Cbl protein has been conserved evolutionarily. In addition to Cbl, the family also contains the proteins Cbl-b and Cbl-c, which display varying degrees of amino acid sequence homology to Cbl.

Like all adapter molecules, Cbl possesses multiple domains that allow protein-protein interactions. The amino-terminus of Cbl contains a divergent SH2 domain (99), the central portion includes a ring finger domain and a proline-rich region, and the carboxy-terminal consists of multiple tyrosine residues and a leucine zipper motif (22). Cbl-b is structurally similar to but slightly larger than Cbl. Cbl-c, in contrast, is a smaller protein that lacks carboxy-terminal tyrosine residues and a leucine zipper region.

Cbl is expressed in both T and B cells, and is rapidly tyrosine phosphorylated after TCR or BCR ligation. This is mediated by PTKs of both the Src and Syk families (100,101 and 102). Phosphorylation of Cbl allows it to interact with other SH2-containing proteins such as Vav, the p85 subunit of PI3K, and the adapter molecule CrkL (101,103,104 and 105). Binding to CrkL provides one method by which Cbl interferes with T-cell activation (Fig. 8.4). A ternary complex consisting of CrkL, Cbl, and C3G, a guanine nucleotide exchange factor for the GTPase Rap-1, has been implicated in regulating T-cell anergy (106). It is thought that formation of this complex allows C3G to activate Rap-1. Active Rap-1 can interfere with signaling through the Ras cascade by sequestering Raf, the kinase immediately downstream of Ras. Thus, signals downstream of Ras are prohibited, and blockade of T-cell activation results.

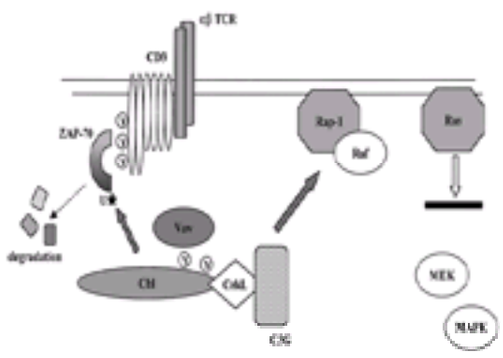

Figure 8.4. Models for the role of Cbl as a negative regulator of lymphocyte signal transduction. A ternary complex consisting of Cbl, CrkL, and C3G may lead to Raf sequestration by Rap-1, thereby blocking progression of the Ras/MAPK pathway. Cbl may also participate in the ubiquitination of Syk and ZAP-70, thereby resulting in degradation of these protein tyrosine kinases.

Cbl also negatively regulates the activity of Syk and ZAP-70, and it may do so through several different mechanisms. Evidence suggests that one method may be the Cbl-dependent ubiquitination and subsequent degradation of these PTKs (Fig. 8.4). In studies examining signals downstream of the platelet-derived growth factor receptor, Cbl was shown to function as an E3-ubiquitin-protein ligase (107,108). E3 molecules bring proteins into contact with E2-ubiquitin-conjugating enzymes, thus promoting degradation of these proteins. Support for the idea that Cbl functions in a similar manner in lymphocytes comes from examination of COS cells made to express Cbl; these cells show a correlation between Cbl expression and decreased levels of detectable Syk protein (109). Cbl has also been shown to bind to negative tyrosine residues on both Syk and Zap-70. This effect appears to be mediated through the SH2 and ring finger domains of Cbl, because mutations of cysteine residues in the ring finger domain abrogate the negative effects of Cbl on Syk function (110).

Cbl also associates with several other key proteins in lymphocyte signal transduction pathways. For example, Cbl associates with the SH3 domains of Grb2 (103), and such an interaction may interfere with the binding of Grb2 to Sos. The proline-rich domain of Cbl also mediates binding to the SH3 domains of Nck, Fyn, and Lck. The interactions with Fyn and Lck are constitutive, but they increase after TCR ligation, a finding implying that SH2 domain-mediated binding may also occur (22). Similarly, constitutive association with the p85 subunit of PI3K also increases after antigen receptor engagement. At this time, however, the physiologic effects of these Cbl interactions are not understood.

Although the exact mechanisms by which Cbl exerts its negative effects on lymphocyte signaling have not been elucidated fully, the role of this adapter molecule as an inhibitor of lymphocyte activation is clear. The most compelling evidence comes through examination of T cells isolated from Cbl-deficient mice. In these cells, TCR and CD3 surface expression is enhanced, and thymocytes show increased levels of tyrosine phosphorylation on ZAP-70, LAT, and SLP-76 (111,112). Downstream events such as activation of the MAPK pathway are also elevated. Mice lacking the Cbl-b molecule illustrate an even more important role for this isoform in both T- and B-cell signaling, because both cell types exhibit spontaneous activation in the periphery, leading to autoimmunity. Closer analysis of these $Cbl\text{-}b^{-/-}$ lymphocytes reveals enhanced signaling through both the TCR and BCR and an ability of the cells to proliferate in response to antigen receptor ligation alone, without a requirement for costimulation (113). These findings support the role of Cbl as a negative regulator of lymphocyte signaling and suggest that it plays a unique role in these cells that cannot be filled in its absence.

ROLES OF DOWNSTREAM EFFECTOR MOLECULES

The signal transduction events initiated by TCR or BCR ligation are propagated by activation of PTKs and coordinated by a variety of adapter molecules. These receptor-proximal occurrences eventually lead to the involvement of downstream effector molecules. Although numerous effectors become activated in T and B lymphocytes after antigen receptor engagement, the remainder of this chapter focuses only on the best-characterized among them. The selected examples demonstrate how ligation of a surface receptor is ultimately translated into transcription of activation-induced genes.

Phospholipase Cg and Ca^{++} Mobilization

One of the primary targets of PTK activation is the enzyme PLC-g. PLC-g functions by cleaving membrane-bound PIP_2 into IP_3 and DAG, a potent inducer of multiple protein kinase C (PKC) isoforms (26,27). The activation of PLC-g correlates with its tyrosine phosphorylation, and this appears to be accomplished coordinately by the activity of ZAP-70 and Tec kinase family members (2,37). Correct cellular localization of PLC-g is required for its phosphorylation to occur. Evidence of this has been provided by examination of T cells that lack either LAT or SLP-76, or B cells that are deficient in BLNK, because these cells display greatly decreased levels of PLC-g

phosphorylation and function (86).

Production of IP_3 controls the release of Ca^{++} from stores in the endoplasmic reticulum. Ca^{++} release occurs when IP_3 binds to ligand-gated ion channels in the endoplasmic reticulum membrane (114). This leads to a rapid, but transient, increase in the concentration of cytosolic, or intracellular Ca^{++}. Many proteins are sensitive to alterations in the level of intracellular calcium and become activated as a result. Two examples are the Ca^{++}–release-activated Ca^{++} current (CRAC) channels located in the plasma membrane, and the serine phosphatase calcineurin. The opening of CRAC channels mediates an influx of extracellular Ca^{++}, and produces a sustained elevation in intracellular Ca^{++} concentration. Activation of calcineurin depends on the function of the Ca-binding protein, calmodulin.

Important substrates of calcineurin include members of the NFAT family of transcription factors. In resting lymphocytes, NFAT proteins are confined to the cytosol. Dephosphorylation of key regulatory residues by calcineurin allows NFAT members to translocate to the nucleus, where they coordinately regulate transcription of activation-induced genes such as IL-2, IL-4, and tumor necrosis factor-a (115). Inhibition of NFAT translocation is mediated by two potent immunosuppressive agents, cyclosporine (Cyclosporin A or CsA) and FK506. These drugs form complexes with the cellular proteins cyclophilin and FKBP, respectively, and subsequently block calcineurin function (116). Thus, treatment of T cells with CsA specifically blocks a downstream effector of the PLC-g/ Ca^{++} pathway, NFAT, and results in complete loss of T-cell function. This underscores the critical importance of PLC-g-mediated events during the course of T-lymphocyte signal transduction.

Phosphoinositide-3-Kinase

The PI3K family of enzymes also assumes a key role in both T- and B-cell signaling. The PI3K family consists of several different isoforms, but the best studied in lymphocytes is composed of two subunits, an 85-kd protein that provides regulatory functions and a 110-kd protein possessing enzymatic activity (117). The regulatory subunit of PI3K is encoded on three separate genes that give rise to the p85a, p85b, and p55g proteins. This discussion focuses primarily on p85a, which comprises two SH2 domains, one SH3 domain, two proline-rich regions, and a p110-binding domain. PI3K is a unique enzyme in that it displays both serine kinase activity and lipid kinase activity. The lipid kinase functions to phosphorylate the D3 position of lipid molecules. Although several different products can be generated by this enzyme, phosphatidylinositol 3,4,5-trisphosphate (PI 3,4,5P_3) has been studied most as a modulator of lymphocyte signal transduction.

The lipid kinase activity of PI3K is essential for sustained Ca^{++} mobilization in lymphocytes. This is thought to result from its indirect role in Tec kinase activation. PI3K products, such as PI 3,4,5P_3, are bound by the PH domains of Tec kinases (118,119). This association targets Tec kinases to the plasma membrane, where they can be activated by src PTKs and can subsequently contribute to phosphorylation of PLC-g.

In B lymphocytes, the phosphorylation of PI3K was initially thought to result from activity of the PTK Lyn. However, more recent data suggest that the kinase Syk participates indirectly in PI3K activation through tyrosine phosphorylation of Cbl (120). In this model, Cbl interaction with the SH2 domain of the p85 subunit of PI3K, results in PI3K localization to the plasma membrane. Studies using B-cell lines deficient in Syk demonstrate that formation of D3 phosphoinositides is diminished, as is phosphorylation of a substrate of PI3K, Akt (121).

Akt, also known as protein kinase B, is a serine-threonine kinase that has been implicated in modulating survival signals in a variety of cell types (122). After antigen receptor ligation, Akt is recruited to the plasma membrane through its PH domain, where it binds lipid products generated by PI3K. This allows Akt to become activated through phosphorylation of key serine and threonine residues. It is currently thought that two discrete PI3K-dependent enzymes are responsible for Akt phosphorylation, although only one, PDK1, has been rigorously proven to play such a role.

Akt modulates, both directly and indirectly, the activity of several transcription factors. Examples of indirect effects include regulation of nuclear factor-kB (NF-kB) activity by phosphorylation of the upstream inhibitory kB kinase (or IKK) (123). Phosphorylation of IKK results in degradation of the inhibitory kB protein, which then releases the transcription factor NF-kB so it may translocate to the nucleus. Akt indirectly blocks activation of Erk-dependent transcription factors by phosphorylating a regulatory serine residue on the upstream Raf kinase, rendering it inactive in some cell types (124). An example of Akt directly regulating the activity of transcription factors is seen by the dual serine and threonine phosphorylation of the Forkhead proteins, which prohibits their translocation into the nucleus (122). Thus, PI3K-dependent activation of Akt can either enhance or reduce gene transcription, depending on which transcription factors are involved.

The requirement for PI3K in lymphocyte signaling has been demonstrated by studies examining the phenotype of mice engineered to lack expression of specific PI3K isoforms. In mice with disruption of only p85a, T-cell maturation and activation remain largely unaffected, although PI3K activity is shown to be reduced by as much as 60% in these cells (125). In contrast, B-lymphocyte development is blocked at an early pro-B cell stage. A small population of mature B lymphocytes is present in $p85a^{-/-}$ mice, but these cells display diminished proliferation and antibody secretion in response to stimulation with T-independent antigens such as lipopolysaccharide (LPS). Mice lacking p55a and p50a expression in addition to p85a possess a similar phenotype, with no observable defects in T-cell function, but profound impairment of B-cell development and activity (126). Loss of a PI3Kg isoform produces the reverse phenotype in which T-cell development and function are impaired, whereas B-cell responses appear normal (127). These findings suggest that although PI3K is an important effector of signal transduction in both T and B lymphocytes, specific PI3K isoforms are used differentially by the two cell populations.

Ras and the MAPK Cascade

One of the most intensively studied downstream effectors of antigen receptor engagement is the low-molecular-weight GTPase, Ras. This ubiquitously expressed protein is required for the induction of many different cellular responses in activated lymphocytes. Ras represents just one of many low-molecular-weight GTPase families. Although the various families participate in differing signal transduction pathways, all share a characteristic pattern of activation and inactivation events. Much like the larger heterotrimeric GTPases, Ras cycles between existence in a GDP-bound versus a GTP-bound state (1). In its inactive state, Ras is bound to GDP. Activation of Ras occurs when it releases GDP and binds the more abundant cytosolic GTP. Release of GDP occurs with the assistance of proteins known as GEFs, or guanine nucleotide exchange factors. Once bound to GTP, Ras becomes and remains active, until it hydrolyzes its bound GTP. Hydrolysis of GTP is aided by a second category of proteins referred to as GAPs (for GTPase activating proteins). The generation of GDP again returns Ras to its inactive state.

Once activated, Ras initiates a multistep kinase cascade that traverses from the inner surface of the plasma membrane to the nucleus. Ras proteins undergo posttranslational lipid modifications that result in their constitutive localization at the plasma membrane (128). The protein activated immediately downstream of Ras is Raf, a serine-threonine kinase. The exact mechanism by which Ras activates Raf remains unclear. However, it is known that the normally cytosolic Raf is recruited to the plasma membrane, where it associates with Ras. Activation of Raf is linked to its phosphorylation status, but Ras does not appear to phosphorylate Raf. Instead, experimental evidence supports a model in which binding to Ras permits other kinases to phosphorylate Raf (129). Raf then directly activates a family of dual-specificity threonine-tyrosine kinases known as MAPK kinases (MAPKKs), or MEKs. MEKs, in turn, phosphorylate specific MAPKs, including the Erk 1 and Erk 2 proteins (for extracellular-signal–regulated kinases) (130,131). Activated Erk molecules migrate from the cytosol into the nucleus, where they influence gene transcription by activating a variety of transcription factors.

Although this linear cascade of Ras and MAPK has been well defined, it is becoming increasingly clear that Ras activation participates in a complex network of signal transduction events (129). For example, multiple families of MAPKs, MAPKKs, and the upstream equivalents of Raf proteins, also designated as MAPKK kinases, exist. Ras activation likely contributes to the induction of these kinases cascades, thereby tying together several parallel pathways. The cellular result is that Ras indirectly regulates the activity of numerous transcription factors that lie downstream of not only Erk 1 and 2, but additional MAPK family members, including JNK (for Jun NH_2-terminal kinase) and p38. Positive feedback mechanisms within the Ras/MAPK pathways have also been described in which activated MEKs phosphorylate Raf, leading to an augmentation of its activity. Further complexity is provided by evidence for the involvement of PKC molecules and PI3K in Ras activation, although the molecular basis for these events is unclear. Ultimately, the activation of many different upstream effector molecules converges on the Ras/ MAPK pathways, and the induction of these cascades is essential for a vast array of cellular responses in lymphocytes after TCR or BCR ligation.

SUMMARY

Ligation of antigen receptors on T and B lymphocytes triggers a multitude of intracellular biochemical events. These reactions transduce signals from receptors on the cell surface to the nucleus, where transcription of activation-induced genes occurs. Receptor-proximal activation of PTKs leads to phosphorylation of adapter molecules, which coordinate the formation of multimeric protein complexes. These complexes bring downstream effector molecules, such as PI3K and PLC-g, into contact with the PTKs that regulate their function.

Although this chapter focuses on the signal transduction events that arise from antigen receptor ligation, TCR or BCR engagement does not occur as an isolated event. Instead, costimulatory molecules such as CD28 on T cells and CD40 on B cells are bound simultaneously by their ligands. These costimulatory receptors initiate biochemical changes within lymphocytes that complement signals originating from the TCR or BCR. For a naive T or B lymphocyte, costimulatory signals are essential for activation, and in their absence, cells progress into a state of anergy, or into the apoptotic pathway referred to as programmed cell death. Thus, biochemical pathways initiated by costimulatory receptors provide unique signals to naive lymphocytes that are not present after antigen receptor engagement alone.

The fundamental importance of lymphocyte signal transduction pathways is evidenced by the various immunodeficiencies that develop when the progression of these events are disrupted. Loss of function in a specific signaling mediator may adversely affect T cells without noticeably impacting B cells, as is seen with deletion of SLP-76. The reverse situation is also observed; for example with the loss of Btk resulting in agammaglobulinemia. These findings highlight the differences between T- and B-lymphocyte signal transduction; although both cell types use the same families of effector and adapter molecules, individual members often are used differentially.

Significant advances have been made in elucidating the relationships among various components of lymphocyte signal transduction path-ways; however, much remains to be learned. New adapter molecules continue to be identified, and novel functions are being described for well-known effector molecules. Our appreciation for crosstalk between pathways that were once thought to be discrete is growing. Future efforts focused on understanding the relationships of signaling molecules with respect to each other and to their intracellular localization before and after antigen receptor ligation will enhance our appreciation of the intricate mechanisms that control lymphocyte activation.

9 T-Lymphocyte Activation, Costimulation, and Tolerance: Signals, Mechanisms, and Clinical Applications

Rebecca J. Greenwald, Ph.D., Arlene H. Sharpe, M.D., Ph.D., and Abul K. Abbas, M.D.

The mammalian immune system has evolved a complex system of humoral and cell-mediated responses for protection against infectious pathogens. All adaptive immune responses are initiated by the recognition of antigen by specific clones of lymphocytes. However, antigen alone is insufficient to trigger the proliferation of naive lymphocytes and their differentiation into effector cells. The development of effective immune responses usually requires additional signals, which are typically induced by microbes or by innate immune reactions to microbes. In the absence of such signals, the antigen-specific lymphocytes either fail to respond or are shut off. The requirement for these signals ensures that lymphocytes respond to foreign agents but not to harmless substances, such as self-antigens. Elucidating the nature of the signals that influence the choice between lymphocyte activation and tolerance is likely to provide important clues not only about physiologic immunity, but also about pathologic states, such as autoimmunity, that result from a failure of self-tolerance. Furthermore, defining these signals may suggest potential targets for stimulating desired immune responses and for limiting pathologic responses. In this chapter, we describe the nature of the signals that determine lymphocyte activation versus tolerance and the physiologic and potential clinical importance of these signals.

The concept that lymphocytes need stimuli in addition to antigen to mount effective responses dates from 1970, when Bretscher and Cohn postulated that B cells require two signals to become activated (1). More than a decade later, Jenkins and Schwartz showed that T cells also require two sets of signals to be activated (2). The first signal is triggered by antigen, that is, peptide-major histocompatibility complex (MHC) on antigen-presenting cells (APCs), which are recognized by the clonally distributed antigen-specific T-cell receptor (TCR). The second signal is provided by molecules on APCs that were called *costimulators.* These early studies, using cloned lines of $CD4^+$ T cells, also showed that antigen recognition without costimulation led to long-lived unresponsiveness, or anergy, of the T cells. We now know that several molecules on APCs may function as costimulators for T cells. In this chapter, we describe the biology of the two major costimulatory pathways, the B7:CD28 and the CD40:CD40 ligand pathways, and discuss the role of costimulation in regulating T-cell activation versus tolerance.

B7:CD28 FAMILIES OF COSTIMULATORY LIGAND-RECEPTOR PAIRS

The first T-cell molecule found to deliver costimulatory signals was CD28 (3,4). This discovery came from the observation that cross-linking CD28 on human T cells using anti-CD28 mAbs greatly enhanced the response of the T cells to engagement of the TCR/CD3 complex (5,6 and 7). The search for the CD28 ligand led to the next important discovery, that CD28 binds to a molecule called B7 that was thought to be a marker of the B-cell lineage and was later shown to be expressed on most APCs (8,9 and 10). Thus, B7 is a costimulator, and CD28 is its receptor on T cells. As discussed later, the story of costimulation became much more complex and fascinating in the 1990s.

B7 MOLECULES

Two ligands for CD28, called B7-1 (CD80) and B7-2 (CD86), are recognized (10,11 and 12) (Fig. 9.1). These proteins are approximately 25% identical, with greater homology in the extracellular domain than in the cytoplasmic domain, and they have largely overlapping functions (13). The expression of B7-1 and B7-2 has several important characteristics. First, both proteins are expressed on professional APCs, consistent with their roles as costimulators for T cells. Second, the expression of B7-1 and B7-2 is enhanced by microbes interacting with the APCs, by cytokines such as interferon-g (IFN-g) and interleukin-4 (IL-4), which are produced during innate immune responses to microbes, and by activation of the APCs by CD40-mediated signals (discussed later in the chapter) (14,15). Thus, the regulated synthesis of costimulators ensures that they are expressed during the immune response to infection. Third, the kinetics and levels of expression of B7-1 and B7-2 have subtle differences. On most APC populations, B7-2 is present even in the resting state or appears more rapidly after activation and at quantitatively higher levels than does B7-1 (8,16). This finding suggests that B7-2 may be the more important costimulator for initiating immune responses. Finally, B7-1 and B7-2 may be induced on cell types other than APCs. For instance, both molecules are expressed on activated T cells, but the role of T-cell B7 remains uncertain.

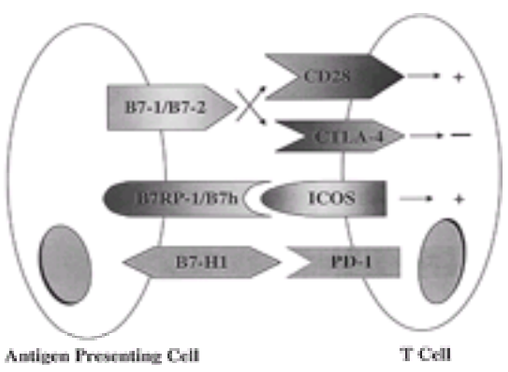

Figure 9.1. B7 costimulatory ligand-receptor pairs. B7-1 and B7-2 on antigen-presenting cells (APCs) interact with CD28 to deliver positive costimulatory signals to T cells, whereas binding to CTLA-4 transmits negative signals. Engagement of B7RP-1:B7h with ICOS provides a stimulatory signal to T cells. B7-H1 is expressed on APCs, and the counterreceptor is PD-1.

Other proteins homologous to B7-1 and B7-2 have been described. One, variously called B7RP-1 (B7-related protein) or B7h (B7 homolog), is expressed on APCs and other cell types in response to endotoxin and cytokines that activate the nuclear factor-kB (NF-kB) transcription factor (17). This response is a characteristic component of innate immunity to microbes. Similar to B7-1 and B7-2, B7RP-1 is a cell surface glycoprotein with costimulatory function for T cells. Two more B7 homologs, called B7-H1 (PD-L1) and B7-DC (PD-L2) have been identified (18). The possible functions of these proteins are described later.

CD28/CTLA-4 FAMILY OF RECEPTORS

The CD28 receptor for B7-1 and B7-2 is expressed on all naive $CD4^+$ helper T (Th) cells and on most naive $CD8^+$ T cells (3). When T cells recognize antigens presented by APCs, CD28 interacts with B7-1 or B7-2. The engagement of CD28 delivers signals to the T cells that initiate immune responses. Thus, CD28 is an activating receptor of T cells.

Several years after the discovery of CD28 and B7, investigators found that T cells express a second receptor for B7-1 and B7-2. This protein was called CTLA-4 (CD152), because it was as the fourth antigen identified in a search for molecules expressed in cytotoxic T lymphocytes (CTLs) (19). CTLA-4 is expressed on activated

CD4$^+$ and CD8$^+$ T cells at lower levels than is CD28, and CTLA-4 is not detectable on resting T cells (20). Importantly, binding of B7 on APCs to CTLA-4 on T cells delivers inhibitory signals that shut off T-cell responses. Thus, engagement of CTLA-4 has the opposite effect on T cells as engagement of CD28, although both receptors bind the same B7 molecules on APCs (Fig. 9.2). How the balance between CD28-mediated activation and CTLA-4-mediated inhibition is achieved during the initiation and termination of physiologic immune responses remains an intriguing question without a clear answer. There are several other differences between CD28 and CTLA-4. CD28 is an integral membrane protein; in contrast, greater than 90% of cell-associated CTLA-4 is present in intracellular vesicles and is rapidly shuttled to the cell surface on antigen recognition by T cells (21). *In vitro,* CTLA-4 binds to B7 with 20- to 50-fold higher affinity than does CD28 (22). The cytoplasmic domains of CD28 and CTLA-4 are also distinct, which may account for the differences in the signals transduced by these receptors (discussed later).

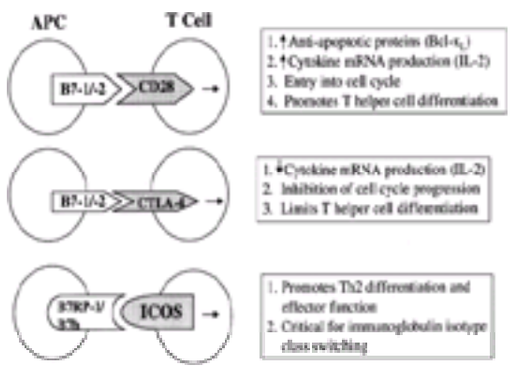

Figure 9.2. Functional effects of B7 costimulatory interactions. Antigen-presenting cells express ligands that engage costimulatory receptors on T cells. The functional effects of B7-1:B7-2 interactions with CD28 and CTLA-4 and B7RP-1:B7h with ICOS are described.

A CD28 homolog called ICOS (inducible costimulatory molecule) has been identified on activated T cells (23). ICOS binds to B7RP-1/B7h and stimulates T-cell responses that are distinct from the responses triggered by CD28. The biologic implications of these multiple receptor-ligand pairs are discussed later.

FUNCTIONAL EFFECTS OF THE B7:CD28 LIGAND-RECEPTOR FAMILY

Binding of CD28 to B7-1 and B7-2 induces a series of biologic responses in T cells that are critical for the initiation of T-cell clonal expansion and differentiation into effector cells. All these biologic responses are the consequence of costimulation functioning together with antigen recognition. In other words, CD28 signals synergize with signals transduced by the TCR/CD3 complex.

Costimulation induces the production of antiapoptotic proteins, notably Bcl-xL, in T cells (24). In the absence of costimulation, T cells die by apoptosis. Thus, costimulation prolongs the survival of antigen-recognizing T cells. At the same time, costimulation stimulates the transcription of cytokine genes and increases the stability of cytokine mRNA, thus leading to increased production of cytokines (13,25,26,27,28,29,30 and 31). The first of these cytokines to be detected in T cells is the growth factor, IL-2, which is largely responsible for the initiation of T-cell proliferation. Costimulation also enhances the expression of high-affinity receptors for cytokines, such as IL-2 receptor. In addition, stimulation through the B7:CD28 pathway promotes cell-cycle progression from the G_1 phase into the S phase by downregulating the cell-cycle inhibitor, $p27^{kip}$ (32,33). Thus, CD28 regulates T-cell expansion through synergistic effects with the TCR, and this leads to production of T-cell survival factors, T-cell growth factors, and cell-cycle progression.

Costimulation enhances the differentiation of antigen-stimulated T cells into effector cells. In CD4$^+$ Th lymphocytes, differentiation is reflected in acquisition of the capacity to produce effector cytokines, such as IL-4, IL-5, and IFN-g (34). CD28-mediated signals appear to be more important for the differentiation of naive T cells into IL-4–producing and IL-5–producing Th2 effectors than in the development of the Th1 subset (35,36). In part, this may be because Th1 differentiation may be induced by other signals such as the macrophage and dendritic cell-derived cytokine, IL-12 (37). In CD8$^+$ T cells, costimulation is required for the development of fully active effector CTLs.

These functional effects of B7:CD28 interactions have been demonstrated by many experimental approaches, such as the use of agonistic and blocking antibodies, and APCs or T cells from knock-out mice. The soluble CTLA-4 fusion protein, CTLA-4Ig, has been particularly effective at blocking B7 interactions with CD28 and CTLA-4 and useful in determining the functional role of this pathway (22). Although such studies clearly illustrate the significance of the B7:CD28 pathway, it is also apparent that many T-cell responses may be partially or largely independent of CD28 signaling. The effect of B7 blockade may depend on the strength of the TCR signal. For example, intensifying the strength of signal by increasing the quantity of specific antigen can overcome the effects of CD28 deficiency in a transgenic autoimmune disease model (38).

Antagonists and gene knock-out mice have proved extremely valuable for analyzing the critical functions of the B7:CD28 pathway during immune responses *in vivo*. Mice lacking both B7-1 and B7-2 are profoundly immunodeficient. These mice fail to exhibit T-cell responses to immunization with protein antigens in adjuvants, are susceptible to microbial infections, and fail to reject vascularized organ allografts (39,40). Likewise, Th-cell–dependent humoral immune responses are impaired, as shown by defects in immunoglobulin class switching and germinal center formation. Mice deficient in B7-2 only respond poorly to immunization with antigens and weak adjuvants, but they respond normally when strong adjuvants are used. Mice lacking B7-1 only do not show significant immunologic defects. These results support the view that B7-2 is the more important costimulator for initiating T-cell responses, but B7-1 and B7-2 serve similar functions. The question whether B7-1 and B7-2 are functionally identical or distinct is controversial. Some earlier studies suggested that these two proteins differ in their ability to induce Th1 or Th2 development. It is likely that such observed differences are related more to the kinetics of B7-1 and B7-2 expression than to intrinsic differences in the way these molecules bind to and signal through CD28.

Surprisingly, mice lacking CD28 show only modest immune defects and no abnormality in many T cell-mediated responses, such as allograft rejection. Basal immunoglobulin levels are reduced, and germinal center formation is blocked in CD28-deficient mice as compared with wild-type mice (41). T cells isolated from CD28-deficient animals exhibit impaired responses to alloantigens and stimulation through the TCR with anti-CD3 mAbs (42). Other *in vivo* studies involving infectious agents have shown that the host immune response is not strictly dependent on CD28 engagement. After LCMV infection, CTL responses and the host-protective delayed-type hypersensitivity reaction are intact in CD28-deficient mice (43). Likewise, CD28-deficient mice infected with *Leishmania major* develop Th2 responses and disease on the susceptible genetic background (44). Differences in results using CD28-deficient and B7-1/B7-2–deficient mice are difficult to explain. Although CD28 is the only known activating receptor for B7-1 and B7-2, CD28 deficiency does not result in the same abnormalities as the absence of B7-1 and B7-2. The observed differences raise the possibility that there are other activating receptors for B7-1 and B7-2, but these have not been identified yet.

Engagement of CTLA-4 by B7 molecules inhibits T-cell cytokine production and cell-cycle progression. Based on *in vitro* studies using anti-CTLA-4 mAbs, signaling through CTLA-4 can block CD28-dependent IL-2 production, IL-2 receptor expression, and cell-cycle progression of activated T cells leading to arrest in the G_0/G_1 phase (45,46,47 and 48). Unlike CD28, CTLA-4 does not influence the induction of cell survival factors such as bcl-xL (49). Stimulation of CTLA-4–deficient T cells skews differentiation toward a Th2 phenotype (50). Thus, in the B7:CD28/CTLA-4 pathway, signaling through CD28 and CTLA-4 has opposing effects on Th cell differentiation: B7:CD28 interactions promote Th2 differentiation, whereas B7:CTLA-4 interactions limit the extent of Th2 differentiation. The definitive proof of the physiologic importance of CTLA-4 came from the finding that knock-out mice lacking this protein develop severe lymphadenopathy and splenomegaly and die of a multiorgan disease associated with infiltrates of activated T cells and macrophages (51). The disease has many features of an autoimmune disorder, but neither the target antigen nor the specificity of the pathogenic T cells is established.

Much less is known about the more recently discovered B7RP-1/B7h:ICOS pathway. *In vitro* studies have shown that engagement of this pathway triggers T-cell responses that are distinct from the responses to B7:CD28 interactions. For instance, binding of B7RP-1 to ICOS induces T-cell secretion of the cytokine, IL-10, which mainly inhibits the functions of macrophages and other APCs and terminates T-cell responses (23). These findings suggest a model in which different costimulatory ligand-receptor pairs function at different phases of T-cell–mediated immune responses. The activation of T cells may be initiated by B7-2:CD28 interactions and amplified by B7-1:CD28. As the activated T cells express ICOS, this receptor may induce the production of regulatory cytokines that dampen the response. Finally, activated T cells may express CTLA-4, which terminates further T-cell activation. Although this model is interesting, it is not formally proved. In fact, defining the relationships between these multiple ligand-receptor pairs and the way in which their activities are orchestrated during physiologic immune responses are among the major challenges in the field.

BIOCHEMISTRY OF COSTIMULATION: SIGNAL TRANSDUCTION BY CD28 AND CTLA-4

Despite considerable effort, little is known about the mechanisms by which CD28 and CTLA-4 transduce activating and inhibitory signals, respectively. In all species examined, the CD28 receptor has a high degree of structural homology; however, fundamental questions about CD28 signaling are unresolved. According to one model, CD28 ligation enhances biochemical signals triggered by the TCR, which include the activation of phosphatidylinositol-3-kinase and the Ras pathway. Consistent with this hypothesis are the findings that CD28 coaggregates with the TCR/CD3 complex when T cells bind to APCs displaying antigen (52). Furthermore, engagement of CD28 enhances the time for which the TCR remains in membrane microdomains at the site of contact with APCs. An alternative hypothesis is that CD28 delivers signals that are distinct from and independent of TCR-mediated signaling, and the two sets of signals are integrated inside the cells. The IL-2 transcription factor, cJun, is activated after CD28 engagement, but whether this transcription factor is required for CD28-mediated T-cell costimulation is not established. Furthermore, these hypotheses are not mutually exclusive, because CD28 may increase TCR signaling and may also trigger independent signals. Studies have shown that cross-linking of the TCR and CD28 results in the activation of the transcription factors NFAT (nuclear factor of activated T cells), activation protein-1 (AP-1), and nuclear factor kappa B (NF-kB)/rel (53,54) (Fig. 9.3). By contrast, stimulation of the TCR alone may be sufficient for the activation of NFAT (55,56).

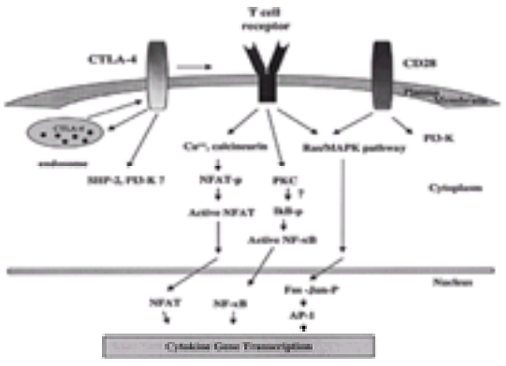

Figure 9.3. T-cell receptor (TCR) and costimulatory molecule signal transduction pathways. The *arrows* between the signaling molecules do not necessarily reflect direct interactions.

Even less is known about the biochemistry of CTLA-4–mediated inhibition. CTLA-4 has a short cytoplasmic tail that is 100% conserved between species and contains two tyrosine-containing motifs. The first tyrosine motif, YVKM, plays a pivotal role in the tightly controlled cellular localization of CTLA-4 as well as in the interaction with key signaling molecules (57,58 and 59). The nonphosphorylated YVKM can associate with a clathrin-associated adapter complex AP-2, which is responsible for continuous translocation of CTLA-4 to and from the cell surface (58,60). Phosphorylation of CTLA-4 releases binding to AP-2 and results in increased cell-surface expression. In a phosphorylated state, CTLA-4 can interact with phosphatidylinositol-3-kinase or the tyrosine phosphatase, SHP-2 (60,61,62 and 63). One of the mechanisms by which CTLA-4 may disrupt TCR-mediated signals is by dephosphorylating key signaling proteins (63). Engagement of CTLA-4 may activate SHP-2, resulting in removal of critical phosphate residues from molecules downstream of CD28 or the TCR. Both the target substrates of SHP-2 and the functional consequences of this interaction are not yet known. Some results suggest that the inhibitory activity of CTLA-4 is related to its ability to antagonize CD28-mediated activation by sequestering signaling molecules such as phosphatidylinositol-3-kinase away from CD28. Other studies indicate that CTLA-4 may bind to proteins of the TCR/CD3 complex and may directly alter TCR signaling. Evidence indicates an interaction of CTLA-4 with the CD3-z chain of the TCR complex intracellularly, a finding suggesting that CTLA-4 interferes with early TCR-signaling events (61). However, studies have suggested that tyrosine phosphorylation of the CTLA-4 cytoplasmic tail may not be required for inhibitory signaling (64,65 and 66). Further studies are needed to examine how these findings relate to B7 engagement of CTLA-4.

Finally, investigators have suggested that when B7 on APCs binds to CD28 or CTLA-4 on T cells, the signaling is bidirectional; that is, the APCs also receive some signals. However, there is no evidence that B7 molecules can function as signal transducers, and it appears likely that they only serve as ligands for the CD28/CTLA-4 signaling receptors.

CD40:CD40 LIGAND PATHWAY OF COSTIMULATION

The CD40 molecule is expressed on macrophages, dendritic cells, B lymphocytes, and many other cell populations (67,68). CD40 ligand (CD154) is expressed on activated T lymphocytes (69). The principal function of this ligand-receptor pair is in the effector phases of cell-mediated and humoral immune responses (Fig. 9.4). Activated $CD4^+$ Th cells use their CD40L to bind to the CD40 receptor. This interaction activates macrophages to kill phagocytosed microbes and stimulates B lymphocytes to proliferate and differentiate into antibody-producing cells. Deficiency of CD40 or CD40L results in profound defects in cell-mediated and humoral immunity. Hyper-IgM syndrome dramatically illustrates the essential role for CD40 signaling in humans. Hyper-IgM syndrome results from mutations in the X-linked CD40L gene (70). Loss of CD40L function manifests as defects in germinal center formation, isotype class switching, and cell-mediated immunity (71). The compromise of cell-mediated immunity leads to death of these patients by infectious agents.

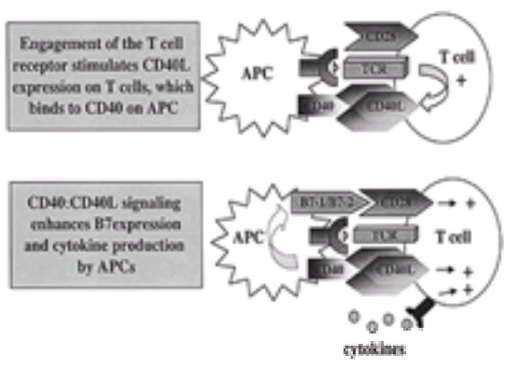

Figure 9.4. CD40:CD40L interactions. The recognition of antigen by T cells (in the presence or absence of costimulators) leads to upregulation of CD40L on T cells. B7:CD28 interactions also enhance CD40L expression. CD40L binds to CD40 on antigen-presenting cells (APCs) and stimulates the expression of B7-1 and B7-2. Cytokines produced by the APCs initiate T-cell differentiation and effector function.

The findings that CD40L-deficient T cells respond poorly to antigens and CD40L antagonists inhibit T-cell activation have led to the hypothesis that this ligand-receptor pair also serves to costimulate T cells. The likely mechanism of this costimulatory effect is that CD40:CD40L interactions activate APCs to become more potent APCs by increasing the longevity of peptide-MHC complexes. CD40L on antigen-stimulated T cells binds to CD40 on dendritic cells and macrophages. These professional APCs respond by increasing their expression of B7-1 and B7-2 and by secreting IL-12, a powerful inducer of Th1 differentiation (72,73,74 and 75). As a result, the APCs stimulate more T cells to respond to the antigen and to develop into Th1 cells. *In vivo* CD40L:CD40 interactions serve to amplify and sustain T-cell responses, whereas B7:CD28 interactions are critical for initiating these responses (76). There is little evidence that CD40L itself delivers a signal to the T cell that directly enhances T-cell responses.

IMMUNOLOGIC TOLERANCE

Tolerance to self-antigens may be induced in the generative lymphoid organs, when immature lymphocytes recognize self-antigens, or in peripheral tissues. The former is called central tolerance. Central tolerance is an integral component of lymphocyte maturation. It is also called negative selection and is discussed in Chapter 5.

Peripheral tolerance is induced when mature lymphocytes recognize antigens under particular conditions. Interest in the mechanisms of peripheral tolerance has been increasing, for several reasons. First, in animal models of autoimmune diseases in which the pathogenesis is understood, the abnormalities giving rise to autoimmunity appear to usually disrupt peripheral tolerance. Second, if we understand how self-antigens induce peripheral tolerance in mature lymphocytes, we may be able to exploit this knowledge to develop methods for shutting off unwanted immune responses. Costimulatory molecules are potentially involved in each of the mechanisms of maintaining peripheral tolerance. In the following section, we describe the mechanisms of peripheral tolerance in mature T lymphocytes, particularly $CD4^+$ T cells, with

an emphasis on the role of the B7:CD28/CTLA-4 pathway.

Peripheral T-Lymphocyte Tolerance

Three principal mechanisms of peripheral tolerance involving mature $CD4^+$ T cells are recognized (Fig. 9.5). When T cells recognize antigen with deficient or no costimulation, the T cells become functionally inactivated. This phenomenon is called clonal anergy, because it affects the antigen-specific clones of lymphocytes. When mature T lymphocytes are repeatedly stimulated by an antigen, the T cells undergo apoptosis, a process called activation-induced cell death (AICD). Self-antigens may induce anergy and AICD in specific T cells because self-antigens are normally displayed to the immune system without costimulation (the condition that induces anergy), and self-antigens are persistent and can repeatedly stimulate lymphocytes (expected to result in AICD). The third mechanism of peripheral tolerance is suppression, in which some T lymphocytes develop into cell populations that secrete immunosuppressive cytokines and terminate further lymphocyte activation.

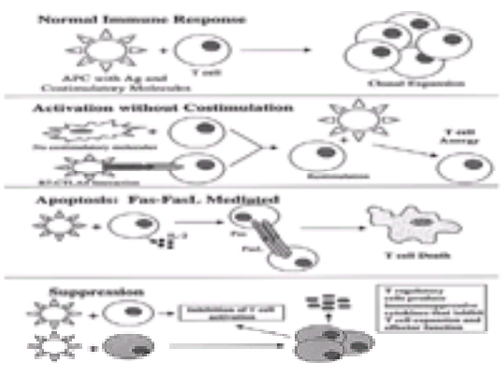

Figure 9.5. Mechanisms of peripheral T-cell tolerance. Model of T-cell:antigen-presenting cell interactions that are required for a normal immune response versus an immune response that leads to anergy induction.

Clonal Anergy

Clonal anergy was first described in cloned lines of $CD4^+$ T cells (2,77). Culture of these clones with antigen presented by APCs lacking costimulators induced a state of long-lived unresponsiveness. It has proved difficult to demonstrate the same phenomenon in normal T cells, because T cells deprived of costimulation die by programmed cell death. Several studies suggest that in normal T cells, anergy is induced when these lymphocytes use the inhibitory CTLA-4 receptor to recognize B7 molecules on APCs (78,79). This function of CTLA-4 may explain the autoimmune phenotype of the CTLA-4 knock-out mouse (51). However, many questions remain unanswered. For instance, how do T cells choose between using CD28 or CTLA-4 to interact with B7 molecules on APCs? Why is CTLA-4 the predominant receptor used when self-antigens are recognized by T cells?

Multiple strategies have emerged for investigating the induction of T-cell anergy *in vivo.* Designing an experimental system to analyze self-tolerance is challenging given the difficulty of identifying self-antigens and quantitating the levels of self-antigens. As a result, the initial studies of T-cell anergy *in vivo* compared administration of immunogenic versus tolerogenic forms of a model foreign antigen (80). Immunogenic antigen is a low dose of antigen administered subcutaneously with an adjuvant, which upregulates costimulators on host APCs at the site of injection and in regional lymphoid tissues. By contrast, tolerogenic antigen is a large dose of aqueous antigen administered systemically. Distinct effects were observed when immunogenic and tolerogenic forms of antigen were administered to naive animals. Immunogenic antigens induce T-cell expansion and differentiation *in vivo,* whereas tolerogenic antigen inhibits the ability of the T cells to respond to subsequent antigen challenge.

Our understanding of tolerance induction *in vivo* has been greatly advanced through the use of transgenic technology. An adoptive transfer approach for investigating immune responses and tolerance *in vivo* was developed by Jenkins and colleagues (81). To track a small population of antigen-specific T cells, T cells from transgenic mice specific for the ovalbumin (OVA) peptide were transferred into normal, syngeneic recipients. The transgenic T cells were allowed to home to the lymphoid tissues, and mice were either left untreated (naive) or given an immunogenic (primed) or tolerogenic (tolerized) form of OVA. At the peak of the immune response, T cells were recovered from the recipients and were stained with an antibody that recognizes the transgenic TCR, to detect the *in vivo* expansion of the T cells. To perform functional asssays, TCR transgenic T cells were isolated and cultured *ex vivo* with APCs and OVA. Under these conditions, both naive and primed T cells responded to antigen, with primed T cells showing a more vigorous response. In marked contrast, tolerized T cells failed to respond to antigen. This adoptive transfer approach has been modified to examine the individual contributions of key immunoregulatory molecules and costimulators on tolerance induction *in vivo.* By treating adoptive transfer recipients with inhibitory antibodies or by breeding TCR transgenics with the desired knock-out mice, the effect of specific genes on the development of tolerance in the periphery can be assessed. For example, using this approach, a novel role for CTLA-4 was reported in which B7:CTLA-4 interactions provided a tolerizing signal to T cells at the time of antigen recognition (78). Adoptive transfer of TCR transgenic T cells and administration of anti–CTLA-4 mAbs to mice given a tolerogenic form of antigen resulted in the development of antigen-reactive T cells and cytokine production, findings suggesting that tolerance induction may require B7:CTLA-4 interactions. These results, together with the fatal lymphoproliferative disease in the CTLA-$4^{-/-}$ mice, suggest a critical role for CTLA-4 in tolerance induction.

Transgenic approaches also have provided a way to test the hypothesis that peripheral tolerance results from antigen presentation in the absence of costimulation. If this hypothesis is valid, then overexpression of a costimulator should activate self-reactive T cells, resulting in autoimmunity. Transgenic mice overexpressing B7-1 in pancreatic islet b cells demonstrate that B7-1 expression alone is not sufficient to break *in vivo* peripheral tolerance to islet cell or keratinocyte antigens (82). Spontaneous inflammatory changes arise when B7-1 overexpression is combined with additional predisposing factors. Interbreeding of transgenic mice overexpressing B7-1 in pancreatic b cells with transgenic mice expressing tumor necrosis factor-a (TNF-a), which develop nondestructive insulitis, resulted in double transgenic mice that spontaneously developed immune-mediated b cell destruction and diabetes (83).

Although the use of transgenic technology has provided great insights into our understanding of the immune response *in vivo,* the scope of these systems is limited for several reasons, including limitation of the lymphocyte repertoire by expressing one transgenic receptor, expression levels of the transgenic receptors that are higher than physiologic expression, and constitutive expression of the transgenic receptor throughout thymic development and in the periphery. In some transgenic models, the self-antigen is ignored and does not induce anergy. The reasons that encounter of some antigens leads to anergy and others result in ignorance are unclear. It is important to consider these factors when interpreting results of studies using transgenic T cells.

Although *in vitro* and *in vivo* studies have investigated the induction of anergy, the molecular events that occur after the development of T-cell anergy are poorly understood. The failure to produce IL-2 is a key characteristic of anergic T cells. *In vitro* studies have shown that the expression of IL-2 mRNA and protein secretion were markedly reduced in anergic T-cell clones (84). This profound defect in IL-2 production has led to intense study of the signaling pathways that eventually result in IL-2 transcription. Engagement of the TCR leads to phosphorylation of the g and z chains in the associated CD3 complex (85). This phosphorylation event triggers a cascade of events that results in downstream activation of $p21^{ras}$. $p21^{ras}$ activation is important because it regulates the activation of several kinases, including MEK (MAPKK) and MAP/ERK, which are critical to the induction of AP-1 (86,87). AP-1 is a transcription factor that is required for activation of the IL-2 promoter (88).

Some studies have provided mechanistic insights into the downstream signaling events that occur after anergizing signals. The pattern of CD3 phosphorylation is different in anergic versus primed T cells (89). Decreases in $p21^{ras}$ activity have been seen. Because $p21^{ras}$ affects the activation of several downstream signaling pathways, which, in turn, regulate IL-2 gene transcription, this block in $p21^{ras}$ activity could be critical for induction of tolerance. Adding further support to this hypothesis is the observation that the decrease in $p21^{ras}$ activity correlated with a similar decline in MAPK activity (90). Because the MAPK pathway regulates Fos and Jun, which are the transcription factors that activate AP-1, the decreased MAPK activity could ultimately cause a decrease in IL-2 transcription (91). In anergized T cells, the level of AP-1 binding to the IL-2 promoter was shown to be markedly reduced, as compared with primed T cells (88). This effect was observed 3 hours after stimulation, which is the peak of AP-1 binding after stimulation *in vitro.* The levels of other transcription factors, such as NFAT and NF-kB were similar in normal and anergized T cells. Thus, the reduction of IL-2 in anergized T cells was attributed to the lack of AP-1 binding to the IL-2 promoter. In summary, although the molecular mechanisms responsible for the blockade of IL-2 production are not fully understood in anergized T cells, more recent work has shown that IL-2 production is controlled by several pathways. Studies of anergic cells have shown decreases in $p21^{ras}$ MAPK, and AP-1, activity all of which correlate with decreased IL-2 transcription.

Activation-Induced Cell Death

Repeated activation of $CD4^+$ T cells leads to coexpression of the death receptor Fas (CD95) and its ligand, FasL. AICD occurs as a result of active signaling to

lymphocytes through the Fas:FasL pathway (92,93 and 94). Fas is part of the TNF receptor (TNFR) family, which includes the costimulatory molecule, CD40 (95). The cytoplasmic domain of Fas features a conserved “death domain,” which serves as a docking site for signaling molecules. FasL is a homotrimeric protein that is a member of the TNF family. The structure of FasL allows for effective cross-linking of Fas on the surface of the same and neighboring cells. Both Fas and FasL are expressed on the surface of activated T cells and are upregulated after repeated stimulation.

Studies have begun to elucidate the biochemical events that occur during AICD. Cross-linking of Fas by FasL binding stimulates the interaction with the adaptor protein Fas-associated death domain (FADD). Binding of FasL to Fas activates a signaling cascade that results in activation of the initiator caspase, caspase-8, followed by activation of several effector caspases that ultimately lead to apoptosis. Some evidence suggests that caspase-8 affects mitochondrial membrane permeability, which stimulates apoptosis. The mitochondrial pathway of apoptosis is active primarily in cells that are deprived of survival signals. This form of apoptosis, which has been called passive cell death or death by neglect, is associated with caspase-9 activation, does not involve death receptors, and is prevented by antiapoptotic members of the Bcl family (96).

A surprising result has been that IL-2, the prototypic T-cell growth factor, actually potentiates Fas-mediated AICD. Thus, antigen in the presence of IL-2 initiates T-cell responses, but excessive amounts or persistence of antigen and IL-2 may terminate the response by triggering AICD. Failure of this death pathway may also contribute to the autoimmunity seen in knock-out mice lacking IL-2 or the a or b chain of the IL-2R (97,98). Thus, IL-2 may be a critical negative feedback inhibitor of lymphocyte responses, and other cytokines can substitute for IL-2 as a T-cell growth factor.

The importance of the Fas:FasL pathway in maintaining self-tolerance is illustrated by the autoimmune disease of Fas or FasL-mutant mice (lpr and gld) and in children with Fas mutations (autoimmune and lymphoproliferative syndrome, ALPS). The lpr and gld strains of mice develop progressive severe lymphadenopathy, systemic lupus erythematosus–like autoantibodies, and hypergammaglobulinemia (99). The rare human disease, ALPS, is caused by mutations in Fas or downstream caspases (100,101 and 102). In a murine model of multiple sclerosis, it was shown that FasL expression is critical in the initiation and recovery stages of disease (103). Thus, apoptosis through the Fas:FasL pathway may provide a critical means of destroying self-reactive T cells that are exposed to high levels of self-protein in the periphery. Paralleling these results, transgenic T cells stimulated with specific peptide undergo T-cell activation followed by AICD (104).

T-Cell–Mediated Suppression

Suppressor T cells are a population of regulatory cells that inhibit the development of self-reactive T cells. Since the 1960s, studies have suggested that tolerance to self-antigens can occur by an active process in which a population of suppressor T cells inhibits the clonal expansion and effector functions of potentially autoreactive T cells. The administration of protein antigens under conditions that induce tolerance, such as oral administration, often leads to the activation of T cells that produce immunosuppressive cytokines such as transforming growth factor-b (TGF-b) and IL-10 (105,106). These results raised the possibility that cytokine-mediated lymphocyte suppression contributes to the maintenance of tolerance. Evidence of the importance of suppression in self-tolerance has come from many studies showing that naive T cells transferred into lymphopenic mice induce multisystem autoimmune disease, but cotransfer of activated T cells protects from such disease. The interpretation of these results is that the activated T-cell population contains some cells that have encountered self-antigens and developed into regulatory cells, and in their absence potentially pathogenic autoreactive lymphocytes can function unchecked. The mechanism of action of the regulatory T cells is unknown. Studies indicate that some of these regulatory cells express CTLA-4, a finding suggesting that CTLA-4 may limit the activation of regulatory T-cell responses.

Several specialized subsets of suppressor T cells have been identified and are under investigation. Production of IL-10 and TGF-b appears to be particularly important in this immunoregulation. The relationship between these cytokines and suppressor T cells is not yet defined. A role for $CD4^+$ $CD45RB^{lo}$ T cells in suppression comes from a murine model of inflammatory bowel disease (107). Transfer of sorted $CD45RB^{hi}$ $CD4^+$ T cells from normal mice into *scid* or lymphopenic recipients lead to disease. When the combination of $CD45RB^{hi}$ and $CD45RB^{lo}$ subsets from normal mice were transferred into scid recipients, inflammatory bowel disease was prevented (108). These findings demonstrated the ability of the $CD45RB^{lo}$ $CD4^+$ T-cell population to neutralize the clonal expansion of the potentially disease-causing $CD45^{hi}$ $CD4^+$ T cells. Subsequent studies in this model system have pointed to critical roles for TGF-b and IL-10 in regulating the inflammatory reponse toward intestinal antigens (109,110).

A population of $CD4^+$ $CD25^+$ T cells also has identified as suppressor cells (111,112). In response to stimulation through the TCR, $CD4^+$ $CD25^+$ T cells, but not $CD4^+$ $CD25^-$ T cells, are unresponsive (113). Addition of $CD4^+$ $CD25^+$ T cells to the culture of $CD4^+$ $CD25^-$ T cells suppressed proliferation and IL-2 production. When $CD4^+$ $CD25^+$ T cells were isolated from TCR transgenics, similar effects were observed; however, the effect was not antigen specific. The lack of the $CD25^+$ suppressor T cells in CD25-deficient mice may be one reason that these mice develop autoimmunity. Taken together, these studies suggest that distinct populations of T cells secrete regulatory cytokines involved in T-cell suppression.

POTENTIAL THERAPEUTIC APPLICATIONS OF COSTIMULATION AND TOLERANCE

Because the B7:CD28/CTLA-4 and CD40:CD40L costimulatory pathways deliver signals that are required for T-cell activation, there has been great interest in manipulating these pathways for therapy. Costimulatory blockade could inhibit undesired T-cell responses occurring during autoimmunity, transplant rejection, or allergy, and enhanced costimulation could promote T-cell responses for tumor and vaccine immunity. Clinical trials that involve manipulation of these pathways are in progress.

Antitumor Immunity

Progress in our understanding of the antitumor immune response has led to novel strategies for developing T-cell–mediated cancer immunotherapies. The challenge in designing effective immunotherapy is to enhance the host immune response to tumors. In general, tumors are poor inducers of immunity as a result of inappropriate expression of MHC molecules, weakly immunogenic antigens, or inadequate levels of costimulatory or adhesion molecules (114). Although the long-term goal of identifying dominant tumor antigens for common cancers is important, the antitumor therapies would be more effective if they were augmented in a context that enhanced the T-cell response. One approach to increase the T-cell response is by expressing B7 costimulatory molecules on tumor cells. Genetic modification of tumors to express B7-1 or B7-2 enhances the host antitumor immune response (115,116 and 117). The rejection of tumors is accelerated by the administration of anti–CTLA-4 Abs in animal models (118). Thus, *in vivo* blockade of B7:CTLA-4 interactions with antibodies to CTLA-4 can result in the rejection of tumors, including preestablished tumors, presumably by enhancing T-cell activation (119). Therefore, there is great interest in designing immunotherapies that enhance the antitumor response either by stimulating expression of B7 or by blocking B7:CTLA-4 interactions.

Transplantation

Based on the premise that tolerance can result from antigen recognition in the absence of effective costimulation, numerous attempts have been made to prevent rejection of organ allografts by inhibiting B7:CD28/CTLA-4 or CD40:CD40L interactions *in vivo.* The efficacy of costimulatory molecule blockade in delaying graft rejection was reported first in a murine cardiac allograft model (120). When recipients of MHC-mismatched cardiac allografts were treated with CTLA-4Ig at the time of transplantation, graft rejection was delayed as late as 60 days. Later studies demonstrated that coblockade of the CD40:CD40L and B7:CD28 pathway with antagonists prevented the rejection of vascularized cardiac allografts and promoted the long-term survival of allogeneic skin grafts (121). The findings from the murine models were extended to a primate model. Treatment of primates with CTLA-4Ig and anti-CD40L mAbs was shown to prevent and reverse acute transplant rejection of MHC-mismatched renal allografts (122). As a consequence of these promising results, clinical trials are under way using costimulatory molecule antagonists to prevent transplant rejection.

Graft-versus-Host Disease

Graft-versus-host disease (GVHD) occurs when transplanted T cells mount a vigorous immune response against host tissue alloantigens. The development of GVHD is a major obstacle to successful bone marrow transplantation. Blockade of the B7:CD28/CTLA-4 and CD40:CD40L pathways has been a key strategy in the prevention of GVHD. Studies in animal models have shown that treating recipients of mismatched donor bone marrow with anti-CD40L antibodies or CTLA-4Ig prevents the expansion and cytolytic activity of the donor T cells characteristic of acute GVHD (123,124). Findings from the first clinical trial to adapt this approach to bone marrow recipients have been published (125). The strategy was to induce tolerance in donor T cells to host alloantigens *in vitro* before bone marrow transplantation. To induce tolerance, peripheral blood lymphocytes were collected from the bone marrow recipients before irradiation. The recipient lymphocytes were irradiated and were used to stimulate the donor bone marrow mismatched for one HLA haplotype, and the cells were cultured with CTLA-4Ig. After this treatment, donor bone marrow was transferred into patients who were monitored for signs of GVHD. Although this initial clinical trial was small, five patients exhibited remission several months after the bone marrow transplantation, whereas three patients exhibited acute signs of GVHD. These results are impressive, considering that other forms of treatment had failed in the patients in this study. Future clinical trials will be necessary to assess the potential benefits of this type of immunotherapy.

Autoimmunity

By using animal models, the role of costimulatory molecules in the development of autoimmunity has been an area of intense investigation. In a murine model of

multiple sclerosis, EAE, blocking B7-2 interactions increased the incidence of Th1-mediated disease, whereas similarly blocking B7-1 interactions ameliorated disease (126). Later studies demonstrated that B7-1/B7-2 deficient mice were highly resistant to EAE during the induction and effector phase of the response (127,128). Given the importance of CD40:CD40L interactions in upregulating B7-1 and B7-2, the CD40:CD40L pathway has also been investigated in EAE. Treatment with anti-CD40L mAbs either at the time of induction or after initial onset of disease resulted in dramatic reduction in EAE severity (129). Combined, these studies indicate that CD40 and B7 molecules have a critical role in the development and maintenance of EAE. Similar results have been observed in other models of autoimmunity. Studies have shown that CD40:CD40L blockade inhibits the development of collagen-induced arthritis (123). In systemic lupus erythematosus models, protective effects were observed after blockade of CD40 and CD28 pathways (130). Patients with this disease were shown elevated levels of CD40L and dysregulated expression of B7-1 and B7-2 (131). Thus, the B7:CD28 and CD40:CD154 pathways have complementary and required roles in T-cell differentiation and influence the development of autoimmunity.

In several models of autoimmunity, CTLA-4 has been shown to downregulate T-cell responses during the course of an autoimmune disease. Treatment with anti–CTLA-4 mAbs exacerbated EAE when therapy followed adoptive transfer of primed T cells (132,133 and 134). Similar effects were observed in a TCR transgenic model of diabetes in which administration of anti–CTLA-4 mAbs accelerated the development of diabetes (135). The onset of diabetes was only affected when the anti–CTLA-4 Ab was given before the onset of insulitis. These results suggest a critical role for CTLA-4 at the initiation of the autoimmune response as well as the downregulation of the ongoing response.

In light of the role of CTLA-4 in the development of autoimmunity in experimental systems and the phenotype of the CTLA-4–deficient mouse, there has been great interest in assessing whether CTLA-4 contributes to human autoimmunity. Several polymorphisms have been identified within the human CTLA-4 gene and have proven informative in genetic linkage studies (136). Polymorphisms in the CTLA-4 gene have been genetically linked to several human autoimmune diseases, which include insulin-dependent diabetes mellitus, Graves disease, Hashimoto's thyroiditis, rheumatoid arthritis, and other disorders (137,138,139,140,141 and 142). The crucial unresolved issue is whether the predisposing gene is actually CTLA-4 or another closely linked gene. This is particularly critical because other genes (e.g., CD28) expressed by T cells and other immune cells are closely linked to the CTLA-4 locus. Further studies are needed to determine whether these polymorphisms either result in altered expression of the CTLA-4 gene or modify CTLA-4 protein function.

A promising phase I clinical trial using CTLA-4Ig for the treatment of the T cell-mediated autoimmune skin disease, psoriasis vulgaris, was published recently (143). This is the first report in which blocking T-cell costimulatory activity has altered the course of disease in humans. In this study, patients with psoriasis vulgaris were treated with CTLA-4Ig, and 46% of the patients exhibited a 50% or greater improvement in clinical disease. Greater effects were observed in a subset of patients given a higher dose of CTLA-4Ig. The findings of this clinical trial provide great promise for the treatment of psoriasis vulgaris as well as other T-cell–mediated autoimmune diseases.

Allergy

Allergic reactions develop when a sensitized individual responds to innocuous foreign proteins. Although the triggers of an allergic reaction are harmless, effector T cells and the associated inflammation result in significant disease. The allergic response is characterized by elevations in IL-4 and other Th2 cytokines, serum immunoglobulin G1 (IgG1) and IgE levels, eosinophils, and mast cells (34). Interestingly, the same effector populations aid in the immunologic attack against parasites. The question whether it is possible to block the differentiation of a naive Th cell into a Th2 effector cell has been studied in animal models. In a murine model of asthma, administration of CTLA-4Ig before antigen sensitization or before reexposure to antigen blocked asthma (144). Likewise, levels of IL-4, serum IgG1 and IgE, and pulmonary eosinophilia were markedly reduced. Although CTLA-4Ig treatment has been shown to be effective in some models of allergy, some evidence suggests that Th2 cells may be more resistant to tolerance induction than Th1 cells. In a model of contact dermatitis, both anti-CD40L and CTLA-4Ig treatment were required to block the immune response to a Th2 allergen, whereas CTLA-4Ig alone was sufficient to inhibit the response to a Th1 allergen (145). Despite successful intervention by costimulatory molecule blockade, it is unclear whether this type of treatment will be effective in patients with long-term exposure to allergens. Effective immunotherapy for allergy may require a strategy that prevents naive, effector, and memory T cells from responding on subsequent exposure to the allergen. To date, there are no clinical trials for allergy using costimulatory molecule blockade as a strategy.

CONCLUSIONS

Many factors contribute to the decision of immunity versus tolerance. Costimulatory molecules play a key role in the activation and differentiation of T cells. After TCR engagement, CD28 delivers stimulatory signals to the T cells that can prevent the development of anergy by promoting T-cell activation and survival. By contrast, CTLA-4 delivers downregulatory signals to T cells by inhibiting proliferation and IL-2 production and can promote the induction of anergy. The costimulatory effects of the B7:CD28/CTLA-4 pathway depend on stimulation, at least in part, through the CD40:CD40L pathway. Engagement of the CD40 receptor results in APC activation, upregulation of B7-1 and B7-2, cytokine production, and cell survival. The activation of the APC, in turn, affects Th cell differentiation. The profound effects of disrupting the B7:CD28/CTLA-4 pathway and the CD40:CD40L pathway have been demonstrated in several models of autoimmunity, infection, and transplantation.

Several mechanisms are recognized for maintaining T-cell tolerance in the periphery. T cells that receive inadequate costimulation may be rendered anergic or unresponsive. Repeated T-cell stimulation induces apoptosis, which can be mediated through the Fas:FasL pathway. Finally, tolerance induction can be mediated by the development of suppressor T cells, which can alter T-cell differentiation and can cause immune deviation. Understanding which pathways are critical to the induction of tolerance is key to developing rational strategies of therapeutic intervention.

10 CYTOKINES AND TYPE 1 IMMUNITY

J. David Farrar, Ph.D., and Kenneth M. Murphy, M.D., Ph.D.

The *immune response* elicited against a particular pathogen can be categorized as either cell mediated (involving phagocytes or cytolytic cells) or humoral (involving antibody), and the $CD4^+$ T helper (Th) cell is the primary cell type responsible for orchestrating both of these responses. The capacity of Th cells to direct such responses is exerted by selective secretion of unique cytokines. For example, Th secretion of interferon-g (IFN-g) induces a cell-mediated response by activating macrophages to produce inflammatory cytokines, whereas Th secretion of interleukin-4 (IL-4) elicits a humoral response by inducing B-cell proliferation and Ig production. In 1986, Mosmann and Coffman discovered that $CD4^+$ Th cells could be classified into two subsets (designated Th1 and Th2) according to their cytokine secretion profiles (1). Th1 cells were shown to secrete IL-2 and IFN-g, and Th2 cells secreted IL-4 and IL-5. Moreover, the development of these two subsets proceeds through a mutually exclusive process such that a single pathogen favors the development of either the Th1 or the Th2 phenotype. This remarkable discovery explained how a single cell type could direct two such dissimilar immune responses.

Since the initial discovery of Th1 and Th2 cells, it has become clear that the resolution of many disease states relies almost exclusively on the development of the "appropriate" Th phenotype. For example, in the murine model of *Leishmania major* infection, IFN-g secretion by Th1 cells is required for both limiting the disease to the site of infection and eradicating the organism from resident infected macrophages (2). If, however, a Th2 response is generated to *L. major* infection, the organism will not be contained and, instead, will become systemic, ultimately causing the animal to succumb to the disease. Another important disease state associated with aberrant Th responses is autoimmunity. Autoreactive Th1 cells have been shown to be involved in such diseases as arthritis (Chapter 37 and Chapter 38) and diabetes (Chapter 48), whereas Th2 cells mediate allergy (Chapter 61) and asthma (Chapter 65). Thus, understanding the mechanism governing the development of these two distinct Th phenotypes is critical for disease diagnosis and prognosis and for designing therapeutic interventions. In this chapter, we explore the basic cellular and molecular mechanisms that link the innate immune response with the instructive process of Th1 development. Further, we examine how the type I response results in adaptive cell-mediated immunity.

CHARACTERISTICS OF TH SUBSETS

Patterns of Cytokine Expression

Early *in vitro* studies classified antigen-specific Th clones into Th1 and Th2 subsets based solely on their cytokine secretion profiles (3). Th1 cells exclusively produced IL-2 and IFN-g, whereas Th2 cells produced IL-4, IL-5, IL-10, and IL-13 (Fig. 10.1). Later, it was recognized that IL-10 expression was not always restricted to Th2 cells, and in some cases, particularly in human $CD4^+$ T cells, Th1 cells could produce both IFN-g and IL-10 (4). In addition, expression of IL-1, IL-3, and granulocyte-macrophage colony-stimulating factor (GM-CSF) was shared between Th1 and Th2 subsets. The Th1 and Th2 phenotypes were not restricted to *in vitro*–derived T-cell clones. Th subsets have been characterized from *in vitro*–derived bulk cultures and from *in vivo*–derived peripheral blood and biopsy samples. Additionally, Th subsets have been identified in a variety of species ranging from mice to humans (5).

	Molecule Expressed	Th1	Th2
Secreted Cytokines	IL-1	++	++
	IL-2	+++	-
	IL-3	++	++
	IL-4	-	+++
	IL-5	-	+++
	IL-10	+/-	+++
	IL-13	-	+++
	GM-CSF	++	++
	IFN-γ	+++	-
Chemokine Receptors	CCR3		+
	CCR4		+
	CCR5	+	
	CCR8		+
	CXCR5	+	
	CXCR4		+

Figure 10.1. Cytokine secretion and chemokine receptor expression profiles of Th1 and Th2 cells. **Top**: Relative levels of secreted cytokines are expressed as + (expressed) or – (not expressed). **Bottom**: Chemokine receptor expression is correlated with Th1 and Th2 subsets, but their expression cannot be considered as a useful marker for the identification of Th1 or Th2 cells.

The exclusive nature of cytokine expression fits well with the functional capabilities of these two subsets. For example, the Th1 subset, by virtue of IFN-g secretion, orchestrates a protective cell-mediated response to both intracellular and extracellular bacterial pathogens (6). In this case, IFN-g is required for the oxidative burst and delayed-type hypersensitivity (DTH; discussed later). This type of response would be ineffectual to pathogens such as helminths because these large organisms are resistant to phagocytosis and intracellular oxidative bursts. Thus, a protective type II response is mediated by Th2 cells in response to helminth parasites (7). In this situation, Th2 secretion of IL-4 elicits B-cell production of helminth antigen-specific immunoglobulin E (IgE) and secreted IgA, and IL-5 induces the recruitment and activation of eosinophils to sites of infection (Chapter 11). Clearly, host-pathogen interactions have provided a necessary selective pressure for the evolution of Th subsets.

Expression of Chemokine Receptors

Chemokines are a family of low-molecular-weight (8- to 14-kd) proteins produced by many cell types. Their function is mainly in chemoattraction of leukocytes, and chemokine activity is mediated through a family of seven transmembrane-spanning G-protein receptors (see Chapter 16). Initially, $CD4^+$ T-cell subsets could only be distinguished based on their unique cytokine secretion patterns, and efforts to identify differentially expressed cell surface markers largely failed. More recently, several chemokine receptors have been identified as selectively expressed between Th1 and Th2 cells (8), and their expression pattern is listed in Fig. 10.1. However, the expression pattern of chemokine receptors is not as phenotype restricted as that of cytokines because only a subpopulation of each Th subset expresses a given chemokine receptor. Thus, chemokine receptors cannot be used as reliable surface markers for the identification of Th1 or Th2 cells. It is interesting to speculate on the function played by each chemokine receptor, particularly those receptors whose expression is relatively phenotype specific (9). However, no such function has been ascribed to chemokine receptors and Th subsets with regard to either tissue-specific migration or cell activation.

TH1 DEVELOPMENT

Cytokine Receptors and Signaling

The hallmark of an adaptive $CD4^+$ T-cell response is the expansion of antigen-specific cells concomitant with the differentiation of the expanding clonal populations into distinct cytokine-secreting subsets. Various signals, delivered through the action of cell-surface receptors, are required for the Th developmental process to occur (10,11). The T-cell receptor (TCR) and cytokine receptors together play the most critical role in this process. TCR recognition of peptide-major histocompatibility complex (MHC) on antigen-presenting cells (APCs) leads to cellular activation and proliferation, provided the appropriate coreceptors are present. Initiation of cell division through the TCR is a critical component for both cell division and cytokine gene expression. However, the TCR signal, rather than directly mediating Th polarization, subtly influences the initial cytokine milieu that acts directly to mediate Th development (12). Thus, the signals delivered by cytokines are the critical factors governing the differentiation of Th subsets. In this section, we explore the molecular basis by which cytokines signal through their receptors and the consequence of those signals on Th1 development.

In general, the effects of the cytokines discussed later, with the exception of IL-18, are mediated through a heterodimeric complex consisting of two receptor subunits (diagrammed in Fig. 10.2A) (13). Each chain of the receptor is constitutively associated with the Janus family of tyrosine kinases referred to as JAK kinases (14,15,16 and 17). On receptor activation by cytokines, the associated JAK kinases become phosphorylated and, in turn, phosphorylate critical tyrosine residues within the cytoplasmic domains of both receptor subunits (Fig. 10.2B). Tyrosine phosphorylation of the receptor tails acts to recruit members of the signal transducer and activator of transcription (STAT) family (Fig. 10.2C). STAT molecules harbor several domains important for functions such as receptor binding, dimerization, and gene transactivation. The Src-homology-2 (SH2) domain, located near the C terminus of all STAT molecules, is responsible for both receptor binding and STAT dimerization. SH2 domains are characterized by their ability to bind phosphotyrosine residues, and their specificity of binding is determined by the amino acid sequence located adjacent to the phosphotyrosine residue within the receptor tails. The specific phosphotyrosine-containing sequences within the cytoplasmic domains of cytokine receptors dictate which unique STAT family member is recruited to a particular receptor. On docking to the receptor tails, STATs become phosphorylated by the action of the associated JAK kinases and subsequently form homodimers and heterodimers with other STAT family members. Dimerization of STATs is also accomplished through phosphotyrosine/SH2 domain interactions. These activated STAT dimers translocate to the nucleus and participate in transcriptional regulation of cytokine-inducible genes.

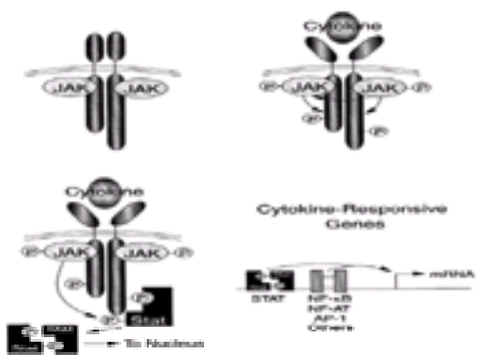

Figure 10.2. Cytokine receptor signaling mechanisms and STAT activation (see text for details).

Interleukin-12

IL-12 is a heterodimeric molecule consisting of p35 and p40 subunits and is secreted predominantly by activated professional APCs such as dendritic cells, activated macrophages, and Langerhans cells (18). Initially, IL-12 was characterized as a factor that promoted IFN-g production by natural killer (NK) cells (19 and 20). IL-12 was later shown to be responsible for promoting Th1 development when it was secreted by macrophages in response to antigens derived from heat-killed *Listeria monocytogenes* (21). Since the initial discovery of this cytokine, the essential role played by IL-12 in $CD4^+$ Th1 development was repeatedly demonstrated by gene ablation studies including the IL-12- (22), IL-12 receptor (IL-12R)b1- (23), and the Stat4-deficient (24,25) mice. In each of these murine gene knock-out models, deficient for specific components of the IL-12 signaling cascade, Th1 development is severely impaired when analyzed both *in vivo* and *in vitro.*

The IL-12R is composed of two b-type subunits (26,27). The b1 subunit is constitutively expressed on $CD4^+$ T cells, whereas the b2 subunit, required for signaling, is strictly regulated during the earliest phases of Th development (28,29). Stimulation through the IL-12R leads to the recruitment and activation of Stat1, Stat3, and, most important, Stat4 in both mouse and human T cells (30,31). The activation of Stat4 is the obligatory gateway through which Th1 differentiation proceeds. Stat4 was shown to bind directly to a unique phosphotyrosine-containing sequence within the IL-12Rb2 subunit (32), and in the absence of b2 expression, Stat4 fails to be activated in response to IL-12.

The expression of the IL-12Rb2 component is the basis for IL-12 responsiveness in $CD4^+$ T cells, and both genetic and environmental factors influence the expression of the b2 subunit during early Th priming. As mentioned earlier, certain infectious disease models have been shown to rely on the development of an appropriate Th response for the resolution of the disease. For example, studies of inbred strains of mice revealed a genetic component to resistance to *L. major* infections (2). In this murine model, BALB/c mice infected with *L. major* were unable to control the growth of the organism, whereas C57BL/6 and B10.D2 animals were able to control the infection and clear the organism. The clearance of *L. major* strictly depends on the development of a Th1 response that both C57BL/6 and B10.D2 mouse strains are able to mount.

An important insight to the genetic component of Th1 development was revealed when the difference for Th1 development was demonstrated *in vitro* between BALB/c and B10.D2 $CD4^+$ T cells. B10.D2, but not BALB/c, T cells were able to acquire and maintain the ability to respond to IL-12 during the early phases of priming (33). Thus, under neutral priming conditions (in which all endogenous cytokines are allowed to be expressed), B10.D2 cells acquired the ability to respond to IL-12, but BALB/c cells lost such responsiveness as determined by their loss of Stat4 activation in response to IL-12 and lack of IFN-g production after a third stimulation (34). This genetic difference in IL-12 responsiveness was explained by the ability of B10.D2 cells, but not BALB/c cells, to upregulate and maintain the expression of the IL-12Rb2 subunit required for IL-12 signaling (35). By intercross breeding of BALB/c and B10.D2 strains, the genetic locus controlling the ability of B10.D2 cells to acquire IL-12 responsiveness was mapped to murine chromosome 11 (36). This locus was designated *Tpm1* (T-cell phenotype modifier 1) and has been more finely mapped to include the resident genes *IL-4, IL-13, Tcf1*, and *ITK* (37). The specific genetic component and the mechanism by which *Tpm-1* regulates IL-12 responsiveness remain to be discovered.

Tpm1 seems to exert effects on IL-12 responsiveness by an intracellular pathway and is dominantly inherited. However, *Tpm-1* is not the only locus controlling IL-12 responsiveness or *L. major* resistance. For example, a region of murine chromosome 15 also influences IL-12 responsiveness, but this genetic locus seems to exert extracellular effects, that is, secreted factors, and is inherited in a recessive manner (37,38). Other genetic loci have been identified that have direct effects on resistance to *L. major* infections including loci encoding genes responsible for the oxidative burst as well as MHC genes (39,40 and 41). Finally, genetic components regulating human host-pathogen interactions have been linked to *Mycobacterium leprae, L. donovani,* and *M. tuberculosis* (42), although it has not been determined whether these loci directly influence Th development.

Interferon-g

IFN-g is a 21- to 24-kd monomeric protein and binds a heterodimeric receptor composed of a and b subunits. Signaling through the IFN-gR leads to Stat1 activation (Fig. 10.3), and the induction of Stat1-responsive genes such as IFN regulatory factor-1 (IRF-1) and MHC class II transactivator protein (CIITA) (6). IFN-g is the hallmark of the Th1 subset, its presence is not required for Th1 development, and $CD4^+$ IFN-g–producing cells can develop in the presence of neutralizing a-IFN-g antibodies, as well as in Stat1-deficient (43) and IFN-gR–deficient (44) mice. Although IFN-g does not directly promote Th1 development, IFN-g plays a pivotal role in positively regulating the expression of the IL-12Rb2 subunit.

Cytokine Receptor	JAKs Associated	STATs Activated	Others
IL-4R (α & Cγ)	Jak1/Jak3	Stat6	IRS-1 & 2
IL-10R (α & β)	Jak1/Tyk2	Stats 1,3 and 5	
IL-12R (β1 & β2)	Jak2/Tyk2	Stats 1, 3 and 4	
IL-18R	–	–	NF-κB IRAK MyD88
IFN-γR (α & β)	Jak1/Jak2	Stat1	
IFN-α/βR (R1 & R2)	Jak1/Tyk2	Stats 1, 2 and 3 (Stat4 Only in human)	

Figure 10.3. Cytokine receptors and JAK/STAT association (see text for details).

The analysis of *in vitro* Th development has been greatly advanced with the use of transgenic TCR mice. In this system, most of the $CD4^+$ T cells within these animals express the identical TCR with a known antigen specificity. Thus, *in vitro* T-cell culture systems were established with these T cells to study the effects of soluble factors in Th development. Data from these studies demonstrated that the IL-12Rb2 subunit is not expressed in naive $CD4^+$ T cells; however, after primary stimulation with either IL-12 or IL-4, IL-12Rb2 mRNA is markedly induced in Th1 and is weakly expressed in Th2 cells 3 days after stimulation (28). Yet, this expression was transient in Th2 cells because the b2 chain was completely extinguished by 5 days after stimulation. Loss of IL-12Rb2 expression correlated precisely with the loss of IL-12-induced Stat4 activation in Th2 cells. Conversely, b2 mRNA expression was dramatically increased and maintained in IL-12–treated Th1 cultures up to 9 days after stimulation, a finding suggesting that the b2 subunit was stably expressed in Th1 cells but not in Th2 cells. The effect of IL-12 was not direct because neutralizing antibodies to IFN-g inhibited IL-12Rb2 mRNA expression. Furthermore, b2 expression was also increased when T cells were primed in the presence of both IL-12 and IL-4, and the induction of b2 could only be inhibited when the activity of IFN-g was blocked during the early phase of T-cell priming. These results suggested that IFN-g acted directly and dominantly over IL-4 to induce the expression of the IL-12Rb2 subunit.

Interferon-a/b

Type 1 IFNs comprise a large class of highly related molecules. IFN-a is a family of individual monomeric proteins encoded by more than 20 unique genes, whereas IFN-b is a single protein encoded by a single gene (45). Additionally, IFN-a/b is expressed by many cell types and is induced by viral infection through the cytoplasmic detection of double-stranded RNA molecules (46). Although many isoforms of type I IFNs exist, only one IFN-a/b receptor (IFNAR) complex has been identified. Remarkably, all IFN-a/b isoforms tested can bind and activate the IFNAR in a species-specific manner.

Early studies of human $CD4^+$ Th development suggested that IFN-a/b could act directly to induce Th1 development (47). In contrast, IFN-a could not act either directly or indirectly to influence Th1 development in mice (48). Furthermore, both IFN-a and IFN-b induced the development of human Th1 cells, even when endogenous IL-12 was neutralized, a finding suggesting that IFN-a/b was acting in a direct manner (29). Thus, the activity of type I IFNs to induce IFN-g expression is selectively lost in mice, but it is likely not unique to human T cells.

The ability of IFN-a to induce Th1 development in human T cells was particularly puzzling until it was shown that IFN-a could recruit and activate Stat4 in response to IFN-a/b in human, but not murine, $CD4^+$ T cells (Fig. 10.3) (49,50). Although no known human disorders have been attributed to Stat4 deficiencies, the lack of Th1 development in Stat4-deficient mice implicates the involvement of Stat4 in Th1 development in human T cells as well. Thus, Stat4 activation in response to IFN-a/b in human, but not murine, T cells explains the species-specific ability of type 1 IFNs to induce Th1 development only in the human system.

The ability of the human IFNAR to activate Stat4 affords human $CD4^+$ T cells specific advantages regarding diseases. First, human T cells proceed through Th1 development in the absence of both IFN-g and IL-12 because both the IFN-aR1 and R2 receptor subunits are constitutively expressed on virtually all cells. Thus, virally infected cells directly influence Th1 development by the production of IFN-a. Two unique cases of IL-12 unresponsiveness, caused by mutation in the IL-12R, have been reported in humans (51,52). These patients had severe susceptibilities to bacterial infections, yet their antiviral responses were relatively intact. One possible explanation is that bacterially induced IL-12 production has no effect in driving Th1 development because their T cells failed to respond to IL-12. However, viral immunity was maintained in these patients because IFN-a alone (produced by infected cells) may support Th1 development, thus allowing for a productive antiviral response.

Interleukin-18

IL-18 is structurally related to the IL-1 family of cytokine molecules and is secreted by a variety of cell types, most notably by activated macrophages. IL-18 was first identified as an activity that magnified IFN-g production by Th1 cells (53), and like IL-1, IL-18 is synthesized as an inactive precursor and is cleaved to an active form by caspase 1 before secretion (54). The receptor for IL-18 is also structurally related to the IL-1R and activates the downstream signaling components IRAK (IL-1 receptor-associated kinase) and MyD88 (Fig. 10.3) (55,56). Furthermore, stimulation of the IL-18R pathway leads to the activation of NF-kB family members and possibly AP-1.

T cells display restricted and regulated expression of the IL-18R; however, neither naive $CD4^+$ nor $CD8^+$ T cells express any measurable cell-surface IL-18 binding activity (57,58). Within 48 hours of TCR stimulation, $CD4^+$ and $CD8^+$ cells demonstrated increased IL-18R expression. Th2 cells do not express IL-18R, and it is not clear whether the expression of the IL-18R absolutely requires a signal from IL-12 (because Th2 cells do not express IL-12Rb2) or whether Th2 cells have downregulated the expression of the IL-18R as a result of other factors responsible for differentiation.

Initial reports suggested that IL-18 could influence Th1 development independently of IL-12 activation. Indeed, both the IL-18-deficient (59) and the Myd88-deficient (56) animals showed decreased Th1 responses *in vivo* to bacterial pathogens such as *Propionibacterium acnes.* However, the diminished Th1 response in IL-18–deficient mice was not as severe as demonstrated for the IL-12–deficient or Stat-4–deficient animals. Studies demonstrated that IL-18, alone, could not direct the development of Th1 cells *in vitro* (55). Rather, IL-18 synergized with IL-12 to induce high and sustained levels of IFN-g secretion by Th1 cells and Th1 clones. Furthermore, stimulation with IL-12 and IL-18 in the absence of TCR activation led to remarkably high IFN-g secretion by Th1 cells.

Thus, two separate signals lead to IFN-g production by Th1 cells (60). First, the signal delivered by the TCR induces IFN-g mRNA in Th1 cells in the absence of either IL-12 or IL-18. The second signal delivered by combined treatment of Th1 cells with IL-12 and IL-18 leads to sustained IFN-g secretion when compared with TCR stimulation. These two separate signals (TCR and IL-12/IL-18) seem to act independently of each other but have similar effect on Th1 cells by positively regulating IFN-g gene expression. The factors responsive to these two pathways that positively regulate the IFN-g gene have yet to be identified.

Interleukin-10

IL-10 is secreted as a 17- to 20-kd protein and binds a heterodimeric receptor composed of two distinct subunits (61). The high-affinity binding a chain is paired with a low-affinity b chain required for signaling and activates Stats 1, 3, and 5 (Fig. 10.3) (62,63). Although IL-10 is predominantly secreted by the Th2 subset, it is expressed by other cell types such as mast cells, macrophages, keratinocytes, and many neoplastic T- and B-cell derived lymphomas. IL-10 was first characterized as a factor that suppressed cytokine production by Th1 cells and has now become recognized as a powerful inhibitor of both *in vitro* and *in vivo* Th1 development.

Although IL-10 binds a typical class II cytokine receptor and is linked to the JAK/STAT signaling pathway (64), its molecular mechanism of activity is unique compared with the actions of other T-cell–derived cytokines. First, IL-10 does not inhibit IFN-g production or Th1 development by direct actions on T cells. Rather, IL-10 acts indirectly by inhibiting cytokine production from activated macrophages (65,66). Second, the mechanism of cytokine inhibition seems to be direct on cytokine secretion and not through a global inhibition of IFN-g signaling because many of the actions of IFN-g on macrophages remain intact after treatment with IL-10, such as the upregulation of IRF-1 and class II expression. Finally, the direct molecular target for IL-10 inhibition of both tumor necrosis factor-a (TNF-a) and IL-12 is controversial. One target for IL-10 inhibition has been proposed to be the direct transcriptional inhibition of IL-12p35, IL-12p40, and TNF-a mRNAs (67). In contrast, other studies have suggested that IL-10 blocks IL-12 and TNF-a production at the posttranscriptional level (68,69). This is likely accomplished by decreasing mRNA stability of IL-12 and TNF-a through specific AU-rich sequences encoded in the 3' untranslated regions of both IL-12 and TNF-a mRNAs.

Instructive Developmental Signals

Th1 development appears to proceed through at least two phases, which we refer to as capacitation and differentiation (Fig. 10.4) (70). Because naive CD^+ T cells do

not express any appreciable levels of the IL-12Rb2 subunit, these precursors (Thp) do not have the capacity to respond to IL-12 immediately on T-cell activation. Rather, naive Thp cells must acquire the ability to respond to IL-12 by inducing cell-surface expression of the IL-12Rb2 chain, a process that depends on IFN-g and Stat1. This first phase of development is capacitation and is necessary for a Thp to become fully responsive to IL-12. However, in the absence of IL-12, these capacitated cells still do not have the ability to become fully IFN-g–producing cells. If a strong IL-4 signal is delivered, rather than IFN-g, during the early phases of capacitation, the expression of the IL-12Rb2 subunit is extinguished, thereby blocking Th1 development. Thus, the differentiation phase, proceeding to a full potential to produce IFN-g, requires the signal from the IL-12R and is a Stat4-dependent process. Once a $CD4^+$ T cell passes through the Stat4-dependent differentiation phase, it has the capacity to produce IFN-g on subsequent restimulation. Moreover, a fully differentiated Th1 cell can secrete IFN-g in response to TCR signaling and does not require additional IL-12 stimulation, and this is referred to as factor-independent phenotype stability.

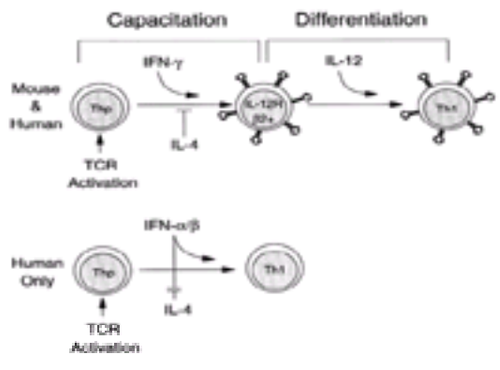

Figure 10.4. Th1 development occurs in two stages: capacitation and differentiation (see text for details).

As discussed earlier, human $CD4^+$ T cells have an inherent second pathway for Th1 development through the action of type I IFNs (Fig. 10.4). Because IFNARs are constitutively expressed, IFN-a/b can act directly on naive Thp cells to induce Th1 differentiation. Moreover, data have demonstrated that IFN-a/b acts dominantly over the effects of IL-4 and can block any negative regulatory mechanism imposed by IL-4, thereby circumventing the need for a capacitation phase of Th1 development in human $CD4^+$ Th cells.

IN VIVO TYPE 1 RESPONSES

Induction of Th1 Differentiation

The initiation of a type 1 immune response begins with Th1 development within secondary lymphoid organs, that is, spleen and lymph nodes (Fig. 10.5A). Naive $CD4^+$ Thp cells are instructed toward Th1 development through their interactions with activated macrophages that have immigrated into secondary lymphoid organs from distal sites of infection. Bacterial pathogens are potent stimuli for macrophage activation. Through the action of several pattern recognition receptors, such as CD14 (71) and Toll-like receptors (72), bacterial products elicit proinflammatory cytokine production as well as migration into spleen and lymph nodes. Additionally, IFN-g, secreted by innate immune cells such as NK cells, acts to upregulate MHC class II expression and antigen presentation by activated macrophages (73). Once in the spleen or lymph node, these activated macrophages initiate $CD4^+$ T-cell proliferation through antigen (MHC II/TCR) and coreceptor (B7/CD28) interactions as well as autocrine IL-2 production by activated T cells. However, Th1 differentiation (described earlier) requires signaling through the IL-12R, and experimentally, this process can be blocked *in vivo* by administering neutralizing IL-12 antibodies (inhibiting IL-12 activity) or exogenous IL-10 treatment (inhibiting IL-12 production) (74). After differentiation, Th1 cells orchestrate a type 1 response both within the secondary lymphoid organ and directly at sites of infection.

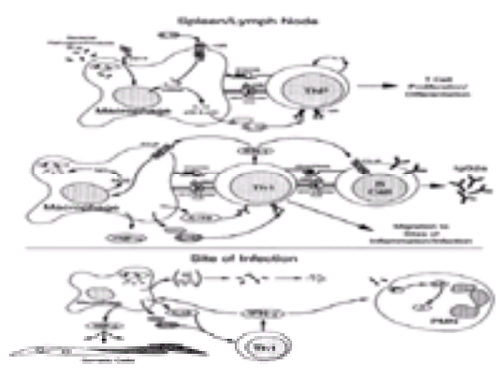

Figure 10.5. *In vivo* Th1 development and type I responses. **A**: Induction of Th1 differentiation. **B**: Initiation of the type I response in secondary lymphoid organs. **C**: Th1 effector functions and delayed-type hypersensitivity.

Th1 Effector Functions and Delayed-Type Hypersensitivity

A fully differentiated Th1 cell arising from this differentiation process has the capacity to secrete high levels of IFN-g in the absence of further IL-12 signaling. Within secondary lymphoid organs, IFN-g, produced by Th1 cells, eliminates bacterial pathogens from within infected macrophages (Fig. 10.5B). This activity is accomplished through signals delivered by the IFN-g receptor leading to macrophage expression of the enzyme inducible nitric oxide synthase (iNOS) (75). Expression of iNOS leads to an intracellular oxidative burst by the production of nitric oxide (NO) from the reaction with L-arginine and molecular oxygen. L-arginine is the only nitrogen donor to this reaction, and the rate-limiting enzyme in L-arginine synthesis, argininosuccinate-synthase, is also induced by IFN-g. The precise mechanism by which NO exerts intracelluar bacteriocidal activity is not known, but many bacterial and viral pathogens are targets for NO-mediated destruction.

The second arm of the type 1 immune response is the induction of specific antibody production mediated by IFN-g. Within secondary lymphoid organs, Th1 cells provide B-cell help through interactions involving TCR/MHC class II and costimulatory molecules, namely CD40/CD40L (Fig. 10.5B) (76,77). In conjunction with these signals, IFN-g induces Ig production and class switching to the IgG2a isotype (78). Among all Ig isotypes produced by B cells, IgG2a is uniquely suited to participate in cell-mediated immunity. IgG2a is poor at inducing complement opsonization because it does not contain sequences required for binding of the initiating complement cascade protein C1q (see Chapter 26). Rather, IgG2a is involved in antibody-dependent cellular cytotoxicity through interactions with FcgRII receptors expressed on the surface of cytolytic cells such as NK cells and polymorphonuclear lymphocytes (PMN, neutrophils).

On differentiation, mature antigen-specific Th1 cells emigrate from secondary lymphoid organs and colonize into sites of inflammation and infection by processes discussed in Chapter 15 and Chapter 16. Th1 cells extravasate into infected tissues, where they undergo further stimulation through interactions with resident activated tissue macrophages (Fig. 10.5C). As mentioned earlier, activated macrophages produce high levels of IL-12 and IL-18, which, in concert, result in sustained high levels of IFN-g production by Th1 cells. IFN-g is the central mediator of the DTH reaction within infected tissues, and the hallmarks of DTH are the oxidative burst and infiltration of PMNs within these tissues (79). In response to IFN-g stimulation, macrophages mediate an extracellular oxidative burst. In addition to NO production, macrophages also secrete superoxide radicals (O_2^-) and hydrogen peroxide (H_2O_2). Synthesis of O_2^- is catalyzed by reduced nicotinamide adenine dinucleotide (NADPH)–dependent oxidase. When combined, these reactive intermediates provide greater target specificity for the eradication of many types of bacterial pathogens than can be accomplished by the production of NO alone.

A second important soluble mediator of DTH is TNF-a and is secreted by activated macrophages (80,81). TNF receptors are ubiquitously expressed and lead to a variety of responses, the most important of which for DTH is apoptosis (82). Apoptosis is a mechanism that is beneficial to the resolution of disease because somatic cells infected with intracellular pathogens do not have the capacity to eradicate the organism. Thus, induction of apoptosis of infected somatic cells serves to eliminate the pathogen through the action of phagocytic cells, which process and eliminate both somatic cell and bacterial cell debris.

In addition to activated macrophages, PMNs also play a fundamental role in DTH and the eradication of bacterial pathogens. IFN-g has pleiotropic effects on

neutrophils. First, IFN-g acts as a chemoattractant for neutrophil migration into sites of inflammation. The sheer numbers of neutrophils recruited to infected sites, in addition to vascular hypertrophy, partially accounts for the swelling phenomenon observed in inflamed tissues. Second, IFN-g induces phagocytosis in PMNs that have immigrated into infected tissues. In addition, phagocytosis is also accompanied by an intracellular oxidative burst and is an important mechanism for the elimination of bacterial pathogens.

The resolution of DTH probably depends on a decrease in the concentration of local bacterial pathogens and by-products that initiated the response. However, if left unchecked in cases in which pathogens are slow to be eliminated, DTH will not be resolved and will form a granulomatous reaction characterized by increased swelling and hardening of the inflamed area. Fibrosis and vasculitis accompany granuloma formation, and in cases of chronic DTH, morphologic changes also occur in the resident macrophage population. These chronic DTH macrophages have increased cytoplasm and intracellular organelles and can resemble epithelial tissue. Because fibrosis is a normal aspect of wound healing, it can be injurious to the host during chronic DTH reaction, particularly in organs where fibrosis interferes with normal organ function, such as the lung.

11 CYTOKINE REGULATION OF TYPE 2 IMMUNITY

Fred Douglass Finkelman, M.D.

A NOTE ON TERMINOLOGY

The terms used to classify cytokines are confusing. The terms “Th1” and “Th2” properly refer to $CD4^+$ T cells that produce distinct sets of cytokines. Although the cytokines produced by these cell types were originally referred to as “Th1 cytokines” or “Th2 cytokines,” respectively, subsequent discoveries that they can also be produced by cell types other than $CD4^+$ T cells led immunologists instead to refer to “Th1-associated” or “Th2-associated cytokines.” For the sake of convenience, the terms “type 1” and “type 2” were later adopted to refer to the cytokines that are produced by Th1 and Th2 cells, respectively, and to the patterns of inflammation produced by these sets of cytokines. Unfortunately, other investigators adopted the terms “type I cytokine” and “type II cytokine” to refer to cytokines defined by particular structure rather than particular function or cellular origin. Perversely, all the cytokines that fall into the type 2 functional classification are structurally type I cytokines, and the quintessential functional type 1 cytokine, interferon-g (IFN-g), is structurally a type II cytokine. To complicate matters further, variants of individual cytokine receptors are referred to as type I or type II, such as the type I or type II interleukin-4 (IL-4) receptor. Because this chapter focuses on cytokine function rather than structure, I use the terms “type 1” and “type 2” to refer to the functional classification.

GENERAL PRINCIPLES

The modern era of cytokine immunology started with Mosmann and Coffman's 1986 report that $CD4^+$ T cells cloned after repeated *in vitro* stimulation can be divided into two groups that produce different sets of cytokines (1). One group, designated Th1, produced IL-2 and IFN-g, but not B-cell stimulatory factor 1 (BSF-1, later renamed IL-4), whereas a second group, designated Th2, produced IL-4, but neither IL-2 nor IFN-g. Some cytokines, including IL-3 and tumor necrosis factor-a (TNF-a), were produced by both Th1 and Th2 cells.

The importance of the Th1/Th2 dichotomy was demonstrated during the next 2 to 3 years by the observation that the cytokine responses associated with Th1 or Th2 cells (termed type 1 and type 2 cytokine responses, respectively) are associated with disease resolution or disease progression and death, respectively, in mice infected with a protozoan parasite, *Leishmania major* (2,3). Production of the Th1-associated cytokine, IFN-g, was shown to be necessary to induce an enzyme, inducible nitric oxide synthetase, that is required for macrophage killing of *L. major,* whereas the Th2-associated cytokine, IL-4, inhibited production of this enzyme and allowed parasite proliferation and dissemination (4).

These seminal observations have guided studies of cytokine biology for the past 14 years. Additional cytokines have been added to both the Th1 subset (lymphotoxin, also called TNF-b) and the Th2 subset (IL-5, IL-9, and IL-13) (5,6). Investigators have come to understand that although the Th1/Th2 dichotomy is useful for characterizing immune-mediated disorders and responses to pathogens, fully polarized Th1 or Th2 cells that produce the complete set of Th1-associated or Th2-associated cytokines, respectively, without producing any cytokines of the opposite set, are more the exception than the rule (7,8 and 9). *In vivo* immune responses, which reflect cytokine production by cell populations, rather than by individual cells, can also be fully polarized or anywhere in between. Within this broader interpretation, the Th1/Th2 concept has been shown to be just as applicable to humans as it is to the mouse (10,11,12 and 13).

$CD4^+$ T cells are not the only cell type that can produce type 1 or type 2 cytokines or the only cell type that can produce polarized selections of cytokines. $CD8^+$ T cells, which were initially thought to secrete only type 1 cytokines (14), were also determined to be capable of secreting type 2 cytokines (15); furthermore, the conditions that stimulate $CD4^+$ or $CD8^+$ T cells to differentiate into type 1 or type 2 cytokine-secreting cells were determined to be similar (16). Natural killer (NK) cells were found to be an important source of the type 1 cytokine, IFN-g, although they can also secrete type 2 cytokines under some conditions (17,18); basophils and mast cells were shown to secrete a selection of predominantly type 2 cytokines, including IL-4 (19,20,21 and 22), and eosinophils were reported to secrete IL-4 and IL-5 (23,24). Determination of the relative importance of different cell types to a particular cytokine response remains an important area of ongoing research.

Much has been learned about the mechanisms by which type 1 and type 2 cytokines produce their effects. Cytokine receptors have been identified, along with some of their associated signaling molecules and cellular distributions. In some instances, it has been possible to track signaling pathways all the way from receptor ligation to the biologic effects that characterize type 1 or type 2 cytokine responses. In additional cases, biologic effects have been characterized sufficiently to reveal how selective production of a particular set of cytokines leads to a characteristic immune and inflammatory response, even though the route from receptor ligation to biologic effect remains incompletely mapped.

Much has also been learned about the cellular physiology and molecular biology of the process by which naive T cells differentiate into cytokine-secreting effector cells. Conditions that favor differentiation to Th1 or Th2 have become understood, and transcription factors that directly induce type 1 or type 2 cytokine production and their binding sites in cytokine gene promoters and enhancers have been identified, although the critical question of what makes some antigens allergenic remains unanswered.

This chapter addresses these issues with regard to the type 2 cytokines. Particular attention is given to the *in vivo* biologic effects of type 2 cytokines that promote immune and inflammatory responses that protect or damage the host in the process of dealing with real or perceived pathogens.

PHYSICAL CHARACTERISTICS OF TYPE 2 CYTOKINES

Characterization of biologic activities in the supernatants of murine Th2 cells and of the mRNA expressed by these cells identified three cytokines in addition to IL-4 that are often produced by $CD4^+$ T cells that secrete IL-4 but not IFN-g. These cytokines, IL-5, IL-9, and IL-13, are related not only in that they can all be produced by the same cell population, but also by the chromosomal location of their genes [IL-4, IL-5, IL-9, and IL-13, along with the IL-3 and granulocyte-macrophage colony-stimulating factor (GM-CSF) genes, are located in region q31-33 of chromosome 5 in humans and in a syntenic region of chromosome 11 in the mouse, except IL-9, which is located on mouse chromosome 13] (25,26), by their sharing of receptors and signaling pathways (27), and by their functional properties (all promote allergic reactions and all promote host protection against gastrointestinal nematodes). In addition, all the type 2 cytokines are members of the short-chain subset of the structural type I cytokine family: each has four a-helical bundles containing approximately 15 amino acids per bundle. Furthermore, all the type 2 cytokines bind to

receptors that are type I membrane-spanning glycoproteins, which include (a) fibronectin type III modules in an extracellular domain that has four conserved cysteines, (b) a membrane-proximal tryptophan-serine-X-tryptophan-serine sequence, and (c) a cytoplasmic domain that includes a membrane-proximal box 1/box 2 region in which box 1 is proline-rich and involved in the initiation of signaling (27). Some physical properties of the type 2 cytokines are shown in Table 11.1.

Cytokine	Chromosomal location (Human/Mouse)	Polypeptide Size	Major Cell Source	Structural Features
IL-4	5/11	20-kd monomer	T cell, mast cell/basophil	Short chain 4 α helices
IL-5	5/11	20-kd homodimer	T cell, mast cell/basophil, eosinophil	Short chain 4 α helices
IL-9	5/13	14-kd monomer	T cell, mast cell/basophil	Short chain 4 α helices
IL-13	5/11	14-kd monomer	T cell, mast cell/basophil, NK cell	Short chain 4 α helices

IL, interleukin; NK, natural killer.

TABLE 11.1. Type 2 Cytokines

An additional cytokine, IL-10, is often described as a type 2 cytokine because it is found in culture supernatants of activated type 2 cells (28), and it can suppress the generation of type 1 cytokine responses by inhibiting antigen presentation and IL-12 production (28,29). I prefer to classify IL-10 separately as an antiinflammatory cytokine, because (a) it can inhibit both type 1 and type 2 cytokine-induced inflammation and responses (29,30), (b) its *in vivo* production does not correlate well with production of IL-4, IL-5, IL-9, and IL-13 (31,32), (c) it is induced by an inflammatory cytokine, IL-12, that inhibits all other type 2 cytokine responses (33), (d) its receptor has a structure that resembles that of the IFN receptors rather than the receptors for the type 2 cytokines (27), and (e) the location of the IL-10 gene is outside the type 2 cytokine gene cluster, on chromosome 1 (in both mice and humans) (34).

COORDINATE PRODUCTION OF TYPE 2 CYTOKINES

An early version of the original Th1/Th2 concept suggested that CD4$^+$ T cells would produce either the complete set of type 1 cytokines or the complete set of type 2 cytokines (1,5). Further experimentation demonstrated a more complex reality. First, on initial stimulation, CD4$^+$ T cells often produce IL-2 in the absence of other type 1 or type 2 cytokines (35,36). On further stimulation, T cells can differentiate into cells that secrete a mixture or type 1 and type 2 cytokines. T cells at this stage have been referred to as Th0 cells (7,37,38). Although it has been argued that all differentiating CD4$^+$ T cells pass through a Th0 stage (38), *in vivo* studies have only established this for a few antigens and immunization protocols; other *in vivo* studies have failed to demonstrate a stage of mixed type 1 and type 2 cytokine production to immunogens that eventually induce a strongly polarized type 1 or type 2 cytokine response (31,32,39). Regardless of the differentiation route taken by CD4$^+$ T cells before they become Th1 or Th2 cells, it is now generally agreed that the Th1/Th2 concept should only be applied to mature, fully differentiated cells.

Second, as noted earlier, even fully differentiated, mature CD4$^+$ T cells do not necessarily produce all type 1 or all type 2 cytokines. Instead, individual T cells may produce a selection of some type 1 or type 2 cytokines or even a mixture of type 1 or type 2 cytokines. Even when they are viewed as a population rather than as individual cells, *in vivo* responses often include production of some, but not all, cytokines of one type or a combination of type 1 and type 2 cytokines. Examples are the production of large amounts of IL-4 without production of IL-5 during *in vivo* responses to some protein antigens (40) and production of IL-5 and IFN-g during respiratory syncytial virus infection (41).

Third, even during the relatively “pure” type 2 cytokine responses made by mice infected with some gastrointestinal nematode parasites, not all type 2 cytokines are made simultaneously; production of IL-5 and IL-9 precedes production of IL-4, which precedes production of IL-13 (31).

Fourth, studies of cells in particular locations, such as the small intestine, have demonstrated CD4$^+$ T-cell populations that produce combinations of cytokines, such as IL-10, and transforming growth factor-b (TGF-b) that may promote gut immune responses, such as immunoglobulin A (IgA) production, but inhibit inflammatory and immune responses at other locations (42). Nomenclatures have been devised that emphasize the unique qualities of these additional cell populations and their contributions to the immune system at the expense of an understanding that cytokines are, to a considerable extent, individually regulated.

Fifth, the same stimuli may have different effects on cytokine production in different individuals; individual genotype and previous immunologic experience both affect the selection and quantity of cytokines produced. This variability is of practical and theoretic importance. For example, although asthma is associated with increased production of type 2 cytokines, the roles played by IL-4, IL-5, IL-9, and IL-13 in disease may vary in different patients with this disease, and even the type 1 cytokine, IFN-g, appears to have a role in asthma pathogenesis (43). Consequently, therapy directed against a particular cytokine may be more efficacious in some patients than in others.

RECEPTORS FOR TYPE 2 CYTOKINES

The general characteristics of type 2 cytokine receptors are described earlier (27) (Table 11.2). Each receptor consists of two polypeptide chains; some of these are shared among receptors for different cytokines. There are two receptors for IL-4 (the type I and type II IL-4 receptors); the type II IL-4 receptor is also the sole known receptor for IL-13 (44). Both IL-4 receptors contain IL-4 receptor (R) a chain, which, in the type I IL-4R, is paired with cytokine receptor common g chain (g_c) and in the type II IL-4R is paired with IL-13Ra_1 chain (the g_c earns its name by participating in the IL-2, IL-7, IL-9, and IL-15 receptors, as well as the type 1 IL-4R) (27,44). IL-4 is bound predominantly by IL-4Ra chain in both the type I and type II IL-4Rs, whereas the type 2 IL-4R binds IL-13 predominantly through an interaction with IL-13Ra_1 chain. The IL-9 receptor resembles the type I IL-4R in that it contains g_c and an a chain that binds IL-9 (45). In contrast, the IL-5R, in addition to its unique IL-5Ra chain, contains the cytokine receptor common b chain (b_c), that is also a constituent of the IL-3 and GM-CSF receptors (46,47).

Cytokine	Membrane Receptor	Secreted			
	Polypeptides	Polypeptides	JAKs	Stats	Additional Signaling Molecules
IL-4	IL-4Rα/γ_c (type I)	sIL-4Rα	1,3	6	IRS-1, IRS-2, IRS-3
	IL-4Rα/IL-13Rα$_1$ (type II)		1,2, Tyk2	6	
IL-5	IL-5Rα/β_c	sIL-5Rα	1,2	5a,5b	CrkL, Btk, Lyn, Fyn, Raf-1
IL-9	IL-9Rα/γ_c		1,3	3,5a,5b	IRS-1, IRS-2
IL-13	IL-4Rα/IL-13Rα$_1$	sIL-13Rα$_2$	1,2, Tyk2	6	IRS-1, IRS-2

IL, interleukin.

TABLE 11.2. Receptors and Signaling Molecules for Type 2 Cytokines

Type 2 cytokine receptor chains exist in secreted as well as transmembrane forms. Alternately spliced versions of IL-4Ra and IL-5Ra mRNA encode secreted proteins that bind IL-4 or IL-5, respectively, without signaling (48). These soluble “receptors” may act as cytokine antagonists that prevent bound cytokine from ever reaching receptors and signaling cells (48). Alternatively, because complexes of cytokine and cytokine binding protein have a longer *in vivo* half-life than the free cytokine and can dissociate to release active free cytokine, cytokine binding proteins may increase the duration of a cytokine effect when a relatively large amount of a cytokine is released over a short period (49).

In the case of IL-13, a more complex situation occurs in which a second IL-13 binding molecule, IL-13Ra_2, is produced in both cell membrane and secreted forms (44).

IL-13Ra$_2$ binds IL-13 more avidly than IL-13Ra$_1$, but it is not known to be part of a signaling receptor. Consequently, IL-13Ra$_2$ may be a particularly effective inhibitor of IL-13.

TYPE 2 CYTOKINE SIGNALING

Each receptor for a type 2 cytokine signals through at least two pathways; one that involves JAK-Stat signaling and a second that involves activation of a more ubiquitous tyrosine kinase, such as phosphatidylinositol-3-kinase (PI3K) (27). In each case, signaling is initiated by linking of the two receptor chains by the cytokine. This linkage allows transphosphorylation of tyrosine residues on Janus kinases (JAKs) associated with box 1/box 2 sites on the cytokine receptors. The activated JAKs also phosphorylate tyrosine residues on cytoplasmic domains of the cytokine receptors; these residues become docking sites for signal tranducers of activation of transcription (Stats), which contain phosphotyrosine-binding SH2 domains. Phosphorylation of Stat tyrosine residues by JAKs causes the Stats to dissociate from cytokine receptor docking sites, to dimerize, and to translocate to cell nuclei, where they can stimulate the transcription of specific genes by binding to elements in the promoter regions of these genes.

Phosphorylated tyrosine residues on cytoplasmic domains of the cytokine receptors also act as docking sites for adaptor proteins, such as insulin receptor substrate-1 (IRS-1) and IRS-2 (50). Once phosphorylated by JAKs, these proteins bind and allow the tyrosine phosphorylation and activation of PI3K, which initiates signaling through the Ras–membrane-associated protein (MAP) kinase cascade, leading to assembly of the transcription factor, AP-1 (51).

As shown in Table 11.2, only four JAKs have been identified (JAK1, JAK2, JAK3, and Tyk2). Each JAK can associate with several different cytokine receptor polypeptides. For example, JAK1 and JAK3 are involved in signaling through all the g$_c$-associated cytokine receptors (JAK3 associates with g$_c$; JAK1 associates with the cytokine receptor a chains), and JAK1 is also involved in signaling through the IFNa/b, IFN-g, IL-10, granulocyte colony-stimulating factor (G-CSF), the gp130 family, and possibly the b$_c$ family cytokine receptors (27). Some Stats are more cytokine specific (Table 11.2). For example, Stat6 is activated only by IL-4 and IL-13 (it docks to phosphotryosine residues on the cytoplasmic domain of IL-4Ra) (52). Studies of Stat6-deficient mice demonstrate that Stat6 is responsible for most effects of IL-4 and IL-13 on cell differentiation and contributes, directly or indirectly, to IL-4 stimulation of proliferation and IL-4 enhancement of B-cell survival (53,54 and 55). Similarly, Stat4 is activated only by IL-12 in mice and is required for IL-12 stimulation of type 1 cytokine expression and inhibition of type 2 cytokine expression (56). In contrast, Stat5a activation and Stat5b activation are stimulated by multiple cytokines in addition to IL-5 and IL-9 (27.,57,58 and 59). This difference in Stat specificity suggests that specificity may be attained by different mechanisms. Some Stats (Stat4, Stat6) may be activated by receptors that have a broad distribution on different cell types; specificity for these Stats is attained through their activation by one or a small number of cytokine receptors. Stats, such as Stat5a and Stat5b, which are activated by multiple cytokines, allow for specificity of cytokine effect because of the limited cellular distribution of receptors for each cytokine that activates those Stats. For example, IL-5 and GM-CSF both activate Stat5a and Stat5b, but they stimulate proliferation and differentiation of different cell types because IL-5 and the GM-CSF receptor a chains are expressed by different cells types (60).

EFFECTS OF TYPE 2 CYTOKINES

Type 2 cytokines generally promote noncytotoxic antibody production and allergic inflammation, whereas type 1 cytokines generally promote antibody-mediated and cell-mediated cytotoxic responses through their effects on several different cell types. Only the effects of the type 2 cytokines on specific cell types are discussed here.

Effects on T Cells

IL-4 is regarded as the master type 2 cytokine because it has the unique ability to stimulate naive CD4$^+$ T cells to differentiate into type 2 cytokine-secreting cells (61,62,63 and 64). Neutralization of IL-4, blocking of IL-4Ra, or a genetic deficiency of IL-4, IL-4Ra, or Stat6 is often (but not always) associated with diminished type 2 cytokine production (54,55 and 56,65,66,67 and 68). IL-4 and IL-13 can also enhance type 2 cytokine production less directly, by inhibiting production or effects of cytokines, such as IL-12 and IFN-g, that suppress T-cell differentiation into type 2 cytokine-secreting cells (44). This view is supported by observations that IL-4 suppresses T-cell expression of the IL-12 receptor b$_2$ chain (69) and that type 2 cytokine production is decreased in IL-13–deficient mice and is increased in IL-13 transgenic mice (70,71), even though T cells lack IL-13R (type II IL-4R) (44).

The possibility that another type 2 cytokine, IL-9, also regulates type 2 cytokine production has been controversial. Although some T cells proliferate in response to IL-9 (6), and thus must express an IL-9 receptor, and although anti–IL-9 antibody has been reported to suppress the Th2 response in mice infected with the gastrointestinal nematode *Trichuris muris* (72), T-cell differentiation and cytokine production appear to be normal in IL-9–deficient mice (73).

Effects on Antigen-Presenting Cells

IL-4 promotes antigen presentation by B cells and dendritic cells by stimulating increases in class II major histocompatibility complex (MHC) expression and expression of the costimulatory molecules CD80 and CD86 (74,75,76,77 and 78). IL-13 may have similar effects, except mouse B cells lack IL-13 receptors (44,79). However, because other cytokines, such as IFN-g, and noncytokine stimuli also promote antigen presentation (80,81), defects in antigen presentation are not generally profound in IL-4 or IL-4Ra–deficient mice.

IL-4 (and possibly, IL-13), can also affect type 1–type 2 cytokine balance through their effects on antigen presentation. IL-4 may promote type 2 cytokine responses by suppressing dendritic cell production of IL-12 or by suppressing T-cell or NK cell expression of IL-12 receptor b$_2$ (69,82). In contrast, IL-4 stimulates the differentiation of CD8$^+$ dendritic cells that promote T-cell differentiation into Th1 cells by producing IL-12 (83,84). Thus, although the overall effect of IL-4 and IL-13 is enhancement of type 2 cytokine responses, these cytokines also have effects on antigen-presenting cells (APCs) that promote T-cell activation in general and limit Th2 polarization.

Effects on B Cells

As a general rule, type 2 cytokines promote B-cell activation, proliferation, and differentiation. IL-4 regulates B-cell receptor expression and function: it increases B-cell expression of class II MHC antigens (74), the T-cell costimulatory molecule, CD86 (B7-2) (75,76), the receptor for cell-mediated T-cell help, CD40 (85), and the low-affinity IgE receptor, CD23 (86), whereas it suppresses IFN-g induction of the low-affinity IgG receptor, FcgRII (87), which activates inhibitory tyrosine and inositol phosphatases (88). Because CD23 participates in antigen presentation by focusing IgE-bound antigen onto B cells (89), and signaling through the B-cell form of FcgRII inhibits B-cell activation (90), these IL-4–induced changes promote the ability of B cells to become activated by antigen, to present antigen to CD4$^+$ T cells, and to be stimulated by contact with activated CD4$^+$ T cells. In addition, IL-4 enhances the survival of unstimulated and antigen-stimulated B cells *in vivo* and *in vitro* (91,92 and 93), and it causes a net migration of circulating B cells to the spleen (94). Once B cells have become activated, IL-4 influences the isotype of Ig secreted by differentiating B cells and promotes isotype switching to IgG1 in the mouse, IgG4 in humans, and IgE in both species (95). IL-4 also inhibits secretion of the cytotoxic antibody isotypes, IgG2a and IgG3 in the mouse; however, no equivalent effect has been shown for humans.

Mice and humans also differ in their response to the IL-4–related cytokine, IL-13. Human, but not mouse, B cells have been shown to express IL-13Ra$_1$ chain, and this allows them to respond to this cytokine. Consequently, IL-13 generally has the same effects as IL-4 on human B cells, but it seems able to stimulate mouse B cells only under special circumstances (44).

Although relatively little is known about how the type 2 cytokine, IL-9, stimulates B cells, it generally appears to enhance the effects of IL-4; it increases isotype switching to IgE, particularly when IL-4 is present in limiting quantity (96). The effects of IL-5 on B-cell responses, although marked in several *in vitro* culture systems, appear *in vivo* to be limited to stimulation of proliferation and clonal expansion of the B1 B-cell subset (97,98), which constitutes a large percentage of peritoneal B cells and produces largely T-independent antibodies to bacterial antigens (99).

Proinflammatory Effects

The effects of type 2 cytokines on inflammatory cells reinforce their stimulation of allergic responses and inhibition of cytotoxic responses. Type 2 cytokines, including IL-4, IL-9, and IL-13, attract neutrophils and eosinophils to the site of cytokine production, most likely by stimulating the production of several CC and CXC chemokines and by acting with TNF-a to enhance the expression of adhesion molecules, including vascular cell adhesion molecule-1 (100,101,102,103,104 and 105). IL-5 can also contribute to migration of eosinophils to an inflammatory focus (106), and, more important, it stimulates eosinophil production, survival, and activation (107). The importance of IL-4 and IL-13 for the development of localized eosinophilia is shown by the greatly decreased number of pulmonary eosinophils in mice treated with IL-4Ra monoclonal antibody (mAb) (which inhibits IL-4 or IL-13 responses) after pulmonary immunization (108), whereas the importance of IL-5 in eosinophil responses is shown by the large decrease in eosinophil numbers in all organs, including blood, that is observed in IL-5–deficient mice (97).

IL-4 and IL-9 also contribute, along with IL-3 and c-*kit* ligand, to the stimulation of mast cell proliferation and differentiation. Systemic IL-4 treatment is associated with increased numbers of intestinal mast cells (109). Pulmonary overproduction of IL-9 (but not IL-4) is associated with increased numbers of mast cells in the lungs (110).

IL-9 appears to be more important for early pulmonary mast cell responses to antigens that localize in the lungs than for responses that develop after repeated immunization; the former are suppressed, whereas the latter are normal in IL-9–deficient mice (73). IL-9 may be less important (and IL-4 more important) for the intestinal mast cell response than for the pulmonary mast cell response; an intestinal mast cell response can be induced by treating normal mice with IL-4 and is normal or near normal in worm-infected IL-9–deficient mice, but it is suppressed when worm-infected mice are treated with IL-4 antagonists (73,109,111). IL-13 stimulation has not been associated with mastocytosis, a finding suggesting that mast cells or their precursors may lack IL-13Ra_1 chain.

All the type 2 cytokines have been associated with increased mucus production. Inhalation of IL-4, IL-5, IL-9, or IL-13, or transgenic overexpression of any of these cytokines in the lungs, causes bronchial goblet cell hyperplasia (110). *In vitro* experiments, however, have not convincingly determined whether the stimulatory effects of any of these cytokines on increased mucus production are direct or indirect. It also remains to be determined whether different type 2 cytokines have distinct effects on the chemical and physical character of the mucus that they stimulate.

Type 2 cytokines have also been associated with stimulation of fibrosis. *In vitro,* culture of fibroblasts with IL-4 stimulates increased collagen production (112,113). *In vivo,* IL-4 and IL-13 have been shown to contribute to the development of a fibrotic response to *Schistosoma mansoni* eggs; fibrosis is decreased to some extent in IL-4 antagonist–treated mice, to a greater extent in mice treated with an IL-13 antagonist, and almost absent in IL-4Ra–deficient mice, which cannot respond to either cytokine (114,115 and 116). Whether the stronger association of IL-13 than IL-4 with fibrosis and the increased gastrointestinal mucus production (70) result from differences in amounts of IL-4 and IL-13 produced or from differences in the effects of these cytokines is not known.

Both IL-4 and IL-13 also contribute to allergic reactions by increasing sensitivity to mediators, such as histamine, serotonin, and platelet-activating factor, that are released by degranulating mast cells, most likely by acting synergistically with these mediators to increase vascular permeability (117). It is unlikely that this effect is restricted to rodents; humans treated with IL-4 in an attempt to suppress tumor growth have developed vascular leak syndrome as a side effect (118). Thus, type 2 cytokines not only stimulate mastocytosis and production of the IgE antibodies that induce mast cells to release inflammatory mediators, but they also increase the responsiveness of vascular epithelial cells to these mediators.

Effects on Epithelial Cells

IL-4 and IL-13 both increase the permeability of epithelial cell monolayers *in vitro* through effects on the tight junctions that connect these cells (119,120). A similar effect on intestinal epithelial permeability has been observed in mice treated with IL-4 and in mice in which gastrointestinal nematode parasite infection has stimulated increased IL-4 and IL-13 secretion (Shea-Donohue T, Sullivan C, Finkelman FD, et al. The role of interleukin-4 in *Heligmosomoides polygyrus*–induced alterations in murine intestinal epithelial cell function. Submitted for publication). IL-4 also causes *in vivo* changes in ion absorption and secretion that result in a net loss of salt and fluid in the intestine, an effect that may contribute to the development of diarrhea when local type 2 cytokine production is high, as in mice infected with intestinal nematodes.

Effects on Smooth Muscle

Mice treated with IL-4 develop changes in intestinal smooth muscle function, with an increased contractile response. This change is most likely indirect and mast cell dependent, because it is not seen in IL-4–treated, mast cell–deficient W/W^v mice (121).

Antiinflammatory Effects

Despite these proinflammatory effects, IL-4 and IL-13 are often referred to as antiinflammatory cytokines, because they can suppress inflammatory responses that are associated with type 1 cytokine production. Some of these antiinflammatory effects result from suppression of production of cytokines (IL-12, TNF-a, IFN-g) that induce precursor T cells to differentiate into cells that kill targets through a contact-dependent mechanism (cytotoxic T lymphocytes). Additional antiinflammatory effects result from suppression of production of inflammatory cytokines, such as TNF-a and IL-12, and from suppression of macrophage responsiveness to IFN-g and TNF-a (82,122,123,124 and 125). These effects of IL-4 and IL-13 decrease the activity of enzymes that produce reactive oxygen and nitrogen intermediates that kill ingested pathogens (124,125). The importance of the antiinflammatory effects of IL-4 is illustrated by the increased inflammation and death observed in IL-4–deficient mice infected with some pathogens, such as *S. mansoni* (126) or *Borrelia burgdorferi* (127,128) (the pathogen responsible for Lyme disease).

In sum, the type 2 cytokines induce an immune and inflammatory response that is characterized by increased antibody production, especially production of IgE and noncytotoxic IgG isotypes, infiltrates rich in eosinophils and mast cells, increased mucus production, increased sensitivity of smooth muscle to contractile stimuli, and increased epithelial cell permeability, including vascular permeability. At the same time, the type 2 cytokines suppress inflammatory responses that are associated with the killing of intracellular or small extracellular organisms, including the production of complement-fixing IgG antibodies, macrophage production of nitric oxide and other reactive molecules that kill ingested organisms, and induction of cytotoxic lymphocytes.

ROLE OF TYPE 2 CYTOKINES IN PROTECTIVE IMMUNITY

Because worm infections usually induce a type 2 cytokine response (129), it was reasonable to hypothesize that these cytokines could protect the host against worms. This hypothesis has not been proven for human infections, because the interventions that would be necessary to demonstrate a protective relationship directly would be unethical. Studies of the association between serum IgE levels and the severity of reinfection of patients living in endemic areas who have been cured of *S. mansoni* infection support this hypothesis, however, by revealing an inverse correlation between serum IgE concentration, an index of IL-4 and IL-13 activity, and severity of reinfection (130,131).

Mouse studies provide direct evidence that the type 2 cytokines can be host-protective. Mouse strains that make a type 1 cytokine response to oral inoculation with *T. muris,* a whipworm that closely resembles the human parasite *T. trichiura,* develop a chronic infection, whereas worm larvae are fully expelled before they mature in mouse strains that make a predominantly type 2 cytokine response to the same parasite (132). Moreover, when mice that would normally develop a type 1 cytokine response and chronic infection were treated with anti–IFN-g antibody or with IL-4, they instead produced type 2 cytokines and rapidly expelled worm larvae, whereas treatment of mice that would normally develop a type 2 response with IL-12 or anti–IL-4Ra antibody induced a type 1 response and chronic infection (133).

Additional studies in one mouse strain, C57BL6, that develops a mixed type 1–type 2 cytokine response to *T. muris* infection, has revealed roles for IL-4, IL-13, and IL-9 in host protection. C57BL/6 mice generally expel *T. muris,* but they do so more slowly and less completely than BALB/c mice, which develop a strong type 2 cytokine response to this parasite. Inhibition of IL-4, IL-13, or IL-9 in C57BL/6 mice is sufficient to tip the balance to type 1 cytokine predominance and to prevent worm expulsion, whereas inhibition of IL-4 generally fails to prevent worm expulsion in BALB/c mice (133,134 and 135). Furthermore, inhibition of IL-4 or IL-13 fails to prevent worm expulsion in C57BL/6 mice if IFN-g is also blocked, whereas chronic infection develops if both IL-4 and IL-13 are inhibited, despite blocking of IFN-g (136). These observations suggest that effector mechanisms that lead to worm expulsion can be induced by either IL-4 or IL-13, perhaps with a boost from IL-9, but they are inhibited by IFN-g.

Studies of mice infected with either of two rodent-specific gastrointestinal nematode parasites, *Nippostrongylus brasiliensis* and *Heligmosomoides polygyrus,* or with *Trichinella spiralis,* a gastrointestinal nematode that infects many mammalian species, allow generalization of the observations made with *T. muris*–infected mice. Despite substantial differences in the life cycles of these worms, the development of protective immunity in every case depends on the presence of IL-4Ra chain, the IL-4Ra–associated signaling molecule, Stat6, and the production of IL-4 and/or IL-13 (129,137,138). Details of how these cytokines, receptors, and signaling molecules contribute to host protection, however, vary considerably from one parasite to the next. Although all elements of a stereotyped Th2 response (eosinophilia, production of IgE and IgG1, intestinal mucosal mastocytosis and goblet cell hyperplasia, and increased smooth muscle contractility and intestinal permeability) are induced by each of these parasites (31,129,138), the importance of each of these elements in host protection varies from parasite to parasite and from primary to second infection with the same parasite. Particularly instructive comparisons can be made between primary and second infections with *T. spiralis* and between primary infections with *T. spiralis* and *N. brasiliensis.*

Expulsion of *T. spiralis* adults and larvae is mast cell dependent in both primary and secondary infections. During a primary *T. spiralis* infection, mast cell degranulation is T-cell dependent, but antibody independent. In contrast, the accelerated worm expulsion that occurs during a second *T. spiralis* infection appears to require triggering of mast cell degranulation by IgE, although a smaller contribution may be made by IgG. Either IL-4 or IL-13 production is sufficient to induce normal expulsion during a primary *T. spiralis* infection, but IL-4 is required for the accelerated secondary response. This is probably because IL-4 is required in the mouse to stimulate IgE production and, possibly, because it also helps to generate and sustain T cells that rapidly produce type 2 cytokines on restimulation (138,139).

Mechanisms of host protection during primary *N. brasiliensis* and *T. spiralis* infections differ in several ways. First, *N. brasiliensis* expulsion can be induced by IL-4 in the absence of mast cells, T cells, and B cells (129,140), whereas IL-4 treatment does not induce T-cell–deficient or mast cell–deficient mice to expel *T. spiralis* (138). Second, Stat6-deficient mice make normal IL-4, IL-5, IL-13, eosinophil, and IgG1 responses to *N. brasiliensis* infection, as well as considerably increased mast cell responses, but they fail to expel this parasite even if they are treated with IL-4 or IL-13 (137). In contrast, IL-3, IL-4, IgG1, and mast cell responses are considerably reduced, IFN-g production is increased, and worm expulsion is blocked when Stat6-deficient mice are infected with *T. spiralis*; IL-4 treatment reconstitutes mast cell

responses and partially reconstitutes worm expulsion (138). Third, mice must express IL-4Ra on both bone marrow–derived and non–bone marrow–derived cells to expel *T. spiralis,* whereas selective expression on non–bone marrow–derived cells is sufficient to allow expulsion of *N. brasiliensis* (141). Finally, although either IL-4 or IL-13 production is sufficient to allow normal worm expulsion during a primary *T. spiralis* infection, IL-13 deficiency retards *N. brasiliensis* expulsion to a much greater extent than IL-4 deficiency (70,137).

These observations may be explained by the following model: expulsion of *T. spiralis* is primarily a mast cell–dependent process. Mast cell release of mediators, such as histamine, induces changes in gut physiology that lead to worm expulsion. Either IL-4 or IL-13, acting on intestinal cells through a Stat6-dependent process, increases sensitivity to mast cell–produced mediators and allows a sufficient response to cause expulsion (117). *T. spiralis*–specific IgE production is sufficiently strong and rapid during a secondary response to *T spiralis* to enhance mast cell responses, thus allowing for more rapid worm expulsion, whereas other T-cell–induced factors are the dominant cause of mast cell activation during a primary infection. Stat6 deficiency allows increased production of the type 1 cytokines that are normally produced in response to *T. spiralis* and suppression of the type 2 cytokine response; these changes suppress the mast cell response that is required for worm expulsion. Treatment with IL-4 reconstitutes the mast cell response in *T. spiralis*–infected Stat6-deficient mice, but it fails to increase the sensitivity to mast cell–produced mediators that is required for optimal worm expulsion.

In contrast, the lack of any type 1 cytokine response in *N. brasiliensis* infection appears to allow development of a normal type 2 response, even in the absence of Stat6, consistent with the view that Stat6 signaling is more important for blocking type 1 cytokine inhibition of IL-4 responses than for directly stimulating type 2 cytokine responses. As a result, *N. brasiliensis*–infected Stat6-deficient mice develop normal eosinophil responses and increased mast cell responses [Stat6 signaling has a suppressive effect on mast cell development (137)], but they fail to expel the parasite because another, still unknown effect of Stat6 signaling on the gut, possibly an increase in the quality and quantity of mucus produced (70), is required to expel this parasite. It is not known why IL-13 is more important than IL-4 for promoting *N. brasiliensis* expulsion. Because both IL-4 and IL-13 bind to the type II IL-4R and IL-4 treatment induces IL-13–deficient mice to expel *N. brasiliensis* (44,129), it seems more likely that the primary importance of IL-13 results from either increased production of this cytokine relative to IL-4 or more efficient signaling by IL-13 of the type II IL-4 receptor, rather than from a qualitative difference in IL-4 and IL-13 effects on the gut.

Demonstration of a role for IL-5 or eosinophils in host protection against worm infections is more difficult than demonstration of roles for IL-4 and IL-13. No defects in expulsion of *T. muris, T. spiralis, N. brasiliensis,* or *H. polygyrus* have been observed in IL-5–deficient mice or in mice treated with a potent IL-5 antagonist, even though these mice are strikingly deficient in circulating eosinophils (129,142,143 and 144). The observation that IL-5–deficient mice can still develop intestinal eosinophilia, which depends on the chemokine eotaxin (145), suggests that it may be premature to conclude that eosinophils have no importance in protection against these parasites. It is more likely, however, that eosinophils contribute primarily to host protection against worms when their larvae migrate through host tissues. Consistent with this view, mice that overexpress IL-5, and consequently have increased peripheral eosinophilia, destroy *N. brasiliensis* larvae shortly after they penetrate the skin (146). In addition, destruction of filarial larvae and larvae of *Strongyloides venezuelensis* and *Angiostrongylus cantonensis* is decreased in IL-5–deficient mice (147,148,149 and 150).

In addition to providing protection against helminthic parasites, type 2 cytokine-associated inflammation appears to protect against some ectoparasites, such as the tick, *Haemaphysalis longicornis.* Protection appears to involve mast cells and IgE (151). Most likely, mast cell degranulation in response to tick antigen cross-linking of IgE bound to FceRI increases vascular permeability and causes sufficient skin edema to prevent the tick from locating a host blood vessel. Consequently, properties common to ticks and other insects (perhaps dust mites and cockroaches) may have become stimuli for the generation of type 2 cytokine responses.

In sum, all elements of type 2 cytokine-associated immunity and inflammation appear to contribute to host protection against the universe of helminth and insect parasites, even though protection against any individual helminth does not seem to require the full panoply of the type 2 inflammatory response. Mammalian hosts may be unable to recognize a specific nematode or insect parasite sufficiently well to make only those responses that would protect against that parasite. Instead, they recognize a property or properties common to these parasites as a trigger for the stereotyped type 2 cytokine response that protects against many worms and some insects. It also seems possible that the grouping of type 2 cytokine genes (along with the genes for IL-3 and GM-CSF, which contribute to mastocytosis and eosinophilia) in a single chromosomal region may facilitate coordinated transcription of these cytokines (25,26 and 27).

Related reasoning can be used to provide an evolutionary rationale for the phenomenon that type 1 and type 2 cytokines not only induce distinct inflammatory responses but also suppress both production and effects of the alternate set of cytokines. Why should any stimulus that can be recognized by the host as foreign and dangerous not induce a mixed type 1–type 2 cytokine response that could protect against every pathogen by activating every inflammatory effector mechanism? A likely explanation may be that inflammatory effector mechanisms nearly always damage the host to some extent in ridding the host of the parasite. Damage can vary from mild irritation to death, as observed in bee venom–induced anaphylaxis or gram-negative bacteria-induced endotoxin shock. Thus, to the extent that a host can recognize a pathogen class and can determine which inflammatory effector mechanisms best protect against that class, the host is best served by activating only those effector mechanisms that provide protection and suppressing those that are nonprotective. Mammalian hosts appear predominantly to recognize two pathogen classes: those, such as worms and ticks, against which only type 2 cytokine-induced inflammation provides protection and those, such as viruses and intracellular bacteria and protozoa, against which only type 1 cytokine-induced inflammation provides protection. By having the appropriate cytokine response suppress the inappropriate alternative cytokine response, the host limits damage to itself without limiting its ability to damage the parasite.

ROLE OF TYPE 2 CYTOKINES IN ATOPIC DISEASES

The host's ability to restrict a cytokine-induced immune response to a situation in which it is host protective is far from perfect. The same type 2 cytokine-induced immune and inflammatory responses that protect the host against parasites (IgE, eosinophilia, mastocytosis, chemokine secretion, adhesion molecule expression, mucus production, and increased vascular and epithelial permeability) cause symptoms in allergic disorders. Human studies provide correlative evidence that supports the association between type 2 cytokines and asthma. The elevated total and allergen-specific serum IgE levels that are found in patients with anaphylaxis, asthma, allergic rhinitis, and atopic dermatitis (152,153,154 and 155) suggest increased production of the cytokines, IL-4, IL-13, and IL-9, that stimulate IgE production, whereas the increased numbers of eosinophils in blood, skin, nasal polyps, and lungs suggest increased production of IL-5. Evidence that treatment with an anti-IgE mAb ameliorates symptoms in patients with asthma and allergic rhinitis (156,157) and that anti–IL-5 mAb treatment decreases eosinophilia in asthmatic patients (158) further implicates these cytokines in the pathogenesis of these diseases.

Biopsy evidence also associates type 2 cytokines with human allergy. Biopsies of skin from patients with atopic dermatitis, nasal polyps from patients with allergic rhinitis, and bronchial tissue from patients with atopic asthma demonstrate increased type 2 cytokine mRNA levels and increased numbers of cells that secrete IL-4, IL-5, IL-9, and IL-13 (T cells and mast cells or basophils) in these tissues (159,160,161,162 and 163). Studies of cytokine levels in bronchoalveolar lavage fluid, cytokine production by lymphocytes from conjunctival, lung, or nasal biopsies, or bronchoalveolar or nasal lavage demonstrate consistent results (164,165,166 and 167). Population studies also support a connection between type 2 cytokines and allergy by demonstrating associations between asthma and a gene or genes that map to the type 2 cytokine locus (region 31–33 of chromosome 5) (168) and between asthma and alleles of the IL-4, IL-9, IL-4Ra, and the IL-13 receptor genes (169,170,171 and 172).

Direct evidence for involvement of type 2 cytokines in allergic disorders is provided by studies with cytokine transgenic mice. Eosinophilia is observed in transgenic mice that systemically overexpress IL-5 (173), mastocytosis is observed in transgenic mice that systemically overexpress IL-4 or IL-9 (174,175), high serum IgE levels are seen in mice that systemically overexpress IL-4 or IL-13 (176,177), and IL-4 transgenic mice develop a disease that closely resembles vernal conjunctivitis (176). Studies of cytokine gene knock-out mice show consistent results: IL-5–deficient mice fail to develop normal eosinophil responses (97), IL-4–deficient mice lack serum IgE (66), both IL-4– and IL-13–deficient mice tend to make type 1 cytokine-biased immune responses (66,70), and the development of mastocytosis and goblet cell hyperplasia is delayed in appropriately stimulated IL-9–deficient mice (73).

Animal models have also been used to investigate the roles of type 2 cytokines in specific allergic diseases, such as systemic anaphylaxis and asthma. Studies with mouse models of anaphylaxis reveal two pathways that can lead to anaphylactic shock: one in which antigen cross-linking of IgE bound to FceRI leads to mast cell release of histamine and platelet activating factor that cause vascular collapse (177a) and a second in which vascular collapse is induced predominantly by platelet activating factor released when macrophage FcgRIII is cross-linked by IgG-antigen complexes (177b). As may be expected, IgE-mast cell–mediated anaphylaxis, but not IgG-macrophage–mediated anaphylaxis, is IL-4 dependent (177b,177c). IL-4 and IL-13, however, also contribute to anaphylaxis through a second mechanism: the severity of anaphylaxis is considerably increased if mice are treated with IL-4 or IL-13 shortly before challenge with antigen, anti-IgE antibody, histamine, platelet-activating factor, or serotonin. At least part of this effect appears to result from synergistic enhancement of vascular permeability by IL-4 and IL-13 and vasoactive mediators (117). Because IgE-antigen interactions induce release of type 2 cytokines by basophils as well as the release of vasoactive mediators by mast cells, this synergy between the effects of type 2 cytokines and vasoactive mediators may well contribute to both the severity of systemic anaphylaxis and the efficacy of IgE-mediated host protection against gastrointestinal nematodes.

Transgenic mice that selectively overexpress a type 2 cytokine in their lungs have helped to establish the importance of these cytokines in the pathogenesis of asthma. Bronchial goblet cell hyperplasia and pulmonary inflammatory infiltrates that include eosinophils are observed in mice that selectively overexpress IL-4, IL-5, IL-9, or IL-13 in their lungs (110). In addition, increased responsiveness to methacholine, a physiologic marker for asthma, has been observed in IL-5, IL-9, and IL-13 lung transgenic mice (110), and impressive bronchial mastocytosis has been observed in IL-9 lung transgenic mice (110). Remodeling changes characteristic of chronic asthma (shedding of bronchial epithelium, subepithelial fibrosis, smooth muscle hyperplasia) have been observed to a limited extent in some of these mice, but they

have been more convincing in transgenic mice that overexpress inflammatory cytokines, such as IL-11, in their lungs (110).

Mouse models have also been used to evaluate the effects of inhibiting one or more type 2 cytokines on the development of asthma in appropriately immunized animals. Mice “primed” with ovalbumin adsorbed to alum adjuvant, then exposed to aerosolized ovalbumin, develop an eosinophil-rich acute perivascular and peribronchial inflammatory response, bronchial goblet cell hyperplasia, increased vascular permeability, and increased responsiveness to methacholine (178,179,180 and 181). Similar changes occur in mice immunized nasally with strong allergens, such as *Ascaris* pseudocelomic fluid, dust mite extracts, or *Aspergillus* extracts, even in the absence of adjuvant and systemic priming (182,183). Allergen induction of pulmonary eosinophilia is greatly reduced, in most studies, in mice deficient in IL-4 or in wild-type mice treated with an IL-4 or an IL-4Ra antagonist (108,178). Development of goblet cell hyperplasia has also been reduced by IL-4 deficiency or IL-4 antagonist treatment (108,184,185 and 186). IL-5 deficiency and IL-5 antagonists even more strongly suppress the development of pulmonary eosinophilia, and virtually no eosinophils are observed in immunized mice that lack both IL-5 and the chemokine eotaxin; however, IL-5 deficiency does not suppress bronchial goblet cell hyperplasia (178,179 and 180,187,188). IL-13 antagonists suppress pulmonary eosinophilia and goblet cell hyperplasia to less of an extent than IL-4 antagonists, but they enhance suppression when added to IL-4 antagonists (189,190 and 191). Similar, strong suppression is observed in mice deficient in IL-4Ra or Stat6 (184,192, and Finkelman FD, unpublished data). IL-9 deficiency does not prevent the development of pulmonary eosinophilia but is associated with delayed development of goblet cell hyperplasia and pulmonary mastocytosis (73). Treatment with IL-4, IL-5, IL-13, and IL-4Ra antagonists can have strong suppressive effects even if it is initiated after pulmonary inflammatory responses have already developed (108,178,179,189,190).

Because IL-4, unlike the other type 2 cytokines, stimulates the differentiation of naive $CD4^+$ T cells into Th2 cells, some inhibitory effects of IL-4 antagonists on allergic pulmonary inflammation may reflect inhibition of Th2 differentiation, rather than direct inhibition of inflammation. For example, IL-4 antagonists may block goblet cell hyperplasia by preventing the differentiation of T cells into cells that secrete IL-4, IL-5, IL-9, and IL-13 (110,185), all of which have been reported to stimulate goblet cell hyperplasia *in vivo.* Because survival and type 2 cytokine secretion by fully differentiated Th2 cells have been reported to be IL-4 independent (193), IL-4 antagonists may be expected to be unable to suppress established allergic responses that are driven by IL-5, IL-9, or IL-13. Contrary to this expectation, both allergic inflammation and type 2 cytokine secretion that develop in IL-4–deficient mice that have inhaled both allergen and IL-4 resolve when IL-4 administration is discontinued, even if allergen administration is continued (182). Thus, in an *in vivo* setting, an effective IL-4 antagonist may well inhibit even an ongoing allergic response.

The relationship between type 2 cytokines and the development of hyperresponsiveness to cholinergic agonists is more complicated. IL-4 or IL-5 antagonists suppress allergen-induced pulmonary hyperresponsiveness in some, but not all, models (178,179 and 180); an IL-13 antagonist has been reported to suppress hyperresponsiveness in some situations in which it was not suppressed by IL-4 antagonists (189,190), and a deficiency of both IL-5 and eotaxin has been reported to prevent the development of hyperresponsiveness that is not prevented by a deficiency in either cytokine alone (188). Differences in immunization procedure, mouse strain, dose and preparation of cytokine antagonist used, and method for characterizing the bronchospastic response to cholinergic stimulation make it difficult to draw a simple conclusion from these studies. Probably, it is safest to summarize all the animal model studies of asthma by concluding that each type 2 cytokine is a reasonable target for therapy, that different patients (like different animal models) may benefit most by suppression of different cytokines, and that only therapeutic trials of antagonists in defined patient populations will reveal their therapeutic efficacy. With this reservation, my own view is that effective blocking of IL-4Ra, which would inhibit the direct effects of both IL-4 and IL-13 and could suppress T-cell production of IL-5 and IL-9, would be the most effective cytokine-related single-agent inhibitor of allergy. In patients with asthma, trials of IL-4, IL-5, and IL-4Ra antagonists that are currently in progress, and planned trials of IL-4 and IL-9 antagonists, should test this view.

ROLE OF TYPE 2 CYTOKINES IN OTHER DISEASES

Although type 2 cytokines have most convincingly been implicated in the pathogenesis of atopic disorders, they may also be involved in the pathogenesis of other inflammatory disorders. Increased IL-4 production has been reported in some patients with systemic lupus erythematosus (194), and lupuslike disease in some mouse models has been ameliorated by deleting the IL-4 gene (195). In contrast to allergy, however, no evidence indicates an imbalance between type 1 and type 2 cytokine production in lupus; increased production of IFN-g has also been detected in lupus, and deletion of the IFN-g gene in mouse models also inhibits disease development (195,196). IL-4 may be more closely involved in the pathogenesis of another autoimmune disorder, systemic sclerosis. Cells that secrete IL-4, but not IFN-g, are overrepresented in the skin of patients with this disease, IL-4 promotes fibroblast synthesis of collagen, and anti–IL-4 mAb prevents development of skin fibrosis in the “tight skin mouse” model of scleroderma (112,197,198 and 199).

Type 2 cytokines may also be important inhibitors of inflammatory diseases. Patients with type 1 diabetes mellitus or multiple sclerosis, NOD mice, which spontaneously develop diabetes, and immunized mice that develop the experimental allergic encephalitis model of multiple sclerosis all have type 1 cytokine predominance in their inflammatory lesions (200,201 and 202). Furthermore, the mouse models of both diseases can be prevented by treatment with IL-4 (203,204). Consequently, there is some reason to fear that treatment of atopic patients with type 2 cytokine inhibitors could increase the risk of development of diabetes, multiple sclerosis, or other type 1 cytokine-related diseases. Paradoxically, although decreased IL-4 production permits development of diabetes in the NOD mouse, IL-4Ra deficiency prevents disease development in this animal model (205), possibly because of contributions made by IL-4 and IL-13 to the differentiation of APCs.

INDUCTION AND REGULATION OF TYPE 2 CYTOKINE PRODUCTION

Evidence that type 2 cytokines protect the host against an important class of pathogens, but induce immunopathology that can threaten the host's well-being and survival, indicates the importance of mechanisms that regulate type 2 cytokine production. Mechanisms that regulate the differentiation of naive T cells into cytokine-secreting cells include the cytokine milieu of the differentiating T cell, antigen dose, T-cell receptor (TCR) affinity, for the MHC II–peptide complex, T-cell costimulation, site of immunization, and characteristics of the APC. These mechanisms are not mutually exclusive but are likely interdependent.

Cytokine Milieu

In vitro studies demonstrate that cytokine milieu can determine whether naive $CD4^+$ T cells differentiate into polarized Th1 or Th2 cells. Th1 differentiation is promoted by IL-12 through a Stat4-dependent mechanism (56,206,207), enhanced, in at least some situations, by IFN-g and IFN-a/b (208), and inhibited by IL-4, through a Stat6-dependent mechanism (209); Th2 differentiation is promoted by IL-4–induced Stat6 signaling (53,54 and 55), and it is inhibited by IL-12 and the IFNs (33,210,211 and 212). Similar results are observed regardless of whether normal, naive T cells are activated by anti-CD3 mAb and APCs and or TCR-transgenic T cells are activated by APCs pulsed with the relevant antigen or peptide. In the absence of APCs or APC-related costimuli, naive, resting $CD4^+$ T cells stimulated with anti-CD3 in the presence of antibodies to IL-4 or IL-4Ra, IFN-g, and IL-12 produce little IL-4 (213,214 and 215), particularly if T cells are restimulated after allowing them to return to a resting state. Although this finding is consistent with the possibility that IL-4 is required to prime for an IL-4 response, more recent studies suggest that combined CD3 and CD28 signaling induces even naive $CD4^+$ T cells to produce IL-4, which then promotes increased IL-4 production and Th2 stabilization by signaling through Stat6 (68,216,217,218,219,220 and 221).

In vivo studies also indicate that IL-4 signaling is important for type 2 cytokine production, particularly if type 2 cytokine production is measured by restimulating T cells *ex vivo* (66). Such studies support the view that production of IL-4 early in an immune response by NK T cells (222), basophils (21,22), or mast cells (19) may be important for generation of a type 2 cytokine response. However, stimuli such as *N. brasiliensis* or anti-IgD antibody, which induce a strong type 2 cytokine response in normal mice, still do so in NK T cell–deficient mice (223,224), as well as in chimeric mice in which a functional IL-4 gene is only expressed by T cells (225). Moreover, the same stimuli induce a relatively normal IL-4 response even in IL-4Ra–deficient mice, which cannot respond to IL-4, and in Stat6-deficient mice, which lack the signaling mechanism by which IL-4 influences T-cell differentiation (68,221). Studies with Stat6-deficient mice suggest that Stat6 signaling may contribute more to the survival of type 2 cytokine-secreting cells or to the stabilization of epigenetic changes in the IL-4 promoter and enhancer that allow rapid type 2 cytokine production when memory cells are restimulated than to induction of an initial IL-4 response (68). *In vivo* studies fully support the importance of IL-12 and the IFNs as inhibitors of type 2 cytokine production (33,210,211); however, $CD4^+$ T cells do not always differentiate to Th2 cells in IL-12– or Stat4-deficient mice (215,226,227), and studies have not yet addressed whether all T cells differentiate into IL-4 secreting cells in the combined absence of IL-12, IFN-g, and IFN-a/b. Thus, it remains unclear whether naive $CD4^+$ T cells differentiate by default into Th2 cells if they are stimulated by antigen and APCs in the absence of any stimuli that promote Th1 differentiation.

Investigators have identified another cytokine, IL-18, that can suppress Th2 differentiation. However, although IL-18 acts synergistically with IL-12 to stimulate IFN-g production and to inhibit IL-4 production, in the absence of IL-12, IL-18 can enhance the production of IL-4 and IL-13 (228,229,230 and 231). Although IL-18 can thus amplify either Th1 or Th2 responses, initial studies in IL-18–deficient mice indicate that this cytokine is not required to induce polarized Th1 or Th2 responses but that the IL-18–deficient mouse is more type 2 cytokine-biased than wild-type mice (232 and Nakanishi K, unpublished data).

Antigen Dose and Affinity

Studies performed long before type 1 and type 2 cytokines were identified demonstrated that antigen dose can influence the characteristics of an immune response: low-dose immunization favored the development of a cytotoxic T-cell response, whereas high-dose immunization favored production of large amounts of antibody (233). Because the former response is consistent with type 1 cytokine dominance, whereas the latter is more characteristic of a type 2 cytokine response, *in vivo* studies were performed to determine directly whether antigen dose could influence T-cell differentiation. Indeed, in mice inoculated with *L. major* or *T. muris,* relatively small inocula favored a Th1 response, whereas larger inocula favored type 2 cytokine production (234,235). However, both these infectious disease models induce

responses that are finely balanced between type 1 and type 2 cytokine production, so any intervention that favors one or the other response even slightly may tip the balance. No evidence indicates that low doses of *N. brasiliensis,* or any other potent inducer of type 2 immunity, will stimulate a type 1 cytokine response or that high doses of *Listeria monocytogenes,* or any other potent inducer of type 1 immunity, will stimulate a type 2 cytokine response. Furthermore, *in vitro* studies that have used antigen or peptide to stimulate TCR transgenic T cells have yielded more complex results; in one study, both low and high peptide doses induced a predominantly type 2 response, whereas intermediate doses stimulated a predominantly type 1 response (236).

Studies of the relationship between TCR affinity for the MHC class II–peptide complex and T-cell differentiation patterns demonstrate that high-affinity interactions induce type 1 cytokine responses *in vitro* and *in vivo,* whereas lower-affinity interactions induce type 2 responses (237,238 and 239). Altering peptides to raise or lower the affinity of the interaction between MHC class II–peptide and TCR has a consistent effect (237,238,239 and 240). These results at first seem inconsistent with the *in vivo* studies of antigen concentration; both increased affinity and increased antigen concentration should increase the number of MHC class II–peptide-TCR interactions between the APC and T cell and the stability of the APC–T-cell interaction. An alternate explanation, that high antigen concentrations are required to allow "low-affinity" T cells to become activated and produce type 2 cytokines, is discussed later in this chapter.

Costimulation

Th2, but not Th1, responses require ligation of CD4 on the responding T cell. Both the increased interaction strength between T cell and APC that is provided by the CD4–MHC class II interaction and signaling mediated by the cytoplasmic domain of the CD4 molecule appear to contribute to the generation of a type 2 cytokine response (241,242). Costimulation of $CD4^+$ T cells by B7 (CD80/CD86) ligation of CD28 is also a requirement for Th2, but not Th1, differentiation in most cases (216,217 and 218), and increasing the ratio of CD28:TCR signaling may shift responses from Th1 to Th2 (242,243). Mechanisms for the CD28 effect on cytokine production are unknown. Th2 responses to some gastrointestinal nematode parasites are at least partially CD28 independent (244), a finding suggesting that these parasites either activate other host signaling pathways that promote Th2 differentiation or directly signal T cells in a way that promotes the Th2 response.

Once naive T cells have differentiated into effector and memory cells, CD28 costimulation appears to contribute to maintenance of both type 1 and type 2 responses, but it may be more important for maintenance of the type 1 response (245,246). In contrast to CD28 costimulation, intercellular adhesion molecule-1 (ICAM-1) and ICAM-2 costimulation, under some circumstances, appears to suppress Th2 cytokine production (247).

Antigen-Presenting Cells

Although antigen-presenting B cells, dendritic cells, and macrophages can induce either a Th1 or a Th2 response, given the appropriate cytokine milieu (248), antigen presentation by B cells appears to favor type 2 cytokine responses, whereas antigen presentation by dendritic cells or macrophages appears to favor type 1 responses (249,250,251,252 and 253). This may reflect greater production of IL-12 and IFN-a/b by dendritic cells and macrophages than by B cells. Alternatively, B cells may produce a molecule (still unknown) that promotes Th2 differentiation.

Site of Immunization

Administration of antigen by an inhaled route is more likely to induce a type 2 cytokine response than intravenous or intraperitoneal administration of the same antigen (254,255). The mechanism for this effect is not known, but it may reflect differences in APC population or cytokine milieu at the different immunization sites.

Attempt at Synthesis

The selection of molecules representative of a particular class of pathogen, such as lipopolysaccharide, as triggers for APC secretion of IL-12 and IFN-a/b, which regulate T-cell type 1–type 2 cytokine production, provides an elegant and direct way to induce naive T cells to produce cytokines that best control a particular infection. It is more difficult, however, to understand the evolutionary logic of allowing antigen concentration, TCR affinity, and costimuli to regulate T-cell production of type 1 or type 2 cytokines. Possibly, the small inoculum that typically initiates a bacterial, viral, or protozoal infection has been selected evolutionarily as a signal to secrete type 1 cytokines, which best defend against most of these pathogens, whereas the large quantity of enzymes and other proteins produced by even a few invasive nematode parasites has been interpreted as a signal for the type 2 cytokine response that generally protects against these parasites. Because only T cells whose TCRs bind peptide-MHC with high affinity are likely to be sufficiently stimulated to differentiate into cytokine-secreting cells when peptide concentration is low, high-affinity binding to the TCR may have been selected as a trigger for a type 1 cytokine response. In contrast, at higher antigen concentration, the density of MHC class II–peptide on APCs should be sufficient to also activate T cells whose TCRs bind MHC class II–peptide with lower affinity; these T cells will be induced to secrete type 2 cytokines. Because more T cells are likely to bind a given MHC class II–peptide complex with low than with high affinity, the predominant cytokine response should shift from type 1 to type 2 as antigen concentration increases and lower-affinity T cells are stimulated. This would be true even if high antigen concentrations enhanced type 1 cytokine production by the relatively small numbers of T cells that bind peptide–MHC class II with high affinity. By the same logic, CD4 and CD28 costimulation may have evolved as a selective requirement for Th2 differentiation because high-affinity MHC–peptide interactions with the TCR do not require costimuli to induce naive T cells to differentiate into effector cells, whereas low-affinity interactions require the additional stimuli to activate naive T cells.

One limitation of this hypothesis is that pathogenic virus, bacteria, and protozoa often proliferate to produce a large antigen load before the immune system is fully activated. This increase in antigen load would stimulate a type 2 cytokine response were it not for the ability of pattern recognition molecules on APCs and NK cells to recognize molecules associated with each of these infectious agents as triggers for the IL-12, IFN-a/b, or IFN-g responses that suppress type 2 immunity and enhance the type 1 response. In contrast, the large antigen loads that are associated with even early nematode infections and the inability of these parasites to activate pattern recognition molecules to induce production of Th1-promoting cytokines (or their production of molecules that actively stimulate Th2 differentiation through an undiscovered pathway) allow predominantly low-affinity T cells, which produce Th2 responses, to be activated without any inhibition by IL-12 or the IFNs. Although this hypothesis ties the different regulators of $CD4^+$ T-cell differentiation together in a way that makes some biologic sense, it is highly speculative and requires experimental verification.

TRANSCRIPTIONAL REGULATION OF TYPE 2 CYTOKINE PRODUCTION

Three excellent reviews of transcriptional regulation of type 1 and type 2 cytokine production have been published (256,257 and 258). Transcriptional regulation of IL-4 production has been particularly well studied because IL-4 is such an important regulator of type 2 cytokine production. Regulatory elements in a promoter immediately 5' of the IL-4 gene and in a distal 3' enhancer of this gene bind the transcription factors GATA-3 and c-Maf, which are selectively expressed in cells that secrete type 2 cytokines, Stat6 (which, in T cells, requires IL-4 for activation), and transcription factors, including NFATc, AP-1, and NIP45, that lack tissue specificity.

The zinc finger protein, GATA-3, is required for the development of T cells and the nervous system and hematopoietic systems, as well as for Th2 differentiation (259). Several studies support its importance as an inducer of type 2 immunity. A dominant negative, inducible mutant form of GATA-3 inhibits Th2 differentiation (260), whereas transgenic overexpression of GATA-3 causes increased production of all type 2 cytokines and stimulates even fully differentiated Th1 cells to produce some type 2 cytokines (259,261). GATA-3 directly transactivates the proximal IL-5 promoter (262,263), but it probably activates IL-4 transcription by binding to a GATA-3 dimer in a 3' enhancer region of the IL-4 gene (264). GATA-3 upregulation of its own transcription may provide a mechanism for stabilizing type 2 cytokine production (261,265). Although IL-4 induces GATA-3 transcription through a Stat6-dependent mechanism, GATA-3 can also be transcribed in the absence of IL-4 and ectopic expression of GATA-3 stimulates IL-4 production even in Stat6- and IL-4Ra–deficient mice (261). Taken together, these observations suggest that GATA-3 is the central, Th2-promoting transcription factor. However, because no system has been devised that completely blocks GATA-3, it is premature to conclude that GATA-3 is an absolute requirement for any type 2 cytokine production.

In addition to stimulating its own transcription, GATA-3 induces transcription of c-Maf, a basic region–leucine zipper factor that binds to a MARE site in the proximal IL-4 promoter (261,266). c-Maf strongly enhances IL-4 production, although c-Maf–deficient T cells can be stimulated to produce some IL-4 (267), and studies have not yet been performed to determine whether strong stimuli of Th2 differentiation can induce Th2 responses in c-Maf–deficient mice *in vivo.* Unlike GATA3, c-Maf has no direct transcription-promoting effect on type 2 cytokines other than IL-4 (267).

Although Stat6 signaling is not required for the generation of a primary type 2 cytokine response, it clearly can enhance the magnitude of the response, perhaps by inducing GATA-3 transcription (261). Because the importance of Stat6 is particularly evident in responses to stimuli that also induce IFN-g production, Stat6 may contribute to type 2 cytokine production by suppressing the inhibitory effects of IL-12 (possibly by decreasing $IL\text{-}12Rb_2$ expression on T cells) and IFN-g. In addition, Stat6 signaling appears to be particularly important for the generation and survival of $CD4^+$ T cells that make rapid type 2 cytokine responses on restimulation with antigen or anti-CD3 antibody (68).

Although members of the nuclear factor of activated T cells (NFAT) family lack tissue specificity, they are important regulators of type 2 cytokine production. The absence of NFATc1 in lymphoid cells results in reduced IL-4 production, whereas the absence of NFATc2 leads to increased type 2 cytokine production and the combined absence of NFATc2 and NFATc3 promotes a particularly strong type 2 cytokine bias (268). Investigators have suggested that all these NFAT family members activate IL-4 gene transcription during the early phase of an IL-4 response, whereas NFATc2 and NFATc3, but not NFATc1, are important in limiting IL-4

gene transcription later in the response (268). Because the NFAT transcription factors bind to the IL-4 promoter and enhancer regions in Th2 cells, but not in naive T cells or Th1 cells, it has also been suggested that Th2-specific factors, such as GATA-3, are required *in vivo* to make these regions NFAT accessible (264). This possibility is consistent with the observation that transfection of T cells with GATA-3 rapidly decreases nucleotide methylation and increases accessibility (as measured by DNAse hypersensitivity) of promoter and enhancer regions of the IL-4/IL-13 locus (264).

Type 2 cytokine gene transcription is negatively, as well as positively, regulated. The IL-12–activated transcription factor, Stat4, suppresses the differentiation of naive $CD4^+$ T cells into Th2 cells (269). The transcription factor Bcl-6, which overlaps with Stat6 in its nucleotide sequence binding specificity, inhibits type 2 responses; increased type 2 cytokine production is found in Bcl-6–deficient mice and even in mice deficient in both Bcl-6 and Stat6 (270). A member of the T box transcription factor family, T-bet, stimulates IFN-g transcription and can suppress type 2 cyotkine production even in fully polarized Th2 cells, although suppression does not involve a direct effect on the proximal IL-4 promoter (271). Thus, both the differentiation of naive T cells into type 2 cytokine-secreting cells and the continuing production of type 2 cytokines by polarized Th2 cells are likely to reflect the balance of several stimulatory and suppressive transcription factors as well as the accessibility of relevant promoter and enhancer regions to these factors, rather than the effect of a single factor.

Although these observations greatly extend understanding of how type 2 cytokine responses are regulated, several important issues require further clarification. Current observations fail to explain independent regulation of the individual type 2 cytokines (if GATA-3 is required for an IL-4 response and directly transactivates the IL-5 gene, why do some stimuli induce IL-4, but not IL-5 transcription?). They also fail to explain why immunogens that induce normal primary type 2 cytokine responses *in vivo* in Stat6 mice fail to induce normal secondary type 2 cytokine responses in these mice. Perhaps Stat6 signaling is required *in vivo* to maintain the viability of differentiated Th2 cells or to maintain GATA-3 transcription when TCR stimulation becomes limiting. A third area that remains mechanistically confusing is regulation of cytokine expression at the level of the individual alleles of a cytokine gene. Only a single IL-4 allele is transcribed in most polarized Th2 cells that have been generated *in vitro* (272). If polarized Th2 cells are rested, then restimulated, they usually again activate a single IL-4 allele; however, the same allele is not necessarily the one activated. Th2 cells derived from a clone in which one allele is preferentially activated preferentially activate the same allele to the same extent after restimulation (273). This finding suggests that certain mechanisms regulate the probability of activation of a particular IL-4 allele in a single cell, but chance has a role in the final event that induces activation (i.e., allele activation is a crap shoot with subtly loaded dice).

TH2-SELECTIVE RECEPTORS

Both naive T-cell differentiation and the function of polarized, differentiated T cells may depend on receptors that are expressed differently by Th1 and Th2 cells. IL-4–secreting cells lose expression of the b_2 chain of the IL-12R and thus lose susceptibility to the inhibitory effects of IL-12 on type 2 cytokine production (69). This loss, however, is neither absolute nor necessary for Th2 stability: Th2 cells can be induced to reexpress IL-12Rb_2 by exposure to IFN-g, and polarized Th2 cells that express a transgenic IL-12R remain insensitive to IL-12 effects on type 2 cytokine production (69). IL-4–secreting cells, unlike Th1 cells, continue to express IFN-gRb chain and thus retain sensitivity to the inhibitory effects of this cytokine on cell growth. IFN-gRb is lost, however, by Th2 cells that survive IFN-g treatment (274,275). Although the IL-18R has been reported to be Th1-specific, observations that IL-18 can enhance IL-4 and IL-13 production make it likely that this specificity is also less than absolute (231,276).

Chemokine receptors are also differentially expressed, with Th2 cells more likely than Th1 cells to express CCR3, CCR4, and CCR8 and less likely to express CXCR3 and CCR5 (277,278). These differences, and the preferential expression of P-selectin ligand-1 by Th1 cells (279,280), suggest that differential chemokine and selectin expression can determine whether predominantly type 1 or type 2 cytokine-secreting cells are attracted to an inflammatory site. Because chemokines can activate, as well as attract, lymphocytes (281), it is likely that chemokines can contribute to the polarization of a cytokine response. In this regard, CCR1 and MCP-1 have both been reported to enhance Th2 responses (282,283 and 284).

Additional molecules that are preferentially expressed by Th2 cells include the IL-1–like molecule T1/ST2, which may contribute to type 2 cytokine production (285,286), and inducible costimulatory molecule, a CD28 family molecule that may be important for the reactivation of Th2 memory (287,288 and 289).

CHALLENGES FOR THE FUTURE

Research during the past 14 years has defined the type 1 and type 2 patterns of T-cell cytokine production and has provided considerable information about how these responses are regulated, how they control infection, and how they contribute to immune pathology. This increased appreciation of the importance of these cytokines has encouraged further studies, which, during the next 20 years, should further elucidate important basic issues and lead to the development of therapeutics that modify type 2 production and effects. Basic research should determine the mechanisms by which allergens and worms selectively induce the type 2 cytokine response; should determine whether the type 2 cytokine response is actively induced or defaults from a lack of cytokines that stimulate the type 1 response, should identify the mast cell–independent mechanisms by which type 2 cytokines protect against gastrointestinal nematode parasites, should identify the distinct contributions of IL-4 and IL-13 to type 2 immunity, should determine the signaling and transcriptional mechanisms by which IL-9 enhances type 2 inflammation and immunity, should identify the mechanisms that create stable Th2 memory and the stimuli that suppress established type 2 responses, and should elucidate the interactions among transcription factors that allow tandem or independent expression of different type 2 cytokines. Translational research should develop cytokine agonists and antagonists that improve control of infectious diseases (particularly through improved vaccines) and treatment of allergic and autoimmune disorders. Most first-generation therapeutics will probably be proteins, including soluble cytokine receptors and anticytokine antibodies that neutralize specific cytokines and anticytokine receptor antibodies and mutant cytokines that block cytokine receptors. Considerable effort will be required to identify possible untoward effects and to establish the safest, most convenient, and most efficacious means of protein delivery. As specific signaling mechanisms become better understood and the precise molecular interactions among cytokines, receptors, and signaling molecules are elucidated, it seems likely that small molecule agonists and antagonists will be produced, along with small molecules that stimulate or suppress the production of specific cytokines. At every stage of development, difficult decisions will have to be made about the safety, efficacy, and cost of type 2 cytokine-related therapeutics relative to alternative therapies for the same diseases. Despite uncertainties, it seems safe to predict that the dramatic advances in type 2 cytokine biology that have occurred during the past 14 years and will continue during the next 20 years will translate into equally dramatic improvements in the treatment of allergy and infection.

ACKNOWLEDGMENTS

I thank my close friends and collaborators, Suzanne C. Morris and Joseph F. Urban, Jr., for their continuing and important contributions to many of the studies discussed in this chapter and the United States Veterans Administration (VA) and Public Health Service for supporting these studies with a VA Merit award, a VA REAP award, and four National Institutes of Health grants (RO1 AI44971, RO1 AI45766, R21 AI46972, and RO1 AI35987).

12 APOPTOSIS AND THE IMMUNE RESPONSE

Douglas R. Green, Ph.D

The process of apoptotic cell death affects essentially all cell types in all multicellular animals; therefore, it should not be surprising that it has roles in the immune system. In this case, however, the functions of apoptosis may extend further than in other systems because many apoptotic defects (through spontaneous or designed mutations) appear to impact predominantly on the immune system. I believe there are at least three reasons for this effect:

First, apoptosis plays a major role in the control of cell number, and in most systems, considerable flexibility exists in how tightly cell number can be regulated. In two cases, however, a failure in the apoptotic machinery of a single cell and its progeny can lead to the patient's death: (a) when a cell has transformed and will become a cancer and (b) when a lymphocyte responds to autologous antigen and will cause a devastating autoimmune disease. Because efficient functioning of apoptotic pathways prevents these occurrences, these diseases are rare (considering the many opportunities for these problems to arise in any patient). Second, apoptosis is an important effector mechanism in the immune system. Cytotoxic lymphocytes mediate their effects through the induction of apoptosis in target cells, and many cytokines function to either induce or inhibit apoptosis.

Third, cell death in any cell has an impact on the immune system through the consequences of the clearance of the dead cells. Cells that die via necrosis appear to simulate inflammatory responses, whereas apoptotic cells are rapidly cleared without associated inflammation. As will discussed herein, the phagocytosis of apoptotic cells is not “silent” but impacts on immunologic function through effects on the phagocytes.

This chapter begins with a brief overview of the machinery of apoptosis in vertebrates, and these probably apply to all cell types (not only to cells of the immune system). After the overview is a consideration of many of the ways these mechanisms function in the cells of the immune system.

MACHINERIES OF DEATH

Fate of an Apoptotic Cell

Apoptotic cell death is defined by the morphologic appearance of the dying cell (and this remains the definition, despite our current understanding of the biochemistry of the process). The cell undergoing apoptosis will display some or all of the following features (Fig. 12.1): blebbing, chromatin condensation, nuclear fragmentation, loss of adhesion and rounding (in adherent cells), and cell shrinkage. The DNA cleaves and can take the form of high-molecular-weight fragments or fragmentation into an oligonucleosomal “ladder” (Fig. 12.1). It is important to note that ladder formation or its absence *per se* is not proof that apoptosis has or has not occurred; *bona fide* apoptosis can occur in the absence of a DNA ladder, and laddering can occur in necrotic cells (1). The *in situ* DNA nick and labeling (TUNEL) assay, which detects double-strand DNA breaks in cells, also should be evaluated cautiously.

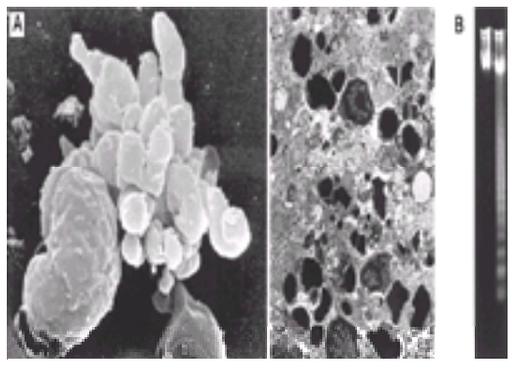

Figure 12.1. Apoptotic changes. T cells undergoing apoptosis *in vitro* and in the thymus after activation. **A:** Blebbing **(left)** and nuclear condensation **(right)**. **B:** Oligonucleosomal DNA fragmentation in apoptotic T cells is apparent in the **right lane** (**left lane**, DNA from untreated, viable cells).

Arguably, the most important change in an apoptotic cell is the change that leads to its phagocytosis. If a cell is eaten, it is essentially already dead, whether or not any other changes associated with apoptosis occur. During apoptosis, cells alter their plasma membrane so that they are rapidly taken up by both “professional” (macrophages, dendritic cells) and “nonprofessional” (e.g., epithelial cells) phagocytes. Although several receptors on phagocytes have been implicated in this clearance process (2,3,4 and 5), only one change in the apoptotic cell has been identified (although we know there are others): the externalization of phosphatidylserine (PS). Normally, PS is sequestered to the inner leaflet of the plasma membrane, and during apoptosis it equilibrates to both inner and outer leaflets. This can be most easily detected by the use of annexin V-FITC, which specifically binds PS (6), but care must be taken in interpreting results because any disruption of the plasma membrane will expose PS. A receptor for PS on phagocytes recently was identified as a major player in the recognition of apoptotic cells (7).

Executioner Caspases and Their Substrates: The Orchestration of Death

In most cases, the apoptotic phenomena described above are a result of the cleavage of specific substrates by caspases, a collection of cysteine proteinases that become active during apoptosis. Several different caspases are constitutively present in cells, and these reside in the cytosol in an inactive form (8). The most prevalent of these, caspase-3, is ultimately responsible for most of the effects, although it is supported by two others, caspases-6 and -7. These three caspases are often referred to as the *executioner caspases* to indicate their role in coordinating the death of the cell.

When the executioner caspases become active during apoptosis, however, this does not in itself kill the cell (i.e., these are not digestive enzymes). It is the cleavage of specific substrates that results in the changes we see as apoptosis.

For example, high- and low-molecular-weight DNA fragmentation is caused by the action of caspase-3 on a complex of a nuclease (CAD/DFF40) and its inhibitor (iCAD/DFF45) (9,10). Caspase-3 cleaves the inhibitor, allowing the nuclease to cut the chromatin (it appears that the amount of activated nuclease determines whether DNA fragmentation will proceed to a ladder) (Fig. 12.2). Following DNA cleavage, the chromatin condenses, but this change is due largely to another caspase substrate, called acinus (11).

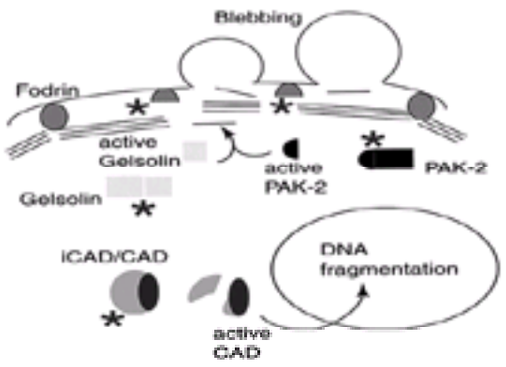

Figure 12.2. Caspase substrates cause apoptotic changes. Caspase cleavage (*) of molecules in the cell triggers the changes seen as apoptosis. CAD nuclease is activated by caspase cleavage of its chaperone inhibitor, iCAD; gelsolin and PAK-2 are activated by caspase cleavage to remove the regulatory domains of these enzymes; fodrin activity is destroyed by caspase cleavage. Many other substrates are known, and several have probable functions in apoptosis.

Blebbing is orchestrated via the cleavage of gelsolin (12) and p21-activated kinase-2 (13,14) to activate these enzymes and probably through cleavage of fodrin (15) to dissociate the plasma membrane from the cytoskeleton. The result is probably an effect of microfilament tension and local release because depolymerization of actin prevents blebbing (16). Interestingly, in some cells undergoing apoptosis, blebbing appears to occur independently of caspase activity (17), but in others, it is caspase dependent.

The externalization of PS during apoptosis is usually caspase dependent (18), although the precise mechanisms have not been elucidated. In some cells, PS externalization appears to be caspase independent (19), although, again, the mechanism is unknown. PS externalization in platelets does not involve caspases (20).

Many other caspase substrates are known in the cell, although their functions are often unclear or unproved. Similarly, many of the effects shown in Fig. 12.1 are caspase dependent (i.e., caspase inhibitors block them), but the mechanisms have not been elucidated.

Cruel Cuts: Activating the Caspases

In general, caspases are activated when the single-chain proform is cleaved to remove the prodomain and separate the large and small subunits (Fig. 12.3). The active caspase is a tetramer of two large and two small subunits, with two active sites.

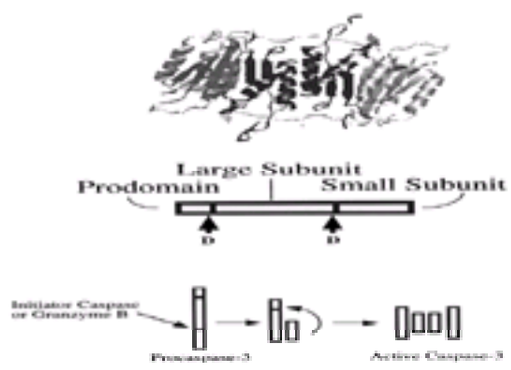

Figure 12.3. Cleavage of caspases activates them. **A:** Structure of mature caspase-3. **B:** Organization of the procaspase-3 polypeptide. *Large arrows* indicate aspartic acid cleavage sites for generation of the mature, active enzyme. **C:** Activation of procaspase-3 by cleavage.

With one interesting exception, the best enzymes for converting pro- to active caspases are other caspases. The exception is a serine protease, granzyme B that plays a major role in the killing of target cells by cytotoxic lymphocytes (discussed in more detail in the section entitled Apoptosis in the Immune System). Granzyme B can directly cleave and activate caspases, including caspase-3 (21,22), and thereby has the potential to bypass most of the regulatory processes discussed herein.

The ability of caspases to activate other caspases leads to the idea of a caspase cascade, with other caspases first becoming active and in turn activating executioner caspases (which can activate all remaining caspases as well as cleaving key substrates). These “upstream” caspases sometimes are referred to as *initiator caspases* to indicate their roles in trigger apoptosis by activating the executioners. The discussions here focus on two of the initiator caspases, caspase-8 and caspase-9, which have quite different functions in triggering apoptosis. Both of these caspases, however, have in common an excellent ability to cleave and activate executioner caspases. So the problem becomes, “how are the initiator caspases activated in the first place?”

One clue to the difference between initiator and executioner caspases is the nature of the prodomains. The executioner caspases have extremely short prodomains, whereas those of the initiators are longer. The latter contain protein–protein interaction motifs that give us further insights into how they function. These interaction motifs bind to adapter molecules that permit the autoactivation of the initiator caspases. For the two initiator caspases discussed here, this happens in different ways. Caspase-8 interacts with its adapter molecule via a motif called the death effector domain (DED); caspase-9 interacts with a different adapter molecule via a caspase recruitment domain (CARD) (23,24). Interestingly, however, the protein interaction motifs in these two caspases, although unrelated at the level of primary sequence, are structurally similar (Fig. 12.4), a similarity they also share with another domain, the death domain (DD), the function of which is discussed later (DDs are not present in caspase prodomains).

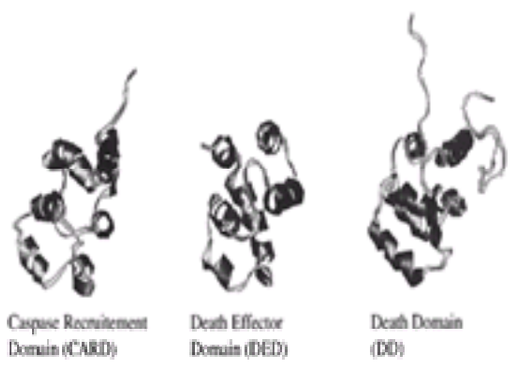

Figure 12.4. Protein–protein interaction domains with major roles in apoptosis.

In addition to caspases, cells also contain natural inhibitors of the caspases. These inhibitors of apoptosis proteins (IAPs) were first identified in baculovirus but subsequently were found in human cells (25). IAPs can inhibit caspases directly and also may promote their degradation via ubiquitination. Not all IAP molecules function specifically in apoptosis, but it is likely that at least some of them play an integral role in the process.

Here we consider two general types of signaling pathways leading from a triggering event to activation of an initiator caspase (and from there to apoptotic death). The

first involves specific binding of certain cytokines to a class of cytokine receptors. The second depends on the participation of mitochondria.

Death Ligands, Death Receptors

The tumor necrosis factor (TNF) receptor family includes molecules that provide essential signals for inflammation, lymphocyte activation, and the genesis of secondary lymphoid organs (26,27 and 28). A subset of these receptors provides another function: the induction of apoptosis. These “death receptors” include TNFR1, Fas (CD95), DR3/WSL, and the TRAIL/Apo-2L receptors (TRAIL-R1/DR4, TRAIL-R2/DR5). Other members of this family also trigger apoptosis, although the mechanisms are less well understood.

When any of these death receptors are bound by their ligands (TNF or lymphotoxin, Fas-ligand (FasL), the ligand for DR3[1] or TRAIL/Apo-2L, respectively) apoptosis can occur as a consequence. The Fas-FasL interaction is perhaps the simplest scenario to understand the process. Ligation of Fas (by FasL or stimulatory antibodies) causes the rapid formation of an intracellular signaling complex. The intracellular region of Fas (and all the other death receptors) contains a death domain (DD) (Fig. 12.4). Ligation of Fas causes recruitment to the DD of another protein, FADD (28), which also contains a DD, and these bind via a DD–DD interaction. FADD also contains a DED, and this in turn recruits procaspase-8, which binds via its DED (Fig. 12.5).

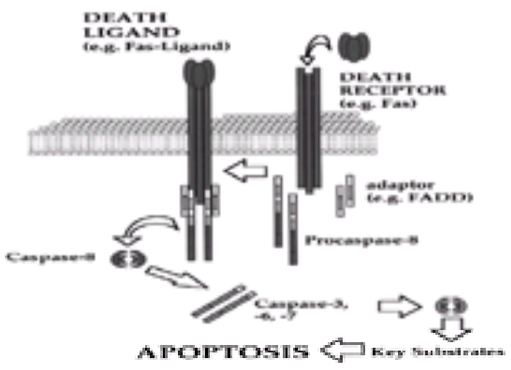

Figure 12.5. Signaling from a death receptor. The activation of caspase-8 by ligation of Fas is illustrated. Ligated Fas recruits FADD to the intracellular region, which in turn recruits procaspase-8. The caspase transactivates and the mature caspase now can cleave and activate procaspase-3, leading to apoptosis.

Bringing two or more procaspase-8 molecules together is sufficient to activate them because the procaspase-8 molecules have a low level of activity, and in close proximity, two procaspase-8 molecules can process each other to the mature, active forms. The active caspase-8 now triggers the apoptotic caspase cascade. DR3 also binds FADD and requires this adapter for induction of apoptosis (30,31). It is likely that DR3 signals similarly to Fas. In contrast, TRAIL receptor signaling for apoptosis can occur in the absence of FADD (31), although the receptors do appear to bind this adapter (32).

Signaling from TNFR1 is made more complicated by the need for another adapter protein, TRADD. TRADD binds ligated TNFR1 via DD–DD interaction, and then TRADD recruits FADD. FADD now recruits caspase-8, leading to its activation.

Ligation of a death receptor does not necessarily lead to caspase-8 activation and death. TNFR1 also can activate NF-kB. In cells that are resistant to TNFR1-mediated apoptosis, inhibition of this transcription factor can sensitize the cells to this form of death (33). One way in which NF-kB works is to induce expression of two TNFR1-binding proteins (TRAF-1 and -2) and an IAP (c-IAP), which is recruited to the receptor by the other proteins and inhibits the apoptotic signaling (34). Most likely, several other antiapoptotic functions of NF-kB exist.

Interestingly, NF-kB has no effect on Fas-mediated apoptosis (35), which is certainly regulated as well, however, because freshly activated T cells are resistant to this form of apoptosis despite expressing Fas and the necesssary signaling molecules (36). A molecule with a number of different names, often referred to *as c-FLIP* (37), can block Fas-mediated apoptosis. c-FLIP resembles procaspse-8, but without the active proteinase site, and can be recruited to the ligated Fas-signaling complex. Interleukin-2 (IL-2) can downregulate c-FLIP expression (38), which might explain why IL-2 can sensitize activated T cells to Fas over time. Other studies, however, have shown that c-FLIP is not recruited to the signaling complex in resistant T cells (36), and therefore other regulators may be important.

Mitochondria and the Functions of the Bcl-2 Family

Bcl-2 is among the best known antiapoptotic proteins (39), and its discovery as an oncogene in follicular lymphomas has helped to shape our thinking about the roles of apoptosis in preventing oncogenesis. It is one of a family of proteins that include antiapoptotic (Bcl-2, Bcl-xL) and pro-apoptotic (Bax, Bak) molecules. In addition, numerous proteins that share limited homology but probably similar structure are also in this family (e.g., Bid, Bad, Bim); these are called *BH3-only* proteins because of four Bcl-2 homology regions, and these share only the third.

Bcl-2 and Bcl-xL reside on the mitochondrial outer membrane, and the proapoptotic family members are either cytosolic or present on the mitochondrial membrane as well. Although they also are found elsewhere (endoplasmic reticulum, nuclear envelope), their major effect appears to be on the mitochondria.

A stress-induced apoptotic pathway, which also can function in response to other inducing signals, triggers apoptosis by the induction of oligomerization of cytosolic Bax or Bak and localization to the mitochondrial outer membrane (40,41). Although it is not known precisely how this occurs in all forms of apoptosis, one factor that can cause Bax oligomerization is a sudden increase in cytosolic pH (42), which was seen in the case of IL-7 withdrawal.

The translocation of Bax or Bak then can induce a dramatic event in the mitochondria. These organelles then release the proteins in the space between their inner and outer membranes, including one key protein: cytochrome c. Cytochrome c is encoded by a nuclear gene, but when it is imported into the mitochondria, it is coupled with a heme group to become holocytochrome c, and it is only this form that functions to induce caspase activation (43).

The antiapoptotic proteins Bcl-2 and Bcl-xL work to prevent this cytochrome c release from mitochondria and thereby preserve cell survival (43,44). Studies using cell-free systems provide strong support for the idea that this is the major site of action of these proteins in preventing apoptosis.

When cells release cytochrome c, they do so suddenly and completely and apparently from all the mitochondria in the cell (this has been established for only one cell line, but it may be generally true) (45). Following cytochrome c release, caspases are activated and the cells undergo apoptosis.

Apoptosis occurs through the formation of an “apoptosome,” which is dependent on both cytochrome c from the mitochondria and either adenosine triphosphate (ATP) or dATP in the cell Fig. 12.6). Cytosol contains a protein called apoptotic protease activating factor-1 (APAF-1) (46,47), and cytochrome c binds and induces it to oligomerize. This, then, recruits an initiator caspase: procaspase-9 (47,48). Unlike other caspases, procaspase-9 does not appear to be activated simply by cleavage but instead must be bound to APAAF-1 to be active (49,50). These proteins interact via CARD–CARD interactions. The apoptosome now recruits procaspase-3, which is cleaved and activated by the active caspase-9 and released to mediate apoptosis.

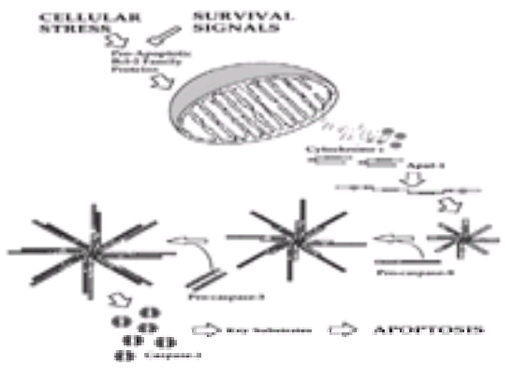

Figure 12.6. Induction of apoptosis via the mitochondrial pathway. Cellular stress induces proapoptotic Bcl-2 family members to translocate to from the cytosol to the mitochondria, where they induce the release of cytochrome c. Cytochrome c catalyzes the oligomerization of APAF-1, which recruits and promotes the activation of procaspase-9. This in turn activates procaspase-3, leading to apoptosis.

Death Receptors and Mitochondria: A Bid Farewell

The mitochondrial pathway involving Bcl-2 family members, mitochondria, cytochrome c, Apaf-1, and caspase-9 is fundamentally distinct from that of the death receptors. Cells lacking caspase-8 (51) or FADD (31) do not respond to death ligands but undergo apoptosis induced by other agents, such as cellular stress; cells that lack caspase-9 (52,53) or APAF-1 (54,55) do not undergo apoptosis induced by such stressors but readily die in response to death ligands.

Controversy arises, however, when we consider the antiapoptotic effects of Bcl-2 on signaling by Fas. In some cells, Bcl-2 can interfere with Fas-mediated apoptosis, whereas in others it cannot (56). [This remains controversial; some investigators contend that Bcl-2 family members never interfere with Fas-mediated apoptosis (57)]. If Bcl-2 sometimes interferes with death mediated through Fas, is this through a new function of the antiapoptotic protein or a role for mitochondria?

Evidence suggests the latter. One of the BH3-only proteins, Bid, is cleaved by active caspase-8 (activated by ligation of the death receptors), and this then translocates to the mitochondria, where it triggers cytochrome c release (58,59 and 60), probably through interaction with Bax (61,62) or Bak. Bcl-2 can prevent this Bid-mediated effect. In cells, expression of Bid can sensitize for TNF-induced apoptosis (58). *In vitro*, the ability of caspase-8 to activate caspase-3 is greatly facilitated by the presence of Bid and mitochondria (63). These observations suggest that when caspase-8 is limiting, the action of Bid on mitochondria can determine whether a cell will undergo apoptosis (via cytochrome c release and activation of caspase-9). In support of this, Bid-deficient mice are relatively resistant to the lethal effects of anti-Fas antibody *in vivo*, and their hepatocytes do not readily undergo Fas-mediated death (64). In contrast, lymphoid cells from these mice are fully sensitive to death via Fas ligation.

I have touched on only a few of the mechanisms at work in the apoptotic process in this brief overview to begin to create perspective on how this form of death impacts on the function of the immune system, which is the next topic.

APOPTOSIS IN THE IMMUNE SYSTEM

The basic mechanisms for the process of apoptosis apply to nearly all cell types, and the cells of the immune system are not an exception. Apoptosis plays roles in effector mechanisms of target cell destruction, in controlling immune cell numbers, and in the effects of the phagocytosis of apoptotic cells on immune function. In each case, I address only those aspects of each that relate directly to apoptosis. The reader should keep this in mind because apoptosis is not the only mechanism of relevance to these phenomena and processes.

Cytotoxic Effector Mechanisms

Cytotoxic lymphocytes kill their target cells, such as infected or transformed cells, and in many cases, this is via induction of apoptosis. There are two major mechanisms for this cell death: granule-mediated and death ligand-mediated cytotoxicity, both of which work by caspase activation involving all of the major pathways discussed in the last section.

Activated cytotoxic lymphocytes (cytotoxic T cells, natural killer cells) often contain granules that are released on contact with the specific target cell. These granules contain two key mediators of cytotoxicity: perforin and a collection of serine proteases called *granzymes*. Perforin is essential for granule-mediated cytotoxic killing (65), and by itself it can induce necrotic cell death (but only at relatively high concentrations). To induce apoptosis, perforin requires additional mediators, and this is the function of the granzymes (66,67). Perforin forms pores in the target cell membrane, which led to the idea that the mediators of apoptosis pass through these pores into the cytotoxic cell. This is an oversimplified view, however.

When a cytotoxic cell releases the contents of its granules, the granzymes enter the target cell via endocytosis (this has been shown only for one key granzyme, granzyme B). The internalized granzyme is inactive until perforin also acts on the target, causing the granzyme to be released into the cytosol (68,69). A model for this sequence of events is shown in Fig. 12.7.

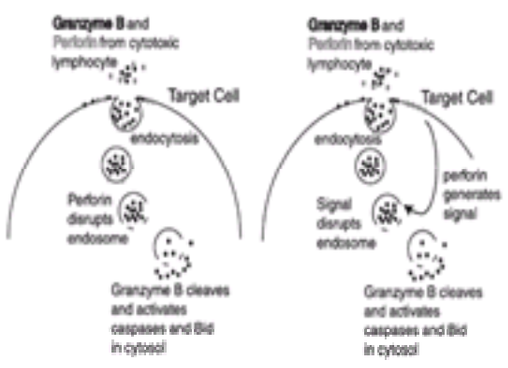

Figure 12.7. Perforin plus granzyme B induce apoptosis on engagement of target cells by cytotoxic lymphocytes. Only the target cell is shown following the release of the contents of a cytotoxic granule at the point of contact. Two possible modes of action of perforin on the target cell are shown. **A:** Perforin directly causes dissolution of the endosome containing granzyme B, either by incorporating as the endosome forms or through fusion with an endosome containing perforin. **B:** Perforin generates a signal at the plasma membrane that causes dissolution of the endosomes to release granzyme B to the cytosol. The nature of such a signal is unknown.

Once the granzymes enter the cytosol, they act to trigger apoptosis. Several granzymes are capable of doing this, but the most rapid and important one is granzyme B. As discussed in the section on basic mechanisms, granzyme B is capable of directly processing and activating several of the caspases, including caspase 3 (21,22). Granzyme B also can process and activate Bid, leading to cytochrome c release from the mitochondria (70). This appears to be important under conditions in which the amount of granzyme B introduced into the cell is low, and the involvement of Bid can amplify the process. Other granzymes also can induce apoptosis, albeit more slowly (67), but the precise mechanisms are not fully elucidated.

Cytotoxic lymphocytes also kill their targets via the expression and action of death ligands. TNF, lymphotoxin, and FasL all can be expressed by cytotoxic lymphocytes and often play roles in the death process via the ligation of their receptors on the targets and the ensuing apoptotic process.

Both granule-mediated and FasL-mediated cytotoxic mechanisms have been implicated in cytoxicity, and in some cases it has been proposed that these mechanisms have distinct functions. For example, both mechanisms have been implicated in graft-versus-host disease (71,72 and 73), but it has been suggested in one model that graft-versus-leukemia was mediated predominantly by granules, whereas FasL contributed to graft-versus-host disease (73).

Control of Cell Numbers

The elimination of selected clones of antigen-specific lymphocytes is at the core of modern immunology, embodied in the concept of clonal deletion. This occurs, at least in part, through an apoptotic process; but the role of apoptosis in the control of cell number extends beyond this principle to phenomena that include cell longevity, the response to cell damage, hormonal effects, immunologic privilege, and others.

GROWTH FACTOR DEPRIVATION

Growth factors maintain the survival of both myeloid and lymphoid cells, and this is through inhibition of apoptosis. For example, targeted disruption of the IL-7 gene

causes a loss of thymocytes, which can be prevented by transgenic expression of Bcl-2 (74,75). The ability of growth factors to maintain cell survival is due to both transcription-dependent (e.g., expression of anti-apoptotic Bcl-2 family members) and -independent events (e.g., activation of Akt/PKB). For example, neutrophils undergo spontaneous apoptosis in culture, which can be prevented by granulocyte macrophage–colony-stimulating factor (GM-CSF); this effect can be seen even by using anucleate neutrophil cytoplasts (76). Most growth factors are also survival factors, although there are exceptions (in both directions: growth without survival and survival without growth). Arguably, deprivation of growth factors may be the major inducer of apoptosis in the body (77).

ACTIVATION-INDUCED CELL DEATH

Another critical mechanism for the induction of apoptosis in the immune system is activation-induced cell death (AICD), especially via antigen receptors (78). This permits the elimination of lymphocytes capable of recognizing a specific antigen. During B- and T-cell development, AICD results in negative selection. Interestingly, although we have long suspected that negative selection of self-reactive thymocytes proceeds via activation-induced apoptosis (79,80 and 81), the precise mechanism responsible for this effect in thymocytes remains unknown. The mechanism for AICD in immature or mature B cells is similarly largely unknown.

Mature lymphocytes also can undergo AICD. In T cells, this happens if the cells are previously activated or transformed before the ligation of the antigen receptor. Under these conditions, activation does two things: It sensitizes the cells to Fas-mediated apoptosis and induces expression of the FasL (82,83,84 and 85). The FasL engages Fas, and the cells die via the Fas-mediated apoptotic pathway. In the absence of Fas or FasL, AICD can be mediated by TNF, acting through either the TNFR1 (and the death pathway discussed earlier) or via TNFR2 (which engages the apoptotic process in a manner that has not been fully elucidated) (86). AICD is probably important in the process of peripheral deletion, wherein activated T cells expand in number and then undergo depletion via apoptosis *in vivo* (87). Animals lacking Fas or FasL display defects in peripheral deletion (88,89), although TNF signaling also can be involved (90). IL-2 is thought to be important for the priming of T cells for AICD (91), and animals lacking IL-2 or IL-2 receptors can show defects in peripheral deletion (92,93) [although this is not universally the case (94)].

Effective transplantation tolerance for allogeneic grafts also appears to require a process of AICD. Pharmacologic treatments that promote AICD in host lymphocytes promote such tolerance, while those that interfere with it can prevent it (95,96). Compellingly, expression of antiapoptotic Bcl-2 proteins in the lymphocytes can interfere with the generation of long-term tolerance, strongly implicating apoptosis in the process (96). It therefore appears that elimination by apoptosis, and not simply via anergy, is required for the manifestation of this “holy grail” of transplantation biology.

IMMUNOLOGIC PRIVILEGE AND FASL

The phenomenon of immunologic privilege has been recognized for more than a century, and in the last few years we have gained some insights into how it is maintained. Sites in the body that appear to preclude cell-mediated immune responses are “privileged;” and this effect is mediated in part by the expression of FasL in the tissue. For example, when an immune response is induced by the injection of virus into the anterior chamber of the eye, infiltrating cells die by apoptosis (97). This is dependent on the expression of functional Fas on the infiltrating cells and functional FasL in the tissues of the eye (97,98). Under normal circumstances (i.e., privilege), there are no immune consequences in the eye, but in Fas- or FasL-defective animals, the failure of the cells to undergo apoptosis results in a massive, destructive inflammatory response (97).

Similarly, a role for FasL has been proposed for acceptance of allogeneic grafts from privileged tissues. Transplanted allogeneic testes were observed to be accepted if functional FasL was present (99), but this result is controversial (100). Similarly, murine allogeneic corneal grafts were accepted at a high rate (as is the case with humans) unless there were defects in FasL (graft) or Fas (recipient) (101,102 and 103). Human cornea expresses functional FasL (101), which might be relevant for the most common form of tissue transplant performed today.

Some tissues that normally do not constitutively express FasL will do so during potent immune responses, which may represent a form of “inducible immune privilege” (Fig. 12.8). Examples include the liver and small intestine, which express functional FasL only if activated T cells are present (104). This effect is at least partially responsible for peripheral deletion *in vivo* because FasL on peripheral tissues was found to be important in this phenomenon (104). It is likely that inducible privilege plays a role in recovery from autoimmune attack; autoimmune T cells that trigger transient encephelomyelitis in wild-type mice can induce persistent, lethal disease in animals that lack functional FasL (105,106). It is not unlikely that the inducible expression of FasL in cells of the nervous system (107) trigger apoptosis in the infiltrating lymphocytes and thus bring about remission.

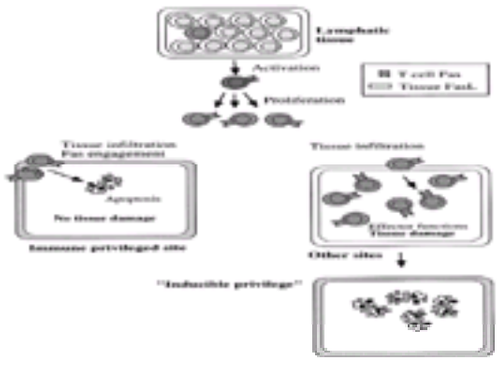

Figure 12.8. Constitutive and inducible immune privilege. Sites such as the anterior chamber of the eye have constitutive FasL and display privilege because any infiltrating cell undergoes Fas-mediated apoptosis. Other sites express FasL only if there is a strong immune response and therefore may have “inducible privilege,” limiting the numbers of activated lymphocytes and thus restricting the amount of damage the tissue sustains.

Similarly, ultraviolet (UV) irradiation of skin induces FasL expression in keratinocytes, and this causes deletion of activated lymphocytes entering the site (108). The immunosuppressive effect of UV was thus shown to be dependent on this FasL expression.

Our understanding of the role of FasL in immunologic privilege is confounded by the observation that FasL can also induce a potent granulocytosis *in vivo*. Whereas some studies have shown that FasL expression by tumors can inhibit immune responses [the “Fas counterattack” (109)], others found that enforced expression of FasL induced eradication of the tumor by neutrophils (110). Similarly, transgenic expression of FasL in pancreatic islet cells, rather than inhibiting diabetes, triggered islet cell destruction by neutrophils (100). Clearly, additional signals are required for FasL to provide tissue protection. One candidate for this second signal is transforming growth factor-b (TGF-b), which blocks the FasL-induced granulocytosis (110).

OTHER INDUCERS OF APOPTOSIS

In many cell types, DNA damage causes cell-cycle arrest and DNA repair, but in lymphocytes, the result is usually apoptosis. This is presumably an adaptation to limit mutations because, as we noted, the progeny of a single autoimmune lymphocyte can cause catastrophic damage. It also can initiate apoptosis during development, when the first antigen receptor chain (in B or T cells) rearranges, and the death process then halts on surface expression of the immature receptor and generation of survival signals (of course, this is conjecture).

The way in which DNA damage triggers apoptosis is different in different cells. Immature thymocytes require p53 to undergo this form of apoptosis (111,112), whereas mature T-cell blasts do not (113). In the latter, at least some of the death may be caused by stress-induced expression of FasL (114). It is most probable, however, that other pathways also participate. In thymocytes, DNA damage-induced apoptosis is blocked by Bcl-2 (115), and thus the mitochondrial pathway is likely to be involved. The ability of DNA damage to trigger apoptosis in cells of the immune system is important clinically (e.g., in patients undergoing radiotherapy or chemotherapy) and may explain the potent antiinflammatory effects of methotrexate, which is a potent inducer of apoptosis (116).

Cell numbers in the immune system also are controlled by hormones. One of the best-known examples is the apoptotic effect of glucocorticoids on immature T cells. Although this was one of the first models for the study of apoptosis (117), we still do not know precisely how it comes about. Bcl-2 can block this form of death, and therefore it may be mediated via the mitochondrial pathway discussed in the last part. This has not been formally demonstrated, however. Nevertheless, glucocorticoid-induced apoptosis is clearly important in a variety of scenarios, including lymphoid development, the response to stress, and in immunomodulation.

The signals triggered by glucocorticoids and those triggered by ligation of the antigen receptor leading to apoptosis in thymocytes are mutually antagonistic; if both are provided at the same time, they can cancel each other out and the cell survives (118). This idea has been integrated into a hypothesis to explain how similar signals

(engagement of the antigen receptor) can mediate cell death through negative selection and cell survival through positive selection (when the affinity for the receptor is lower than in the first case); in the latter, cell death may be countered by glucocorticoid signals. Cells that receive a strong antigen receptor signal die by AICD (negative selection), and cells that receive no antigen receptor signal die of glucocorticoid-induced apoptosis ("neglect") in this model (Fig. 12.9). Cells that receive an antigen receptor signal that is neither too weak nor too strong survive and mature (positive selection). Recent evidence has provided support for this model (119,120).

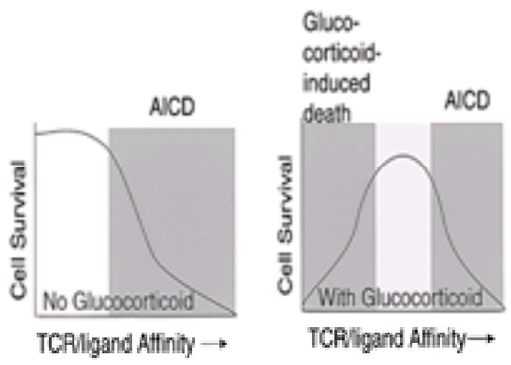

Figure 12.9. A model for positive and negative selection based on the dual inhibitory effects of the signaling pathways initiated by glucocorticoids and T-cell receptor ligation. This is based on the experiments and ideas of Ashwell and colleagues (118,119,120,121,122,123,124,125,126,127,128,129 and 130).

Impact of Apoptotic Cells on the Immune System

In addition to the various roles of apoptosis in the life and death of cells of the immune system, apoptosis has another role: Apoptotic cells are taken up by phagocytes and alter their functions.

Unlike apoptosis, necrosis induces an inflammatory response, although it remains unknown what components of a necrotic cell do this. In addition, the uptake of necrotic cells by dendritic cells can activate them to express costimulatory molecules (121). Cells that undergo secondary necrosis following apoptosis (this occurs *in vitro* when the apoptotic cells are not phagocytosed) do not stimulate dendritic cells in this way (121). Apoptosis, in contrast, was long considered "silent" with respect to inflammation and immunity. This view has undergone a number of modifications in recent years.

The uptake of apoptotic cells by macrophages or dendritic cells has a number of consequences. First, it can stimulate the production of inhibitory cytokines, such as TGFb, and prevent the production of proinflammatory cytokines, such as TNF (122,123). This has obvious benefits in situations where apoptosis occurs physiologically, but it also can have pathologic consequences. For example, trypanosomes trigger T-cell apoptosis through an unknown mechanism, and uptake of the apoptotic cells dramatically inhibits the antiparasite response by macrophages, such that the infection escalates (124). This effect could be mimicked simply by administering apoptotic cells *in vitro* or *in vivo*; the parasite gained a tremendous growth advantage through the inhibition of macrophage and other inflammatory effector mechanisms.

This antiinflammatory effect is mediated at least in part through one of the receptors for apoptotic cells on the phagocyte. Several receptors have been identified on phagocytes that play roles in the uptake of apoptotic cells: the vitronectin receptor (2), CD36 (3,4), CD14 (5), and a recently identified receptor for PS (7). The last of these is interesting for two reasons: First, many apoptotic cells externalize PS early in the apoptotic process (see section entitled The Machineries of Death); second, ligation of this receptor generates a signal that induces expression of inhibitory cytokines and inhibits production of inflammatory ones (7). Regarding the other receptors, little is known about what they recognize on apoptotic cells or how their binding might affect cellular processes.

Another effect of the uptake of apoptotic cells is the phenomenon of cross-priming. Dendritic cells can present antigens they take up via the class I major histocompatibility complex (MHC) pathway, which normally is reserved for cytosolic proteins (125). This process appears to be engaged when the antigen is taken up on or with apoptotic cells (126,127), suggesting that the phagocytic process for uptake of apoptotic cells may be different from that of other materials. Alternatively, something about the apoptotic cell may disrupt the endosome and permit access to the cytosol. Whether active caspases or other effector molecules (e.g., reactive oxygen) in the apoptotic cell are necessary for this effect is currently unknown but, if so, could provide keys to the process. The antigenic peptides present in the class I MHC molecules of dendritic cells that have engulfed apoptotic cells are now prepared to present the antigen to CD8 cells for the generation of cytotoxic effector cells. This would have obvious value in the induction of immune responses to cells infected with intracellular parasites that induce apoptosis or under conditions where innate responses trigger apoptosis in the infected cells; dendritic cells that take up the dying infected cell would now present the parasite antigens to CD8 cells.

The preceding scenario makes sense in the setting of infection but perhaps not for other situations in which apoptosis occurs, such as in normal cellular turnover. It has been suggested, though, that in such a case, the presentation of antigenic peptides (from normal self-components) would function to maintain tolerance because, in the absence of infection, there would not be costimulatory signals, such as those induced by activated CD4 cells (128).

This idea, that tolerance is maintained by cross-priming of self-antigens through dendritic cell uptake of apoptotic cells has appealing features and is consistent with some experimental evidence. For example, introduction of antigen-coupled cells into the anterior chamber of the eye induces a state of tolerance for cell-mediated immune responses (anterior chamber-associated immune deviation, ACAID), but this depends on the induction of apoptosis in the antigen-coupled cells (98), which can occur through the effects of the FasL at the site or artificially by induction of apoptosis in the cells before administration. Injection of apoptotic, antigen-coupled cells that have been phagocytosed by splenic adherent cells also induced tolerance, suggesting that the phenomenon is related to those we have been discussing. The effect also depends on the apoptotic cells expressing functional IL-10, which they do as they die, and this influences the cell that engulfs them to deviate the responses to T-helper cell (Th2) type (129). Other cells, such as keratinocytes (130), also produce IL-10 under conditions of stress that lead to apoptosis, although how this influences the immunologic effects of their engulfment is not known.

CONCLUSIONS

Apoptosis clearly has a range of roles and effects in the immune system, some of which have been discussed here. Because the effects are often dramatic (cells live or die), it is tempting to think they are the predominant ways in which the system is controlled. In some cases, I think this is true, but any system as complex as the immune system will employ many overlapping mechanisms to ensure proper function, and the control of cells by induction or prevention of apoptosis is only one of them. It is likely that we need necrotic cell death to initiate immune responses in many cases, and we need apoptotic cell death to control them. Cell death can be a healthy thing.

[1] A ligand capable of binding DR3 has been described (29) but induces apoptosis poorly. Nevertheless, DR3 can function as a death receptor; therefore, another ligand may exist.

13 ANTIBODIES AND THEIR RECEPTORS

Rafael Casellas, M.D., and Michel C. Nussenzweig, M.D., Ph.D.

ANTIBODIES

The first experiments that proved the physical existence of antibodies were performed in 1890 by von Behring and Kitasato (1), who showed that serum obtained from rabbits immunized with tetanus or diphtheria toxins could prevent disease in mice infected with such pathogens. The unknown substance present in serum that provided protection on transfer was salt-precipitated a year later by Tizzoni and Cattani and named *antitoxin* (Italian *antitossin*).

These initial observations on passive immunity soon were generalized by the work of Paul Ehrlich with plant toxins and by Jules Bordet, who demonstrated that a protective response could be generated even against whole cells (*erythrocytes*). The more inclusive term *antibody* (German *Antikörper*) thereby replaced antitoxin.

In an attempt to explain the formation of antibodies, Paul Ehrlich advanced a comprehensive theory (2), which postulated that antigens induced cell damage by binding to preexisting chemical “side chains” or receptors (antibodies) at the surface of host cells. This binding would result in a selective cell-surface depletion of those side chains specific for the antigen. To compensate for their loss, the cell would produce an excess of receptors, which then will appear in the serum as free antibodies. Although highly speculative, Ehrlich's theory was surprisingly insightful for two reasons: First, it implied that the antigen–antibody interaction would send a signal to the cell nucleus to manufacture large amounts of antibody. Second, the theory stressed the antibody's chemical nature and suggested that its specificity for antigen would be dictated by the stereochemistry of its binding site. These ideas fascinated chemists such as Arrhenius (3) and others, whose theoretical and experimental contributions established the basis of immunochemistry. This field, which dominated the first half of the twentieth century, was more concerned with the chemical nature of antigen-antibody interaction than with its biologic consequences.

The first successful attempt to identify antibody molecules was accomplished in 1939 by Tiselius and Kabat (4), who demonstrated that hyperimmunization increased the concentration of gamma globulins in serum and that this fraction contained antibody activity. Because g-globulins are large-molecular-weight proteins, it was inferred that further characterization of antibodies, now termed *immunoglobulins,* necessitated splitting them into smaller, easily handled fragments. In 1959, Porter succeeded in digesting rabbit immunoglobulin G (IgG) with limiting concentrations of the proteolytic enzyme papain. This generated two discrete fragments: a monovalent *f*ragment with *a*ntigen *b*inding activity (Fab) and a second fragment that retained the antibody's effector functions and crystallized readily into a lattice, termed Fc (5). It should be noted that the inability of the antigen specific Fab fragments to crystallize correlated with chemical heterogeneity, that is, differences in amino acid sequence, a prelude to the characterization of variable domains. Edelman and Poulik used a similar strategy, assuming that antibodies, like many other proteins, would be composed of a number of independent polypeptides held together by disulfide bounds. When methods that usually disrupt such bonds were tested, myeloma globulins were separated into two distinct chains, which, based on their sizes on starch gels, subsequently were termed *heavy* (H) and *light* (L) chains (6).

Similar studies using the protease pepsin were successful in digesting antibodies into an F(ab') fragment with bivalent antigen binding activity and several small fragments derived from the Fc portion of the molecule, the largest termed pFc' (7,8 and 9). These pioneer studies, the results of which are summarized in Fig. 13.1, were fundamental in deciphering the structure of immunoglobulins by establishing the existence of heavy and light chains and predicting that antigen-binding and antibody-effector functions were located in distinct protein domains.

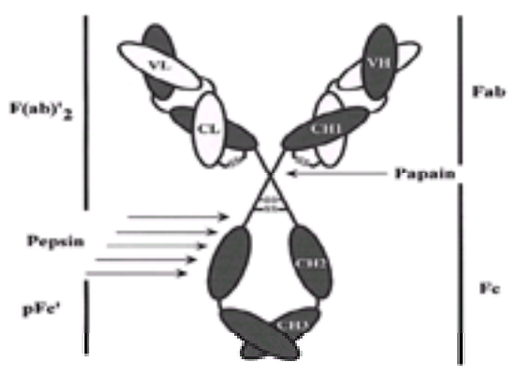

Figure 13.1. Schematic diagram of an immunoglobulin G (IgG) molecule. Immunoglobulin domains are represented as *dark ovals* for heavy chains and as *clear ovals* for light chains. *SS* indicates the interchain and intrachain disulfide bridges. Treatment of the molecule with the proteolytic enzyme papain (or trypsin) generates three fragments: a crystallizable Fc portion and two identical Fab fragments. Pepsin digestion, on the other hand, cleaves the IgG molecule below the heavy-chain interchain disulfide bonds, yielding the entire F(ab)'2 fragment and numerous smaller polypeptides from the Fc domain, the largest one being pFc'. VL and CL, variable and constant region of the light chain; VH, variable region of the heavy chain; CH1 to CH3, constant regions 1 to 3 of the heavy chain.

Sequencing studies in the 1960s subdivided light chains, and later heavy chains, into an amino terminal V (variable) region, which varied substantially in amino acid composition between different antibodies, and a C (constant) domain, whose sequence was conserved between antibodies of the same isotype (10,11). Radiographic crystallography, on the other hand, confirmed the proteolytic experiments of Porter and Edelman by showing that indeed all immunoglobulins were composed of two pairs of heavy and light chains of approximately 25 and 55 kd (12,13). The overall structure of immunoglobulins was stabilized by a series of interchain and intrachain disulfide bounds as well as strong hydrophobic interactions created at heavy- and light-chain interfaces (Fig. 13.2). Perhaps most interestingly, both chains were found to share a basic three-dimensional structure, the Ig fold (Fig. 13.2). This fold or domain consists of two antiparallel b-pleated sheets, each containing between three to four b-strands joined at their hydrophobic core by a disulfide bridge. The loops connecting the strands are not critical for generating the proper folding of the Ig domain and are therefore free to vary and contribute to the diversity required for immune responses. This assumption was sustained at the time by the comparative studies of Wu and Kabat on myeloma light-chains sequences (14). Wu and Kabat defined *variability* as the ratio between the number of different amino acids found at a given position and the frequency of the most common amino acid seen at that position (Fig. 13.3). By graphing the distribution of variability (Wu and Kabat plot) in heavy-chain V regions, three *h*yper*v*ariable domains emerged (HV1, HV2, HV3), separated by four relatively invariant or *f*ramework *r*egions (FR1, FR2, FR3, FR4). The conserved framework regions correspond to the b-strands in the Ig-folded structure, whereas the hypervariable (HV) domains constitute the loops connecting the strands. All HV loops from heavy- and light-chain V regions are brought together at the apex of the Fab fragment, generating the antigen-binding site. Because this site forms a surface complementary to the antigen, the HV regions are also known as *c*omplementarity *d*etermining *r*egions, or CDRs (15).

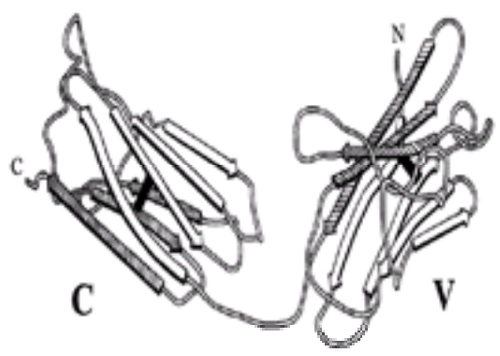

Figure 13.2. Schematic representation of the V and C domains of an immunoglobulin light chain. The b strands composing the immunoglobulin domain are represented as *arrows*. *Shading* of the arrows distinguishes between the two antiparallel b-pleated sheets, each containing three (shaded) and four (unshaded) b strands. The disulfide bridge connecting the two b sheets are depicted as *black bars*. (Adapted from Edmundson A, Ely K, Abola E, et al. Rotational allomerism and divergent evolution of domains in Ig light chains. *Biochemistry* 1975;14:3953–3961, with permission.)

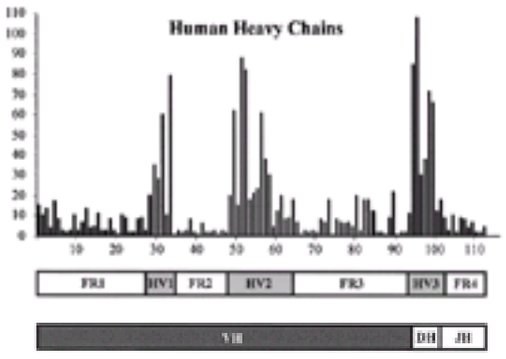

Figure 13.3. Variability plot generated by comparing human heavy-chain sequences. Y axis, degree of variability. X axis, amino acid position for the variable region of the heavy chain. From these comparisons, the framework (FR) and hypervariable (HV) domains were defined as shown. For comparative purposes, the approximate distribution of the variable (VH, *dark box*), diversity (DH, *gray box*), and joining (JH, *white box*) heavy-chain domains is aligned. Variability plot is based on Kabat EA, National Institutes of Health (U.S.) Columbia University. Sequences of proteins of immunological interest. Bethesda, MD: U.S. Department of Health and Human Services, Public Health Service, National Institutes of Health; 1991.

GENERATION OF DIVERSITY

At the time Ehrlich proposed his comprehensive theory, scientists had only immunized experimental animals with a limited number of antigens, namely toxins. The work of Obermeyer, Pick, and Landsteiner in the second decade of the twentieth century clearly established that antibodies could be elicited against a myriad of antigens, including substances that never would be found in nature, such as haptens coupled to protein carriers. These observations established the basis of a new biologic puzzle: How could an animal generate antibodies against such a variety of synthetic substances? At the time, it seemed most logical to imagine that antigens would convey the information necessary for the synthesis of the antibody molecule. The first theory based on this assumption was forged in 1930 by Haurowitz and later was refined in 1940 by Linus Pauling (16). The *instructive or template theory*, as it became known, proposed that antigens served as templates to nascent antibody molecules, which would coil around them, creating the complementarity. The idea of instruction was widely accepted by chemists and biochemists working in the antibody problem. The theory, however, failed to explain several of the more important biologic aspects of the immune response, such as the presence of long-term memory responses and the increase in antigen specificity on repeated immunizations. Perhaps more importantly, it did not explain how immunological tolerance was acquired. These objections were the basis for a new theory conceived by the ideas of Burnet and Lederberg: the clonal selection theory (17,18). This theory revisited Ehrlich's concept that antibody recognition patterns preexisted before the introduction of antigen into the animal and proposed that diversity was generated by somatic mechanisms that randomly generated the antibody specificity in individual cells. The interaction of antibody–antigen determinant at the cell surface would result in the clonal expansion of that particular cell and the secretion of immunoglobulins. In turn, tolerance would result from the deletion of self-reactive cells early in development. An important corollary of the theory was that lymphocytes were monospecific, that is, “one cell per one antibody.” This notion was tested and corroborated by Nossal and Lederberg (Nossal JV, Lederberg J. Antibody production by single cells. *Nature* 1958;181:1419–1420.) on single-cell cultures and Edelman's work establishing Bence Jones proteins, isolated from multiple myeloma patients, as immunoglobulins carrying a single specificity (Edelman GM, Gall E. The antibody problem. *Annu Rev Biochem* 1969;38:415–466). The clonal selection theory, as recognized by Burnet himself, was a darwinian answer to the more Lamarckian instructionalistic view of the antibody problem. What the novel theory did not explain were the molecular mechanisms of the selection, which remained untouched for almost two decades.

As stated, preliminary sequencing studies recognized that light chains were composed of a V domain whose amino acid sequence varied from antibody to antibody and a conserved C domain. This raised the possibility that Ig chains were the result of a fusion of two genes, as advanced by Dreyer and Bennett (19). This hypothesis, which challenged Garrod's “one gene one polypeptide” theory (20), was validated by the work of Tonegawa and co-workers (21). The study showed that a light-chain mRNA probe containing both the V and the C regions hybridized to different DNA fragments as digested with restriction enzymes and separated by electrophoresis. Shortly after, RNA–DNA R-loop (22,23) and sequencing experiments (24) not only confirmed that V and C regions were coded by different genes but also defined a new set of genes, the *J segments*. These data shed light for the first time into the mechanism of diversity by proving that a given V gene segment was joined to a J segment through a recombination process, later termed *V(D)J recombination.* A meticulous comparison between the k J region DNA with known antibody protein sequences revealed more variability at the junction point between the V and J segments (25). This new diversity, called *junctional,* predicted that, in addition to successful rearrangements, “forbidden” or out-of-frame recombinations would occur as well.

Heavy-chain assembly turned out to be more complicated because three independent gene segments are involved: VH, D, and JH of approximately 98, 3-7, and 12-17 amino acids, respectively. The VH segment encodes a leader peptide sequence and both the CDR1 and CDR2 regions. The CDR3 is encoded by the D segment and the VH-D and D-JH junctions (Fig. 13.3). The remainder of the J segment encodes the last framework region. Conversely, the light chain is encoded by two gene components: VL, which comprises all CDRs, and the JL segment. Despite variations in their number and organization, these segments are arranged in clusters along the same chromosome in nearly all species that were studied (26).

At the heavy-chain locus, V(D)J recombination initiates random D to JH joining, followed by VH to DJH rearrangements (27). The V(D)J recombinase complex recognizes recombination signal sequences (RSSs) flanking the gene segments involved (26,28). RSSs are composed of a palindromic conserved heptamer, CACAGTG, followed by the nonamer ACAAAAACC. These elements are separated by a nonconserved spacer of either 12 ± 1 or 22 ± 1 base pairs (bp) (27), which constitute one and two complete turns of the DNA helix, presumably allowing the DNA groove of both RSSs to be aligned during the recombination process (29). In fact, recombination will occur only rarely between gene segments flanked by like spacers, a phenomenon known as the *12-23 rule* (30). This “rule” precludes aberrant recombination events, such as VH to JH, from happening (24,31).

Depending on the alignment of the gene segments on the chromosome, V(D)J recombination can occur by two mechanisms: inversions and deletions (32,33) (Fig. 13.4). When the recognition sequences are facing each other, recombination proceeds by deletion of the intervening DNA as circles containing the fused heptamers. Inversions occur when the RSSs are oriented in the same orientation. In these reactions, the heptamers and nonamers are retained in the chromosome, and no DNA is lost. It has been estimated that about 40% of Vk-genes are in opposite orientation with respect to the Jk-segments (34).

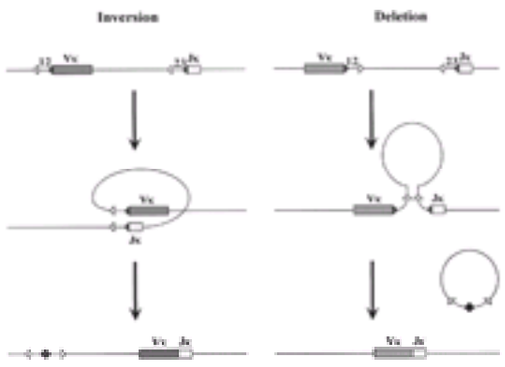

Figure 13.4. Inversional and deletional recombination of the k locus. Inversions occur when the recombination signal sequences (RSSs) of the Vk and Jk genes are in the same orientation in the chromosome (*open triangles*: nonamers; *closed triangles*, heptamers; 12 and 23, DNA spacers). When the recognition sequences are facing each other (approximately 40% of the time), the recombination proceeds by deletion of the DNA intervening sequences as circles.

Secondary recombinations at the Vk-chain gene recombination revealed that most primary rearrangements occur by inversions followed by secondary deletions (38). At the VH locus, the elimination of all 12-bp spaced signal sequences by any VDJ rearrangement would, in principle, hinder further recombination. Nevertheless, 70% of all VH genes harbor at their 3'-ends a sequence similar to the consensus heptamer. Such sequences have been reported to engage in secondary recombinations with the expressed VHDJH gene (39,40 and 41), but the extent of these events *in vivo* is unknown.

RAG PROTEINS

To isolate the genes involved in Ig recombination, Schatz and Baltimore relied on the fact that only immature lymphoid cell lines carried out V(D)J gene assembly (42); however, on transfection of human or mouse genomic DNA, 3T3 fibroblasts displayed V(D)J recombinase activity (42). The cloning and sequencing of the locus responsible for such an activity revealed the presence of two genes, with no apparent sequence similarity: RAG-1 and RAG-2 (43,44). These genes are separated in the mouse genome by only 8 kb and are aligned in opposite transcriptional orientation with respect to each other. The linked genomic organization, conserved in all vertebrates so far analyzed, and the lack of sequence resemblance between RAG-1 and RAG-2, prompted speculation that these genes arose as part of a fungal, or viral recombination system (44). Later studies, in fact, demonstrated a portion of the RAG-1 protein to be related to the homeodomain of the *Salmonella typhimurium* Hin invertase, which also recognizes a nonamer-like sequence in the genome (45).

V(D)J recombination also was linked to transposition based on the similarity between RSS sequences and the inverted repeats found at the end of transposons (46). This relationship was reinforced by mechanistic similarities shared by both reactions (47,48) and the similarities between the disintegration reaction carried out by the human immunodeficiency virus (HIV) integrase and the generation of hybrids and open-and-shut joints catalyzed by the RAG proteins (49,50). *In vitro* studies found RAG-mediated insertions of cleaved RSSs into new DNA by a mechanism akin to retroviral integration (51,52). Finally, the coordinate transcriptional regulation of RAG genes suggests that the original integration of the primordial transposon most probably occurred at a site near a transcriptional element that captured these proteins for the evolving immune system (53).

V(D)J RECOMBINATION

Much of what is known with regard to the molecular details of Ig gene recombination has been inferred from cell-free *in vitro* assays. The current model of V(D)J recombination derived from such studies describes first the recognition and cleavage of the heptamers signal sequences mediated by RAG1 and RAG2 proteins (43,44,54) (Fig. 13.5). The stereochemistry of this reaction shows that RAG proteins generate first a nick at the 5'-end of the heptamer. The 3'-hydroxyl group created by the nick then attacks the phosphodiester bond at the end of the 7-mer of the bottom strand (*transesterification*). This reaction creates a DNA hairpin at the coding end and a blunt end at the signal end (48). Although RAG proteins can cleave DNA alone *in vitro*, other factors, such as the high mobility group (HMG) proteins, have been shown to enhance the reaction (55,56).

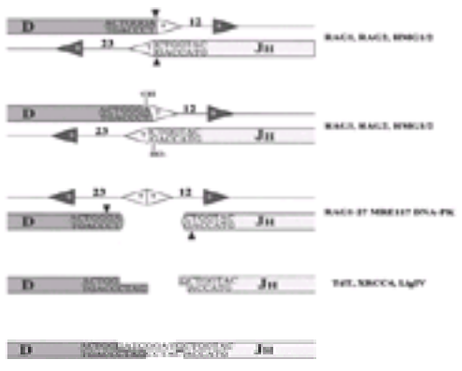

Figure 13.5. Proposed model for V(D)J recombination. **A**: Nicking. The RAG1 and RAG2 proteins recognize and bind to the recombination signal sequences (7, heptamer; 9, nonamer; 12 and 23, DNA spacers). RAG1 and 2 then cleave the recombination signal sequences (RSSs) at the 5'-end of the heptamer. **B**: Transesterification. The 3' nucleophilic OH group created by the nick (bases A and G) attacks the phosphodiester bond at the end of the 7-mer of the bottom strand (bases T and C), generating hairpins at the coding ends and blunt ends at the signal ends. **C**: Signal and coding end processing. DNA-PKcs, Ku70, and Ku80 form a protein complex around the DNA ends generated by the transesterification reaction. Signal ends are joined bluntly; the hairpins formed at the coding ends are opened by either RAG1 and RAG2 or the Mre11/RAD50/Nbs1 complex. **D** and **E**: N and P nucleotide additions. The terminal deoxynucleotide transferase (TdT) catalyzes the addition of nontemplate-dependent nucleotides (N nucleotides) at the opened hairpin ends. XRCC4, Ligase IV, and probably a polymerase seal the DNA gaps.

Hairpin intermediates were first characterized in severe combined immunodeficiency disease (SCID) mice, which accumulate such unprocessed ends due to a deficiency in the catalytic subunit of the DNA-dependent protein kinase (DNA-PKcs) (57). This kinase, in association with two other factors, Ku70 and Ku80, form a protein complex not only required for V(D)J recombination (57,58 and 59) but also for repair of ionizing radiation (IR)-induced DNA damage (60). Ku70 and Ku80 bind as a heterodimer with high affinity to DNA ends (61). This binding has been suggested to protect the ends from nucleolytic degradation (62) and physically to juxtapose them for further processing, as revealed by scanning force microscopy (63,64 and 65). The Ku-DNA interaction is also believed to recruit the catalytic subunit DNA-PKcs to the DNA ends and enhance its kinase activity (66). From these observations, it can be concluded that the accumulation of coding ends in SCID mice would result from failure of DNA-PKcs to phosphorylate and activate the hairpin endonuclease. Hairpin opening was shown to be carried out by the RAG1 and RAG2 proteins (67,68), although another report evoked the concerted action of the nonhomologous end-joining factors Mre11, RAD50, and Nbs1 as possible candidates (69).

The opening of hairpins at asymmetric positions is believed to generate *p*alindromic repeats at some coding joints (P nucleotides) (70) (Fig. 13.5C). Another enzyme, terminal deoxynucleotide transferase (TdT), catalyzes the addition of nontemplate-dependent nucleotides (N nucleotides) (71) to the open DNA ends. N-nucleotide additions are commonly found at the heavy chain but are rarely seen in light-chain genes, perhaps as a results of transcriptional downregulation of the TdT gene by the µ-surrogate light-chain complex on the surface of preB cells (72). The addition of P and N nucleotides, as well as the deletions created by the imprecise joining reaction, generate junctional diversity.

The final step of V(D)J recombination involves the joining of the processed DNA ends. This step is mediated by two genes, the gene mutated in the radiographic complementation group 4 (XRCC4) (73), a ubiquitously expressed factor also essential to repair DNA double-stranded breaks caused by ionizing radiation, and ligase IV (74,75). *In vitro* studies demonstrated that the XRCC4 protein interacts with and is phosphorylated by DNA-PKcs (76). XRCC4 also binds and activates another member of the V(D)J recombination machinery, DNA ligase IV, which seals the last DNA gap (74,75). *In vivo* data supporting this hypothesis come from ligase IV-deficient mice, in which lymphopoesis is blocked at the V(D)J joining step (77).

Combinatorial Diversity

Shortly after V and J gene segments were discovered, Weigert's group performed a detailed analysis of Vl21 protein sequences and proposed that antibody variability could be explained in part by combinatorial diversity, that is, the random associations of V, D, and J DNA segments (78). Assuming no bias in the combination process, the maximal collection of antibody specificities possible would be equal to the product of the number of V, D, and J genes present in each of the Ig loci. Translating this assertion to the recently characterized mouse Vk locus (79) results in 100 (functional Vs) × 4 (functional Js) = 400 potential Vk genes generated.

Junctional Diversity

Because of the nature of V(D)J recombination, the point at which V and J segments are joined can vary over a range of several nucleotides. As a result, codon 96 of the light chain becomes the most variable position of the molecule, as comparative studies of light chain sequences reveal (14,25). Theoretically, in every V-J combination event, four different amino acids can be placed at position 96, which in turn would result in 1,600 potentially different Vk genes (400 × 4). For the heavy-chain locus, junctional diversity operates both at the level of V-D and D-J joints, increasing diversity by a factor of 16 (4 × 4). As noted, heavy-chain junctions also are diversified by the addition of N nucleotides by the TdT enzyme. Equally important, the random opening of hairpin intermediates generates palindromic (P) nucleotides in the process. Because of the extent of junctional diversity, antibodies show the greatest diversity at the CDR3 (Fig. 13.3), the portion of the Ig molecule that contributes the most to the antigen binding pocket.

Somatic Hypermutation

Burnet conceived the clonal selection theory to a great extent by extrapolating the darwinian concepts he acquired while working on bacterial genetics. He imagined lymphocyte populations undergoing constant physiologic and mutational changes. Much as antibiotics select resistant bacterial strains, antigenic determinants would induce lymphocytes with which they can interact to proliferate and secrete immunoglobulins. Above all, Burnet's theory suggested that subclones would constantly arise as a result of somatic mutation “in that region of the genome concerned with immunologically significant pattern” (17). The first direct evidence for somatic diversification of antibody variable regions came from a comparison of k1 protein sequences to the number of Vk1 genes (80). The study showed that of 19 k1 protein sequences analyzed, 12 were identical and seven differed in two to three amino acids. The interpretation was that there existed only one k1 gene in the genome and that the substitutions had arisen, as predicted by Burnet, by somatic mutational events. The idea became unambiguously validated by sequencing of the k1 genomic locus (81).

The mechanism of somatic hypermutation, which is confined to germinal center B cells, randomly introduces mutations downstream of the VH and VL promoters modifying the affinity or specificity of the antigen-binding sites of the Ig. Those B cells expressing higher affinity for antigen are selected for further expansion and differentiation. B cells that have lost the affinity for the antigen in question or those that react to self-antigens (change in specificity) are eliminated through apoptosis. A role for transcription, or at least for accessibility, has been demonstrated by several reports (82,83 and 84). Somatic mutation is not completely Ig gene specific because the Bcl6 oncogene has been found mutated in GC B cells (85,86).

IMMUNOGLOBULIN CONSTANT REGIONS AND CLASS SWITCHING

The existence of different isotypes was first hinted by the work of Bauer and Stavisky, who discovered that after immunization, antigen-specific antibodies appeared first with a sedimentation coefficient of 19S, followed within several days by the additional synthesis of a 7S form (87). The results demonstrated that distinct-molecular-weight antibodies were generated during an immune response. The favored interpretation at the time was that different plasma cells synthesized the 19S or the 7S immunoglobulins, and the idea that a single cell could “switch” from one isotype to another was proposed by Nossal in 1964 (88). Nossal isolated single antibody producing cells at different time points after immunization and characterized the antibodies they produced. In the first 5 days after antigen challenge, all plasma cells isolated produced the heavy 19S antibody form (IgM). At day 7 and later, only 7S (IgG)-containing cells could be found. At days 6 and 7, however, single cells were isolated, producing both IgM and IgG. That this switching was the result of another recombination event was first suggested by the demonstration that IgG1 cells shared the same variable domain with their IgM predecessors (89). The finding by Honjo and Kataoka that specific CH genes were deleted in mouse myeloma cells and that deletion accompanied class switching unequivocally validated the recombination theory (90).

Heavy-chain constant regions exist in five classes: mu (μ), delta (d), gamma (g), epsilon (e), and alpha (a). Accordingly, individual immunoglobulins are named based on their constant region isotype: IgM, IgD, IgG, IgE, and IgA. In the mouse, CH genes span a region of approximately 200 kb in chromosome 12 (91) and are organized from 5' to 3' in the order μ, d, g3, g1, g2b, g2a, e, and a. The human CH locus is located in chromosome 14q32 and is composed of two copies of the g-g-e-a unit (92). Contrary to the light-chain k and l constant regions, the CH proteins are functionally divergent as to their ability to dimerize, interact with different Fc receptors, activate the complement cascade, or cross the placenta (see later).

Isotype switching can be induced *in vivo* or in cell culture on activation with a variety of mitogens and cytokines. For example, culturing mouse B cells in the presence of lipopolysaccharide (LPS) and interleukin 4 (IL-4) induces switching from IgM to IgG1 and IgE. In the absence of IL4, however, LPS activates recombination to IgG3 and IgG2b. *In vivo* studies indicate that switching is not a random process. In the mouse, immunization with soluble antigens generates IgG1 responses, whereas carbohydrate antigens stimulate switching to IgG3. Viruses, on the other hand, induce IgG2a responses in mice and IgG3 and IgG1 production in humans. In summary, the environmental stimuli elicited by an immune response appear to target switching to particular isotypes. Switch factors include IL4, IL5, IL10, interferon g (INF-g), transforming growth factor-b (TGF-b), LPS, and CD40 ligand.

Class-switch recombination occurs between highly repetitive DNA sequences, known as *switch (S) regions* (93), located 5' of each constant region gene, with the sole exception of Cd, which is cotranscribed with Cμ, and requires mRNA differential splicing for its expression. Although all S regions are composed primarily of the nucleotides repeats GAGCT and TGGGG, the exact sequence composition and length vary among CH genes. Unlike V(D)J recombination, isotype switching occurs anywhere within or near these S regions, with no apparent regard to the sequence specificity of the site of recombination (94,95 and 96).

As explained, switching results in deletion of chromosomal DNA located between the two S regions engaged in the recombination process (97) (Fig. 13.6). The direct visualization of circular DNA products generated during switching and V(D)J recombination provided clear evidence that both these mechanisms occurred through the formation and excision of a DNA loop (98,99 and 100). Both of these lymphocyte-specific recombination events are associated with loci that are transcriptionally active before recombination (101,102). This observation led to the hypothesis that transcription may render the chromatin accessible to the DNA-binding proteins involved in the recombination. This hypothesis, known as the *accessibility model*, proposes that cytokines target switch recombination by inducing transcription of specific heavy-chain constant regions. Recent work suggested that proper splicing of switch transcripts and not transcription *per se* is required for recombination to occur (103,104).

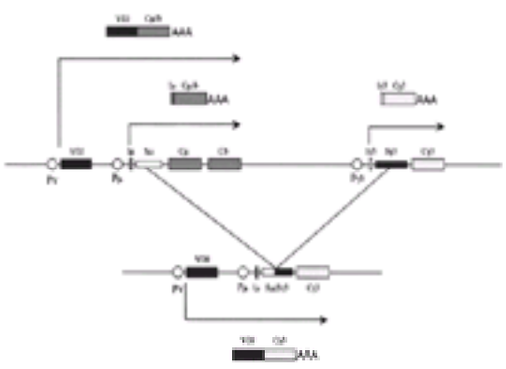

Figure 13.6. Class switching to g3. Before switch recombination, cytokines and B-cell activators specifically target the genes involved in the reaction (μ and g3) by initiating germline transcription from promoters (Pμ and Pg3) upstream of the respective CH genes. The I exons are spliced to the C exons, deleting the switch regions (S) from the germline transcripts. On switching, the intervening DNA is deleted from the chromosome, bringing the Cg3 into proximity to the VDJ gene so that the mature transcript initiated from the V promoter (PV) now contains the Cg3 domain.

Although the identity of the alleged class switch recombinase remains unknown, recent experiments indicated that some of the components known to participate in both V(D)J recombination and DNA double-stranded break repair (DNA DSB), such as DNA-PKcs, Ku70, and Ku80 are also directly involved in isotype switching (105,106

and 107).

BIOLOGY OF IMMUNOGLOBULIN ISOTYPES

Immunoglobulin M is the first antibody produced by plasma cells in primary immune responses and is expressed either in a membrane-bound form or as a secreted hexamer or more commonly as a pentamer. At the cell surface, IgM (as well as the rest of the isotypes) forms the B-cell receptor (BCR) composed of the Ig molecule noncovalently associated with two pairs of cytoplasmic subunits: Iga and Igb. These molecules have conserved amino acid sequences known as *immune receptor tyrosine activation motifs* (ITAMs), which interact with cytoplasmic tyrosine kinases transducing antigen–antibody signals downstream.

In its polymeric secreted form, IgM displays an increased avidity for antigen compared with the IgM monomer. Because primary immune responses proceed in the almost complete absence of affinity maturation, this increase in avidity would compensate for the overall lack of affinity for the antigen. Furthermore, IgM disposes of foreign particles by recruiting the classic complement pathway, leading to macrophage activation and phagocytosis of antibody–antigen complexes. This activation is initiated by the association of IgMs Cμ1 and Cμ3 domains with the complement components C3b and C1q (108).

Immunoglobulin D is expressed at high concentrations in the surface of mature B cells, but it is secreted only at extremely low levels and is present in serum at one order of magnitude lower than the other isotypes, with the exception of IgE. Although $IgD^{+}IgM^{-}$ germinal center and memory B cells exist in humans (109), IgD is most often seen coexpressed with IgM, and the function of the IgD only cells is not known. Coexpression is the direct result of the VDJ, Cμ, and Cd units being present in the same primary transcript. Alternative splicing ultimately dictates the isotype being translated. Despite the fact that the cytoplasmic levels of VDJ-Cμ mRNAs are consistently higher than those of VDJ-Cd, the mean IgD surface expression exceeds that of IgM by tenfold on mature B cells. Despite these differences between IgM and IgD, there is no known unique role for IgD in B cell development (110,111).

The four IgG subclasses constitute the most abundant Ig isotypes in serum and body fluids. Two of the most important functions of IgG molecules are activation of the classic complement cascade, which in turn leads to the destruction of antigens and pathogens. Likewise, IgGs exert their effector functions by interacting with Fcg receptors present in a variety of cell types. These interactions result in functional effects that range from modulation of the transducing signals generated by B-cell receptor cross linking, induction of phagocytosis in macrophages, or antibody-mediated cytotoxicity in mononuclear cells (112). Another fundamental role of IgGs is in protecting the fetus and newborn against infection. Before birth, IgGs are the only antibody isotypes capable of crossing the placenta. After birth, maternal IgGs found in milk are transported to the bloodstream of newborns via the neonatal Fc receptor (FcRn) expressed in the gut. It appears that FcRn binds IgG at the slightly acidic pH of milk in the proximal intestine and delivers it at the almost neutral pH of blood (113). The FcRN structurally resembles the major histocompatibility complex (MHC) class I molecules. Remarkably, the FcRn molecule, as their MHC counterparts, interacts with b_2 microglobulin and mice rendered deficient for this last molecule can not internalize maternal IgGs (114).

Immunoglobulin E antibodies are present in serum at the lowest concentration when compared with the other isotypes. This antibody class is unable to activate complement or opsonize antigen. Antigen recognition by IgE molecules bound to its high affinity receptor FceRI, expressed both in basophils and mast cells, leads to exocytosis of potent inflammatory mediators such as histamine and serotonin (115,116). This immune response, also known as *immediate hypersensitivity*, functions prevalently in the clearance of parasitic infections, although it often leads to anaphylaxis and allergic responses to innocuous molecules in predisposed persons.

Immunoglobulin A is the most abundant immunoglobulin in all body surfaces, with the exception of the skin, hence playing a key neutralizing role in mucosal immunity. In fact, IgA is synthesized at the amazing rate of 65 mg per kilogram daily, nearly twice as much as all other isotypes combined. In humans, IgA exists in two subclasses: IgA1, which is mostly found in serum as a monomer, and IgA2, secreted as a polymer by plasma cells found in the digestive, urogenital, respiratory, and mammary tissues. Once secreted, IgA is competent to cross the epithelial barriers by interacting with the poly-Ig receptor, also known as the *secretory component*. Oligosaccharides located at the a chain of IgA molecules prevent pathogens from adhering to mucosal epithelial cells, which would inevitably result in infection (117), although IgA-deficient mice do not appear more susceptible to mucosal viral infections than wild-type litter mates (118). Finally, IgA opsonizes antigens and pathogens, leading to their destruction via the FcaR found on polymorphonuclear leukocytes.

OTHER MEMBERS OF THE IMMUNOGLOBULIN SUPERFAMILY

The Ig domain first characterized in antibodies was later recognized in a variety of molecules with cell adhesion or molecular recognition functions. Remarkably, to date, more than 100 members of the “immunoglobulin superfamily” have been identified in species as diverse as *Saccharomyces cerevisiae*, *Caenorhabditis elegans*, zebrafish, and humans (119). Many of these members are grouped in multigene families such as VL, VH, MHCI, MHCII, TCRs, CAM, and FcRs.

Fc Receptors

Cells of the immune system “see” antigens through BCRs, T-cell receptors (TCRs), and Fc receptors. The last of these do so indirectly because they associate with the Fc portion of antibodies before eliciting effector functions. There are three groups of Fc receptors. The first group resembles TCRs and BCRs in that the ligand-binding component of the receptor is noncovalently associated with accessory proteins that signal through ITAMs (120). This group includes FceRI, FcaR, FcgRI, and FcgRIIIA. A second type of Fc receptor, typified by FcgRII, does not couple with ITAM-containing subunits but is instead a single-chain receptor possessing inhibitory motifs (ITIMs), which counteract the activity of the ITAM receptors (121). A third class of Fc receptors includes those that do not trigger or inhibit cell activation. As discussed, these receptors are implicated in transcytosis of antibodies through epithelia, such as the pIgR, specific for IgM and IgA, and the neonatal FcRn, which transports IgGs. Finally, Fc receptors exist as membrane-bound and soluble forms, the latter being the result of alternative RNA splicing or proteolysis of membrane forms (122). To date, the raison d'être of soluble Fc receptors is unknown.

The first FcR characterized was the high-affinity IgE receptor, which was identified shortly after the discovery of the IgE molecule (123). This receptor is expressed at relatively high levels in mast cells and basophils and at lower concentrations in human Langerhans cells, monocytes, eosinophils, and peripheral blood dendritic cells. The FceRI is composed of a ligand-binding a chain, which contains two Ig domains, a b chain, and two identical g chains, that are covalently linked by a disulfide bridge (Fig. 13.7). Both the b and g have ITAMs, which allow them to interact and activate downstream effectors such as the lyn and syk kinases (124). The g homodimer subunit was found not only to be structurally related to the TCR-associated molecule CD3z , but the former can be functionally substituted by the latter in transfected CV-I origin SV-40-7 (COS-7) cells (125). Most of the IgE released by plasma cells is thought to associate quickly and stably ($kd = 10^{-10}$ M) through its Ce2 and Ce3 domains to the FcaRI a-chain of basophils and mast cells (126). The binding of multivalent antigens to these IgE molecules induces aggregation of the FceRI molecules as well. Once activated, these granulocytes release histamine, serotonin, and other potent inflammatory mediators, such as prostaglandins, leukotrienes, and selected cytokines. A second IgE receptor, the FceRII or CD23, interacts with IgE molecules, but with lower affinity ($Ka = 10^{8}\ M^{-1}$) compared with FceRI ($10^{10}\ M^{-1}$) (127). This receptor, composed of a single transmembrane segment, lacks Ig domains and belongs instead to the calcium-dependent lectin family of receptors (128).

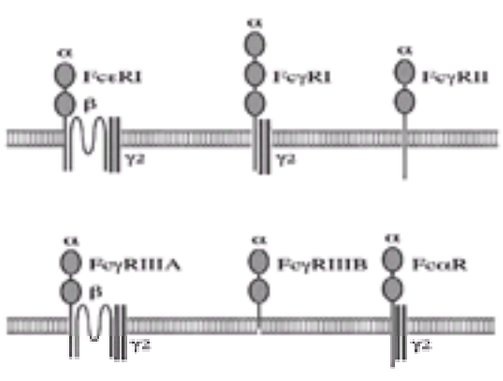

Figure 13.7. Fc receptors of the immunoglobulin (Ig) superfamily. The Ig domains of the a chains are depicted as *ovals* and associate with the Fc domains of antibodies in the extracellular milieu. b chains traverse the cytoplasmic membrane four times, and in conjunction with the g chains, they initiate intracellular signals through their immune receptor typrosine activation motifs.

FcgRI is expressed constitutively in macrophages and monocytes, and its expression can be induced in neutrophils upon IFN-g exposure (129). Activation through FcgRI is believed to stimulate phagocytosis and antibody-dependent cell-mediated cytotoxicity (ADCC) on these cells. FcgRI is able to bind all IgG subclasses, although it does so with much higher affinity to IgG1 and IgG3.

The inhibitory receptor FcgRII exists in at least six different spliced forms, some of which are secreted extracellularly. Its pattern of expression includes all hematopoietic cells, with the exception of natural killer (NK) cells and red blood cells. This single a-chain receptor functions as a negative regulator of ITAM-mediated signals and nullifies cell activation when coligated with stimulatory receptors (121). The inhibitory action of FcgRIIB (the only inhibitory version expressed in B cells) was first suggested by the observation that anti-µ F(ab') antibody fragments induced B cells to proliferate in culture, whereas whole IgG antibodies did not (130). Cross linking the BCR induces tyrosine phosphorylation of a variety of proteins and depletion of Ca^{2+} from intracellular stores and subsequently Ca^{2+} influx from the extracellular milieu. One of the early targets of the BCR, the lyn kinase, activates the FcgRIIB by phosphorylating Tyr-309 from its ITIM domain, leading to the recruitment and phosphorylation of the SH-2 domain phosphoinositol phosphatase SHIP (131,132). Once activated, SHIP partially abrogates BCR signaling by selectively blocking Ca^{2+} influx without interfering with intracellular Ca^{2+} mobilization (133). FcgRIIB-deficient mice exhibit three to ten times higher antibody titers than normal mice on T-cell-dependent and -independent immunizations (134), which shows that in B cells, FcgRIIB functions as a downmodulator of antibody production. Additionally, these mice are hyperresponsive to IgG- and IgE-mediated anaphylaxis as well as to collagen-induced arthritis and immune complex-induced alveolitis (134), suggesting that FcgRIIB normally sets thresholds to FcgRIII and FceRI (135,136).

The FcgRIII receptor is synthesized in two different forms: FcgRIIIA and FcgRIIIB. The former is expressed in monocytes, macrophages, and NK cells; the latter appears to be solely present in neutrophils. Analogous to the FceRI, the FcgRIIIA is a transmembrane glycoprotein that associates with the b and g2 signaling molecules. The FcgRIIIB, on the other hand, is anchored to the cytoplasmic membrane through a glycophosphoinositol linkage, hence lacking signaling activity (Fig. 13.7). Persons who have defective FcgRIIIB form suffer from a condition know as *paroxysmal nocturnal* hemoglobinuria, characterized by susceptibility to infections and delayed clearance of immune complexes (137,138). The physiologic role of FcgRIII receptors includes induction of superoxide synthesis, ADCC, and phagocytosis.

The most recently discovered and perhaps least characterized of the Fc receptors is FcaR (CD89). It is expressed in a variety of polymorphonuclear leukocytes, especially those found in mucosal areas, where IgA is the predominant isotype. Structurally, the Fca receptor, much like the FcgRs and FceRI, consists of an a chain associated with the FcRg-signaling homodimer (Fig. 13.7). Signals from this receptor result in phagocytosis and elimination of IgA-opsonized particles such as viruses and bacteria; thus, this receptor is thought to play a significant role in mucosal immunity (139).

14 BIOLOGY OF B CELLS

Norman R. Klinman, M.D., Ph.D.

B cells can be defined as the population of lymphoid cells that, when antigenically stimulated, generates clones of antibody forming cells (AFC). It is through the production of antibodies that B cells function to protect the body against viruses, bacteria, parasites, and toxins. Adult mice have 2 to 4 x 10^8 B cells and adult humans have 10^{11}-10^{12} B cells distributed throughout the body. B cells are numerous not only in the spleen and bone marrow but are also present in lymph nodes, Peyer's patches, gut and bronchial associated lymphoid tissues, the peritoneal cavity, and throughout the lymphatic and circulatory systems. Within the spleen and lymph nodes, B cells distribute in and around the follicular areas. Structures within the lymphoid follicles known as germinal centers (GC) appear to be the major site of memory B cell generation and are highly enriched for B cells following immunization (see Chapter 2).

B cells express numerous cell surface antigens, some of which are known to function as adhesion molecules or as receptors for interleukins, hormones, mitogens, complement components, or immunglobulins while other cell surface antigens have been identified as essential for interactions with T cells (see Chapter 8 and Chapter 9). The cell surface antigens that are most characteristic of B cells are class II major histocompatibility (MHC) antigens, which function in the presentation of antigens to helper T cells (T) thus facilitating T cell–B cell collaborations (see Chapter 3 and Chapter 6), and immunoglobulin (sIg) which serves as the B cell's specific antigen receptor. By virtue of the efficiency of sIg in binding and concentrating antigens and the ability of B cells to process and present peptides of internalized antigens in a complex with class II MHC molecules, B cells subserve a second major function in the activation or inactivation of T cells.

CLONAL SELECTION AND B-CELL RESPONSES

The hallmarks of the humoral immune response are the enormous diversity of antibody specificities, the absence of reactivity to self-antigens (tolerance), the ability to selectively induce the production of antibodies that specifically recognize an immunizing antigen, and the capacity to mount an even more vigorous response to that antigen upon subsequent contact (immunologic memory). In order to account for these phenomenon, Burnet proposed in his “Clonal Selection Theory” that the specificity of humoral immune responses was a consequence of “the existence of multiple clones of immunoglobulin-producing cells each responsible for one genetically determined type of antibody” (1). He further posited that antigen would stimulate cells by interacting with an antibody representative of that cell's potential secreted antibody product expressed “on the surface of the cell which produced it.” This would ensure that a vast repertoire of antibody specificities would be clonally distributed among the population of B cells enabling antigen to either selectively stimulate or selectively inactivate specificities individually.

During subsequent years, most of Burnet's postulates have been validated and the underlying molecular mechanisms have been defined. By the early 1970s experiments had been conducted demonstrating that B cells bore cell surface immunoglobulins (2,3), that these immunoglobulins reflected both the specificity (4,5) and variable region antigenic determinants (idiotypes) of the cell's potential secreted antibody product (6), and that B cells and their clonal progeny were committed to the production of antibodies with a single variable region (clonotype) (7,8). This was consistent with earlier findings that neoplastically transformed B cells (myelomas) produced homogeneous immunoglobulins (9,10) and later successful efforts to obtain homogeneous antibodies by the fusion of B cells to myeloma cells (hybridomas) (11). The extensive heterogeneity of serum antibodies, therefore, reflected the participation in immune responses of numerous antibody forming cell (AFC) clones each producing a homogeneous antibody product (7). Since the early 1970s the molecular mechanisms responsible for generation of a vast array of heavy and light chain variable regions (12,13,14 and 15) and the expression of one antibody clonotype per cell (allelic exclusion) (16,17,18 and 19) have been defined (see Chapter 13).

Because an adult mouse has more than 2 x 10^8 B cells, each expressing a single clonotype, and any clonotype would infrequently be expressed by more than one B cell (20), the B-cell repertoire of a mouse exceeds 10^8 clonotypes (5,20,21,22 and 23). Thus, during the course of an immune response, antigen should have access to B cells expressing a diverse array of clonotypes. Most microorganisms present a spectrum of antigens, each of which is likely to display several constellations of amino acids or carbohydrates that could be recognized by B cell sIg receptors as distinct antigenic determinants. Furthermore, most individual antigenic determinants interact with sufficient affinity with sIg receptors of B cells of numerous clonotypes to enable stimulation to AFC formation. Therefore, foreign agents confronted by the immune system generally stimulate hundreds to thousands of B cells with distinct antibody clonotypes (5,21,22 and 23). The diverse array of antibody molecules produced by these B cells would comprise the humoral immune response to that particular immunogen and these antibodies would have in common the fact that they all can bind that immunogen.

The antigen combining sites of most antibodies are capable of accommodating a spectrum of antigenic determinants, including those that mimic the structure of the immunizing determinant as well as some that may be dissimilar but bind fortuitously to an alternate orientation of the combining site (24). Therefore, among antibodies within the response to a given antigen, some bind other antigenic determinants (cross react). However, because the entire population of antibodies binds with high affinity to the immunizing antigen, and only a few cross react with any other antigen, antibody responses as a whole are highly specific for the immunizing antigen and almost unlimited, at the population level, in their capacity to discriminate among antigens.

B-CELL DEVELOPMENT AND REPERTOIRE SELECTION

In mice functional B cells are first observed in the liver toward the end of the second trimester of fetal development (25). The liver remains a source of B cells throughout fetal development, but during the third trimester the fetal spleen becomes a source of B cells and remains so for several days after birth. After birth B-cell development is initiated in the bone marrow; and after the first week of neonatal life and throughout adulthood the marrow of large bones remains the major source of B cells in mice and humans (26). In adult mice approximately 5 x 10^7 B cells are generated from the marrow per day, which is sufficient to replace 15 to 25 percent of total mature B cells on a daily basis (26). However, the half-lives of B cells vary considerably, such that most newly generated B cells live for only a few days, whereas others may live for several weeks or months (27,28). Figure 14.1 depicts a scheme that correlates the molecular events that accompany B cell development in adult bone marrow with clonal differentiation and expansion. Multipotential stem cells, as defined by their capacity to generate all myeloid, erythroid, and lymphoid elements, have been isolated as fewer than 0.1 percent of bone marrow cells of mice and humans (29). Such cells can give rise to B cells, but it is not yet certain whether B cells routinely generate from such multipotential stem cells or alternatively from a more differentiated but still self-renewing stem cell population. The earliest detectable event in the commitment of bone marrow cells to the B cell lineage is the expression of various B lineage specific markers, including cell surface B220, the pre-B cell specific proteins V pre-B and l5, which together appear to constitute a light chainlike structure (surrogate light chain) (30,31 and 32), and Iga and Igb, which serve as part of the receptor complex on pre-B cells and B cells (see Chapter 13) (33,34 and 35). Additionally, enzymes such as terminal deoxynucleotide transferase (TdT), RAG1, and RAG2, which participate in V gene segment rearrangement, are expressed (36,37).

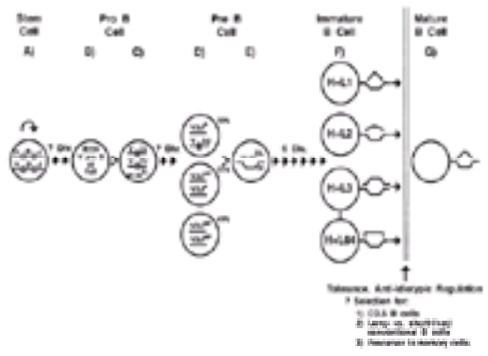

Figure 14.1. Precursors of B cells pass through several definable states during their development in the adult bone marrow: **A**: Multipotential stem cells self-renew (↷) and have the capacity to reconstitute all myeloid, erythroid, and lymphoid cells. **B**: Pro-B cells begin to express B lineage specific antigens, the enzymes necessary for Ig gene segment recombination, and V preB and l5 which together can comprise a surrogate L chain (SL) and co-receptors Iga and Igb. **C**: Pro-B cells initiate Ig gene segment recombination by recombining a D gene segment to a J gene segment on both chromosomes. It is possible that cells divide after this event. **D**: During the pre-B cell stage of differentiation, cells recombine a V gene segment to the rearranged DJ on one chromosome. If this rearrangement is productive (P) (~30%) and the resultant H chain is functional (assembles with SL) further V gene segment rearrangements are precluded (allelic exclusion). If the first V-D-J rearrangement cannot encode an H chain (non-productive = NP) a V gene segment of the second chromosome rearranges. Since ~30% of the second rearrangements will be productive, approximately half of the cells should have a productive rearrangement and synthesize an H chain. **E**: A proportion of pre-B cells that successfully express H chains will be selected, in part by H chain-SL chain interaction, to clonally expand. These cells will undergo at least 5-6 divisions prior to expressing L chains. Cells at this stage express the enzymes necessary for gene segment recombination, SL, and accessory molecules (Iga and Igb) for Ig membrane insertion. They express on their surface B220 and perhaps SL-μ complexes. **F**: Immature B cells represent those members of an expanded clone of pre-B cells that have rearranged a V and J gene segment productively and whose L chain interacts with the H chain to yield sIg expression. Each cell of the clone would presumably express the same H chain but a different L chain. At this stage, cells express on their surface IgM, as well as well as μ-SL complexes, MHC class II, and B220. At the stage at which immature B cells first express their sIg receptors, they are subjected to receptor-specific selective processes including inactivation by self-antigens (tolerance) that includes the potential for "receptor editing," anti-idiotypic regulation, and possibly subpopulation and longevity determination. In the presence of T and antigen, these cells can be stimulated to AFC clone formation but otherwise they do not divide. **G**: Mature precursor cells are tolerance resistant and do not normally divide. These cells express on their surface all B cell specific markers including MHC class II, B220, sIgM and sIgD. Upon stimulation, mature primary B cells give rise to AFC clones whereas mature precursors of memory cells give rise to memory B-cell clones.

As described in Chapter 13, the first critical molecular event in V gene expression is H chain V gene segment recombination and the generation of a productively rearranged H chain V region (14,18). The first known selective event in repertoire expression appears to be at the level of selection among nascent H chains, by virtue of their capacity to interact with surrogate L chains (V pre B + l5 (19,20,38,39 and 40). Cells with an appropriate nascent H chain form a pre-B cell receptor comprised of H chain, surrogate L chain and Iga and Igb. Such cells undergo at least 5-6 divisions prior to L chain V gene segment rearrangement (Fig. 14.1) (20,41). This process favors both the expansion of cells whose nascent H chains can interact with L chains and the expression of clones of B cells with identical H chains but a variety of L chains (20,42). Because the heavy chain-surrogate light chain complex is expressed on the surface of developing B cells, environmental selection by virtue of recognition of such complexes may also be possible (31).

The brief stage of B cell development following light chain gene segment recombination, wherein sIg expression is initiated, is the most critical with regard to repertoire selection. At this stage, immature B cells are highly susceptible to sIg receptor-mediated inactivation by environmental antigens (43,44 and 45) or anti-idiotypic antibodies (46,47 and 48). Furthermore, it may be at this stage that other receptor mediated interactions determine whether emerging cells will be long- or short-lived and what functional subpopulations they will enter (49,50 and 51). In addition to clonal inactivation of cells whose sIg receptors have high affinity for self-antigens, newly emerging B cells are also susceptible to a process called receptor editing (52,53 and 54). By this process, cells whose sIg receptors interact with self-antigen down-regulate their receptor expression, up-regulate or maintain RAG expression, and initiate further L chain rearrangement. Cells that are successful in expressing a new L chain re-express this L chain with their original H chain, thus creating a new receptor. If the "new" receptor does not recognize self-antigen the B cell can continue its maturation.

B-cell repertoire development during the fetal-neonatal period differs substantially from that described above for adults. In fetuses and neonates B-cell development occurs primarily in the liver and spleen. Although the sequence of gene segment recombination events is similar, the expression of various markers differs between neonates and adults (55,56). Furthermore, tolerance susceptibility of immature adult bone marrow B cells markedly decreases within hours of sIg expression (43), whereas neonatal sIg^+ cells appear to remain tolerance-susceptible for several days (44). Finally, repertoire diversity is far more restricted in neonates than adults (57,58,59,60,61 and 62). Indeed, among neonates of an inbred murine strain, not only do individuals express a limited clonotype repertoire (10^5), but also much of the same limited repertoire is reproducibly expressed from individual to individual. One reason for the limited neonatal repertoire is that neonates selectively overutilize certain V_L and V_H gene segments (especially V_H gene segments that are D_H proximal). However, the major basis for restricted repertoire expression during the fetal and early neonatal periods is the lack of TdT in developing fetal B cells and consequently a lack of N additions at the V_H-D and D-J_H junctions of the V_H regions (63,64 and 65). More than 95 percent of adult bone marrow B-cell precursors have N additions: as a consequence, diversity of the third complementarity determining region of heavy chains (HCDR3) exceeds 10^5 sequences for any pair of rearranged V_H and J_H gene segments (20). Because there are 10^2 to 10^3 V gene segments and four J gene segments, total V_H region diversity exceeds 10^8 sequences (20). In contrast, more than 95 percent of early neonatal B cells have no N additions in their heavy chains (63,64 and 65). The absence of N additions not only limits the potential for sequence diversity but also favors V_H-D and D-J_H recombinations wherein small overlaps of identical sequences occur in the 5' and 3' ends of the recombining gene segments (63,64,65 and 66). Thus, a few D-J_H and V_H-D junctional sequences frequently recur, which greatly limits HCDR3 diversity (64,65). Because sequences with a paucity of N additions recur within and among individuals (predominant clonotypes) and are often found to be specific for bacterial antigens or immunoglobulin idiotypes (66,67), they may represent specificities that are evolutionarily conserved (68,69,70 and 71). This situation is unlikely to be the case for the repertoire of clonotypes comprised of heavy chains with N additions, as such clonotypes should rarely recur whether with or among individuals (20).

B-CELL SUBPOPULATIONS

B cells are expressed as three subpopulations that differ functionally, developmentally, and in their expression of cell surface antigens. Each of these subpopulations can be perceived as occupying a distinct functional niche. Because the progeny of all three subpopulations can isotype switch, the antibody products of all three subpopulations contribute to the biologic effector functions that are peculiar to each immunoglobulin isotype (see Chapter 13).

"Conventional" Primary B Cells (B-2 B Cells)

"Conventional" primary B cells comprise most of the B cells in nonimmune adult mice. Generation of these cells from adult bone marrow is described above. Although as many as 5×10^7 of these cells may be generated daily from the bone marrow, most appear to be short-lived, however, selected longer-lived cells ultimately represent most B cells in the spleen and other peripheral tissues (26,28,51,72 and 73). Repertoire diversity among cells of this subset is extensive, as more than 95 percent express heavy chains with N additions at their V-D and D-J junctions. This subpopulation is characterized by expression of intermediate to high levels of cell surface IgM, IgD, MHC class II antigens, B220, and the cell surface heat-stable antigen (HSA) recognized by the J11D monoclonal antibody (74,75,76,77 and 78). These cells respond vigorously to various mitogens and to all categories of antigens including carbohydrates, bacteria, viruses, proteins, and hapten-protein complexes. Upon T_H-dependent stimulation, these cells give rise to AFC clones expressing multiple immunoglobulin isotypes; the progeny of these cells do not accumulate somatic mutations, however, nor do they generate memory B cells (77,79,80). Because of their abundance, broad distribution throughout the lymphoid system, and extreme repertoire diversity, "conventional" primary B cells are the subpopulation best suited to provide an early response to a broad array of pathogens. They would be particularly relevant in responses to pathogens such as viruses wherein repertoire diversity is essential to ensure determinant recognition (71,81).

CD5 B Cells (B-1 B Cells)

Like "conventional" B cells, stimulation of CD5 B cells, which represent a small proportion of B cells except in neonates and the peritoneal cavity of adults (43,76,82,83), give rise to AFCs but not germinal centers or memory B cells (77,80). These B cells can be distinguished from "conventional" B cells by their low levels of surface CD23 and their expression of CD43. Additionally, many of these cells express CD5 (T-cell marker) and Mac1 (macrophage marker). Among B cells, these cells are unique in that they produce high levels of IL-10 and may require IL-10 for their growth (43). Although under appropriate conditions these cells can respond to the same spectrum of antigens as "conventional" B cells, they respond more vigorously to bacterial antigens (43,76,82,83). In addition, these cells spontaneously produce high levels of IgM

antibodies being largely responsible for such antibodies in nonimmune serum.

Because B cells of the CD5 subpoplation can be generated from adult bone marrow, their repertoire may include V_H genes containing N additions and, therefore, extensive diversity (63). However, this subpopulation is enriched for cells whose V regions lack N additions (43,83). This appears to be the result of both selection of cells with certain V genes as cells acquire sIg receptors in the bone marrow (50,52) and because cells of this subpopulation, generated during fetal and neonatal development, self-renew and thus persist into adulthood (43,83). Although the repertoire generated in the absence of N additions is relatively restricted, the resultant antibodies are often antibacterial, and the B cells bearing such clonotypes may be present at high frequency (68). Therefore, such antibodies and the CD5 B cells that produce them may play a critical role in antibacterial responses, particularly when high concentrations of antibody are needed.

Memory B Cells

Memory B cells are the subpopulation of precursors whose generation requires antigenic stimulation. Memory B cells, like primary "conventional" and CD5 B cells, respond to antigenic stimulation by the generation of AFC clones. Also, as with primary B cells, the clonal progeny of these cells readily isotype switch (84,85). Memory B cells can be distinguished from primary B cells in that they express low to intermediate levels of HSA (74) and no surface IgD (84,86). Although some memory B cells express sIgM (85), most express a surface immunoglobulin other than IgD or IgM (84,85 and 86). Memory B cells are more likely than primary B cells to recirculate from the lymph to the blood and populate lymph nodes (27).

The most marked differences between memory and primary B cells is that the variable region sequences of memory B cells are generally highly mutated (87,88,89,90,91 and 92). These mutations accumulate by virtue of the process of somatic hypermutation that accompanies the generation of memory B cells in GC after antigenic stimulation (see Chapter 2).

Memory B cells appear to originate mainly from a small subset of primary precursors generated from the bone marrow of adult mice (77,79,80). These precursors of memory B cells are characterized by having relatively low cell surface levels of HSA and high levels of sIgD (77). Unlike primary CD5 and "conventional" B cells, upon stimulation these cells do not give rise to AFCs, but rather, generate clones of secondary B cells (77,79,80). Also, unlike primary B cells these precursors efficiently originate germinal centers and their progeny somatically hypermutate (77,79,80).

The V gene repertoire of the memory B-cell subpopulation includes sequences with N additions and those without. Thus, responses of this subpopulation are likely to be inclusive of both conserved and highly diverse clonotypes. Although the spectrum of clonotypes available for primary immune responses is likely to be inclusive of V regions that recognize most relevant antigenic determinants, the quality (affinity spectrum) of responses to any given determinant may be suboptimal. The special function of the precursor cell subpopulation that generates memory B cells may be perceived as providing the potential to refine and improve the clonotypes that recognize invading organisms by the combined process of somatic hypermutation and antigen selection. Because memory may be retained for months to years, this subpopulation also appears specialized to act as a repository for high affinity responses against microorganisms proved by previous contact to be a threat to the individual.

B-CELL TRIGGERING

Although B cells can be stimulated nonspecifically, the specificity of immune responses derives from the ability of any given antigen to selectively stimulate, from among a vast array of B cells, those whose sIg receptors interact with that antigen with sufficient affinity. This pivotal role in immunologic specificity of the sIg receptor is reflected in its role in B-cell triggering.

The sIg receptors contain the V region clonotype of the cell's productive V_H and V_L rearrangement and the membrane form of IgM and IgD, which are created by appropriate splicing of the immunoglobulin RNA transcript (see Chapter 13). Memory B cells can express sIg receptors of immunoglobulin isotypes other than IgM or IgD, which also represent an alternate splicing of RNA that provides a membrane insertion region. Regardless of the surface isotype, B cells express approximately 10^5 sIg receptor molecules. The sIg receptor functions as both a triggering receptor for B cells and a device for concentrating antigen on the B cell surface for either mitogenic stimulation or internalization, processing, and presentation to T cells.

Role of sIg as a Triggering Receptor

The triggering of B cells via the sIg receptor requires receptor cross-linking and appears maximized by the stable interlinkage of several receptor molecules in a complex with antigen (5,44,93,94). The aggregation of several such complexes can be visualized on the B cell surface as patches of receptor-antigen complexes (*patching*) (2). Owing to cell motility and cell surface fluidity such patches can aggregate to one pole of the cell (*capping*) (2). Although receptor interlinkage is a requisite for sIg-mediated B-cell triggering, neither patching nor capping appear to be essential for this process.

Receptor cross-linking by antigen is maximized by multivalent presentation of antigenic determinants and by high affinity receptor-determinant interactions. Multivalent antigen presentation is readily accomplished by bacteria, viruses, mammalian cells, certain polymeric macromolecules, and hapten-protein complexes, all of which can present multiple repeats of a relevant antigenic determinant. Smaller molecules, such as monomeric proteins, generally express only a single copy of each determinant but can be polymerized if bound by antibodies or on cell surfaces, which would enable them to be immunogenic.

For sIg receptor-mediated B-cell triggering to proceed, the affinity of the receptor-ligand interaction must exceed a minimum threshold affinity (5,44,62,93,94). Thus, low-affinity interactions are not stimulatory even when multiple sIg receptors participate, presumably because the stability of engagement of each receptor within the complex is not sufficient.

Although both sIgM and sIgD exist as complexes with isoforms of the intracytoplasmic accessory molecule Iga and Igb (33,34 and 35), sIgM appears to be the principle triggering receptor of primary B cells. The cascade of intracellular events initiated by sIg receptor engagement are described in Chapter 8. The stable interlinkage of sIg receptors rapidly induces protein tyrosine phosphoylation, the breakdown of phosphatidylinisitol biphosphate, and the resultant activation of protein kinase C and increased cytoplasmic Ca^{2+} (95,96). However, B-cell stimulation to proliferation and AFC generation generally requires engagement of other cell surface receptors such as those that mediate T_H-B cell interactions or mitogen receptors (95) (see Chapter 9). The functional consequences of interlinking a B cell's sIg receptors is most apparent in the process of B-cell inactivation by antigen (*tolerance induction*). This process is generally mediated by sIg receptor engagement alone. As is discussed below, relatively immature B cells or newly generated adult primary or memory B cells, appear to be most susceptible to sIg receptor-mediated inactivation (44,45,93,97). Although most of the subcellular events triggered by sIg receptor engagement appear to be similar for mature and immature B cells, immature cells show a much higher propensity for "receptor editing" (53), exhibit altered phosphatidylinisitol hydrolysis and may fail to activate the egr growth competence gene which appears necessary for activation of mature B cells (98,99). Whether these differences correlate with the increased sIg receptor mediated tolerance susceptibility of immature B cells is not yet known; however, the inactivation process of any of these immature cells can be reversed by concomitant T_H-mediated stimulation.

sIg Receptor-mediated Antigen Presentation

B cells are generally stimulated through collaborative interactions with T_H (see Chapter 9). This process requires that antigen be internalized by B cells for processing and presentation of the resultant peptides in association with class II MHC molecules (see Chapter 3). Although in the presence of high antigen concentrations internalization can ensue via pinocytosis, the usual means of concentrating and internalizing antigens is via their binding by the B cell's sIg receptor (100). This process ensures that B cells, whose receptors are specific for a given antigen, present peptides of that antigen in their MHC molecules (see Chapter 6). By this process B cells with high affinity receptors for an antigen are stimulated selectively, especially at low antigen concentrations (100). Furthermore, antigens that present determinants multivalently and thus bind to sIg receptors multivalently stimulate B cells more efficiently because of the increased affinity of such interactions. However, unlike triggering via the sIg receptor per se, the mode of B cell triggering that utilizes the sIg receptor as an antigen concentration and internalization device requires neither that the receptor-ligand interaction exceed an affinity threshold nor that antigenic determinants be presented multivalently. Thus, although high affinity and multivalent interactions are advantageous, this triggering mode can be accomplished by high concentrations of low affinity monovalent interactions.

Numerous macromolecules contain determinants that can interact with one of the myriad non-sIg receptors on the surface of a B cell, including receptors for mitogens (see below) and for immunoglobulin constant regions (Fc receptors). An additional mode by which B cell sIg receptors function in B cell triggering is by concentrating such macromolecules on the cell surface, thereby enhancing their interaction with other B cell surface triggering receptors (101). In some instances, such as with mitogens, these interactions facilitate stimulation of B cells whose receptors interact with determinants on the macromolecule; they thereby serve as an important component in the generation of specific immune responses (101). In other instances, such as with focusing immunoglobulins on the cell surface for interactions via Fc receptor binding, the interaction may foster either B cell activation or, more often, inactivation (102). Because the V regions of sIg may bind the same antigen as serum antibodies they can concentrate immune complexes on the B cell surface and in so doing would facilitate triggering via immunoglobulin-Fc receptor interactions (103).

T Cell-B Cell Collaboration

B cell stimulation is maximized by the collaborative interaction with antigen-specific T_H (see Chapter 6 and Chapter 9). At the core of these interactions is the dedication of T receptors to the recognition of class II MHC-peptide complexes and the efficiency with which B cells, by virtue of their sIg receptors, bind antigens for internalization processing and presentation.

Although T_H-B cell interactions maximize B cell stimulation, the effects of such interactions on the participating T cell depend on the state of activation of both B and T cells. On activation, B cells up-regulate cell surface co-receptors for T cell activation (e.g., B7) (see Chapter 2, Chapter 3, Chapter 4, Chapter 5, Chapter 6, Chapter 7 and Chapter 8). These up-regulated co-receptors appear to be essential for stimulation of collaborating T cells because in the absence of co-receptor participation resting T cells can be inactivated by interacting with antigen-presenting B cells (103).

The mutual stimulatory interaction of B and T cells mediated through T_H recognition of the B cell's class II MHC-peptide complex and co-receptors results not only in triggering of the B cell to initiate the cascade of intracellular events that lead to proliferation and differentiation but also the stimulation of T_H cells to release interleukins. The composition of the set of secreted interleukins is determined by the subset of participating T_H in that T_H cells release IL-2 and interferon-g, and T cells release IL-2 as well as IL-4 and IL-5. The importance of the released interleukins is not only their role in propagating T_H and B cell proliferation but also their capacity to selectively enable the secretion of antibodies of various isotypes.

In the RNA of primary B cells the V region is juxtaposed to the first domains of the µ constant region. These cells express an RNA transcript that encodes the V region as well as the µ and d constant domains (see Chapter 1). Primary B cells splice this RNA such that the predominant form of mRNA encodes the V_H region in conjunction with the membrane from the µ and d constant regions. Upon T_H-dependent antigenic stimulation, RNA synthesis is increased and RNA splicing changes to greatly favor the expression of V_H in conjunction with the secreted form of the µ constant region. The physical interaction of T_H and B cells also appears to affect the DNA encoding some of the other heavy chain isotypes in that the accessibility of their switch regions and their capacity to generate sterile transcripts increases (104,105). This situation, in conjunction with the action of various interleukins, enables the V region to splice with switch regions of downstream isotypes; it also enables expression of immunoglobulins comprised of the B cells' V regions with either membrane or secreted forms of isotypes other than µ or d (104,105).

Nonspecific B-Cell Activation

B cells have surface receptors that, upon interaction with moieties on various microorganisms, induce proliferation. Such moieties are deemed mitogens, and often such mitogenic stimulation yields AFC formation (101). Neither engagement of the sIg receptor nor T_H recognition is required for this form of B-cell activation (see Chapter 1). Although not all B cells have receptors for all mitogens, when a high concentration of a given mitogen is present, as many as 30% to 50% of all B cells can be stimulated. In these cases a highly diverse array of antibodies can be produced (*polyclonal stimulation*). Physiologically, this form of stimulation is most relevant when low amounts of the mitogen are present. In this case, the sIg receptors of B cells that recognize other determinants on the microorganisms concentrate the mitogen to the surface of those B cells, facilitating mitogenic stimulation and the production of antibody against the pathogen. This form of stimulation plays an important role in responses where T cell help is not available presumably because of a paucity of peptides derived from the antigen that would be appropriate for class II MHC presentation. Because of an absence of T_H-B cell interaction with this form of stimulation, isotype switching and memory B-cell generation are minimal.

B-Cell Differentiation and Regulation

On binding antigen to a B cell's sIg receptors, activation can ensue by several pathways. If antigenic determinants are presented multivalently and are bound with high affinity, the stable interlinkage of sIg receptors can initiate the cascade of intracellular events described above. Although this process does not necessarily lead to B-cell proliferation, it can enhance this process and alone can initiate the inactivation of immature cells.

The binding of antigen by sIg, whether monovalent or multivalent, can also facilitate the engagement of the major pathways of B-cell stimulation, antigen processing for T_H collaboration, and mitogenic stimulation. Once stimulated, B cells initiate mitosis, dividing every 8 to 16 hours for several days. These cells begin to synthesize and secrete IgM antibodies. At the DNA level, cells stimulated via interaction with T_H begin to express their V regions in conjunction with downstream constant regions (see Chapter 13). This is generally accomplished via the process of switch recombination, wherein a switch region down-stream of the rearranged V region is spliced with an accessible switch region upstream of a g, a, or e constant region with the excision of intervening constant regions. This process can be repeated in single cells by further rearrangement to more downstream isotypes. The expressed downstream isotype appears, at least in part, to be dictated by the set of interleukins produced by the collaborating T cell or surrounding tissues.

Clonal analyses of B cells stimulated individually have demonstrated that essentially all primary B cells can generate progeny expressing the same V region in conjunction with any constant region isotype (106,107). Although individual AFCs may retain mRNA for more than a single isotype, eventually they are committed to the production of only one isotype. As AFC clonal differentiation proceeds, sIg decreases, the concentration of polysomes increases, the cell's nucleus becomes smaller, and the cell becomes a plasma cell. Ultimately, these cells no longer divide, although they can survive and continue to secrete antibodies for several days to several weeks.

GENERATION OF MEMORY B CELLS

A hallmark of the immune system is the capacity to mount more rapid and vigorous humoral immune responses upon second contact with an antigen. This enhanced responsiveness is the result of numerous alterations in the immune system resulting from the first (primary) antigen contact. Subsequent to primary antigen contact, the frequency and reactivity of T_H that recognize peptides of that antigen in the context of class II MHC molecules is greatly enhanced. Additionally, antibodies generated as a result of primary B-cell stimulation have had the opportunity to adhere to the surfaces of macrophages and dendritic cells, arming such cells to better bind and process antigen. Most importantly, substantive changes in the B-cell population eventuate from primary contact with antigen.

Because of their stimulation by initial antigen contact, primary B cells generate AFC and terminally differentiate, so their frequency is generally decreased after primary stimulation. Furthermore, presumably in response to the high levels of primary antibodies present after this initial stimulation, anti-idiotypic reactivity is generated and suppresses subsequent responses by primary B cells (108,109). However, as a consequence of primary antigenic stimulation, memory B cells are generated, ultimately exceeding the frequency of the original primary B cells by a few-fold up to several hundred-fold (5,23).

The dramatically improved reactivity of the B-cell population subsequent to primary stimulation is not due solely to the increased frequency of B cells responsive to that antigen; it also reflects qualitative differences between primary and memory B cells. Functionally, memory B cells differ from primary B cells in that their receptors and potential secreted antibody products can be of isotypes other than IgM or IgD (84,85 and 86), they are more readily stimulated (5), their stimulation is resistant to anti-idiotypic down-regulation (108), and they often accumulate in the bone marrow wherein their plasma cell progeny can secrete antibody for several months (110). Most significant is that, as a consequence of a gradual increase in the affinity for antigen during the course of the primary response (immunologic learning), the affinity for antigen of the antibody products of memory B cells is significantly higher than that of primary B cells (111). This is the result of two ongoing processes that accompany the generation of memory B cells. First, presumably owing to progressively decreasing concentrations of the immunogen and increasing amounts of serum antibody that could compete for antigen with sIg receptors, there is a progressive selection for B cells whose sIg receptors are of higher affinity (5,111). Second, within a few days of their stimulation, precursors giving rise to memory B cells begin to somatically hypermutate their rearranged V region genes. Mutations accumulate at a rate approaching one mutation per 10^3 base pairs per division (88,89,90,91 and 92). Whereas most mutations do not directly affect antigen binding and some are deleterious, occasional mutations increase affinity for antigen. B cells expressing such antibodies would be favored by antigenic selection. Evidence of the significance of somatic mutations to antigenic selection of memory B cells comes from analyses of accumulated somatic mutations in high affinity memory B cells. Mutations yielding amino acid substitutions can be shown to cluster in complementary determining regions (CDRs), whereas silent mutations are favored in regions that would not affect antigen binding (88,92).

The alteration of antigen-combining sites by somatic mutation might be expected occasionally to create new anti-self specificities. As is discussed below, newly emerging memory B cells, like newly emerging primary B cells, appear to pass through a phase of high tolerance susceptibility wherein memory B cells expressing such anti-self specificities could readily be inactivated (97,112,113).

The generation of memory B cells is a complex process that requires participation of at least three cell types and occurs in special sites within lymphoid follicles called germinal centers (80,86,114,115). In addition to the stimulatory T_H-B cell collaborative interaction, the progression of memory B-cell generation appears to require a dendritic cell within the lymphoid follicles [follicular dendritic cells (FDCs)] that is specialized for antigen presentation via antibodies that coat small bodies (iccosomes) along their extended processes (114). In the milieu of T_H and FDCs, newly emerging memory B cells rapidly divide (every 6-12 hours) to form a cluster of B cells that

are the clonal progeny of one or a few original precursors (115,116 and 117). These clusters of cells include numerous dividing cells, many dead cells, and cells that appear to have ceased dividing. Cells being generated in germinal centers acquire several activation markers, including receptors for peanut agglutinin, which distinguish them from cells in surrounding tissues.

The cellular origins of memory B cells remains a controversial issue. Evidence indicates that, although it is possible that cells giving rise to primary AFCs can also give rise to memory B cells, most memory B cells are derived from a separate precursor cell subpopulation (77,79,80). By enriching for cells from the spleen of nonimmunized mice on the basis of their low expression of HSA and high expression of sIgD, it has been possible to identify a subpopulation comprising 10-20% of all precursor cells (77). These cells appear unable to give rise to AFCs after primary antigenic stimulation, but they do give rise to memory B cells. Thus, if these cells are antigenically stimulated *in vivo* after being transferred along with primed T_H to mice with severe combined immunodeficiency (SCID) that have no T or B cells (118), they give rise to germinal centers and memory B cells but not serum antibody (77,80). Such mice respond by the generation of AFCs, serum antibodies, and fusion partners for hybridomas only after a second antigenic stimulation. Similarly, if stimulated *in vitro*, these HSA^{lo} precursor cells generate clones of memory B cells but no primary AFC (77). Additionally, the progeny of these cells accumulate somatic mutations both *in vitro* and *in vivo* (77,79). Conversely, under the same experimental conditions, “conventional” primary B cells and $CD5^+$ B cells give rise to AFCs but not germinal centers or memory B cells (77,79,80).

Following primary immunization newly generated antigen-responsive secondary B cells can be detected with 4 days (77). Although these early memory B cells have not accumulated somatic mutations, their sIg receptors may reflect isotype switching. Furthermore, because antigen is often retained for several days, these cells may be stimulated to AFC formation as early as the second week during the course of a primary immune response. Thus, depending on the availability of antigen and T_H, the immune response to a single dose of antigen is likely to progress from domination by the AFC progeny of primary B cells during the first week or two to a response dominated by the AFC progeny of newly generated memory B cells at later stages.

After a secondary B-cell response subsides, animals retain memory for the immunizing antigen; a third or fourth contact with antigen elicits tertiary or quaternary responses. These responses are often more vigorous and of higher affinity than the secondary response. Indeed, even somatic mutations appear to contine to be induced after several courses of immunization (79,88,89,117). One component of the immune system that appears essential for the maintenance and propagation of memory is the retention of antigen on FDCs (114). However, the responsible cellular mechanism may reflect in part the capacity of the subpopulation of cells that give rise to memory B cells to also generate new precursors of memory B cells. These “immune” precursors of memory B cells, which can be isolated from the spleen of immunized mice, differ from “nonimmune” precursors of memory B cells found in naive mice in that they are generally isotype switched and bear somatically mutated receptors. Thus, after immunization two precursor cell types dominate the repertoire, both of which are somatically mutated and isotype switched (negative for sIgD): (a) secondary B cells, which can give rise to AFCs; and (b) precursors to tertiary B cells, which cannot give rise to AFCs but whose progeny can further somatically mutate and generate germinal centers and tertiary B cells. Cells of this precursor lineage would continue to propagate responses upon multiple antigen contact.

SELF-NONSELF DISCIMINATION BY B CELLS

A major challenge for immune recognition is the generation of a repertoire that is sufficiently diverse to ensure recognition of myriad foreign antigens but devoid of clonotypes that recognize the vast array of self-antigenic determinants. This challenge is compounded by the fact that most relevant determinants, both foreign and self, represent constellations of amino acid or carbohydrate residues, and the distinction between foreign and self may be subtle.

Numerous mechanisms are utilized to minimize the existence or stimulation of B cells reactive to self-antigens. Because B-cell stimulation by most antigens requires T_H participation, in some instances B cells that recognize self-antigens do not respond because the relevant T_H cells are tolerant or their reactivity is suppressed. However, when T_H reactivity to a self-antigen is absent, B cells that recognize that antigen have the potential for being activated by the presentation of determinants of that self-antigen on a mitogenic macromolecule or on a nonself carrier whose peptides can be recognized by T_H. Therefore, mechanisms are available that render inactive B cells that recognize self-antigens (*peripheral tolerance*) or preclude them from entering the repertoire (*central tolerance*).

Peripheral inactivation of mature B cells can occur in several ways. Stimulation of B cells can be prohibited by the action of either antibodies or T cells that recognize idiotypic determinants on the sIg receptors (*idiotypic* or *network suppression*) (108,109,119). Similarly, occupancy of B-cell receptors by molecules that cannot be internalized or processed and presented as peptides can also prohibit B-cell stimulation (*antigen blockade*) (120,121). Additionally, monovalent antigens that cannot interlink sIg receptors can block access of the cell's sIg receptors to immunogens (5). In some cases, a blockadelike effect can be obtained with antigen-antibody complexes (102). Finally, certain interactions of B-cell receptors and multivalent (and possible monovalent) antigens have the capacity to induce a temporary state of nonreactivity wherein the B cell's sIgM (but not sIgD) receptors may be down-regulated (122). This state, called *anergy*, may be reversed with time or by providing the B cells with excessive mitogenic or T_H stimulatory signals (123).

The principal means by which self-reactive clonotypes are purged from the B-cell repertoire is central tolerance, which appears to represent the permanent inactivation or elimination of B cells. This inactivation is induced by the stable cross-linking of sIg receptors by multivalent antigens in the absence of T-cell help (44,45,93,97). Although mature B cells may be inactivated by the continuous high concentration of certain cell-surface antigens (121,124), nonbiodegradable macromolecules (120), or antigens that can engage Fc receptors (antigen-antibody complexes) (102), under most circumstances central inactivation obtains only to newly developing B cells (44,45,123). This dichotomy in the susceptibility to tolerance induction of immature versus mature B cells was anticipated many years ago by Lederberg as a means to explain the difference between self and nonself antigens (125). By these precepts, self is defined as antigens that are present in the milieu of newly developing B cells, whereas substances (even determinants of sequestered self-moieties) that are not in this milieu would first encounter B cells after they had matured and would be recognized as foreign. Thus, the discrimination of self versus nonself would be determined by the maturity of encountered B cells and not by any structural features of the antigen. The attractiveness of this mechanism is that, although self-macromolecules vary enormously in structure and concentration, if present in the environment of developing B cells they all could eliminate emerging B cells that recognize their antigenic determinants.

The general rules for the induction of tolerance appear equally applicable to newly developing neonatal, bone marrow, or memory B cells. These rules include the requirements that determinants be presented multivalently (44,93,94,97), that the affinity of interaction exceeds a minimum threshold (62,93,97), and that tolerance can be circumvented by concomitant T cell help (44,97,122). It should be noted that, except in the case of newly generating memory B cells, antigen reactive T_H would rarely be present in the milieu of developing B cells. Newly generating adult bone marrow B cells are tolerance-susceptible for only the first several hours after sIg expression, whereas neonatal B cells appear tolerance susceptible for several days (44,45). Newly generating memory B cells may also have a prolonged period of tolerance susceptibility and appear to have a lower affinity threshold for tolerance than primary B cells, as they are susceptible to inactivation by cross-reactive determinants (97). Indeed, the affinity threshold for tolerance induction of newly generating primary B cells is sufficiently high that low affinity antigen-stimulatable cells are likely to escape the tolerance gauntlet (62,93,94). As mentioned above, another unique mechanism termed “receptor editing” has been shown to play a major role in eliminating self-reactivity among newly generated bone marrow B cells (53,54 and 55). By this mechanism, cells whose sIg receptors recognize self-antigens are induced to further rearrange L chain genes and ultimately express a receptor with altered specificity due to the complex of their H chain with a non-L chain. This mechanism appears to obtain to cells soon after sIg expression and cells remain susceptible through their later stages of bone marrow maturation wherein cells have been characterized as “transitional cells” (126). This transitional cell stage, which is characterized by high HSA and IgM expression and low to negative IgD expression, is also characteristic of 5%-15% of splenic B cells that have recently emigrated from the bone marrow. However, once in the spleen these cells no longer appear competent to undergo receptor editing. Since both inactivation and “receptor editing” may be applicable at the same B-cell maturational stages, and cells that attempt but fail to receptor edit may be inactivated in any case, the relative contribution of these mechanisms to the elimination of anti-self reactivity is not yet known.

Given the requisites for central inactivation of newly emerging primary B cells, it would be anticipated that potentially self-reactive cells could escape tolerance induction and mature. It would be especially true of cells with relatively low affinity for self-antigens and those reactive to monovalent self-determinants. Because of this it is neither surprising that reactivity to self-antigens can be found among mature B cells (127,128), nor that numerous peripheral mechanisms are available to ensure against the generation of anti-self antibodies.

15 ADHESION MOLECULES

Michael L. Dustin, Ph.D.

Adhesion molecules play key roles in mediating and regulating cell-cell interactions required for initiation of immune responses and for effector functions and leukocyte migration (1,2 and 3). Beyond the immune response, adhesion molecules are also critical for development, tissue integrity, blood coagulation, and wound healing (4). Adhesion molecules are cell surface receptors that physically link cells and transduce signals across the cell membrane (5). The processes of adhesion and signaling are tightly linked since signaling regulates adhesion (inside-out signals) and adhesion receptors generate signals (outside-in signals). This chapter will focus on a discussion of four examples of leukocyte adhesion that are presented as current paradigms of adhesion in the immune response. These are leukocyte extravasation, leukocyte migration, cell-mediated killing, and immunological synapse formation. These biological examples will be followed by a discussion of the major adhesion molecule families that participate in these interactions. Finally, the mechanistic basis of adhesion regulation will be addressed. An effort will be made to integrate the structural and mechanistic information back to the functional paradigms. Particular attention will be focused on diseases effecting adhesion in the immune system and what these have taught us about molecular mechanisms.

It is common in biology to define interacting molecules as receptors and ligands, however, in cell-cell interactions it is often difficult to make this distinction since both interacting molecules on apposing cells may be of similar size and may both be capable of transducing signals. Thus, we will use the term receptor and counter-receptor to describe the pair of molecules in an interaction. The time scale for the cellular interactions spans the range from fractions of a second to hours or even days. However, the underlying molecule interactions are almost always transient with half-lives on the order of 0.1-30 seconds (6). These surprising molecular dynamics are correlated with the requirement that all the important cell-cell interactions are eventually reversible. Thus, the long duration of some cell-cell interactions in the immune response is not determined by the duration of the molecular interaction, but by how large numbers of transient molecular interactions are organized to create a stable interface. Figure 15.1 outlines a continuum of four immunologically important cellular interactions in terms of their duration and relates this to the duration and number of the dominant molecular interactions. As can be seen, duration of cellular interactions is better correlated with the number of interactions than with their individual duration. An understanding of molecular interaction in cell adhesion requires an appreciation of both the intrinsic molecular interactions and the geometry and forces in the interface between the interacting cells. The molecular interactions can be characterized in terms of solution affinity and kinetic constants that can be determined experimentally by surface plasmon resonance. This technique is well suited to the low affinities characteristic of adhesive interactions (7,8 and 9). An even more difficult problem is the analysis of the molecular interactions in contact areas. We will focus attention on these issues throughout the chapter. The following sections focus on these four types of cellular interactions: rolling adhesion, migration, killer cell conjugates, and immunological synapse formation.

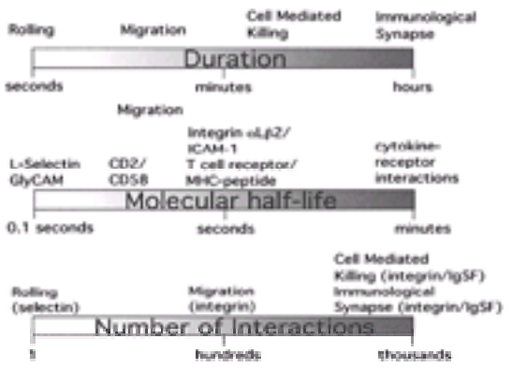

Figure 15.1. Cellular and molecular scale of adhesive interactions. IgSF = immunoglobulin superfamily.

FUNCTIONAL CONTEXTS OF CELL ADHESION IN THE IMMUNE RESPONSE

Leukocyte Extravasation

The process of leukocyte extravasation is critical for host defense against pathogens that enter the tissues. Leukocytes must enter tissue sites from the blood to isolate and clear these pathogens. Lymphocytes must enter lymph nodes and tissues to encounter antigen-presenting cells and cells infected with intracellular bacteria or viruses. Normal development of the hematopoietic system requires the migration of stem cells from the fetal liver to the bone marrow. In all of these processes, the challenge is to take cells that are flowing rapidly in the blood and have them arrest on the endothelial surface in a site-specific manner. The current paradigm for this process is based on multiple sequential adhesion steps with distinct molecular mechanisms (10,11). Figure 15.2 provides a schematic outline of the steps in the extravasation process. The first step is the tethering of the leukocyte to the vessel wall in a manner that allows the leukocyte to pause for a few seconds or to actually roll along propelled by the blood flow. The archetype molecular mechanism for this step is the interaction of receptors known as selectins with specific glycoprotein structures on the apposing surface (12). The time frame for this process is subseconds to a few seconds and one or a few molecular interactions are sufficient at any moment (13). The second step is the interaction of G-protein coupled receptors on the leukocyte with ligand on or near the surface of the endothelium. G protein coupled receptors, the same receptor type responsible for vision, are known for high speed signaling to the cytoplasm (14). In the third step, G-protein coupled receptors rapidly trigger the use of integrins, a class of adhesion molecules, with counter-receptors on the endothelium (15). The integrins on the activated leukocyte mediate the firm arrest within a few microns of the G-protein coupled receptor engagement. Hundreds or thousands of integrin to counter-receptor interactions mediate firm adhesion. Integrins also contribute to the movement of the leukocyte through intracellular junctions of the endothelium (16,17). This latter process is also facilitated by endothelial cells that respond to attached leukocytes through a contractile response that facilitates passage of the leukocytes (18). The individual steps of this multistep process are independently regulated and in combination can give rise to a large number of possible targeting or “area codes” for site specific leukocyte extravasation (19). Such combinatorial systems for guiding migration were previously proposed for the nervous system (20). Examples of area codes for site specific homing are included in Table 15.1.

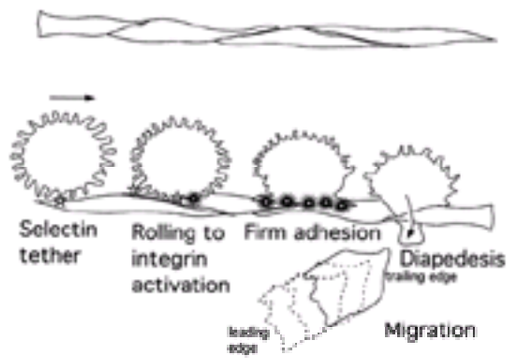

Figure 15.2. Leukocyte extravasation and migration. Five-pointed star = selectin interactions. Multipointed star = activating signals. Spread cells have many interactin interactions.

Target tissue	Tethering from flow	Activation	Arrest and diapedesis
Peripheral lymph nodes (naive and central memory T cells and naive B cells)	L-selectin/sulfated sialyl-Le^x or 6-sulfo sialyl-Le^x	CCR7-ligand(s) in lymphoid tissue chemokine (SLC, 6Ckine)	Integrin $\alpha_L\beta_2$ (LFA-1)/ICAM-1 and ICAM-2; integrin $\alpha_4\beta_1$ (VLA-4)/VCAM-1
Inflamed skin (effector memory T cells and monocytes)	PSGL-1 and/or sialofucosylated VLA-4	CCR4/TARC chemokine	Integrin $\alpha_4\beta_1$ (VLA-4)/ICAM-1 and integrin $\alpha_4\beta_7$ (LPAM-1)/ICAM-1 and ICAM-2
Mucosa (naive and subset of memory T cells that express β^7 integrin subunit)	CD44/hyaluronic acid and L-selectin/sulfotransferase 6 or 7/6-sulfo sialyl-Le^x	CCR9/TECK and CCR10/MEC	Integrin $\alpha_4\beta^7$ (LPAM-1)/MAdCAM-1, β^7 integrin $\alpha_E\beta_7$ (LPAM-1)/ICAM-1 and ICAM-2
Inflamed lung (subset of effector T cells [Th2] and eosinophils)	VLA-4/FIDAM-1	CC chemokine chemokine	VLA-4/FIDAM-1; β^7 integrin $\alpha_E\beta_7$ (LPAM-1)/ICAM-1 and ICAM-2

CCR = and C chemokine receptor; ICAM, intercellular adhesion molecule; LFA-1, leukocyte function antigen-1; MAdCAM-1, mucosal vascular addressin molecule 1; VLA, very late antigen.
These digits of [area code] are formed by combinatorial expression of receptors and counterreceptors on each step in extravasation. The format for each combination is expression/counterreceptor/FIMBO counterreceptor or ligand.

TABLE 15.1. Area Codes for Site-Specific Leukocyte Homing[a]

Leukocyte Migration

The migration of leukocytes is initiated by chemoattractants during extravasation and is sustained in the tissues by a hierarchy of chemoattractant and targeting signals (21,22). The environment in the tissue may include the surfaces of stromal and epithelial cells and an extracellular matrix. In contrast, the parenchyma of lymphoid tissues appears to be predominantly cellular, with no clearly defined extracellular matrix in contact with lymphocytes (23). Leukocyte migration requires adhesion molecule interactions and cellular polarity. The adhesion molecules that are utilized in migration include the integrins, CD44 and cell surface proteoglycans. Polarity is a cell biological concept that describes the difference behavior of one end of a cell from the other. In this context, one end of the cell is specialized for chemoreception and formation of adhesive interactions (the leading edge), while the other end is specialized to break adhesive interactions (the trailing edge) (Fig. 15.2) (24). The leading edge is rich in cytoskeletal proteins involved in actin polymerization, while the trailing edge is rich in myosin II, which may be involved in generating force that translocates the adhesive sites toward the trailing edge of the cells and for adhesion molecule detachment (25,26,27 and 28). Leukocytes can move at rates up to 10 µm/min in tissues (29). Since leukocytes are about 10 µm long this indicates that the longest duration of an adhesive interaction with another cell during migration is less than a minute. Migration involves a balance of directional cytoskeletal force and adhesion such that optimal migration may occur at relatively low levels of adhesion (30). When leukocytes reach a target cell or bacterium they may respond by stopping migration in response to high levels of cytoplasmic Ca^{2+} triggered by antigen receptors or other activating receptors (31).

Cell-mediated Killing

Cell-mediated killing is an important effector function carried out by leukocytes in tissues. Cell-mediated killing is directed at other nucluated cells and is triggered by T-cell antigen receptors or the immunoglobulin Fc receptors (32,33 and 34). The cells that carry out these functions are differentiated cytotoxic T cells, natural killer cells, neutrophils, and macrophages. Antigen receptors are very potent triggers for cell-mediated killing. It has been argued that a single T-cell receptor engaged by its counter-receptor, the MHC-peptide complex, can trigger the T cell to kill target cells (35). This great sensitivity is possible because adhesion molecules supply the preliminary interactions that are then augmented by antigen receptor signals (36,37 and 38). Adhesion molecules of the immunoglobulin superfamily such as CD2 and the integrin family such as LFA-1 play an important role in cell-mediated killing (Table 15.2). The killing mechanisms operate by triggering programmed cell death. The classical mechanism involves the use of perforin to form large channels in the target cell membrane through which specific proteases like granzyme B are introduced (39,40). The perforin and proteases are stored in granules in the cytoplasm of the killer cells and are discharged directly at the target in a process that relies on formation of a tight gasketlike adhesion zone into which the granules are exocytosed (Fig. 15.3) (41). The proteases do not digest the target per se, but trigger a protease cascade in the target that leads to DNA degredation and death by apoptosis within a few hours. A similar cascade leading to apoptosis can also be triggered by engagement of Fas on the surface of target cells by Fas ligand on activated T cells. The killer cell can trigger apoptosis in a few minutes and can engage and initiate death of many targets in the span of an hour (42,43 and 44). The peak junctional strength of the cytotoxic T cell–target cell interaction is so great that the cells are difficult to pull apart by mechanical means (45), but within a few more minutes the T cells can spontaneously separate to engage other targets. While the details of this signaling process are still poorly understood, the ability of adhesion mechanisms to display these rapid changes in avidity can be readily understood based on changes in killer cell polarity that accompany dissociation from one target to attack another.

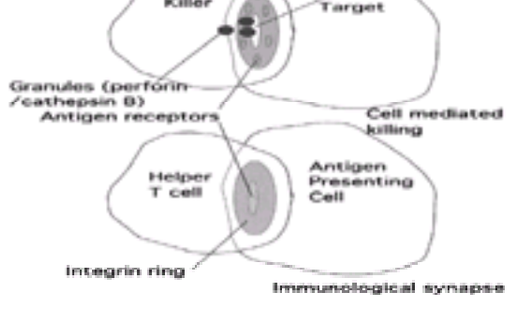

Figure 15.3. Cell-mediated killing and immunological synapse formation. Side-view showing the molecular pattern in the cell-cell interface at a small angle.

Receptor	Counterreceptor	Characteristics	Reference
CD2 (SRBC receptor)	CD58 (LFA-3) TIT3 on (mice) CD48 (rodents)	K_d 1 µM (k_{off} >5 s^{-1}); not regulated	[53a,179] [54]
3M	CD48 (human and rodents)	K_d 6 µM	[180]
Integrin $\alpha_L\beta_2$ (LFA-1, CD11a/CD18)	CD54 (ICAM-1), CD50 (ICAM-3), CD11a (ICAM-2)	K_d > 100 µM (k_{off} >1 s^{-1} to 0.03 s^{-1} [ligand induced]; Ac1: regulated	[57–59]
T-cell antigen receptor	MHC class I or II with cognate peptide	Vesicles: Ac1 0.1–40 µM (k_{off} < 0.1 s^{-1}	[1]
CD2a	gp120	K_d ~ 1 µM (k_{off} ~ 1 s^{-1}	[181]
ILAR and ILR	MHC class I allele; ILAR: cytotoxic killing and ILR: cytocidal killing	K_d ~ 1 µM (k_{off} ~ 1 s^{-1}); ILR has higher affinity than ILAC; ILR: form many interactions	[58,59,182]
CD8 (one or all forms)	MHC class I	Ac1↑ C_d↑ Ac1: regulated	[183,184]

ICAM, intercellular adhesion molecule; Ig, immunoglobulin; ILAR, killer cell activating receptor; K_d, dissociation constant; ILR, killer inhibitory receptor; LFA-1, leukocyte function antigen-1; MHC, major histocompatibility complex.

TABLE 15.2. Characteristics of Molecular Interactions in Cell-Mediated Cytotoxicity and Immunologic Synapse

Immunological Synapse Formation

The induction of T-cell help is perhaps the most critically regulated process in the adaptive immune response. The reason for this care is that the decision to mount an immune response and the nature of the response itself rests with these cells. Naive CD4 T cells are only activated by “professional” antigen presenting cells in a process that requires up to 20 hours of contact (46). Activated helper T cells are required for production of most antigen specific immunoglobulins by B cells, the ability of macrophages to kill intracellular bacteria and the generation of killer T cells (47). The long duration of the interaction appears to present a barrier to helper T-cell activation that may increase the fidelity of the process (48). The long duration interactions of helper T cells may also be important for the ability of the T cells to regulate the behavior of B cells, macrophages, and dendritic cells. Helper T cells direct secretion of cytokines at antigen bearing cells to deliver help for a variety of responses with high specificity (49,50). Bill Paul coined the term immunological synapse to describe this specialized cell-cell junction and its directed secretory function (47). The ability to sustain contact for prolonged periods is correlated with a specific molecular pattern in the interface between the T cell and antigen presenting cells. This pattern can be described in terms of the location of engaged integrin adhesion molecules in a ring around engaged antigen receptors in a pattern that evolves over a period of 0.5-10 minutes and is then stable for many hours (Fig. 15.3) (51,52). Other cell biological indications of immunological synapse formation include the transport of particles toward the contact area and the accumulation of glycolipid enriched membrane domains at the interface (53,54). This is the molecular pattern of a mature immunological synapse. Despite the stability of the immunological synapse, the molecular interactions are still highly dynamic. A possible exception to this is the interaction of T-cell antigen receptors with MHC-peptide complexes in the center of the synapse, which appear to be stabilized by an unknown process (52). Immunological synapse formation is determinative for full activation of helper T cells and is related to both the number of MHC-peptide complexes available and the kinetics of their interaction with a particular T-cell receptor. Besides integrins and antigen receptors other molecules can contribute to immunological synapse formation including CD28, ICAM-1, and CD2 (54,55 and 56). This emphasis on the pattern of molecules is important since overlapping sets of adhesion molecules are utilized in all of the examples of functional adhesion provided here, while the molecular interaction dynamics are similar, the cellular interaction dynamics are controlled by the organization of the contact areas.

ADHESION MOLECULES FAMILIES

The Selectin Family

The selectin family consists of three related gene products expressed on leukocytes or endothelial cells. The molecules are placed in cluster of differentiation (CD)62 with the three genes designated CD62L(for leukocyte) or L-selectin, CD62E (for endothelial) or E-selectin, and CD62P (for platelet) or P-selectin (57). L-selectin (schematic in Fig. 15.4) is constitutively expressed on many leukocyte populations, but can be lost from the surface on activation due to proteolytic cleavage (58,59 and 60). E-selectin is expressed on endothelial cells following endothelial cells activation by lipopolysaccharide or monokines like interleukin 1 or tumor necrosis factor (61). P-selectin is expressed on platelets and endothelial cells where it is stored in the a-granules or Weibel-Palade bodies, respectively, and can be moved to the cell surface by fusion of these granules with the plasma membrane within seconds of platelet or endothelial cell activation (62,63). Activated platelets can attach to the surface of leukocytes and can then impart P-selectin adhesive activity to leukocytes, which do not normally express this receptor (64).

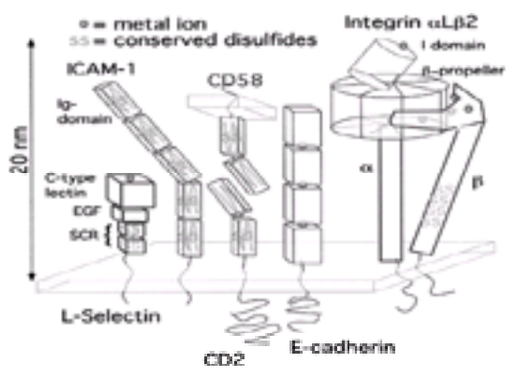

Figure 15.4. Adhesion molecule families. Schematics of molecules to scale. Integrin and ICAM-1 size based on electron microscopy images (185,186 and 187).

All selectins share a common structural plan. Selectins are type I transmembrane proteins with N-terminal lectin domains, a single epidermal growth factor (EGF) homology domain and 2-9 short consensus repeats similar to those in complement receptors (Fig. 15.4) (61,65,66). The lectin and EGF domains determine ligand binding specificity while the SCR domains are important for determining the distance of the ligand binding site from the membrane surface (67). The structure of the C-terminal lectin domain of E-selectin has been determined (68,69).

Selectin ligands are glycoproteins expressed on the surface of leukocytes and endothelial cells. The basic oligosaccharide motif is a fucosylated and sialated structure identical to or closely related to the sialyl-Lewis X blood group antigen (70). These oligosaccharides are generated at the termini of aspargine (N)-linked and serine/threonine (O)-linked oligosaccharides on a number of core polypeptides as they pass through the Golgi apparatus. The key regulatory enzymes that generate sialyl Lewis X are fucosyltransferases IV and VII (71). The interaction of selectins with sialyl Lewis X is Ca^{2+} dependent. The affinity of selectins for sialyl Lewis X is very low and is not sufficient for physiological interactions (72). Each selectin binds a family of ligands with modifications that enhance the affinity and bring it into a physiologically useful range. L-selectin prefers sulfated structures in which the sulfates are included in the vicinity of the sialyl Lewis X structure (73). Sulfation is regulated by sulfotransferases that are selectively expressed in specialized or activated endothelial cells (74). E-selectin prefers to interact with sialyl Lewis X structures on N-linked oligosaccharides (75). P-selectin prefers the core polypeptide P-selectin glycoprotein ligand-1 (PSGL-1) with sialyl Lewis X like structures on O-linked oligosaccharides in combination with sulfated tyrosines on an N-terminal domain (76,77 and 78). PSGL-1 is expressed on all leukocytes. However, the ability of PSGL-1 is dependent on the expression of the appropriate fucosyltransferases and tyrosyl sulfotransferases (79,80). For example, only a small subset of skin homing T lymphocytes express a functional form of PSGL-1 (81).

C-type lectin domains are utilized in a number of other important leukocyte interactions. The Ly49 family is another major group of immunologically relevant receptors that share the C-type lectin related domain with selectins (82,83). However, Ly49 family members are type II transmembrane proteins that form disulfide-linked dimers. The lectin domain is at the C-terminus and the N-terminus is in the cytoplasm. The C-type lectin domain retains the ability to interact with carbohydrates, but the known physiologically relevant ligands are actually MHC molecules that interact through protein surfaces (84,85 and 86). Negative regulatory forms of Ly49 and the functionally related immunoglobulin family members, the killer inhibitory receptors or KIRs, act by recruiting the inhibitory phosphatase SHP-1 to sites of cell-cell contact (87,88 and 89). The phosphatase is thought to extinguish signals transduced by activating receptors such as CD16 or activating NK cell receptors of the C-type lectin or immunoglobulin superfamilies. Another C-type lectin type II transmembrane protein has been described on dendritic cells. This molecule, termed DC-SIGN, interacts with the immunoglobulin superfamily member ICAM-3 to mediate initial interaction of denditic cells and naive T cells in lymph nodes (90).

CD44 binds hyaluronic acid and mediates initial leukocyte interactions with endothelium. CD44 is a type I membrane protein with an animo terminal “Link” domain (91). The Link domain is a homology unit also found in collagen binding extracellular matrix proteins. Determination of the Link domain structure revealed that it is structurally homologous to a C-type lectin domain, although they share little primary structure homology (92). Cell surface proteoglycans may also serve as counter-receptors for CD44 and as receptors for the heparin binding sites of fibronectin participate in signal transduction to regulate formation of focal adhesion and migratory behavior (93). These cell surface proteoglycans include the syndecans, which have multiple roles in regulation of cell migration (94,95). Syndecans are expressed in leukocytes, particularly antibody producing B cells (96).

A class of selectin ligands, particularly for L-selectin, are large mucins. These molecules are membrane or sectreted proteins that have serine and threonine rich ectodomains that are modified by O-linked oligosaccharides terminating in sialic acid. These molecules are very effective at presenting ligand for L-selectin because of the very high density of oligosaccharides. Members of this group include the transmembrane proteins CD43, CD34, and podocalyxin and the secreted protein GlyCAM (72). The selectin ligands P-selectin glycoprotein ligand 1 and MAdCAM also have mucin domains along with other regions (76,97). In addition to carrying selectin ligands on cells expressing the appropriate enzymes, mucins also are major charge carriers on the cell surface, and extend this charge a significant distance (>50 nm) from the plasma membrane surface. This charged surface results in repulsion between neighboring cells. In fact, it has been proposed the CD43 acts as a negative regulator of leukocyte interactions through this charge barrier mechanism (98,99). Charge repulsion is a barrier to cell-cell contact that is overcome by adhesion

molecules.

The Immunoglobulin Superfamily and Related b-Sheet Domains

The immunoglobulin superfamily is a very diverse group of interactive molecules that share a common folding motif (100). The basic immunoglobulin domain is formed from ~100 amino acids that form a sandwich of two anti-parallel b-sheets with a hydrophobic core. One or more disulfide bonds typically link the two b-sheets. The overall homology between Ig family member is frequently quite low (~20%) and inclusion in the family is based on shared patterns of hyrodphobic residues that define the hydrophobic core and structural determination (101). The domains form roughly rectangular globular structures of ~4 nm length and ~2 nm depth and ~3 nm width. Family members may have from one to 9 of these domains in a tandem array and many family members are part of dimeric or multisubunit complexes. The interacting surfaces can be the loops at the end of the domain as in classical immunoglobulins and the T-cell antigen receptor or through the flat faces of the domains as in CD2 interaction with CD58 (102,103). These interactions have a wide range of affinities for ligands with dissociation constants in the 10^{-12} to 10^{-5} M range. The high affinity interactions of immunoglobulins typically involve significant hydrophobic interactions, while low affinity interactions like CD2/CD58 involve electrostatic and hydrogen bond interactions that provide high specificity, but relatively low affinity due to fast off-rates (> 1 s^{-1}) (103). Immunoglobulin domains can also be combined with other structural motifs, such as the peptide binding domains of major histocompatibility molecules and the mucin domains (rich in O-linked oligosaccharides) of CD8 and MadCAM (97,104).

There are other families of interactive proteins that are closely related to Ig domains. These related folds include the fibronectin type III repeat and cadherin repeats. Fibronectin type III repeats are distinguished by a lack of disulfides and a different pattern of b-strands, but have similar overall geometry and functionality to Ig domains (105). Cadherin repeats are similar to immunoglobulin domains in the number of amino acids (~100) and the b-strand pattern, but are distinct in two important ways (106,107). The residues making up the hydrophobic core of cadherins are larger so the domains are more barrel-shaped than rectangular. In addition the domains are linked together by interdomain bound Ca^{2+} ions that make the arrays of domains very rigid. When Ca^{2+} ions are removed the molecules become flexible and lose their adhesive activity (108,109). Thus, the Ca^{2+} ion is a structural element of the cadherin. Cadherins are primarily expressed by epithelial cells and neural cells where they engage in interactions with other cadherins (110), but E-cadherin can be used as a ligand for integrin family member aEb7 on lymphocytes (111).

The Integrin Family

Integrins are a family of large heterodimeric glycoproteins expressed on the surface of all nucleated cells (5,112). The two subunits, identified as a and b are both large type I transmembrane glycoproteins. Integrins can be divided into three subfamilies based on subunits that each share multiple partners to form functionally distinct receptors: the b1, b2, and aV subfamilies (Fig. 15.5). Leukocytes express members of all three subfamilies. b subunits are rich in highly conserved cystein residues and have a highly conserved N-terminal regions that harbors many mutations that lead to leukocyte adhesion deficiency type I (see below) and thus appear to be involved in association with the b subunit. Integrin b subunits share a series of 7 repeats at the N-terminus. While there is no direct structural data on integrins it has been proposed that these 7 repeats form a b propeller structure, a motif also identified in heterotrimeric G protein b subunits and many extracellular proteins (113). Some integrin b subunits have an “inserted” or I-domain between the second and third repeat of the putative b propeller. The I-domain has sequence similarity to the A-domains of von Wilibrand factor that are implicated in interaction of von Wilibrand factor with collagen. The structures of the aL, aM, and a2 I domains have been determined, and they all have dinucleotide folds similar to low molecular weight G proteins (114,115 and 116). The I domains contain a novel divalent cation binding site (the Metal Ion Dependent Adhesion Site motif) at the distal end of the domain from its attachment site to the b-propeller (117). The I-domain can be incorporated into the b propeller model as indicated in Fig. 15.4. The configuration of the I-domain is similar to the configuration of the a and b subunits of heterotrimeric G proteins. Integrins that contain I domains use the I-domain as the major ligand binding site (118,119,120 and 121). I domains appear to exist in two conformations that may correspond to high and low affinity forms based on changes in the position of a C-terminal a-helix and the coordinate exposure of hydrophobic residues around the MIDAS motif (122,123). These changes may be regulated by the interaction of the I-domain with the b-propeller domain (124). In contrast, integrins that lack I domains form a ligand binding site from the b propeller domain of the b subunit and the highly conserved region of the b subunit (125).

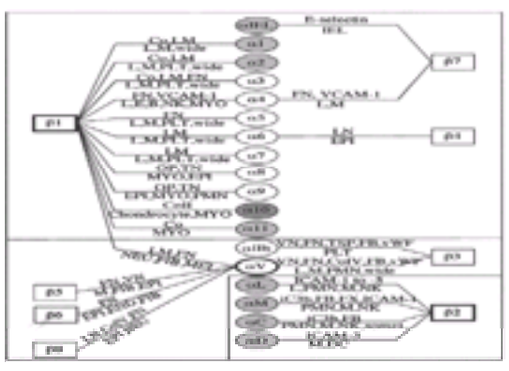

Figure 15.5. Integrin family. The association patterns among the known subunits is shown. In each case the ligands for a heterodimer are indicated above the line, and its tissue distribution is indicated below the line. Abbreviations: Co= collagen, LM= laminin, FN = fibronectin, VN = vitronectin, TSP = thrombospondin, FB = fibrinogen, vWf = von Willebrand factor, OP = osteopontin, FX = factor X, BSP1 = bone sialoprotein 1, L = lymphocytes, M = monocyte/macrophages, PMN = granulocytes, E = eosinophils, B = basophils, NK = natural killer cells, PLT = platelets, IEL = intraepithelial lymphocytes, PBL= peripheral blood lymphocytes, EPI = epithelial cells, ENDO = endothelial cells, MYO = muscle cells, NEU = neural tissues, MEL = melanoma, FIB = fibroblast.

Integrins on leukocytes undergo dramatic changes in activity (126,127). These changes regulate extravasation, migrations, and cell-cell interactions in tissues. Integrins on circulating leukocytes are inactive since they do not mediate adhesion to surfaces coated with ligands (127). Upon activation of leukocyte by chemoattractants there is a rapid increase in integrin activity that allows firm adhesion (15). Antigen receptor cross-linking also results in a rapid rise in integrin activity on leukocytes. While it was once proposed that simple affinity changes in the integrin could account for these changes in adhesiveness, this no longer seems likely. It is more likely that a number of events are required for integrin activation. Integrins exist in two affinity states with respect to ligand that can vary by as much as 10-1000 fold in apparent affinity (128,129,130 and 131). However, the most general mechanisms to generate the high affinity form is binding of the ligand itself, which favors a high affinity conformation of the integrin (132,133). This conformational change is detected by a number of monoclonal antibodies recognizing at least four different integrin heterodimers based on epitopes in the ectodomain and the cytoplasmic domain (133,134). There is only one report of a cytoplasmic ligand that will induce this conformational change in the inside to outside direction (135). In this case the N-terminal half of the cytoskeletal protein talin was shown to induce the binding of a ligand mimetic antibody to aIIbb3 (136). The current model for integrin activation involves coordination of cytoskeletal interactions with ligand engagement. A model for this process is discussed below.

The complex regulation process of intergrins appears to be amenable to inhibition by small molecules that have potential as therapeutic agents. This approach has been most broadly applied with respect to integrins that interact with ligands containing the RGD (arginine-glycine-aspartic acid) motif (137). Interestingly, recent progress has been made in finding small molecules that block function of non-RGD binding integrins such as aLb2 (138).

MOLECULAR MECHANISMS

Rolling Adhesion and Capture from Flow

The rolling adhesion of leukocytes observed in the first step of the extravasation process requires the formation of very few molecular interactions and has provided insights into the behavior of single molecular interactions under force (139). When selectin receptors are presented at very low densities, isolated tethering events can be observed between cells and the substrate *in vitro* that reveal the kinetics of the adhesive interaction. The important characteristics of the selectin/counter-receptor interaction were a relatively fast off-rate of ~1 s^{-1} and a small increase in the off-rate with increasing force. Thus, single selectin interactions can hold a cell against physiological blood flow for a fraction of a second, long enough for the next interactions to form to sustain rolling of the leukocyte. The conditions for rolling adhesion and efficient tethering from flow are relatively restrictive and not all adhesion mechanisms can perform these functions *in vivo*. In addition to selectins it has been demonstrated that CD44 interaction with hyaluronic acid (91) and a4b1 interaction with VCAM-1 can capture leukocytes from physiological flow (140). Furthermore, it has recently been reported that the interaction of the chemokine receptor CX3CR1 can mediate capture of leukocytes from flow through interaction with the membrane anchored chemokine called fractalkine (CX3C chemokine 1) (141,142 and 143). However, it is not clear how important this capability is *in vivo*.

Rolling adhesion can also be utilized for analysis of single molecule interaction kinetics in systems where the physiological interaction would not normally mediate rolling adhesion or tethering from flow. This approach has been utilized to study antibody interactions, interaction of CD2 and CD48 and the interaction of the integrin

aL domain with ICAM-1 (120,144).

Very small numbers of interactions also exist in at the moment when adhesion is initiated between two cells (145). The process of initial interactions under static conditions can be studied using micromanipulation to push two cells into contact for a controlled time followed by application of a separating force (146). This procedure is repeated many times under different conditions and the probability of forming an interaction can be used to determine the kinetic rate constants for initiation of a single or small number of interactions in an early contact area. This approach allows predictions to be made about how adhesion is initiated under different initial conditions.

Formation of contacts required for migration, cell-mediated killing, and immunologic synapse formation involve hundreds or thousands of molecular interactions in the interface between cells. The classic study relating large numbers of receptor interactions to the strength of adhesion employed a combination of fluorescence microscopy and micromanipulation (147). In this experiment a rat basophilic leukemia (RBL) cells expressing a high-affinity Fce receptor was coated with fluorescently labeled IgE (the bifunctional ligand for the Fce receptors). This IgE also would bind the small ligand dinitrophenol (DNP). When the RBL cells were brought into contact with beads coated with high densities of DNP, a time-dependent redistribution of the fluorescent IgE from the entire cell surface to the contact area was observed. This redistribution was not energy dependent, but was well correlated with the development of strong adhesion. The accumulation of IgE in the interface was dependent on the random lateral mobility of the Fce receptor on the RBL cell surface and the affinity of the IgE for DNP. The mobility and affinity led to random entry of the IgE/Fce receptor complex into the contact area between the cells and bead and trapping of the IgE/Fce receptor complex in the interface. Lateral mobility is a fundamental property of proteins in biological membranes that can be regulated by a variety of molecular interactions of the surface receptors (148,149). The fractional mobility and diffusion coefficient describes the average motion of molecules on the cell surface. The diffusion coefficient (D) is related to the time (t) required to diffuse a distance (r) is $t = r^2 \div 4D$. Thus as distance increases the time required for the average molecule to diffuse increases with the square of the distance. Lateral mobility contributes to interactions in two important ways. At the submicron level diffusion is an important component of the formation of the encounter complex between molecules that is a key component of the on rate (150,151). Thus, regulation of diffusion changes the effective on-rate. In addition, diffusion can allow receptor recruitment over distances of several microns. This transport effect was highlighted by the study above, which demonstrated large-scale motions of Fce receptors on the cell surface.

An alternative approach to examine interactions is to fix cell-cell conjugates with aldehydes or organic solvents followed by detection of specific surface receptors and cytoplasmic regulatory molecules with fluorescently tagged monoclonal antibodies. An advantage of this approach is that both surface and cytoplasmic proteins can be localized leading to an appreciation of interactions at both faces of the plasma membrane. For example, integrin interactions with counter-receptors are accompanied by accumulation of the cytoplasmic protein talin on the cytoplasmic side of the integrin containing membrane (51). This approach has yielded a number of insights and also has the advantage that many molecules can be examined based on available antibody reagents.

A model system based on supported planar bilayers allows a more quantitative approach to interactions in a contact area from which a two-dimensional dissociation constant can be determined. Supported planar bilayers are phospholipid membranes supported on a glass or quartz microscope slide (152). Counter-receptors can be tethered to the bilayers either through glycophosphatidylinositol moieties (151) or soluble proteins with C- or N-terminal 6 histidine extensions can be noncovalently attached to phospholipids with Ni-chelating head groups (153). In either case, the tethered ligand are laterally mobile in the plane of the bilayer. Fluorescent tagging of counter-receptors in the bilayer allows visualization of interactions between cell surface receptors and the counter-receptors (154). The two-dimensional Kd is obtained from a Golan-Zhu plot, which is based on a simple model for receptor movement on the cell surface that is applicable to highly mobile receptors (155). The key assumption is that the receptor on cells and the ligand in the bilayer can only interact in the contact area and that the free receptor is distributed uniformly on the cell surface. Therefore, the density of bound receptors is measured relative to the contact area, while the density of free receptors is measured relative to the entire cell surface area. The linearized plot is based on taking the mass action equation Kd = [complexes] ÷ ([free ligand]x[free receptor]) and substituting in the [free receptor] = (total receptor number – [complexes]x contact area) ÷ cell area. Algebraic rearrangement leads to a plot of [complexes] ÷ [free ligand] on the Y-axis, versus [complexes] x (cell contact area ÷ cell surface area) (Fig. 15.6). The negative reciprocal of the slope is the 2D Kd. Only a few adhesion mechanisms have sufficiently mobile and nonregulated receptors to apply this model, but these systems have provided important information. The interaction of the immunoglobulin super-family members CD2 and CD58 has a solution (3D) Kd of 2 (M and a 2D Kd of 1 molecules/(m^2. If it is assumed that the kinetics of the 3D and 2D interactions are similar, the geometry of interaction is the only difference between the 2D and 3D Kds. The 2D interaction has an entropic advantage over the 3D interaction because the membrane anchored adhesion molecules have fewer initial degrees of freedom compared to the resulting complex than for the corresponding soluble molecules. The ratio of the 2D Kd and the entropy corrected 3D Kd yields the confinement region (150,156) (Fig. 15.7). This is calculated to be 5 nm for the CD2/CD58 interaction. Thus, the action of hundreds or thousands of CD2/CD58 interactions results in alignment of apposed membranes with nanometer precision. This means that the CD2 and CD58 binding sites are concentrated in a attoliter (10^{-18}) volume in the interface between cells. In the future, it will be possible to determine 2D interaction parameters from interactions in cell-cell interfaces based on tagging proteins with intrinsically fluorescent proteins and developing new methods for calibration of the image data (89). The formation of thousands of transient interactions is an important process in T-cell mediated killing and immunological synapse formation.

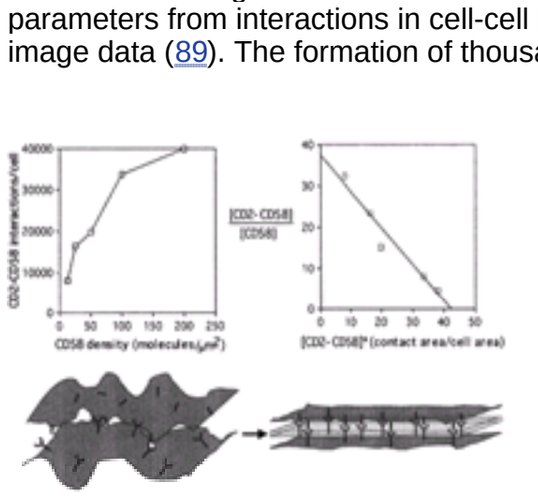

Figure 15.6. Measurement of two-dimensional affinity. The binding curves for CD2/CD58 interaction in contact areas between supported planar bilayers containing CD58 and T cells expressing CD2. The Golan-Zhu plot is based on the equations in the text. The data indicate that the initially dissordered contact areas become highly ordered through many independent interactions.

	3D	comparison	2D
Affinity	3D Kd Free energy	$\sigma = \frac{\text{2D Kd}}{\text{3D Kd}}$ Contact geometry	2D Kd Physiological affinity
Receptor number	Total number of receptors (N_t)	$f = \frac{\text{X-int*cell area}}{N_t}$ Lateral mobility	Maximum number of receptors in contact (X-int*cell area)

Figure 15.7. Interpretation of two-dimensional affinity. The parameters determined by two dimensional affinity and three dimensional affinity can be related to determine physical parameters important for adhesion.

Adhesion receptors of the integrin family undergo complex interactions with the cytoskeleton. Integrin activation is a multistep process that results in coordination of integrin engagement and cytoskeletal assembly that stabilizes the adhesive unit, a cluster of engaged integrins (157,158 and 159). Inactivity of integrins on resting leukocytes is due to lateral immobilization of a low affinity form of the integrin (131,160,161). The lateral immobilization of the integrin requires an intact actin cytoskeleton. There are three hypotheses for how lateral immobilization impairs integrin function. Lateral immobilization may prevent small-scale receptor rearrangements at the interface that are required to form complexes between the integrin and ligand (160). Lateral immobilization may also prevent the large-scale clustering of integrins that is correlated with higher activity (161,162). Finally, the interactions that lead to lateral immobilization may block interactions that are required to coordinate integrin engagement with cytoskeletal assembly that is a component of adhesion strengthening. The first step in integrin activation is mobilization (160). Mobilization is equivalent to an increase in random diffusion with a 10-fold increase in the diffusion coefficient. Mobilization increases both encounter complex formation and is also correlated with clustering. However, mobilization does not result in an increase in integrin affinity. The second step in integrin activation, at least in the context of lymphocytes, is the encounter of the low affinity form of the integrin with ligand. This low affinity interaction triggers a ligand-induced conformational change

that leads to two important effects: the half-life of the interaction (half-life = k/ln2) increases from a fraction of a second to ~30 seconds (for the aLb2 integrin) and new binding sites are exposed in the cytoplasmic domains. The third step is the interaction of poorly defined cytoskeletal factors with the ligand induced binding sites on the cytoplasmic domains. These factors may include the large actin binding protein talin, but may include other regulatory proteins that are not yet identified. These ligand induced cytoskeletal interactions trigger actin polymerization associated with cell spreading and integrin cluster formation. The cytoskeletal assembly process may act by increasing membrane alignment to the substrate, and thereby increasing two-dimensional affinity. Current evidence supports this activation sequence for (L(2 on lymphocytes.

Another important consequence of integrin interaction with the actin cytoskeleton is transport of engaged integrins over the cell surface. Directed transport of molecules on the cell surface is likely to involve that attachment of these molecules to actin-based structures that move due to myosin-based contraction of the actin. This type of transport is much more efficient over longer distances (a few µm) than diffusion and has the potential to transmit energy from the cytoplasm to the substrate for directed processes such as cell motility. The actin filaments that are moved by myosin-based contraction move at 20-40 µm/min. This movement can be transmitted to the engaged integrins to move leukocytes at up to 10 (m/min. Formation of the immunological synapse also involves striking directed transport of both engaged MHC-peptide complexes and adhesion molecules toward the center of the contact interface (Fig. 15.8). This results in an increase in integrin concentration toward the center of the contact, but this concentration drops off within a (m of the center. The central region is occupied by engaged antigen receptors that are transported from peripheral sites in the contact over a period of a few minutes.

LEUKOCYTE ADHESION DEFICIENCY DISEASES

Leukocyte Adhesion Deficiency Type I (LAD I)

LAD I is characterized by life threatening bacterial infections and skin and mucosal ulcers without puss formation (163). These deficiencies in innate immunity are caused by failure of leukocyte extravasation at skin and mucosal sites in response to bacterial products that would normally induce neutrophil infiltrates. LAD I is inherited as a recessive trait with no obvious phenotype in heterozygous individuals. The molecular defect in LAD I is absence or reduced expression of the (2 subunit common to all leukocyte integrins. In one family, the mutations resulted in expression of nonfunctional aLb2 and aMb2 (164). Without (2 integrins there is a complete absence of firm adhesion and extravasation of neutrophils to the blood vessel wall, whereas rolling adhesion is virtually normal (165). A number of LAD I mutations have been mapped and the defects include both large deletions resulting in no protein production, point mutations that block association with the (subunits, and point mutations that lead to nonfunctional complexes on the surface (163,164). Lymphocyte and monocyte migration is less severely affected in LAD I. In the mouse model of LAD I the compensatory mechanism appears to be the a4b1 integrin interaction with VCAM-1 (166). The relatively high level of T-cell function in LAD I patients is consistent with similar compensatory mechanisms in humans (167). Mice with deficiencies in either of the major (subunits of the leukocyte integrin subfamily, (L and (M, have much less severe defects in leukocyte extravasation (168,169). This is consistent with the observations that neutrophils use both (L(2 and (M(2 for interactions with activated endothelial cells. LAD I can be treated by non-MHC matched bone marrow transplantation (170). While the number of patients treated is small, the LFA-1 deficient recipients appears to become tolerant to non-MHC matched grafts with a higher success rate than expected for non-MHC matched transplants into immune sufficient recipients.

Leukocyte Adhesion Deficiency Type II (LAD II)

LAD II patients suffer life-threatening bacterial infections and skin and mucosal ulcers without puss formation, similar to LAD I patients (171). LAD II is also accompanied by severe mental retardation and growth defects. LAD II is inherited as a recessive trait. The molecular basis of the defect has not been fully determined, but it appears to be a global defect in fucose metabolism leading to an inability to generate sialyl Lewis X and related blood group antigens required for selectin function (172). The mental retardation and physical deformities in these patients suggests that fucosylated oligosaccharides have uncharacterized functions in the development of the nervous system and the musculoskeletal system. LAD II patients have defective lymphocyte rolling on endothelial cells that leads to greatly decreased extravasation (171). As with LAD I patients, the lymphocyte function is less profoundly affected than the neutrophil function. The ability of lymphocytes to home and migrate *in vivo* in the absence of selectin ligands may also be due to the ability of lymphocyte integrins like a4b1 and a4b7 to mediate rolling adhesion and the use of CD44 as a mechanism for interaction with endothelial cells. It has also been reported that delayed type hypersensitivity reactions are nearly normal in LAD II patients (173). The only defect noted was reduced redness and swelling at the delayed type hypersensitivity site. This result is consistent with expression of VCAM in delayed type hypersensitivity (174) and the potential role of (4 integrins in mediating tethering from flow.

Wiscott-Aldrich Syndrome (WAS)

WAS is an X-linked immunodeficiency caused by loss or mutation in the cytoplasmic protein WASp (175). WAS patients have deficiencies in T lymphocyte activation and platelet function. These defects are characterized by a loss of actin-based structures such as microvilli and abnormalities in cell shape. T cells from mice lacking WASp expression have defects in formation of T-cell receptor caps, which may be related to the process of immunological synapse formation. The WASp protein is expressed only in hematopoietic cells and platelets. A homolog N-WASP is expressed in a wide variety of nucleated cells and in lymphocytes. Both WASp homologs are multifunctional proteins with domains that interact with molecules involved in regulation of actin polymerization including CDC42, profilin, and VASP (176). The interaction of CDC42 with WASp can both recruit WASp to membrane sites and induce profound changes in WASp structure that enable interactions with the actin polymerization machinery (177). The link between T-cell antigen receptor engagement and WASp recruitment requires the nonreceptor tyrosine kinase ZAP-70 and the adapter proteins SLP-76 and NCK. Recruitment of NCK and WASp triggers rapid actin polymerization (178). The SLP-76 recruited Guanine nucleotide exchange factor vav may play an important role in this process through local activation of CDC42 [Fischer, 1998 #12]. Actin polymerization is likely to play a key role in regulation of adhesion and antigen receptor movements. Thus, WASp is a prototype for cytoplasmic proteins that regulate molecular interactions in the interface between T cells other cells.

PERSPECTIVE FOR FUTURE RESEARCH ON ADHESION MOLECULES

Important areas in research on adhesion molecules include the elucidation of the mechanism of integrin function and how integrin mediated adhesion is integrated with migration, primary activation, and effector functions of the immune response. While there is considerable data in this area and there are well-reasoned hypotheses regarding integrin function and the mechanism of adhesion in a variety of immunological contexts, there are still fundamental discoveries ahead. It will also be important to further evaluate the role of supramolecular organization of interfaces in cellular responses. These are areas where leukocyte systems are likely to provide key paradigms for mechanisms and processes of general importance in many areas of biology. These future endeavors will provide fertile ground for discovery of new therapeutic strategies to improve human health.

16 CHEMOKINES AND CHEMOKINE RECEPTORS

Andrew D. Luster, M.D., Ph.D.

The recruitment of cells to sites of inflammation is an essential component of the host inflammatory response. Cell recruitment relies on the coordinated action of cell activation, cell adhesion, chemoattraction, and transmigration across the endothelial barrier. The chemokines (chemotactic cytokines) are a newly described superfamily of secreted proteins that play an important role in cellular chemotaxis. This chapter reviews chemokine structure, emphasizing how certain structural elements confer differential functional activity. Chemokine receptors, including their cellular expression and intracellular signaling mechanisms, also are included. The role of chemokines in cell trafficking is reviewed in terms of their role in homeostasis and development and in their participation in cell recruitment to sites of inflammation. Illustrative examples of chemokine action *in vivo* are drawn from specific human diseases and animal models.

CHEMOKINE STRUCTURE AND FUNCTION

The chemokines are a superfamily of small secreted proteins (molecular weight, 8–10 kd), that shares the ability to chemoattract leukocytes. To date, about 50 distinct chemokine molecules have been described (Fig. 16.1). The chemokines are structurally homologous and are subdivided into four families based on the position of conserved cysteine residues near the N termini of the molecules. CXC chemokines (also known as a-chemokines) are characterized by the presence of two cysteine residues near the N terminus that are separated by one amino acid (CXC motif). In contrast, CC chemokines (also known as b-chemokines) have two cysteine residues that are adjacent (CC motif). The CC and CXC chemokines represent the largest of the chemokine families and contain many members. The C-chemokine family contains only a single member, lymphotactin, which has one cysteine residue near the N terminus (C motif). Likewise, the CXXXC family has only a single member, fractalkine (also called *neurotactin*), whose N-terminal cysteines are separated by three amino acids (CXXXC motif). Fractalkine is unique in that it is expressed as a cell-surface glycoprotein with the “chemokine domain” setting on top of a mucinlike stalk and has both transmembrane and cytoplasmic domains.

Figure 16.1. Chemokines and their receptors. Chemokines are grouped by subfamily and listed individually according to the standard nomenclature: CCLn, CC chemokine ligand; CXCLn, CXC chemokine ligand where *n* refers to the corresponding human gene symbol number in the SCYAN nomenclature. The commonly used acronyms are listed alongside the new nomenclature with alternative names indicated in parentheses. Receptors for each chemokine are indicated where known.

The cysteines in the chemokine molecules form important intrachain disulfide bonds, which determine, in part, the secondary structure of these molecules. It was proposed that the chemokines be given numeric names, like the interleukins and the chemokine receptors. In the proposed nomenclature, CC chemokines are named CCLn, for CC chemokine ligand, where *n* is the number that corresponds to the gene symbol number given to each chemokine as they were mapped and called SCY “n” for a small secreted cytokine, followed by a number. Likewise, the CXC chemokines are named *CXCLn*, for CXC chemokine ligands. Only time will tell how widely accepted and used this nomenclature will be.

The CXC chemokines can be subdivided further based on the presence or absence of an ELR sequence (glutamatic acid-lysine-arginine) preceding the CXC motif, near the N terminus of the molecule (1). This structural difference is important because it delineates separate functional activities of chemokines in this family. In general, the CXC chemokines that contain an ELR sequence [e.g., interleukin-8 (IL-8) and neutrophil-activating peptide-2 (NAP-2)] are chemotactic for neutrophils, whereas non-ELR-containing chemokines [e.g., interferon-inducible protein 10 (IP-10) and B-cell attracting chemokine (BCA)] are active on lymphocytes.

In general, the CC chemokines are chemotactic for monocytes, eosinophils, basophils, and lymphocytes, with variable selectivity, but are inactive on neutrophils. Within the CC chemokines, the monocyte chemoattractant proteins (MCPs 1–5) and the eotaxin molecules (eotaxin 1–3) share approximately 65% identity and represent a subfamily within the b-chemokines (2). Like the CXC chemokines, the N-terminal amino acids preceding the CC residues of the CC chemokines are critical for their biologic activity and leukocyte selectivity. For example, the addition or deletion of a single amino acid residue at the amino-terminus of monocyte chemoattractant protein-1 reduces its biologic activity on monocytes by 100- to 1000-fold (3), and the deletion converts it from an activator of basophils to an eosinophil chemoattractant (4).

Several chemokines undergo N-terminal proteolytic processing after secretion that alters their activity, which can activate, inactivate, or even create natural inhibitors. For example, the inactive platelet granule chemokine, platelet basic protein, is N-terminally processed by monocyte proteases to generate NAP-2, which is a CXC chemokine that is active on neutrophils (5). In contrast, other chemokines, such as regulated on activation, normal T-cell expressed and secreted (RANTES), and stromal-derived factor-1 (SDF-1), are cleaved and inactivated by CD26, a leukocyte cell-surface dipeptidyl exopepdiase IV (6,7 and 8). CD26 cleaves the first two amino acids from peptides with penultimate proline or alanine residues, a sequence found at the N terminus of many chemokines. Still other chemokines, such as MCP-2, have posttranslation modification that removes the first five amino acids, resulting in a natural inhibitor of MCP-1, MCP-2, MCP-3, and RANTES (9). Thus, posttranslational modification may be a general mechanism whereby local factors can positively or negatively regulate chemokine activity.

CHEMOKINE RECEPTORS

Chemokines induce cell migration and activation by binding to specific G protein-coupled cell-surface receptors on target cells (10,11). Five human CXC chemokine receptors (CXCR1–5) and nine human CC chemokine receptors (CCR1–9) have been identified (Fig. 16.1). Most receptors recognize more than one chemokine, and several chemokines can bind to more than one receptor. There is receptor-ligand specificity within chemokine subfamilies, however, with CXC-chemokines binding exclusively to CXC receptors and CC chemokines binding to CC receptors. The molecular explanation for this ligand-receptor subfamily restriction may be related to structural differences between CC and CXC chemokines. Although they share similar primary, secondary, and tertiary structures, CC and CXC chemokines have different quaternary structures (12).

Chemokine receptors are expressed on multiple cell types, including all mature hematopoietic cells. Certain receptors have a restricted expression (e.g., CCR3 predominantly on eosinophils and basophils and CXCR1 and CXCR2 predominantly on neutrophils), whereas other receptors are more widely expressed (e.g., CXCR4 on most cells, including all leukocytes). Expression of a given receptor on a given cell type can vary with the state of cellular differentiation and activation. For example,

CCR1 and CCR2 are constitutively expressed on monocytes but are expressed on lymphocytes only after stimulation by IL-2 (13). Constitutive chemokine receptor expression can be downregulated following cellular activation. For example, CCR2 is downregulated by lipopolysaccharide, making the cells unresponsive to MCP-1. These cells remain responsive to chemokines, which signal through other receptors, such as macrophage inflammatory protein-1a (MIP-1a), which binds to CCR1 and CCR5 (14).

Certain chemokine receptors are expressed only on activated cells. For example, CXCR3 appears to be expressed only on IL-2 activated T lymphocytes (15). As such, transient upregulation of chemokine receptors on leukocytes allows for the amplification of immune responses. The expression of chemokine receptors has been characterized most extensively on hematopoietic cells; however, chemokine receptor expression is not restricted to cells of this lineage. For example, CXCR4 is expressed on endothelial cells, epithelial cells, and neurons (16,17 and 18), suggesting roles for the chemokine system in addition to leukocyte chemotaxis.

In addition to these receptors, the chemokines interact with two types of nonsignaling receptors. One is the promiscuous erythrocyte chemokine receptor, called Duffy antigen receptor for hemokines (DARC) (19). This receptor has been known since the 1950s as the Duffy blood group determinant and is expressed on erythrocytes and endothelial cells. Although DARC is structurally related to the chemokine receptors and both CXC and CC chemokines bind to it, chemokine binding does not induce a calcium flux. This receptor may function as a chemokine sink, clearing chemokines from the circulation.

The other type of “receptor” that the chemokines interact with is proteoglycans. The chemokines are basic proteins and bind avidly to negatively charged glycosaminoglycans (20,21,22 and 23). Proteoglycans serve to capture chemokines in the extracellular matrix and on the surface of endothelial cells, which may serve to establish a local concentration gradient from the point source of chemokine secretion (20).

Chemokine Receptor Signaling

The signal transduction events activated by ligand binding controlling leukocyte migration are not entirely defined and involve many different signaling pathways (Fig. 16.2) (24,25). A dramatic polarization of the cell occurs in response to a chemotactic gradient, which is the result of asymmetric signal transduction and the establishment of intracellular molecular gradients (26,27). Although all the molecular details remain to be elucidated, certain signaling molecules appear to play important roles in chemokine-induced cell movement. Chemokine receptors are coupled to the Gi subfamily of G proteins, and pertussis toxin (PTX), which adenosine diphosphate (ADP) ribosylates and irreversibly inactivates the Ga subunits of the ai class, inhibits most of the chemokine-induced effects on leukocytes, including chemotaxis, calcium flux, and integrin activation (28). Other signaling events activated by most chemokine receptors include the activation of phospholipase C (PLC), leading to generation of inositol triphosphates, intracellular calcium release, and protein kinase C (PKC) activation. Inhibition of chemokine-induced chemotaxis by wortmannin implicates phosphatidylinositol 3-kinase (PI3K) in chemokine receptor signal transduction. Mouse strains engineered with null a mutation of the p110 subunit of PI3Kg have defects in chemokine-induced neutrophil and macrophage migration, confirming the importance of this enzyme in directed leukocyte movement (29). Phorbol myristate acetate (PMA) activation of integrins implicates PKC as a potential mediator by which chemokines activate integrins. Chemokine signaling also leads to guanine nucleotide exchange on Rho, indicating the activation of Rho (30). Rac and Rho are small guanosine triphoshate (GTP)-binding proteins that are involved in controlling cell locomotion through regulation of actin cytoskeletal rearrangement leading to membrane ruffling and pseudopod formation.

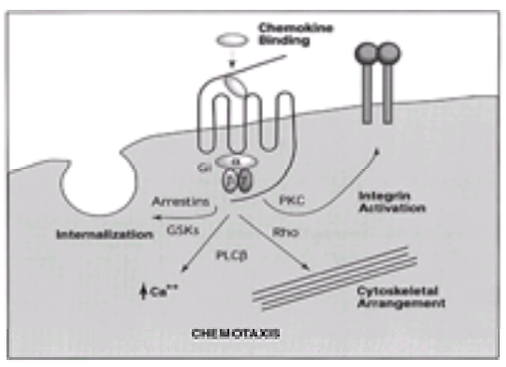

Figure 16.2. Chemokine receptor signal transduction. Chemokine receptors are a subfamily of G protein-coupled seven-transmembrane spanning cell-surface receptors. They are coupled to heterotrimeric G proteins of the Gi subclass, which are distinguished by their pertussis toxin sensitivity. Chemokine receptor activation leads to the stimulation of multiple signal transduction pathways, including the activation of phosphatidylinositol 3-kinase (PI3K) and phospholipase C (PLC), leading to generation of inositol triphosphates, intracellular calcium release and protein kinase C (PKC) activation. Chemokine signaling also induces the upregulation of integrin affinity and the activation of Rho, leading to cytoskeletal reorganization. Agonist-stimulated receptors also activate G protein receptor kinases (GRKs), which leads to receptor phosphorylation, arrestin binding, G protein uncoupling (desensitization), and clathrin mediated receptor endocytosis (internalization).

Agonist-stimulated receptors also activate G protein receptor kinases (GRKs). Activated GRKs phosphorylate serine and threonine residues in the tail of G protein-coupled receptors (GPCRs) (31). Receptor phosphorylation is followed by the binding of arrestins, which bind specifically to phosphorylated receptor, uncouple the receptor from G proteins (*desensitization*), and function as adaptor molecules, leading to clathrin-mediated endocytosis (*internalization*). These internalized receptors are either dephosphorylated by phosphatses and recycled to the cell surface or targeted for degradation. Desensitization and recycling of chemokine receptors may be an important mechanism by which leukocytes maintain their ability to sense a chemoattractant gradient during an inflammatory response, whereas degradation of chemokine receptors may lead to termination of migration. Thus, chemokine receptors activate multiple intracellular signaling pathways that regulate the intracellular machinery necessary to propel the cell in its chosen direction.

ROLE IN THE MULTISTEP MODEL OF LEUKOCYTE RECRUITMENT

Leukocyte extravasation from the blood into the tissues is a regulated multistep process that involves a series of coordinated leukocyte–endothelial cell interactions (Fig. 16.3) (32,33). Several families of molecular regulators, such as the selectins, the integrins, and the chemokines, are thought to control different aspects of the process. In the multistep model, leukocyte extravasation begins with leukocyte rolling, a process that is dependent on selectins. Conversion of rolling to firm adherence depends on the activation of leukocyte integrins, a process that is dependent on cell signaling. Increasing evidence supports a role for chemokines as important activators of the leukocyte integrins.

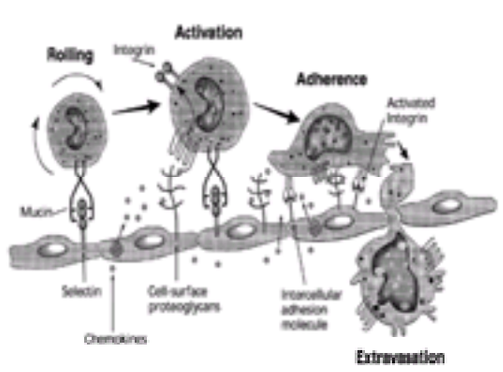

Figure 16.3. Chemokines activate integrins and convert leukocyte rolling to firm adhesion, which ultimately leads to diapedesis. Chemokines are produced by endothelial cells or transported across endothelial cells if produced by cells in tissue and presented bound to proteoglycans, which help maintain a local concentration gradient. Leuokocytes roll along endothelium in a process dependent on selectins and their mucin receptors sampling the endothelial surface. Ligand activation of leukocyte chemokine receptors induces a conformational change in surface integrins that favor binding to intercellular adhesion molecules on the surface of endothelial cells. This leads to firm adhesion and arrest of rolling leukocytes before extravasation through the endothelial layer.

The activation of integrins by chemokines has been shown for many leukocytes, including lymphocytes, monocytes, eosinophils, and neutrophils. The activation of leukocyte integrins by chemokines was demonstrated experimentally by examining the expression of integrin activation epitopes and the adhesion of leukocytes to

purified counterligands or endothelium under static and flow conditions. Using the more physiologically relevant flow-based adhesion assays, SDF-1, secondary lymphoid-tissue hemokine (SLC, also called 6Ckine), and MIP-3b (also called ELC, for Epstein-Barr virus-induced gene 1 chemokine ligand) induced the rapid adhesion of naive lymphocytes to vascular cell adhesion molecule (VCAM-1) (34) and mucosal cell adhesion molecule-1 (MAdCAM-1) (35). In contrast, firm adhesion of naive lymphocytes was not induced by other chemokines, including MIP-1a, MIP-1b, RANTES, growth-regulated oncogene-a (GRO-a), IL-8, interferon-induced protein 10 kd (GRO-a), or eotaxin, demonstrating the selective nature of this chemokine-induced adhesiveness. IP-10 and monokine-induced by g-interferon (Mig) induced firm adhesion of activated but not resting T cells to purified VCAM-1 and intercellular adhesion molecule (ICAM-1) (36). These chemokine-induced increases in integrin affinity and cellular adhesion were PTX sensitive, suggesting a dependence $G_i a$-linked chemokine receptor signaling.

Chemokine-induced adhesiveness to vascular endothelium has also been demonstrated for monocytes. Exposure of peripheral blood monocytes to MCP-1 or IL-8 led to rapid adhesion to vascular endothelium under flow conditions (37). Blocking studies with integrin-specific monoclonal antibodies suggested that this adhesion was mediated in part through b2 integrins.

An additional complexity of chemokine-induced integrin activation is beginning to be unraveled with the demonstration that individual chemokines can differentially activate specific integrin avidity on the same cell type. For example, MCP-1 differentially activates b1 and b2 integrins on lymphocytes (38), whereas RANTES and MCP-3 differentially activate b1 and b2 integrins on eosinophils (39), and IL-8 differentially activate b2, b3, and b7 integrins in a B lymphoblastoid line transfected with the IL-8 receptor (40). The exact signaling pathways downstream of PTX-sensitive G proteins, whereby chemokines induce activation of specific integrins, remains to be established and is an active area of investigation.

Taken together, these data support the concept that chemokines are important activating signals of leukocytes that convert the low-affinity selectin-mediated interactions into a higher affinity integrin-mediated adhesion. This ultimately leads to firm adherence of leukocytes to the vessel wall before the transmigration of the endothelial barrier. As such, at least certain members of the a and b chemokines can function not only as leukocyte chemoattractants but also as proadhesive agents in the recruitment of leukocytes to sites of inflammation.

ROLE OF CHEMOKINES IN DEVELOPMENT AND HOMEOSTASIS

Chemokines provide the directional cues for the movement of leukocytes in development and homeostasis.

Development

The importance of chemokines in development can be demonstrated by analyzing the effects of targeted deletions of chemokines and chemokine receptors in murine systems. Such experiments have elucidated unexpected roles for chemokines *in vivo*. For example, mice deficient in SDF-1 (41) or its receptor CXCR4 (42,43) have defects in B-cell lymphopoiesis and the recruitment of hematopoietic progenitors from the fetal liver into the bone marrow, suggesting an important role for this chemokine in these processes. These mice also demonstrated defects in cardiac, cerebellar, and vascular moprhogenesis. This dramatic phenotype underscores the possibility that, aside from directing the migration of leukocytes to sites of inflammation and infection, chemokines may play an important role in orchestrating the movement of cells during development.

This dramatic developmental defect appears to be the exception rather than the rule, however, for targeted deletions of chemokines or their receptors. For example, mice with a targeted deletion of CCR1 (44,45), CCR2 (46), CCR5 (47), MIP-1a MCP-1 (48), eotaxin (49), or IP-10 (unpublished observations) develop normally and do not manifest any significant pathologic lesions at baseline. In these circumstances, defects in immune function sometimes can be demonstrated after specific immunologic challenge. For example, deletion of MCP-1 and its receptor CCR2 resulted in mice that did not manifest any gross pathologic defect but manifested clear defects of macrophage and monocyte recruitment on stimulation (46,48).

Homeostasis

Chemokines are also believed to control the baseline trafficking of leukocytes through tissues. Lymphocytes continuously recirculate through the blood, tissues, and lymphatics in an organized manner, bringing naive lymphocytes into the lymph nodes, where they encounter antigen and memory lymphocytes into inflamed tissue to ensure immunity. T cells routinely patrol the body in search of foreign antigens and recirculate through the blood, tissue, and lymphatics, making more than 20 round trips each day. Several recently identified chemokines are believed to participate in guiding T cells in this process. One such chemokine that has been independently identified by several groups and given the various names of secondary lymphoid chemokine (SLC), exodus-2, 6Ckine, and thymus-derived chemotactic agent 4 (TCA-4), appears to play an important role in directing naive T cells into peripheral lymph nodes. A role for SLC in the trafficking of T cells into lymph nodes has been suggested from studies that have examined the mutant mouse strain DDD (50). This mutant mouse strain has a paucity of lymph node T cells (and hence also called *plt*) because of a defect in the lymph node stroma. Lymph nodes from the DDD mouse do not express the SLC chemokine (51) because of a mutation in one of two SLC genes that is normally expressed in lymphoid tissue (52).

Much the same way T cells recirculate, B cells also traffic through the body, and this process is also controlled by chemokines (53). The B-cell specific CXC chemokine independently identified as BCA-1 and BLC (B-lymphocyte chemoattractant) is an important participant in this process (54,55). BCA is a potent chemotactic factor for B cells and is expressed in the follicles of Peyer's patches, the spleen, and lymph nodes. BCA is a ligand for CXCR5, which is highly expressed on peripheral blood B cells. A role for BCA and CXCR5 in B-cell trafficking was revealed by the generation of a mouse strain deficient in CXCR5 (56). These mice have an impairment in the trafficking of peripheral blood B cells into lymph nodes.

Other leukocytes, such as macrophages, neutrophils, eosinophils, and mast cells, also traffic into tissue. Although these cells are produced in the bone marrow, they reside primarily in other tissues. The role of chemokines in regulating this process has begun to be elucidated from studies in mice deficient in chemokines. For example, the IL-8 receptor homolog in mice, murine CXCR2, plays an important role in drawing circulating neutrophils into tissues in unchallenged mice (57). Likewise, eotaxin plays a critical role in normal eosinophil recruitment into tissues, especially the gastrointestinal tract where eosinophils are thought to play an important role in host defense against helminthic pathogens (49).

ROLE IN ORCHESTRATING THE IMMUNE RESPONSE: LINKING INNATE AND ADAPTIVE IMMUNITY

Chemokines provide the directional cues necessary to bring together T cells, B cells, and dendritic cells to generate an immune response and to recruit leukocytes into sites of inflammation and infection (Fig. 16.4).

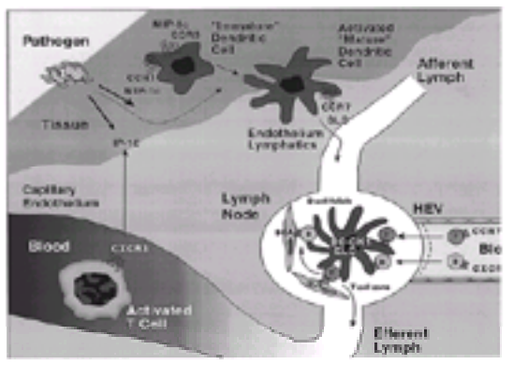

Figure 16.4. Chemokines orchestrate the trafficking of dendritic cells, T cells, and B cells necessary to generate an immune response. In the example depicted, LPS on the surface of bacterial pathogens stimulates the local release of chemokines, such as MIP-1a, MIP-3a, and IP-10. Immature dendritic cells are attracted to this site through the activation of chemokine receptors, such as CCR1 and CCR6, which they constitutively express. Immature dendritic cells are efficient at picking up antigen but need to mature and differentiate into cells capable of activating naive T cells. The local milieu into which the immature dendritic cell has been attracted contains factors, such as lipopolysaccharide (LPS) and tumor necrosis factor (TNF), that induce dendritic cell differentiation and maturation into potent antigen presenting cells. In this process, the dendritic cell downregulates CCR6 and upregulates CCR7, which leads to its migration into the afferent lymphatic. The CCR7 ligand SLC, which is expressed on the endothelium of afferent lymphatics, likely plays an important role in directing the migration of the antigen-loaded mature dendritic cells. Chemokines also play an important role in bringing naive T cells and B cells across high endothelial venules (HEV) into the lymph nodes and into contact with the activated dendritic cell. Although the molecular details remain to be elucidated, it is likely that chemokines, such as DC-CK1 and Epstein-Barr virus-induced gene 1-ligand chemokine (ELC), play an important role in juxtapostioning these cells in the lymph node. SLC and ELC are prodcued from stromal cells in the T-cell zone, whereas B-cell attracting chemokine (BCA) is expressed from stromal cells in the B-cell follicle, helping to guide cells to T- and B-cell areas, respectively. Some activated T cells downregulate CCR7 and upregulate CXCR5 and become directed toward the follicle, whereas other activated T cells upregulate CXCR3 and are attracted into inflamed

tissue. T cells activated in regional lymph nodes, following encounter with antigen-loaded dendritic cells, subsequently return to sites of inflammation by sensing chemokine gradients established at these local sites. Chemokines such as IP-10, a chemokine induced by LPS and IFNg, and a ligand for CXCR3, which is highly expressed on activated T cells, are believed to play an important role in this process.

Generation of Effector Lymphocytes

Dendritic cells are thought to play a pivotal role in generating an immune response by capturing and presenting antigen to lymphocytes in a process that leads to the activation of T and B cells. Dendritic cells in tissue capture and process antigen and transport it to local lymph nodes for presentation to lymphocytes. Several studies suggested that chemokines participate in this process (58,59). Immature dendritic cells reside in the tissue, where they are efficient at engulfing antigen but are not so efficient at activating lymphocytes. Immature CD34+ Langerhans-like dendritic cells respond to a number of chemokines, including the CC chemokine MIP-1a and MIP-3a, which has also been called liver and activation-regulated chemokine (LARC) or exodus. MIP-3a is a ligand for CCR6, which is highly expressed and functional on immature dendritic cells. MIP-3a is constitutively expressed by keratinocytes and venular endothelial cells in normal skin (60) and may be an important role in the trafficking of epidermal Langerhans cells to the skin. In addition, MIP-3a is expressed in tonsils by inflamed epithelium, a site known to be infiltrated by immature dendritic cells (61). Moreover, MIP-3a and MIP-1>a are induced by inflammatory stimuli, such as lipopolysaccharide (LPS) or tumor necrosis factor-a (TNFa). It has been hypothesized that MIP-3a attracts immature dendritic cells into the tissue, a process that is likely amplified by other “inflammatory” chemokines, such as MIP-1a. Once in the vicinity of the inflammatory stimulus, immature dendritic cells pick up antigen and then differentiate into cells more capable of activating lymphocytes. During this maturation process, dendritic cells downmodulate the expression of CCR6 and hence responsiveness to MIP-3a. At the same time, they upregulate their expression of CCR7, allowing them to respond to SLC and ELC. This switch in chemokine receptor expression and chemokine responsiveness results in the dendritic cells leaving the tissue and being drawn into the lymphatics and, ultimately, into the T-cell-rich regions of lymph nodes.

Although the molecular details remain to be fully elucidated, it is likely that the expression of chemokines by lymph node stroma and dendritic cells coordinate the juxtaposition of antigen-loaded dendritic cells with recirculating T and B cells. Chemokines that may play a role in this process are dendritic cell chemokine 1 (DC-CK1) [which was also identified as pulmonary and activation-regulated chemokine (PARC), alternative macrophage activation-associated GC chemokine-1 (AMAC-1), and MIP-4, monocyte-derived chemokine (MDC), thymus-expressed chemokine (TECK), and ELC (MIP-3b)]. DC-CK1 and ELC are expressed by activated mature dendritic cells and recruit naive T cells (62,63). In contrast, MDC is induced in Langerhans cells migrating from contact-sensitized skin during maturation into lymph node dendritic cells and chemoattracts antigen-specific T cells but not naive T cells (64). SLC and ELC are produced from stromal cells in the T-cell zone, whereas BCA is expressed from stromal cells in the B-cell follicle helping to guide cells to T- and B-cells areas, respectively. Some activated T cells may downregulate CCR7 and upregulate CXCR5 and become directed toward the follicle, whereas other activated T cells downregulate CCR7 and upregulate CXCR3 and are attracted into inflamed tissue.

T cells activated in regional lymph nodes, following an encounter with antigen-loaded dendritic cells, subsequently return to sites of inflammation by sensing chemokine gradients established at these local sites. Chemokines such as IP-10, a chemokine induced by LPS and interferon (IFN), and a ligand for CXCR3, which is highly expressed on activated T cells, plays an important role in this process (65) (Fig. 16.4).

Chemokines and Lymphocyte Effector Function: Localization of Cells to Tissue

Chemokines also participate in the effector phase of immune responses to coordinate the localization and specificity of the immune response. This is exemplified in T-cell-mediated immune responses. T-cell-mediated inflammatory responses can be segregated into distinct patterns based on the cytokine secretion pattern of CD4+ T-helper lymphocytes. T-helper (Th)-1 cells secrete mainly IL-2, IFN-g, and IL-12 and mediate immune responses characterized by delayed-type hypersensitivity with activated T cells and macrophages. In contrast, Th2 cells secrete IL-4, IL-5, IL-10, and IL-13, are involved in allergic inflammatory responses, and favor the development of humoral immunity [antigen-specific immunoglobulin E (IgE), and mast cell and eosinophil activation]. Studies suggested that, under certain conditions, Th1 and Th2 cells can express different chemokine receptors (66) (Fig. 16.5 and Fig. 16.6). In these studies, Th1 cells preferentially expressed CXCR3, CCR5, and CCR7 following activation, whereas activated Th2 cells expressed CCR3, CCR4, and CCR8. This differential expression of chemokine receptors may play an important role in the selective recruitment of polarized lymphocyte subsets in different disease states.

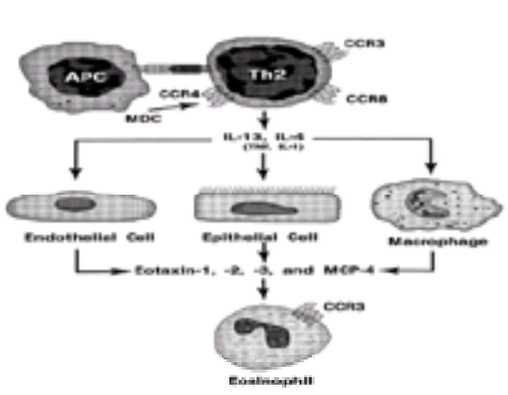

Figure 16.5. Chemokines link T-cell helper (Th2) lymphocyte activation and tissue eosinophilia. Antigen-activated CD4+ Th2 cells elaborate interleukin-4 and -13 (IL-4, IL-13), which synergize with proinflammatory cytokines, such as IL-1 and tumor necrosis factor (TNF), stimulating the production of eosinophil chemoattractants, such as eotaxin-1, eotaxin-3, and MCP-4, from epithelial and endothelial cells are tissue macrophages. These chemokines, in turn, attract activated eosinophils into the tissue, resulting in the hallmark of allergic diseases.

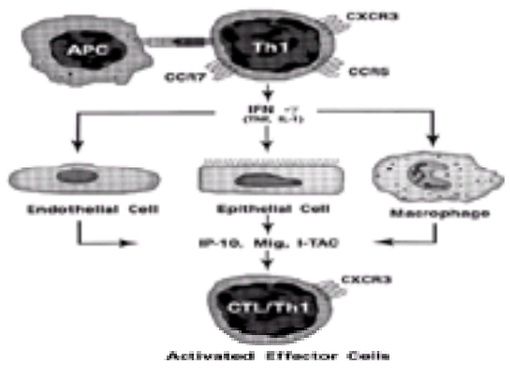

Figure 16.6. Chemokines amplify T-cell helper 1 (Th1) responses and recruit cytotoxic T-lymphocytes (CTLs) to sites of infection. Antigen-activated CD4+ Th1 cells elaborate IFNg, which synergizes with proinflammatory cytokines, such as IL-1 and TNF, stimulating the production of interferon-inducible protein 10 (IP-10), Mig, and interferon-induced T-cell µ chemoattractant (I-TAC) from epithelial and endothelial cells, which are tissue macrophages. These chemokines, in turn, attract activated Th1 cells and CTLs into the tissue.

Allergic pulmonary inflammation exemplifies a specific disease state in which a polarized inflammatory response (Th2 based) occurs. In certain persons, primary sensitization with an airborne allergen leads to the development of antigen-specific CD4+ T cells with a Th2 cytokine secretory phenotype. A secondary encounter with antigen leads to the elaboration of Th2 cytokines that promote the growth and maturation of eosinophils (IL-5) and mast cells (IL-3) and favor the class switch of Ig to the production of IgE (IL-4). These three developments are the hallmark of allergic inflammation. Th2 cells also secrete cytokines that promote the production of eosinophil-active chemokines, such as eotaxin-1, eotaxin-2, eotaxin-3, and MCP-4 (Fig. 16.5). The production of cytokines, such as IL-13, at the site of antigen deposition (e.g., respiratory tract) leads to the localized production of the eotaxins and MCP-4 from endothelial and epithelial cells, resulting in eosinophilic tissue inflammation (2).

Chemokines also play a role in the effector function of Th1 inflammtory processes, such as the host response to intracellular pathogens, and numerous chronic inflammatory diseases, such as multiple sclerosis, sarcoidosis, rheumatoid arthritis, and atherosclerosis. Activated Th1 cells express CXCR3 and CCR5 and respond to the CXCR3 ligands IP-10, Mig, and interferon-induced T-cell a chemoattractant (I-TAC), and the CCR5 ligands MIP-1a, MIP-1b, and RANTES (67,68 and 69). These *in vitro* studies were supported by studies that examined chemokine and chemokine receptor expression in diseased tissue. We reported that human atheroma express high levels of IP-10, Mig, and I-TAC and that virtually all the T cells found in atheromatous lesions were CXCR3 positive (70). Likewise, high levels of IP-10 were found in the bronchoalveolar fluid of patients with active pulmonary sarcoidosis, and all the BAL T cells were CXCR3 positive (71). Similarly, in rheumatoid arthritis patients, T cells recovered from synovial fluid expressed higher levels of CXCR3 and CCR5 than peripheral blood T cells (72). Lymphocytes infiltrating the liver of patients with chronic hepatitis C expressed CXCR3 and CCR5 (73). Whereas the CCR5 ligands MIP-1a and MIP-1b were confined to the vessels within the portal tract, the CXCR3 ligands IP-10 and Mig were selectively upregulated on sinusoidal endothelium. These findings suggest a specific role for CXCR3 ligands, as opposed to CCR5 ligands, in the recruitment of T cells into the hepatic parenchyma. Taken together, these studies implicate the IFNg-inducible CXC chemokines IP-10, Mig, and I-TAC, in regulating Th1 cell trafficking into tissue where there is ongoing Th1 inflammation (Fig. 16.6). In support of this hypothesis, we found that IP-10 plays a critical role in the recruitment of effector T cells into tissue following infection with the intracellular pathogen *Toxoplasma gondii* (65).

Chemokines also play a role in the effector function of CD8+ cytotoxic T-lymphocytes (CTLs). CD8+ lymphocytes play an important role in the host defense against viral infection, including human immunodeficiency virus-1 (HIV-1) (74). CD8+ T cells exert their effector functions through both cytolytic and noncytolytic mechanisms (75). Chemokines are important effector molecules in preventing viral entry into cells by HIV (76). CD8+ T cells are at least one important source of these chemokines. The release of chemokines from CD8+ T cells is dependent on the activation of these cells through their T-cell receptors for antigen (77) (Fig. 16.7). We found that these chemokines, including RANTES, MIP-1a, and MIP-1b, are stored preformed in cytolytic granules, colocalized with granzyme A and proteoglycans (78). Following CTL activation, the contents of the cytolytic granules, including chemokines complexed to proteoglycans, are coordinately released, where they participate in antiviral effector functions by inhibiting viral entry into uninfected cells. This finding demonstrates the coupling of cytolytic and noncytolytic antiviral functions of CD8+ T cells, which is regulated by antigen-specific T-cell activation.

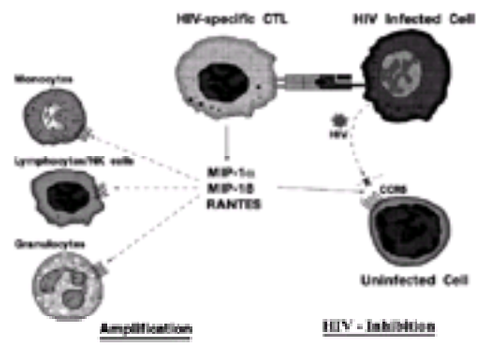

Figure 16.7. Chemokines released from cytotoxic T-lymphocytes (CTL) localize and amplify the immune response by recruiting leukocytes to the site of viral replication and inhibit human immunodeficiency virus-1 (HIV-1) entry into cells. Antigen activation of CD8+ cytotoxic T cells results in the release of MIP-1a, MIP-1b, and RANTES directly onto the target cell. The release of these chemokines at the site of infection serves as a beacon to call in additional leukocytes, such as macrophages, granulocytes, and natural killer (NK) cells, resulting in the amplification of the local immune response. In the case of HIV-1 infection, these CCR5 ligands have the additional property of inhibiting HIV entry into nearby cells.

The release of chemokines from CTLs following antigen specific activation is a general property of these cells and is not restricted to HIV-specific CTLs. CTLs specific for hepatitis B and C virus-infected cells also release large amounts of chemokines when activated by antigen (75). The release of chemokines directly onto the infected cell recruits other inflammatory cells, including professional phagocytes to the site of viral replication, amplifying the response to include the power of the innate immune system.

Role in Human Disease

It is likely that chemokines play a role in most disease processes that result in the accumulation and activation of leukocytes in tissues (79). Chemokines have been detected during inflammation in most organs, including the skin, brain, joints, meninges, lungs, blood vessels, kidneys, and gastrointestinal tract. In these organs, chemokines can be detected in many types of cells, suggesting that most, if not all, cells have the capacity to secrete them given the appropriate stimulus. Major stimuli for chemokine production are early proinflammatory cytokines, such as IL-1 and TNFa, bacterial products such as LPS, and viral infections. In addition, IFNg and IL-4/IL-13, products of Th1 and Th2 lymphocytes, respectively, can induce the production of chemokines and also synergize with IL-1 and TNFa to stimulate chemokine secretion. The capacity to control precisely the movement of inflammatory cells suggests that the various chemokines and their receptors might provide novel targets for therapeutic interventions to modify the courses of these diseases.

The type of inflammatory infiltrate that characterizes a specific disease is controlled, in part, by the subset of chemokines expressed in the disease. For example, many acute disease processes, such as bacterial pneumonia and the acute respiratory distress syndrome, are characterized by a massive influx of neutrophils into the tissue. The concentration of chemokines that are potent neutrophil chemoattractants, such as IL-8, are increased in the bronchoalveolar fluid of patients who have these diseases (80). Other acute diseases, particularly nonbacterial infectious diseases, such as viral meningitis, are characterized by the recruitment of monocytes and lymphocytes into the tissue. The cerebrospinal fluid concentrations of chemokines active on these cells, such as IP-10 and MCP-1, are increased in these patients, and the concentrations are correlated with the extent of mononuclear cell infiltration of the meninges (81).

Many chronic disease processes are characterized by tissue infiltration of lymphocytes and macrophages. The delayed-type hypersensitivity granulomatous lesions of tuberculoid leprosy, sarcoidosis, and multiple sclerosis is characterized by the accumulation of activated lymphocytes, and high concentrations of IP-10 have been detected in these lesions (71,82,83). In addition, levels of IP-10 in the bronchoalveolar fluid of patients with active sarcoidosis correlated with the number of T-lymphocytes in the fluid (71).

In atherosclerosis, macrophages and lymphocytes are the major inflammatory cells found in the diseased blood vessels. These cells are thought to be central to the pathogenesis of this disease, both as progenitors of lipid-laden foam cells and as a source of growth factors that mediate intimal hyperplasia. The CC chemokines [(MCP-1, MCP-4, RANTES), pulmonary and activation-regulated chemokine (PARC), and ELC)] and the CXC chemokines (IL-8, SDF-1, IP-10, Mig, and I-TAC) have all been detected in diseased vessels but not in normal arteries. A functional role for MCP-1 (84) and its receptor CCR2 (85) as well as for the mouse IL-8 receptor CXCR2 (86) in the recruitment of monocytes into atherosclerotic lesions was revealed when mice deficient in these genes were bred with mouse strains prone to develop atherosclerosis, such as the apolipoprotein-E-deficient and low-density lipoprotein (LDL) receptor deficient mouse strains. These “bigenic” (double transgenic) mice had a decrease in the number of lesional macrophages and a decrease in atherosclerotic lesion formation, establishing a role for chemokines in the pathogenesis of this disease.

In allergic diseases, such as asthma, rhinitis, and atopic dermatitis, the selective accumulation and activation of eosinophils and mast cells characterize the inflammatory reaction. Agents that induce the release of histamine from mast cells and basophils, so-called histamine releasing factors, are also strongly associated with the pathogenesis of allergic diseases. Chemokines, in particular eotaxin and the MCPs, are potent eosinophil chemoattractants and histamine-releasing factors, making them particularly important in the pathogenesis of allergic inflammation. In fact, the chemokines may be the major histamine-releasing factors in the absence of antigen and IgE antibody. Many chemokines have been detected in the airways of patients with asthma. In addition, several eosinophil-active chemokines are increased in the epithelial tissue of patients with atopic dermatitis, allergic rhinitis, and asthma after antigen challenge, making it likely that the chemokines are one of the molecular links between antigen specific immune activation and tissue recruitment of eosinophils. In animals with allergic pulmonary inflammation, expression of eotaxin, MIP-1a, and MCP-1, -3, and -5 precede the massive airway recruitment of mononuclear cells and eosinophils. From studies using antibodies that inhibit the action of these chemokines and studies of mice with a targeted disruption of the eotaxin gene, it is clear that all these chemokines are participating in the recruitment of eosinophils into the airways.

SUMMARY

Although initially identified as chemotactic factors profoundly induced by proinflammatory stimuli that mobilize the innate immune system and control the recruitment of leukocytes into inflammatory foci, the chemokines have emerged as important regulators of cellular trafficking in development and homeostasis. In addition, they are critical for the coordinated movement of dendritic cells and lymphocytes necessary to link the acquired immune response to the innate response and generate

long-lasting antigen specific immunity. Chemokines are highly expressed in human inflammatory diseases, and their specific roles in disease pathogenesis are being elucidated, revealing that these fascinating molecules offer a new class of targets for the treatment of a variety of human diseases.

17 HEMATOPOIETIC CYTOKINES

E. Richard Stanley, Ph.D.

Blood contains red cells, monocytes, lymphocytes, megakaryocytes, and the various types of granulocyte. All mature blood cell types turn over rapidly. Investigators have estimated that humans produce 2×10^6 red blood cells every second. White blood cells, which represent at least 0.1% of red blood cell numbers, can be expected to be produced at a proportionally similar rate. In the adult, differentiated blood cells are all ultimately derived from a small bone marrow pool of undifferentiated, pluripotent hematopoietic stem cells. This process, involving extensive cell proliferation and differentiation, is known as *hematopoiesis.* Work carried out since the 1960s has indicated that hematopoiesis is regulated by a specific group of cytokines.

The studies of Till and McCulloch paved the way to our current understanding of the pluripotent hematopoietic stem cell (1), which gives rise not only to mature blood cells (erythroid and myeloid) but also to the lymphoid cells. Previous studies had shown that the intravenous injection of bone marrow cells into lethally irradiated mice could prevent their anemia and death. Till and McCulloch showed that if limiting numbers of normal mouse bone marrow cells were injected into the circulation of the irradiated mouse, colonies could be seen in the recipient animal's spleen 10 days after injection. With other researchers (2,3), they then showed that these spleen colonies were each derived from single cells, and that some contained not only several myeloid cell types but also cells that were capable of generating more splenic colonies after injection into a second lethally irradiated mouse. This finding supported the concept of a hematopoietic stem cell with the capacity to (a) self-replicate; (b) proliferate to produce many cell progeny; and (c) differentiate to generate all the mature blood cell types. Because of their low frequency and difficulty of isolation and maintenance *in vitro,* the existence and characteristics of hematopoietic stem cells have largely been inferred from an analysis of their progeny. In fact, only recently have conditions been established that allow proliferation of such stem cells *in vitro* without their differentiation to more mature cells (4).

It is now generally accepted that the mouse pluripotent hematopoietic stem cell must be capable of the long-term repopulation (longer than 6 months) of both the myeloid and lymphoid systems of lethally irradiated recipient mice. Studies in the mouse have shown that the pool of such stem cells represents only 10^{-5} of the total nucleated bone marrow cells (5). In the normal steady state, cells of this pool are either not cycling or are cycling slowly (6,7). When a stem cell undergoes a stem cell division, it gives rise to a daughter cell that is indistinguishable from the parent cell and a daughter cell that proliferates extensively but also differentiates. Because one exiting hematopoietic stem cell is capable of giving rise to millions of mature descendent cells, only a small proportion of the cells needs to exit the stem cell pool to proliferate and differentiate, despite the high turnover of blood cells. Under the control of several cytokines, the proliferating and differentiating stem cell gives rise to common myeloid (8) and common lymphoid (9) progenitor cells, which, as they proliferate and differentiate, progressively develop a more restricted capacity for differentiation and eventually give rise to cells that are capable of forming only one mature blood or lymphoid cell type (10) (Fig. 17.1).

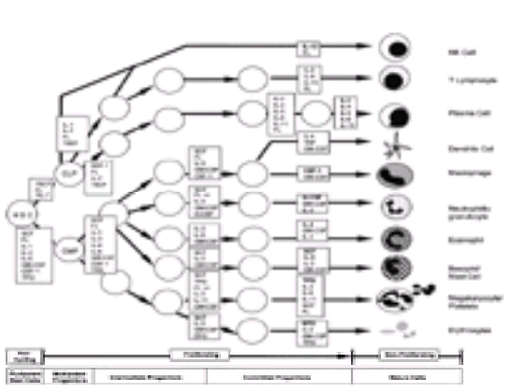

Figure 17.1. Hematopoietic cells, indicating the points of *in vivo* and *in vitro* regulation by hematopoietic cytokines. Note that some cytokines, such as granulocyte-macrophage colony-stimulating factor (GM-CSF), may not regulate steady-state hematopoiesis but can be used to regulate hematopoiesis pharmacologically. Cytokines primarily regulating the proliferation and differentiation of committed progenitors of individual lineages are emboldened. CLP, common lymphoid stem cell; CMP, common myeloid stem cell; HSC, hematopoietic stem cell.

Our understanding of the hematopoietic cytokines arose from the description of semisolid culture methods for bone marrow in which progenitor cells proliferated and differentiated to form macroscopic colonies of mature granulocytes or macrophages (11,12). Colony formation required the presence of a source of a cytokine, or colony-stimulating factor (CSF), and it was subsequently shown that different cytokines caused the development of cells of different lineages. The number of colonies was linearly related to the number of cells cultured, and so these cultures could be used to assay specific progenitor cells in hematopoietic cell populations. In addition, because at a constant cell concentration, the number of colonies was proportional to the concentration of the cytokine, the cultures could also be used as cytokine

assay systems. These *in vitro* bioassays were used to monitor cytokine purification so protein sequence could be obtained and used to clone their genes (13,14 and 15). The analysis of mice with targeted inactivations of the genes encoding most of these cytokines and their receptors has greatly increased our understanding of their biology. Because of the dominant role of cytokines in the regulation of hematopoiesis and the importance of maintaining hematopoiesis in many clinical situations, the production of recombinant cytokines in large amounts has led to their rapid clinical application.

This chapter reviews our current knowledge of the nature and biology of the hematopoietic cytokines, including stem cell factor (SCF), fms-like tyrosine kinase 3 (flt3), ligand (FL), interleukin-3 (IL-3), IL-5, and IL-7, granulocyte-macrophage CSF (GM-CSF), CSF-1 (or macrophage CSF), granulocyte CSF (G-CSF), erythropoietin (EPO), and thrombopoietin (TPO). Also discussed are IL-1, IL-4, IL-6, IL-11, IL-15, leukemia inhibitory factor (LIF), chemokines, and other molecules that are also involved in the regulation of hematopoiesis. Table 17.1 lists the nature, chromosomal gene location, and sources of many of these cytokines, together with the primary hematopoietic phenotypes of the mice deficient in either the cytokine or the cytokine receptor (16,17,18,19,20,21,22,23,24,25,26,27,28,29,30,31,32,33,34 and 35). The hematopoietic lineages they regulate are indicated in Fig. 17.1.

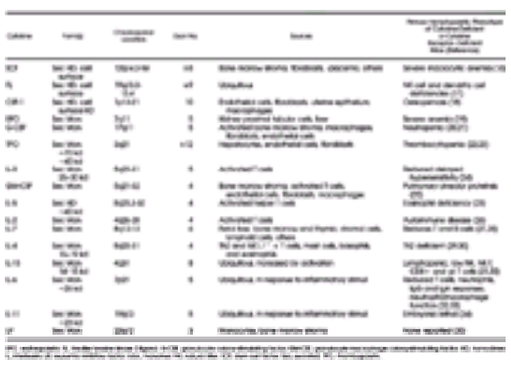

TABLE 17.1. Hematopoietic Cytokines

GENERAL ASPECTS OF CYTOKINES AND CYTOKINE REGULATION OF HEMATOPOIESIS

Sources and Regulation

The hematopoietic cytokines are glycoproteins, which are normally present in the circulation (e.g., CSF-1, SCF, FL, G-CSF, EPO, and TPO) or are induced to appear in response to infection or inflammation (e.g., GM-CSF, IL-3, IL-5, IL-6, and IL-11). They are found in picomolar concentrations, and their concentrations are individually increased in response to specific triggering conditions (e.g., EPO is increased in response to hypoxia) or to depletion of particular blood cell types in various cytopenic conditions (e.g., TPO is increased in response to platelet loss). Apart from EPO, which is synthesized by the kidney, these cytokines are often synthesized by multiple cell types of the bone marrow stroma and immune system. Many are also synthesized by fibroblasts, endothelial cells, and some by yet other cell types, including epithelial cells (Table 17.1).

Cytokine Structure

The carbohydrate moieties of these cytokines are not required for *in vitro* biologic activity, but they may be important for their half-life and localization *in vivo.* Even though there is little conservation of their primary structures, the crystal structures of many of hematopoietic cytokines, including CSF-1 (36), GM-CSF (37), G-CSF (38), IL-2 (39,40), IL-3 (41), and IL-6 (42), have been determined, and they have strikingly similar tertiary structures. In general, like growth hormone (43), they are composed of four a-helical bundles and an antiparallel b ribbon (Fig. 17.2). Some (SCF, CSF-1, FL, and IL-5) are homodimers, whereas the others are monomeric. Three of the cytokines, SCF, CSF-1, and FL, are expressed as membrane-spanning forms that are active at the cell surface and are involved in local regulation (Table 17.1).

Cytokine Receptor Signaling

Hematopoietic cytokine action on target cells is mediated by high-affinity cell-surface receptors (Fig. 17.3) that transduce the binding of their cognate ligands to signals for survival, proliferation, and differentiation. Binding of each of the cytokines to their cognate, high-affinity receptors or to ligand-binding subunits that lead to the assembly of high-affinity receptors results in extracellular cross-linking and dimerization of the signaling subunit and tyrosine phosphorylation of its intracellular domain. This occurs irrespective of whether the receptor contains an intrinsic intracellular tyrosine kinase domain, because the cytoplasmic domains of those that are not receptor tyrosine kinases are preassociated with tyrosine kinases. The end result is the phosphorylation of particular tyrosine residues of the cytoplasmic domains of the receptors that act as binding sites for signaling molecules possessing phosphotyrosine binding domains. Several aspects of the downstream, intracellular signaling pathways of hematopoietic cytokines are similar, because different activated receptor cytoplasmic domains often bind a common signaling molecule or family of signaling molecules.

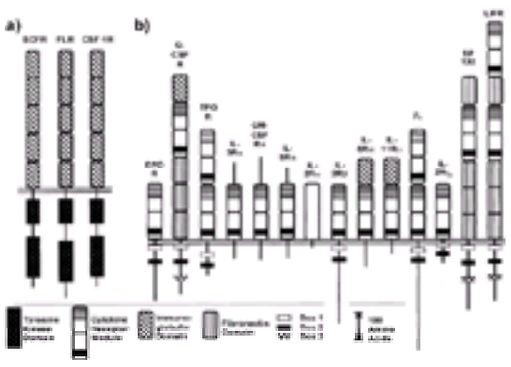

Figure 17.3. Some high-affinity hematopoietic cytokine receptors showing the similarity between those containing intrinsic tyrosine kinase domains **(A)** and the modular

nature of the “cytokine” receptor family **(B),** the signaling subunits of which are preassociated with a tyrosine kinases. The box 1, 2, and 3 motifs of the latter family are the only regions of homology in the cytoplasmic domains. Scale drawing.

Requirement of Multiple Cytokines for the Proliferation and Differentiation of Multipotent Cells

The *in vitro* proliferation and differentiation of primitive hematopoietic cells (pluripotent stem cells and multipotent progenitor cells) require a combination of cytokines (e.g., SCF, IL-1, IL-3, IL-6, GM-CSF, and CSF-1) (44,45). As expected from this multifactorial growth requirement, immature multipotent hematopoietic cells have been shown to coexpress different lineage-specific cytokine receptors at low levels (46). As these cells differentiate, they lose receptors for some cytokines (e.g., SCF or IL-3) while retaining the receptors for the late-acting cytokines (e.g., CSF-1 or EPO). Eventually, they reach the stage of committed progenitor cell, where their further proliferation and differentiation are along one particular lineage and are primarily regulated by one late-acting cytokine. In the case of CSF-1, this transition has been shown to be associated with an increase in the level of expression of the receptor for the late-acting cytokine (Fig. 17.1) that may be critical in conferring responsiveness of the cell to the single cytokine (47). Thus, in the absence of other cytokines, most late-acting cytokines (e.g., CSF-1, G-CSF, and EPO) regulate cells of primarily one lineage that selectively express their cognate receptors. The most primitive target cells within these lineages respond by both proliferating and differentiating (e.g., from committed macrophage progenitor into monoblast into promonocyte into monocyte into macrophage). However, these cytokines also regulate the survival of their target cells, often including the fully differentiated and nondividing end cells (48,49). In many instances, they also play an important role in regulating the function of the terminally differentiated cells. CSF-1 and GM-CSF, for example, prime mature cells for neutrophil and macrophage activation by other agents, such as bacterial lipopolysaccharide or immune complexes (50,51). Despite an apparent overlap in target cell specificity of several cytokines, their functions are largely nonredundant, as indicated by the distinct hematopoietic phenotypes of cytokine or cytokine receptor-deficient mice (Table 17.1).

Mechanism of Synergism between Cytokines

The phenomenon of synergism between late-acting, lineage-restricted cytokines, such as CSF-1, EPO, and G-CSF, with cytokines such as SCF, in stimulating the proliferation and differentiation of primitive multipotent cells, provides a mechanism for coupling the changes in levels of the late-acting cytokine, which are tightly regulated by the primary stimuli (e.g., hypoxia in the case of EPO), to the channeling of multipotent cells into a lineage to satisfy the demand for differentiated cells. The mechanisms underlying synergism among cytokines in the regulation of primitive hematopoietic cell proliferation could occur directly at the level of the receptors for the synergizing cytokines. Alternatively, synergism may occur at the level of the postreceptor signal transduction pathways. No strong evidence indicates that a cytokine directly regulates the increased expression of the receptor for the synergizing cytokine (47). However, in the one case studied in depth, the synergism between SCF and EPO in erythropoiesis, synergism is apparently mediated by the direct association of the SCF receptor (SCFR) with the EPO receptor (EPOR). The activation of the SCFR and its association with the EPOR apparently results in tyrosine phosphorylation of the EPOR at sites that differ from the those phosphorylated as a result of EPOR dimerization induced by EPO (52,53).

Permissive and Instructive Effects of Cytokines in Hematopoiesis

Because hematopoietic cytokines regulate survival and proliferation, one important question is whether their regulation of differentiation is “permissive” or “instructive” (Fig 17.4). Evidence for both mechanisms has been obtained in different systems. The permissive model is one in which the growth factor does not have a role in multipotent progenitor cell commitment but simply allows the survival and proliferation of committed cells. In support of this model, mice in which the thrombopoietin receptor gene was replaced with a gene encoding a chimeric receptor consisting of the extracellular and transmembrane domains of the TPO receptor (TPOR) and the cytoplasmic domain of the G-CSF receptor (G-CSFR) possessed a normal platelet count, a finding indicating that the cytoplasmic domain of the G-CSFR can functionally replace that of the TPOR to support normal megakaryocytopoiesis and platelet formation (54). This finding implies that the cytoplasmic domain of the TPOR does not have an instructive role, or that if it does, it must be shared with the instructive function of the G-CSFR cytoplasmic domain. In fact, the sharing of a common instructive signaling pathway is possible for these two similar receptors because their functions can be largely separated by their different patterns of expression on hematopoietic cells and in cells in which their expression overlaps, by the differential regulation of their cytokines, TPO being constitutively present in the circulation and G-CSF induced. In support of the instructive model, investigators showed that the common lymphoid progenitor cell (Fig. 17.1) can be redirected to the myeloid lineage by stimulation through exogenously expressed IL-2 and GM-CSF receptors, and that the granulocyte and monocyte differentiation signals are regulated by different cytoplasmic domains of the IL-2R (55). Thus, it is possible that both mechanisms are used, and that the one used depends on the receptors and commitment steps involved.

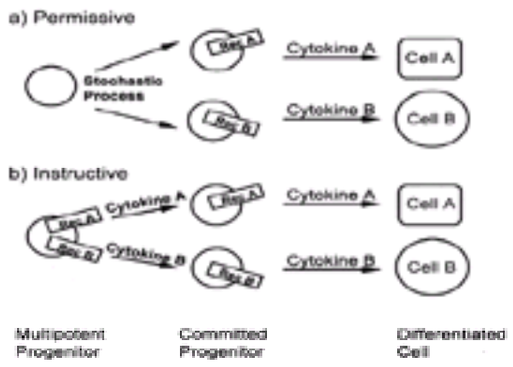

Figure 17.4. Permissive versus instructive models of hematopoietic cytokine action. In the permissive model, multipotent progenitors become committed to either lineage stochastically and consequently express either receptor A or receptor B. Cytokines A and B support the survival and proliferation of committed progenitors expressing their cognate receptor. In the instructive model, multipotent progenitors express receptors for both cytokines A and B. Cytokine A induces their commitment to committed progenitors of the A lineage, whereas cytokine B induces their commitment to the B lineage.

Role of Transcription Factors in the Commitment of Multipotent Progenitor Cells

Experiments with gene-targeted mice (56) and overexpression of transcription factors in multipotent cells clearly indicate that events regulated by nuclear transcription factors are critical for lineage commitment. Thus the transcription factor, GATA-1, reprograms avian myelomonocytic cells from a myeloblast fate into eosinophils, thromboblasts, and erythroblasts, and the transcription factor PU.1 induces myeloid lineage commitment in multipotent hematopoietic progenitors (57,58). Furthermore, investigators have shown that pre-B cells from mice lacking the B-cell transcription factor, Pax 5, not only fail to differentiate to B cells, but also they acquire the capacity to differentiate to macrophages, osteoclasts, granulocytes, natural killer (NK), and T cells (59). These findings suggest that another mechanism underlying lineage commitment may involve the suppression of other lineage fates in multipotent cells by lineage specific transcription factors, such as Pax 5.

CYTOKINES SIGNALING THROUGH TYROSINE KINASE RECEPTORS

General Considerations

The three hematopoietic cytokines signaling through tyrosine kinase receptors, SCF, FL, and CSF-1, are members of a family of homodimeric cytokines that share some sequence similarity and are structurally similar to each other (60,61,62,63 and 64). Because of alternative splicing and differential proteolysis, all three cytokines are expressed as membrane-spanning, cell-surface, and secreted glycoproteins. All three growth factors are widely expressed in tissues. SCF and CSF-1 have been shown to have effects on nonhematopoietic as well as hematopoietic cells, whereas FL has not yet been characterized in this respect.

The SCF, CSF-1, and FL receptors for these cytokines are all members of the PDGFR family (63,65,66). Their mature forms all possess extracellular domains composed of five immunoglobulin (Ig)-like repeats that are heavily glycosylated with N-linked sugars, a transmembrane domain, and intracellular domains containing a juxtamembrane region, an *src*-related tyrosine kinase interrupted by a kinase insert domain, and a carboxy-terminal tail (Fig. 17.3A). The amino-terminal three Ig-like domains incorporate the ligand binding domains of the SCF and CSF-1 receptors. Binding of their cognate bivalent ligands by this class of receptors stabilizes their noncovalent dimerization at the cell surface and permits *trans*-tyrosine phosphorylation of one intracellular domain by the other (Fig. 17.5). Although tyrosine phosphorylation of cytoplasmic proteins in response to cytokine is not restricted to those proteins that stably associate with the receptor, the receptor phosphotyrosines act as “docking sites” for *src* homology region 2 (SH2) domains of signaling and adaptor proteins. These proteins may interact with plasma membrane-associated

proteins, such as the interaction of recruited Grb2/Sos with Ras, leading to their activation, or they may themselves become tyrosine phosphorylated. Many of the signaling pathways activated by these receptors, including the Ras/Raf/mitogen-activated protein kinase (MAPK) cascade, the Janus kinase (JAK)/signal transducers and activators of transcription (STAT) pathway, Src family members, and phosphatidylinositol-3-kinase (PI3K), are shared (67). All three receptors are likely to exhibit ligand-induced, Cbl-mediated receptor downregulation (68). Two of the receptors, SCFR and CSF-1R, are encoded by the protooncogenes c-*kit* and c-*fms*, respectively. v-*kit* and v-*fms* oncogenes are present in retroviruses that cause sarcoma in cats. The viral oncogenes contain mutations in the cellular oncogenes (protooncogenes) that lead to constitutive activation of the receptor in the absence of cytokines (67,69).

Stem Cell Factor

STEM CELL FACTOR AND ITS RECEPTOR

For several decades before SCF was first characterized, the effects of its absence in the Steel (*Sl*) mouse mutants were carefully studied. There are several *Sl* alleles of varying severity, and affected mice variably exhibit defective development in the cell lineages involving pigmentation, hematopoiesis, and fertility (70). Precursor cells of all three lineages undergo migration during normal development for which the cell-surface form of the ligand is apparently important (62). SCF is widely expressed during embryogenesis and in a variety of adult tissues, including bone marrow stromal cells, fibroblasts, and endothelial cells, as well as yolk sac and placenta (71,72). It is synthesized in the endoplasmic reticulum as a 248-amino acid membrane-spanning precursor that dimerizes noncovalently and from which the mature secreted form is subsequently cleaved by metalloproteinases at the cell surface. Tissue-specific alternative splicing eliminates the exon encoding the extracellular proteolytic cleavage site in the membrane-spanning form. Both the secreted 30-kd SCF monomers and the extracellular domain of the cell-surface form are heavily glycosylated and biologically active. The secreted monomer consists of the first 164 residues, and evidence suggests that its tertiary structure is consistent with that described for CSF-1 (Fig. 17.2). An equilibrium exists between the monomers and dimers of both the secreted and membrane forms, but the monomer predominates under physiologic conditions. However, the noncovalent dimerization of the SCF is required for its biologic activity (72,63). The cell-surface form of SCF is more active than the secreted form as a result of more prolonged signaling (73,74).

As with SCF, the biologic effects of mutations in the SCFR gene in the mouse were extensively studied before its identification as the SCFR locus. The locus is known as the dominant white spotting (*W*) locus. Well before the relation between the products of the *Sl* and *W* loci was understood, the *Sl* product (SCF) was proposed to be the ligand for the *W* product (SCFR) on the basis of the complementary results of a series of elegant bone marrow transplantation experiments using mice with *Sl* and *W* mutations (70). Cells expressing the SCFR are frequently contiguous with cells expressing SCF, from the early presomite stage to the mature adult. SCFR is expressed in the germ cells, interstitial cells of Cajal in the gut, melanocytes, and early hematopoietic cells (63,71). SCFR expression in hematopoietic cells is low in primitive multipotent progenitors, is highest in committed progenitors, and decreases as cells mature (72). An alternatively spliced form in which four amino acids encoded by a short exon are inserted into the extracellular domain of the receptor is expressed in mast cells and in the midgestation placenta (75). The significance of this tissue-regulated alternative splicing is not understood, but the shorter isoform appears to have a low but constitutive level of activation in the absence of SCF. A soluble form of the SCFR, found in normal human sera, is able to bind SCF, although its physiologic significance is also unknown (63,71).

BIOLOGY

Apart from its effects on melanocytes and their precursors and on gonadal development, SCF has a broad spectrum of activity on hematopoietic cells. SCF alone cannot stimulate the proliferation of primitive SCFR-expressing progenitor cells. It acts synergistically with many of the hematopoietic cytokines, especially IL-6 and IL-3, to increase the numbers of precursors of most, if not all, lineages (76,77). However, it may not stimulate pluripotent stem cells that do not appear to express the SCFR (78) and that can survive *in vitro* in the absence of SCF (79). SCF-nullizygous *Sl/Sl* mice are embryonic lethals, but *Sl/Sl*^{d} compound heterozygotes bearing the partially functional *Sl*^{d} allele allow embryonic survival, yielding severely anemic mice (70). The severe anemia and mast cell deficiency in *Sl* mice indicate that the major effects of SCF are on erythropoiesis and mast cell development. In combination with EPO, SCF enhances the number of erythroid precursor cells and allows precursors to respond to levels of EPO that are too low to elicit a response in the absence of SCF. Differentiation of intermediate and later precursors requires the presence of SCF (80), after which they become responsive to EPO only. Mast cells and their progenitors require SCF throughout the differentiation of the lineage from early precursors to mature, primed tissue mast cells (72,81), and SCF regulates the migration, maturation, proliferation, and activation of mast cells *in vivo* (71). There is also strong evidence of biologic activity for SCF on the megakaryocyte, granulocyte-macrophage, and lymphoid lineages, yet the effects of the absence of SCF on their development is minimal, a finding implying some redundancy in cytokine action on these lineages. SCF acts on every stage of megakaryocyte development from progenitors to the mature megakaryocyte (72,82), yet circulating platelet levels are normal in *Sl/Sl*^{d}mice.

FL

FL AND FLT3 RECEPTOR

The discovery of the flt3, using cloning approaches to isolate novel receptor tyrosine kinases, preceded the discovery of its ligand, FL, which was identified by its ability to bind a soluble form of flt3 (83,84,85 and 86). FL regulates the proliferation of primitive hematopoietic cells. The predominant isoform of human FL is a biologically active transmembrane glycoprotein that is expressed on the cell surface. It may also be released by proteolysis. The predominant isoform in mice is an active cell-surface form that, although membrane associated, is not membrane spanning and arises from failure to splice an intron. The third isoform, present in both mouse and human tissues, arises from alternative splicing of exon 6 that introduces a stop codon near the end of the extracellular domain and generates a secreted biologically active protein that is relatively rare compared with the other isoforms. The structural similarity between FL and CSF-1, especially in the amino-terminal 150 amino acids essential for biologic activity, suggests that its tertiary structure is similar to that of CSF-1 (Fig. 17.2). Like SCF, FL exist as a noncovalently associated homodimer (63).

As far as the hematopoietic system is concerned, FL receptor (FLR) (flt3) expression is predominantly restricted to the progenitor–stem cell compartment (Fig. 17.1). Although bone marrow monocytes and a small fraction of lymphocytes also express FLR, the functional significance of this expression is not clear. One isoform of the mouse FLR, missing the fifth Ig-like motif in the extracellular domain, is still able to bind ligand and to become tyrosine phosphorylated. Its physiologic significance is not understood (63).

BIOLOGY

Like SCF, FL cannot alone stimulate the proliferation of its primitive hematopoietic target cells, but rather it synergizes with other hematopoietic cytokines. In contrast to SCF, FL has little or no effect on erythroid or megakaryocyte progenitor cells, and FLR knock-out mice have no defects on red cell, megakaryocyte, or platelet production. However, FLR- and FL-deficient mice have reduced numbers of pro-B cells, although they have normal numbers of mature B cells. (63,87,88). FL synergizes with IL-7 in stimulating the proliferation of primitive B lineage cells. FL also synergizes with IL-7 to stimulate proliferation of primitive thymic progenitor cells. FL synergizes with IL-15 to promote the expansion of NK cells from progenitor cells, and FL-deficient mice fail to develop splenic NK cell activity. In combination with GM-CSF, tumor necrosis factor (TNF), and IL-4, FL enhances the production of dendritic cells from BM progenitor cells. Treatment of mice with FL dramatically increases the number of functional dendritic cells in lymphohematopoietic and other tissues, and dendritic cell numbers are reduced in FL-deficient mice (63).

Colony-Stimulating Factor-1

COLONY-STIMULATING FACTOR-1 AND ITS RECEPTOR

CSF-1 regulates the survival, differentiation, and function of cells of the mononuclear phagocytic (monocyte-macrophage) lineage and the function of cells of the female reproductive tract (64,89,90 and 91). It is synthesized in the endoplasmic reticulum to yield a disulfide-linked, homodimeric, membrane-spanning precursor that contains 522 amino acids. In secretory vesicles, the mature forms of CSF-1—glycoprotein (approximately 100 kd) and proteoglycan (approximately 120 to 160 kd) (64)—are cleaved from this precursor and secreted. However, a smaller CSF-1 precursor (224 amino acids), encoded by an mRNA in which the proteolytic cleavage sites have been spliced out, is expressed on the cell surface when the secretory vesicle fuses with the plasma membrane. The amino-terminal 150 amino acids of CSF-1 are sufficient for *in vitro* biologic activity and possess the four a-helical bundle—antiparallel b-ribbon structure (36) (Fig. 17.2).

The approximately 58-kb CSF-1R gene maps to the long arm of chromosome 5, near the genes encoding GM-CSF and IL-3 (69). Extracellular ligand binding by the CSF-1R results in the formation or stabilization of a receptor dimer. Dimer formation is associated with receptor activation and the tyrosine phosphorylation of one intracellular domain of the receptor by the other. The activated, tyrosine phosphorylated CSF-1R mediates the tyrosine phosphorylation of many other, mainly cytoplasmic, proteins, some of which have been shown to have an important role in transduction of the signal for proliferation (92). After activation and signaling, the receptor-ligand complexes are internalized and are destroyed intralysosomally (68,93).

BIOLOGY

CSF-1 is synthesized by a variety of cell types, including fibroblasts, endothelial cells, bone marrow stromal cells, osteoblasts, keratinocytes, astrocytes, myoblasts, and, during pregnancy, uterine epithelial cells (64). Circulating CSF-1 is believed to be synthesized by endothelial cells lining the small blood vessels. Ninety-five percent of circulating CSF-1 is cleared by sinusoidally located macrophages, primarily Kupffer cells, by CSF-1R–mediated endocytosis followed by intralysosomal destruction. Thus, the number of sinusoidally located macrophages determines the concentration of the cytokine responsible for their production, a simple feedback control. The half-life of circulating CSF-1 at physiologic concentrations is about 10 minutes. The half-life of pharmacologic concentrations of CSF-1, which saturate the normal clearance mechanism, is approximately 1.6 hours (94). Circulating CSF-1 is elevated in response to bacterial endotoxin and bacterial, viral, and parasitic infections (64,89,90 and 91). Repeated injections of recombinant CSF-1 in mice elevate the circulating monocyte count about tenfold and increase macrophage numbers in certain areas of the periphery (95).

The role of CSF-1 in the development and regulation of mononuclear phagocytes has been studied in the osteopetrotic (*Csf-1^{op}/Csf-1^{op}*) mutant mouse. This mouse possesses an inactivating mutation in the CSF-1 gene and fails to produce CSF-1 (18,96). Compared with control mice, *Csf-1^{op}/Csf-1^{op}* mice exhibit impaired bone resorption associated with a paucity of osteoclasts and have no incisors, poor fertility, a lower body weight, a shorter average life span, an absence of evoked auditory and visual responses, a thinner than normal dermis, and deficiencies in blood monocytes and macrophages in certain tissues (97,98 and 99). Restoration of circulating CSF-1 in newborn *Csf-1^{op}/Csf-1^{op}* mice cured their osteopetrosis and monocytopenia and improved some but not all the tissue macrophage populations, consistent with local as well as humoral regulation by this cytokine (97,99). Both secreted forms are found in the circulation, and the cell-surface and secreted proteoglycan CSFs are believed to have important roles in local regulation, the latter through its sequestration by specific extracellular matrices (64,99). Studies in the *Csf-1^{op}/Csf-1^{op}* mouse clearly indicate that CSF-1 is the primary regulator of mononuclear phagocyte production. However, the pleiotropic phenotype of these mice and the restricted distribution of the CSF-1R to cells of the mononuclear phagocytic system and female reproductive tract suggest that the major role of CSF-1 is to generate and maintain macrophages that have trophic as well as scavenger (i.e., physiologic) functions and that are important for organogenesis and tissue turnover. The development of macrophages involved in inflammatory and immunologic (i.e., pathologic) functions apparently depends on other cytokines, which, in certain situations, may also regulate the activities of macrophages generated by CSF-1 (64,97,99). Thus, the development of lymph node and thymic macrophages is largely CSF-1-independent. However, CSF-1 does appear to play an important role in priming macrophages to respond to other stimuli, such as TNF-a, IL-1, and IL-6 (50).

The CSF-1R is expressed at low levels on primitive multipotent cells. There is a tenfold increase in its expression as these cells give rise to committed progenitors of macrophages and a further increase in expression in the more mature adherent mononuclear phagocytes. *In vitro* studies indicate that, in contrast to the committed progenitors, the primitive multipotent cells are unable to respond to CSF-1 alone. However, CSF-1 can synergize with other cytokines (e.g., IL-1, SCF, IL-3, IL-6) to stimulate multipotent cell proliferation and differentiation to committed macrophage progenitor cells (44,100,101). Apart from its role as a hematopoietic cytokine, CSF-1 is obviously also critically involved in bone metabolism through its regulation of osteoclast progenitor cell proliferation and differentiation. It is synthesized locally by osteoblasts and stimulates osteoclast differentiation by cooperating with osteoprotergerin ligand (OPGL). CSF-1 alone causes the development of small mononuclear cells, whereas OPGL stimulates the development of active osteoclasts in a CSF-1–dependent manner (102). CSF-1 regulation of macrophages plays an important role in both male and female reproduction (103), and the action of CSF-1 on trophoblast during pregnancy is critical in embryonic resistance to certain infections (104). Under the control of the female endocrine system, CSF-1 is synthesized by the oviduct and uterine epithelium during pregnancy and can influence several CSF-1R–expressing cell populations, including maternal macrophages and decidual cells, as well as early embryonic cells and various trophoblastic cell types (64,99). Circulating levels of CSF-1 are elevated in patients with myeloid and lymphoid malignant diseases and carcinomas of the ovary, endometrium, and breast. In ovarian cancer, elevated levels of CSF-1 in the circulation or ascitic fluid predict a poor prognosis. The etiologic role of CSF-1 in the pathogenesis of these tumors is not clear (64).

CYTOKINES SIGNALING BY DIMERIZATION OF ONE NON–TYROSINE KINASE RECEPTOR POLYPEPTIDE CHAIN

The receptors for EPO, G-CSF, and TPO are transmembrane glycoproteins that belong to a large family of receptors, defined by the presence of an extracellular cytokine receptor motif and referred to as the cytokine receptor family, that includes almost all of the receptor subunits shown in Fig. 17.3B. Within their cytokine receptor motifs, all have conserved short amino acid sequence elements, particularly two pairs of conserved cysteine residues and a Trp-Ser-X-Trp-Ser (WSXWS) motif near the transmembrane domain (105). The function of the WSXWS motif is not clear. EPO, G-CSF, and TPO appear to signal by causing the dimerization of receptors. Although it is clear that the receptor species identified for these cytokines dimerize, studies of all three receptors are still at an early stage, and perhaps other receptor subunits are involved in the high-affinity receptors for at least one of them. Although the receptor subunits for EPO, G-CSF, and TPO do not contain an intrinsic tyrosine kinase domain, activation of the receptor is associated with rapid tyrosine phosphorylation of several cellular proteins, including receptor itself. This is because of the prior association of the receptor with members of the JAK family (EPOR and TPOR with JAK2; G-CSFR with JAK1) that are activated by formation of the high-affinity ligand-receptor complex. Receptor activation on ligand binding leads to receptor tyrosine phosphorylation and recruitment of STATs, which are tyrosine phosphorylated and activated by JAKs, of additional JAKs and other tyrosine kinases, and of SH2 domain-containing protein tyrosine phosphatases (Fig. 17.5). The phosphatases can play positive and negative roles in signaling. The ras-MAPK and PI3K pathways are also activated in response to these cytokines through the recruitment of Grb2/SOS and PI3K. The receptors contain box 1 and box 2 sequences in their cytoplasmic domains that are essential for receptor function.

ERYTHROPOIETIN

Erythropoietin and Its Receptor

EPO, the primary regulator of erythropoiesis, was first of the hematopoietic cytokines to be discovered, its existence first suggested by the early studies of Carnot and Déflandre (106). It was purified from human urine, and the human gene was cloned in 1985 (107). Found at biologically active concentrations in the circulation, EPO is a glycosylated polypeptide of approximately 34 kd that is synthesized primarily by the proximal convoluted tubules of the kidney (108), but also by liver. Its synthesis is primarily regulated by tissue hypoxia sensed by a heme protein (109). The 3' flanking region of the EPO gene contains a hypoxia-inducible element for the assembly of a complex including the hypoxia-inducible factor-1 (HIF-1), hepatic nuclear factor-4 (HNF-4), and the transcriptional activator p300 (110). The 5' flanking region of the EPO gene also contains sites involved in induction by hypoxia and which also bind HNF-4, so HNF-4 may function to bridge the 5' promoter and 3' enhancer regions of the gene (111).

The human EPOR is a membrane-spanning, glycosylated protein of 64 to 78 kd. It appears that the homodimeric EPOR is necessary and sufficient for responsiveness to EPO (112,113), although, as discussed earlier, in response to SCF and EPO, it functionally and physically interacts with the SCFR. *In vitro,* like EPO and SCF, EPO and IL-3 synergize to stimulate the expansion of erythroid burst-forming units (BFU-E), and an interaction between the EPOR and the IL-3 receptor (IL-3R) b-chain has also been reported (114). The first cell within the erythroid lineage in which EPOR is expressed is the late BFU-E that express approximately 300 receptors per cell. Receptor density increases to approximately 1,100 per cell in erythroid colony-forming units (CFU-E) and erythroblasts and then decreases during the terminal stages of erythroid differentiation, to reticulocytes and erythrocytes, where they are virtually absent (115). EPORs are also found in megakaryocytic cells and in endothelial and neural cells.

BIOLOGY

EPO stimulates the proliferation and differentiation of late BFU-E through its synergism with SCF and stimulates expansion of all CFU-E. In addition, it stimulates the release of maturing normoblasts from the bone marrow and increases the amount of hemoglobin synthesized per erythrocyte. Whereas mouse embryos lacking EPO

die by day 13 because of severe anemia (116,117), their fetal livers contain both BFU-E and CFU-E that can be expanded by culturing in SCF and TPO (19), consistent with a primary role of EPO inducing the erthyroid cell survival (49).

Granulocyte Colony-Stimulating Factor

GRANULOCYTE COLONY-STIMULATING FACTOR AND ITS RECEPTOR

G-CSF was purified from the medium conditioned by cultured cells, and the gene was cloned in the mid-1980s (118,119 and 120). G-CSF is unusual in that it possesses only a single O-linked oligosaccharide chain, yielding a molecular weight of 19 kd. It shares significant sequence homology with IL-6. G-CSF is synthesized by a variety of cell types, including stromal cells, fibroblasts, and endothelial cells, but primarily in response to inflammatory stimuli such as lipopolysaccharide (LPS), TNF, and IL-1 (121,122). The G-CSF promoter region contains both kB and nuclear factor (NF)–IL-6 sites and cooperatively binds the p65 and C/EBPb transcription factors induced by IL-1 and TNF in fibroblasts (123,124).

The G-CSFR is 812 amino acids in length, with a large extracellular domain composed of an Ig domain, a cytokine receptor module and 3 fibronectin domains, and a cytoplasmic domain with box 1 and box 2 regions. It binds G-CSF with high affinity and with a 2:2 (2 molecules of ligand to 2 receptor molecules) stoichiometry (125,126 and 127). Hematopoietic control of G-CSFR expression is regulated by the transcription factors PU.1 and C/EBP (128,129).

BIOLOGY

G-CSF, the physiologic regulator of neutrophil production, stimulates the proliferation and differentiation of committed neutrophil progenitor cells without affecting the other granulocytic lineages. Circulating G-CSF concentrations are inversely related to neutrophil levels and are increased during infection (130,131). Administration of G-CSF results in neutrophilia (132). Whereas mice lacking G-CSF or its receptor are neutropenic, they possess some mature neutrophils and have only a modest reduction in the committed granulocyte-macrophage progenitor cells, a finding suggesting that G-CSF is not required for lineage commitment and that other cytokines can contribute to the proliferation and differentiation of the neutrophil progenitors (20,32). G-CSF synergizes with IL-3 or SCF to stimulate the proliferation and differentiation of primitive multipotent hematopoietic progenitor cells (133,134), thus providing a mechanism for expansion of the primitive cell compartment. G-CSF also enhances the survival of mature neutrophils, and it is believed that its local production primes their functional responses to agents, such as bacterial peptide f-Met-Leu-Phe, as well as IL-8 and macrophage inflammatory protein-1a (MIP-1a), that stimulate phagocytic activity, antibody-dependent cellular cytotoxicity, and intracellular killing (135,136 and 137).

Thrombopoietin

THROMBOPOIETIN AND ITS RECEPTOR

Although investigators suggested as early as 1958 that megakaryocytopoiesis was regulated by a circulating cytokine termed “thrombopoietin,” present in thrombocytopenic plasma (138), purification of TPO proved difficult, and it was the identification of the TPOR that led to the cloning of the TPO gene. The TPOR gene, *c-mpl*, was originally identified as the cellular counterpart of *v-mpl*, the oncogene carried by the murine myeloproliferative leukemia virus (139). *c-mpl* was shown to encode a membrane-spanning protein that was structurally and functionally related to members of the hematopoietic receptor superfamily (140,141) and restricted in its expression to megakaryocytes, platelets, and primitive hematopoietic cells (142). Furthermore, mice lacking *c-mpl* exhibited an 80% to 90% decrease in platelet counts with no alteration in the numbers of other differentiated blood cells (22). These results strongly implicated the *c-mpl* protein as the receptor of TPO, and the cloning of the TPO gene was reported by five independent groups in 1994 (142).

TPO is an approximately 70-kd heavily glycosylated 332-amino acid polypeptide that can be structurally and functionally divided into two domains. The amino-terminal (153 amino acids) shows 50% sequence similarity with EPO and is predicted to possess the 4 a-helix bundle characteristic of the cytokine family, whereas the carboxy-terminal domain is widely species divergent, has no homology with other known proteins, and is heavily glycosylated. Whereas the amino-terminal domain can induce the full spectrum of biologic responses, the carboxy-terminal domain is required for efficient biosynthesis and secretion and for stability (142,143). TPO is synthesized primarily by the liver and kidney, hepatocytes, endothelial cells, fibroblasts, and the proximal tubule cells of the kidney and is found in the normal circulation (142). High-affinity TPORs expressed on both platelets (approximately 30/platelet) and megakaryocytes (2 to 12 × 10^3/cell) actively internalize and degrade TPO (142,144).

BIOLOGY

TPO regulates all aspects of megakaryocyte and platelet development, including stimulation of megakaryocyte progenitor cell proliferation and differentiation, augmentation of endomitosis, induction of platelet specific proteins, stimulation of platelet release, and changes in platelet ultrastructure (145,146). As in the case of several of the circulating hematopoietic cytokines, it appears that TPO is removed from the circulation by megakaryocyte and platelet uptake and destruction through the TPOR (147). TPOR-nullizygous mice have high plasma TPO levels (22), as do patients with a low combined megakaryocyte and platelet numbers. In contrast, in thrombocytotic conditions, plasma TPO levels are low (148). Furthermore, it seems likely that TPO synthesis is constitutive and that regulation of plasma TPO occurs by its removal through TPOR-mediated endocytosis and destruction.

TPO- and TPOR-nullizygous mice possess an identical phenotype. However, surprisingly, despite their selective thrombocytopenia, both mutant mice also exhibit a 60% reduction in multipotent and committed myeloid progenitors (149), and they are deficient in stem cells capable of long-term repopulation (150). TPO has also been shown to be an important requirement for the *in vitro* proliferation of hematopoietic stem cells capable of long-term repopulation of both myeloid and lymphoid systems (4). Thus, apart from its regulation of megakaryocytopoiesis, TPO has a pleiotropic effect on hematopoiesis through its action on primitive cells.

CYTOKINES SIGNALING THROUGH RECEPTORS WITH A COMMON b SUBUNIT

The three cytokines signaling through a common b subunit, IL-3, GM-CSF, and IL-5, are members of a subfamily of cytokines that appear to share a common ancestry and structure despite the lack of significant amino acid sequence similarity among them. Their genes have a similar structure, and all map to the long arm of chromosome 5 in close proximity (151) (Table 17.1). The tertiary structures of all three are the four a-helical bundle and antiparallel b-ribbon structure shown for GM-CSF in Fig. 17.2, except IL-5 is a disulfide-linked dimer. All three cytokines signal through receptors composed of a cytokine-specific a chain, which alone exhibits low affinity for the cytokine and a larger, shared b chain, termed b common (bc), that can interact with any of the three low-affinity a chain–cytokine complexes to generate a specific high-affinity ligand-receptor complex (152) (Fig. 17.3B). The bc subunit does not bind cytokine by itself but significantly increases the affinity of the a subunit. Ligand-induced disulfide bonding between an a and b subunit and dimerization of the bc subunit are required for signaling (Fig. 17.6A). The high-affinity complex appears to be similar to the IL-6–IL-6R high-affinity complex, consisting of two receptor a chains, two bc chains, and two ligand molecules (153). Because of the shared b subunit, IL-3, GM-CSF, and IL-5 compete with each other for binding to their high-affinity receptors (Fig. 17.6A), although the biologic significance of this action is not well understood. Their a subunits, transmembrane glycoproteins of 70 to 90 kd, belong to the cytokine receptor family (Fig. 17.3B). The cytoplasmic domains of the these subunits are required for proper receptor function.

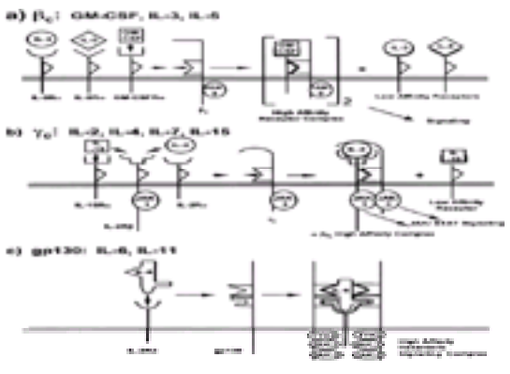

Figure 17.6. Model for the activation of hematopoietic growth factor receptors composed of multiple receptor polypeptide chains. **A:** Receptors sharing the common b subunit, b_c, illustrating the concept of cross-competition between cytokines for the b subunit that is necessary for the formation of the high-affinity signaling complex. Granulocyte-macrophage colony-stimulating factor (GM-CSF) is shown to form the high-affinity complex preferentially, thus preventing high-affinity complex formation by interleukin-3 (IL-3), IL-5, and their a subunits. **B:** Receptors sharing the common g subunit, g_c, that forms a high-affinity receptor complex (abg_c) involving a second signaling subunit (b). **C:** Receptors sharing the common gp130 signaling subunit that forms a hexameric signaling complex with cytokine and subunits in a 2:2:2

stoichiometry.

The 120-kd b subunit also contains the conserved cytokine receptor motif found in the a subunit. It has a much longer cytoplasmic tail, which is required for proliferative signaling, and its box 1 and box 2 motifs contain the docking sites necessary for the recruitment of signaling molecules to the activated receptor. As discussed for EPOR, G-CSFR, and TPOR, receptor activation results not only in the tyrosine phosphorylation of the signaling subunit that creates docking sites for molecules with phosphotyrosine binding (PTB) or SH2 domains, such as the STATs, but also in tyrosine phosphorylation of the recruited signaling molecule and regulation of its function (Fig. 17.5B).

Interleukin-3

INTERLEUKIN-3 AND ITS RECEPTOR

Interleukin-3 is a secreted monomeric 25- to 30-kd glycoprotein with an intramolecular disulfide bridge that stabilizes the loop containing the receptor-binding site. It is essential for biological activity. The mature secreted protein consists of 133 amino acids and is extensively glycosylated (154). The IL-3R consists of a ligand-specific, low-affinity a subunit unique to the IL-3R (155) and the bc subunit. In the mouse, the situation is slightly more complex because a duplication of the bc gene has occurred. The second gene, bIL-3, has low affinity for IL-3 and interacts only with the IL-3 a chain (152,153).

BIOLOGY

IL-3 is synthesized almost exclusively by T cells in response to antigen stimulation (156). IL-3 is a pleiotropic hematopoietic cytokine supporting the proliferation and differentiation of both primitive multipotent progenitor cells and committed myeloid progenitors. IL-3 alone stimulates primitive hematopoietic cells to form multilineage colonies, composed of neutrophils, basophils, eosinophils, monocytes, and megakaryocytes. Moreover, with SCF, IL-1, and CSF-1, it stimulates the proliferation and differentiation of even more primitive precursors present in populations enriched for hematopoietic stem cells (101,157). In concert with other late-acting hematopoietic cytokines, IL-3 stimulates multipotent cells to become cells that are committed to the lineage regulated by the late-acting cytokine. For example, cells of the erythroid lineage do not require IL-3 for terminal differentiation, but in the presence of EPO, IL-3 apparently commits early multipotent progenitor cells to erythroid development and increased expression of the EPOR (154,158). Similarly, the combination of IL-3 and CSF-1 allows the proliferation of primitive cells that do not respond to CSF-1 alone to give rise to committed macrophage progenitors expressing high levels of the CSF-1R that do (100). These committed progenitor cells and their progeny no longer express the IL-3R and have lost the ability to respond to IL-3. Apart from these effects on primitive cells, IL-3 supports the terminal proliferation or differentiation of cells of the megakaryocytic, eosinophilic, and mast cell lineages (154,158). IL-3–nullizygous mice have diminished delayed-type hypersensitivity but no obvious steady-state hematopoietic phenotype (24). This finding, coupled with its highly restricted and regulated synthesis, suggests that this cytokine plays a role only during hematopoietic demand.

Granulocyte-Macrophage Colony-Stimulating Factor

GRANULOCYTE-MACROPHAGE COLONY-STIMULATING FACTOR AND ITS RECEPTOR

GM-CSF is a 127-amino acid monomeric glycoprotein with a molecular weight of 18 to 32 kd, depending on the degree of glycosylation. The GM-CSF receptor (GM-CSFR), like the IL-3R, consists of a ligand-specific a subunit that confers low-affinity binding and the bc subunit. The GM-CSFR a subunit is a membrane-spanning glycoprotein of 80 kd containing the extracellular domain cytokine receptor motif (159). Three alternative transcripts are recognized for the a subunit: one for the main form described earlier, the second for a soluble form that has had the region encoding the transmembrane and cytoplasmic domains spliced out, and the third for an alternative membrane-spanning a subunit that has a slightly longer C-terminal end (160). All are functional, but their relative physiologic significance is not yet well understood.

BIOLOGY

GM-CSF is constitutively synthesized by macrophages, endothelial cells, and fibroblasts; it is inducibly expressed in a variety of cells, especially T cells, which can produce large quantities of GM-CSF after activation by antigens and other inducers (161). GM-CSF has been shown to have a broad range of biologic effects, acting on both progenitor cells and mature, terminally differentiated cells. The early progenitor cells of many lineages are stimulated to survive and to proliferate under the influence of GM-CSF (162). GM-CSF alone supports the survival, proliferation, and differentiation of all cells in the neutrophil, macrophage, and eosinophil lineages from multipotent progenitors to mature cells (163), and GM-CSF appears to be important in the activation and enhancement of function of mature cells of these three lineages (161). However, at most stages of development, the cells in these three lineages also require the presence of other, more specific hematopoietic cytokines: G-CSF, CSF-1, and IL-5. GM-CSF synergizes with EPO and TPO on primitive hematopoietic cells to generate erythroid and megakaryocytic progeny, respectively. *In vivo,* GM-CSF administration increases the number of circulating neutrophils, monocytes, and eosinophils and the number of tissue-fixed macrophages. GM-CSF-deficient mice have pulmonary alveolar proteinosis caused by a deficiency of the pulmonary alveolar macrophage (25). However, because they have normal granulocyte and macrophage production in both steady-state and stressed conditions, GM-CSF apparently does not play an important role in blood cell production.

Interleukin-5

INTERLEUKIN-5 AND ITS RECEPTOR

IL-5 is a secreted, disulfide-linked, 40- to 45-kd homodimer that is heavily glycosylated. Dimerization is essential for biologic activity, and its double 115-amino acid monomers are aligned in a head-to-tail configuration (164). The IL-5R is composed of the IL-5 specific a subunit and the bc subunit. The IL-5R a subunit is a 60-kd transmembrane glycoprotein that is predominantly extracellular, with a short, 54-amino acid cytoplasmic tail. An alternatively spliced form of the a subunit encodes a soluble form that is abundantly expressed (165).

BIOLOGY

Interleukin-5 was originally identified as a B-cell growth factor and was separately identified as a T-cell–derived eosinophil differentiation factor before the two activities were ascribed to the same molecule (166). It is produced predominantly by antigen-stimulated T lymphocytes, but also by NK cells, mast cells, B cells, eosinophils, and bone marrow endothelial cells (167). Eosinophils and basophils, their precursors, and some B cells express both subunits of the IL-5R, and IL-5 has relatively restricted biologic activity, acting principally on cells of the eosinophil and basophil lineages, but also affecting B-lymphocyte production and function. *In vitro* studies suggest that IL-5 is the primary late-acting cytokine for eosinophil proliferation and differentiation and that it also stimulates the survival, activation, and chemotaxis of mature eosinophils. In combination with GM-CSF, IL-3, and IL-4, IL-5 stimulates the survival, proliferation, and differentiation of the basophil-mast cell lineage (168). B-lymphocytes respond to IL-5 by proliferation and differentiation to Ig-secreting cells (169). *In vivo*, IL-5 is important throughout the development of the eosinophil lineage, and it plays a central role in the development of eosinophilia. Complete abrogation of the development of eosinophilia secondary to parasitic infections is observed in mice given anti–IL-5 antibodies or in IL-5–deficient mice (23,170). In contrast, although early eosinophil progenitors respond to IL-3 and GM-CSF, there is no alteration of eosinophil production in IL-3– and GM-CSF–deficient mice (24,25). Transcripts for the soluble IL-5R a subunit are normally more abundant in activated T cells than those of the membrane-spanning subunit. However, in patients with asthma, the expression of the membrane-spanning subunit is directly related to the severity of disease, whereas the expression of the soluble form is inversely related to disease, a finding suggesting that differential expression of surface and soluble receptor can affect eosinophil-mediated disease (171).

CYTOKINES SIGNALING THROUGH RECEPTORS WITH A COMMON g SUBUNIT

Four hematopoietic cytokines, IL-2, IL-4, IL-7, and IL-15, sharing a four a-helical bundle structure, signal through a high-affinity receptor composed of a cytokine-specific a chain and a common g chain (g_c), neither of which have catalytic domains (Fig. 17.3B). The g_c subunit to which these ligands fail to bind, or bind weakly, is also used in the receptor for IL-9 (IL-9R) (172,173,174,175 and 176). As for cytokines signaling through b_c, both a and g_c subunits are required for high-affinity binding, and the cytokine binds the a subunit with low affinity. In the case of IL-2 and IL-15, which map close together and probably have a common ancestry, a common b subunit (IL-2Rb), which binds both ligands, can replace the a chain, but it is usually included in a high-affinity abg_c complex (172,176). The minimum requirement for signaling is bg_c, which can respond to either IL-2 or IL-15. Mice lacking g_c suffer from a severe combined immune deficiency characterized by a tenfold reduction in the number of circulating mature T and B cells and complete loss of NK cells (172).

The known signaling pathways described for all these receptors are similar (Fig. 17.6B). These pathways involve the JAKs. On ligand binding and assembly of the high-affinity receptor-ligand complex, JAK1, constitutively associated with the a or b subunit, and JAK3, constitutively associated with the g_c subunit, become activated, probably by transphosphorylation. They then tyrosine phosphorylate the receptor chains, leading to the recruitment of phosphotyrosine-associating (SH2 domain–containing) signaling intermediates, including STATs 1,3, 5A, 5B, and 6, which, in turn, are tyrosine phosphorylated by the JAKs, thus allowing them to dimerize and move to the nucleus to direct transcription. The ras-raf-MAPK pathway is also activated by Shc interactions with the a or b subunit. The recruitment or involvement of the src-family kinases $p56^{lck}$, $p59^{fyn}$, and $p53/56^{lyn}$ has also been reported, and this, or the recruitment of insulin receptor substrates-1 and -2 to the receptor, leads to recruitment and activation of PI3K (172,173,174,175 and 176).

Interleukin-2

INTERLEUKIN-2 AND ITS RECEPTOR

The structural and functional aspects of IL-2 and the IL-2R have already been discussed. The IL-2Ra and IL-15a chains are closely related structurally and constitute a separate cytokine receptor family from the WSXWS sequence-containing cytokine receptor superfamily to which the IL-2Rb and g_c belong. The *de novo* synthesis and secretion of IL-2 and the expression of the IL-2R by mature, resting T cells are early consequences of their antigen or mitogen–induced activation (172).

BIOLOGY

The primary role of the 15.5-kd IL-2 glycoprotein is to promote rapid expansion of the effector T-cell population activated by antigen. The subsequent decline in expression of both the cytokine and its receptor leads to termination of the T-cell immune response. IL-2 also stimulates T-cells to produce other cytokines, including interferon-g (IFN-g) and IL-4. Targeted inactivation of the genes encoding IL-2 or the IL-2Ra subunits in the mouse indicate that IL-2 prevents autoimmunity and maintains homeostasis of the immune system. Despite normal *in vivo* T-cell responses, these mice die young and develop autoimmune disorders, including hemolytic anemia and inflammatory bowel disease (26,172).

Interleukin-7

INTERLEUKIN-7 AND ITS RECEPTOR

IL-7 is secreted constitutively by nonlymphoid stromal cells that support lymphopoiesis, including those of the fetal liver, bone marrow, and thyroid, as well as other nonlymphoid tissues in which gd T cells are relatively abundant, such as skin and intestine. It is also produced by secondary lymphoid tissues, a feature that reflects its role in the regulation of T-cell, NK cell, and monocyte-macrophage functions. The IL-7R is expressed on pre-pro-B, early pro-B, and late pro-B cells (175).

BIOLOGY

IL-7 is the major growth factor regulating precursor B cells. It is involved only in the antigen-independent stages of B-cell development (early and late pro-B cells) that take place in fetal liver and bone marrow. Although pre-pro-B cells express the IL-7R, their differentiation is independent of IL-7. Downregulation of IL-7 expression and of IL-7 responsiveness is correlated with rearrangement of k light chains and expression of surface IgM by immature B cells (174,175,177). Both IL-7Rg– and IL-7–nullizygous mice have markedly reduced numbers of late pre-B and mature B cells, although pro-B-cell numbers are also reduced in the IL-7Rg–nullizygous mice, probably because of the ability of at least one other cytokine, thymic stromal-derived lymphopoietin (TSLP), to bind the IL-7R (27,28,175). Ig heavy chain V-DJ recombination is also impaired in the latter mice, which, in addition, have reduced levels of the transcription factor, Pax5, that has been shown to regulate V-DJ rearrangements and to commit pro-B cells (59). IL-7 stimulates the *in vitro* proliferation of fetal and adult thymocytes, and antibodies to IL-7 block thymocyte proliferation. IL-7 synergizes with IL-2, SCF, FL, and TNF-a to promote thymocyte growth (175). Thymic cellularity and peripheral T-cell populations are markedly reduced in both IL-7Ra– and IL-7–nullizygous mice (27,28). Again, as in the case of B-cell development, thymocyte development was blocked at an early stage ($CD4^-CD8^-CD25^-$ cell) in the IL-7Ra–nullizygous mice compared with the IL-7–deficient mice, a finding probably reflecting the ability of the IL-7R to bind TSLP. IL-7 is preferentially required for the development of gd T cells because ab T cells develop, albeit with reduced survival, in both IL-7Ra– and IL-7–nullizygous mice, and it seems likely that IL-7 signaling through Stat 5 is essential for TCRg transcription after rearrangement of the TCRg gene complex. IL-7 can stimulate the proliferation of mature, peripheral T lymphocytes, and IL-7Ra–deficient mice have defects affecting peripheral T-cell activation, a finding suggesting a role for IL-7 in mature T-cell responses. NK cells develop and function normally in IL-7Ra– and IL-7–nullizygous mice. IL-7 may have effects on myeloid cells by synergizing with CSF-1, GM-CSF, or IL-3 or combinations of cytokines in stimulating the proliferation and differentiation of myeloid progenitors, as well as mature monocytes-macrophages, by stimulating their production of cytokines. It is also a regulator of T-cell growth in skin and intestine (175).

Interleukin-4

INTERLEUKIN-4 AND ITS RECEPTOR

IL-4 is a secreted glycoprotein of 15 to 19 kd. An alternatively spliced message yields a form lacking amino acids 22 to 37, termed IL-4d2, that is expressed more strongly in thymocytes and bronchoalveolar lavage cells and alone does not act as a costimulator for T-cell proliferation, but inhibits IL-4–induced T-cell proliferation. The high-affinity IL-4R is expressed on a wide range of cell types including T and B lymphocytes, monocytes, granulocytes, fibroblasts, and epithelial and endothelial cells and is upregulated by IL-4 itself. Two forms of the IL-4R are known. The classic form, consisting of the IL-4Rb and g_c subunits and requiring JAK3 for STAT6 activation, is predominantly expressed in hematopoietic cells. The alternative form, consisting of the IL-4Rb and IL-13Ra subunits and requiring JAK2 for STAT6 activation, is predominantly expressed in nonhematopoietic cells (178). A soluble form of the IL-4Ra binds IL-4 with high affinity (173).

BIOLOGY

IL-4 is expressed in TH_2 cells, which are generated from T-helper precursors through the action of IL-4, as well as $NK1.1^+$ T cells, basophils, mast cells, and eosinophils. IL-4 can act on many cell types and at various stages of maturation of a given cell type. Because it modulates cytokine production by many different cell types, some IL-4 effects may be indirect (173). *In vitro,* IL-4 stimulates B lymphocyte activation and enhances the antigen-presenting capacity of B cells toward T lymphocytes. It enhances antigen receptor and CD-40 triggering of B-cell proliferation and differentiation, but it antagonizes IL-2–induced costimulation, possibly because of its sequestering of the $g_c$chain. However, normal B lymphopoiesis is observed in IL-4–nullizygous mice, a finding indicating that the stimulatory and inhibitory effects that have been observed *in vitro* may be subserved by other cytokines *in vivo* (179). IL-4 stimulates the generation of Th2 cells and the proliferation and maturation of immature thymocytes, although it inhibits early T-cell development in fetal thymus organ culture. IL-4 inhibits CSF-1–induced macrophage colony formation and megakaryocyte colony formation, but it enhances G-CSF–induced granulocyte colony formation and, with IL-3, the generation of basophils, mast cells, and eosinophils. IL-4 regulates the production of mediators in a pattern consistent with its antiinflammatory role (173). IL-4–nullizygous mice have a Th2 cell deficiency and diminished IgG1 and IgE responses consistent with a primary role for IL-4 in the regulation of T-helper cell differentiation and Ig switching (29,180).

Interleukin-15

INTERLEUKIN-15 AND ITS RECEPTOR

IL-15 mRNA is expressed ubiquitously, and its expression can be enhanced by a variety of stimuli, including IFN-g, infectious agents, and bacterial lipopolysaccharide. However, translational and secretory control mechanisms play predominant roles in the production of IL-15 protein (174,176). The high-affinity IL-15R comprises IL-15Ra, IL-2Rb, and g_c subunits. Antibodies specific for either IL-2Rb or g_c block IL-15–induced responses, whereas antibodies specific for IL-2Ra have no inhibitory effect. Three alternatively spliced forms of IL-15Ra mRNA have been identified, and all three encode proteins that bind IL-15. One form is homologous to IL-15Ra, one has deleted an exon in the extracellular domain, and the third has an alternative cytoplasmic domain. As in the case of the IL-2–IL-2R system, IL-15Ra is required for high-affinity binding of IL-15, but not for signaling. In contrast to IL-2Ra, IL-15Ra alone binds ligand with high affinity and is more widely expressed. Because expression of the IL-2R subunits is more restricted than the expression of IL-15Ra, it is likely that IL-15Ra can function with other subunits in some tissues (174,176).

BIOLOGY

IL-15 can substitute for IL-2 in the induction of cytotoxic T lymphocytes and in the generation of lymphokine-activated killer cells. In addition, it augments antibody-dependent cellular cytotoxicity by human NK cells. IL-15 stimulates the proliferation of $CD56^{bright}$ human NK cells and cytokine production by NK and T cells. It also acts as a differentiation factor for these cells. It has other effects on several other cell types. The presence of IL-15 mRNA in many normal tissues and the

increased production of IL-15 in response to a variety of stimuli suggest that it plays a role in protective immune responses, allograft rejection, and the pathogenesis of autoimmune disorders (174,176). IL-15– and IL-15Ra–nullizygous mice are deficient in NK cells, NK T cells, and gd T cells (30,31,181).

CYTOKINES SIGNALING THROUGH A COMMON GP130 SUBUNIT

Three hematopoietic cytokines, IL-6, IL-11, and LIF, signal through a shared gp130 subunit, as do oncostatin M, ciliary neurotrophic factor, and cardiotrophin-1. The known components of the IL-6, IL-11, and LIF receptors include a cytokine-specific a subunit and the shared gp130 subunit (Fig. 17.3B). The binding of IL-6 to IL-6Ra induces the formation of a hexamer consisting of two molecules each of IL-6, IL-6Ra, and gp130 (Fig. 17.6C). One site on IL-6 binds IL-6Ra, and two additional sites on each IL-6 bind one gp130 and the other gp130, causing gp130 dimerization, which is required for signal transduction. The intracellular domain of IL-6Ra is not required for IL-6–mediated signal transduction. A similar situation is believed to exist for the IL-11R and LIFR, except IL-11 does not induce gp130 homodimerization, and thus another novel receptor subunit is implicated in the process. IL-6 signal transduction is mediated by the actions of JAK1, JAK2, and Tyk-2 tyrosine kinases that are constitutively associated with gp130 and STAT1, STAT3, and STAT5, which are activated, in turn. The ras-MAPK pathway is also activated through SHP-2 or Shc adapters. In addition, other nonreceptor tyrosine kinases are activated through the IL-6R. Two types of IL-6–responsive elements have been identified in the genes encoding acute-phase proteins. Type I IL-6RE is a binding site for NF-IL6/IL6DBP/LAP/C/EBPb. gp130-deficient mice die *in utero* because of severe deficiencies in hematopoietic and cardiac development.

Interleukin-6

INTERLEUKIN-6 AND ITS RECEPTOR

IL-6 is a multifunctional cytokine produced by both lymphoid and nonlymphoid cells. The IL-6R is also expressed on a wide range of cells (182).

BIOLOGY

Identified as one of the factors produced by T cells and macrophages that acts on B cells, IL-6 regulates immune responses, acute-phase reactions, and hematopoiesis. It acts on activated B cells, but not on resting B cells, to induce Ig production, and it is required for IL-4–dependent IgE synthesis, for IL-2–induced Ig production by B cells, and for antigen-specific antibody production by primary B cells (182). IL-6 also stimulates T-cell activation, growth, and differentiation and induces the biosynthesis of acute-phase proteins by hepatocytes. In hematopoiesis, IL-6 acts synergistically with SCF or IL-3 to induce the proliferation of primitive multipotential hematopoietic cells and to increase myelopoiesis and augment megakaryocyte production. IL-6–deficient mice showed reduced IgG and IgA responses and reduced numbers of cytotoxic T cells, and they are severely defective in the inflammatory acute-phase response after tissue damage or infection. They have decreased numbers of primitive multipotent progenitor cells, a reduction in megakaryocyte progenitors, and a predominance of monoblast, myeloblasts, and macrophages in granulocyte-macrophage progenitor cell colonies, as well as decreased neutrophil production and function. (32,182,183 and 184).

Interleukin-11

INTERLEUKIN-11 AND ITS RECEPTOR

IL-11 mRNA is expressed in a wide variety of cell types and tissues, but the protein is normally expressed at low levels and cannot be detected in serum. Depending on cell type, its expression can be induced by proinflammatory cytokines IL-1a and TNF-a, the antiinflammatory transforming growth factor-b (TGF-b), phorbol esters, retinoic acid, and histamine. The IL-11Ra mRNA is also widely expressed. Myeloid, erythroid, and megakaryocytic cells, as well as other cell lines, express IL-11Ra (185,186).

BIOLOGY

The effects of IL-11 on hematopoiesis are also largely synergistic and resemble those of IL-6, almost certainly because their receptors share the signaling gp130 subunit. IL-11 can enhance multilineage growth in combination with certain cytokines including SCF, KL, IL-3, GM-CSF, CSF-1, G-CSF, IL-4, IL-12, and TPO, in general paralleling the effects of IL-6. Moreover, like IL-6, IL-11 stimulates megakaryocytopoiesis *in vitro* through synergism with IL-3, KL, and TPO, by recruiting more progenitors to proliferate, by enhancing colony size, and by promoting megakaryocyte maturation and ploidy but without any effect on mature platelets. The synergistic effects of IL-11 on myeloid and erythroid progenitor cell proliferation and differentiation are less prominent, but it also enhances the generation of early B-cell progenitors. As predicted from *in vitro* studies, the predominant effects of *in vivo* administration of IL-11 are the stimulation of megakaryocyte and platelet production and progenitor stem cell expansion. Despite these effects of IL-11 on hematopoiesis, adult IL-11Ra–nullizygous mice are hematopoietically normal (187), and the residual megakaryocyte and platelet production in TPOR-deficient mice is not dependent on the action of IL-11 or any of the other cytokines known to signal through gp130 (188). Consistent with the broad expression of IL-11 and the IL-11R, like IL-6, IL-11 has many effects outside the hematopoietic system (185,186).

Leukemia Inhibitory Factor

LEUKEMIA INHIBITORY FACTOR AND ITS RECEPTOR

LIF is a monomeric secreted glycoprotein produced by monocytes and stromal cells in response to activating stimuli. The LIFRa is a membrane-spanning protein with a 238 amino acid cytoplasmic domain.

BIOLOGY

The hematopoietic effects of LIF are similar to those of IL-6 and IL-11 (189). LIF-nullizygous mice have no obvious hematopoietic phenotype. As mothers, they are unable to support blastocyst implantation (35).

OTHER CYTOKINES REGULATING HEMATOPOIESIS

Several additional cytokines not covered in detail appear to play important roles in hematopoiesis and are briefly discussed here.

Interleukin-1

The genes encoding three evolutionally related interleukin 1 polypeptides, IL-1a, IL-1b, and IL-1 antagonist (IL-1a), are clustered on human chromosome 2q, and their products mediate acute-phase and febrile responses to inflammatory stimuli. These three cytokines can interact with four receptor-like proteins, but signaling is only observed by ligand-receptor complexes involving either or IL-1a or IL-1b and the IL-1R1 and IL-1R AcP subunits, the latter increasing the binding affinity of ligand for IL-1R1. IL-1a–deficient mice remain able to mount acute-phase and febrile responses, whereas IL-1b–deficient mice fail to do so, a finding suggesting that IL-1b is biologically more important than IL-1a. IL-1R1 and IL-1R AcP are expressed on a wide variety of cell types (190,191,192 and 193). IL-1 stimulates synthesis of several hematopoietic cytokines, including G-CSF, GM-CSF, CSF-1, IL-6, LIF, and IFN-g, and it increases the expression of several cytokine receptors, adhesion molecules, and protooncoproteins (194). IL-1 also synergizes with IL-3, GM-CSF, and CSF-1 to allow multipotent cells to proliferate and differentiate *in vitro* (45,195).

Interferon-g

IFN-g is a noncovalent, homodimeric glycoprotein of 50 kd that is produced by activated or cytokine-stimulated T lymphocytes and NK cells. Its action is mediated by a receptor composed of two or three subunits: a ubiquitously expressed and ligand-binding IFN-g R-a subunit, an IFN-g R-b subunit that exhibits regulated expression, and a third subunit that is required for some responses (196). IFN-g–deficient mice have defects in the immune system that become apparent during infection. IFN-g augments immune responses by activating macrophages and enhances antigen recognition by increasing the expression of the major histocompatibility class I and II antigens. It is also a general inhibitor of cell proliferation. IFN-g inhibits hematopoietic cell proliferation by a variety of mechanisms (197).

Transforming Growth Factor-b

Of the various forms of TGF-b, hematopoietic tissues primarily produce TGF-b1. TGF receptors are expressed almost ubiquitously in the form of the type I and II membrane-spanning serine kinase receptor subunits (198). An important role of TGF-b1 is to inhibit cell proliferation by reducing the phosphorylation of Rb and by increasing the expression of the cell-cycle inhibitor, p27, and arresting cells in the G_1 phase of the cell cycle (199,200). In the case of TGF-b1, this antiproliferative

effect is clearly important for inflammatory cells because TGF-b1–deficient cells die perinatally with an intense inflammatory reaction (200). TGF-b1 directly inhibits the proliferation and differentiation of primitive multipotent cells, as witnessed by the enhancing effects of adding anti–TGF-b antibodies to cultured cells (201). Indirectly, TGF-b1 affects hematopoiesis by inhibiting the production of SCF and the expression of several hematopoietic cytokine receptors (202,203).

Tumor Necrosis Factor

Activated lymphocytes and macrophages are the major sources of TNF-a and TNF-b (also known as lymphotoxin-a). Receptors for these TNFs are essentially ubiquitous, and they serve important functions in sepsis, granulomatous disease, autoimmunity, and graft-versus-host disease, in particular as activators of neutrophils and macrophages. TNF-deficient mice have a disorganized splenic architecture and/or a peripheral lymph node deficiency, with a reduced ability to combat infection (204,205). The TNFs induce the production of the myeloid CSFs, IFN-g, IL-1, IL-6, and chemokines by various cell types, and they inhibit TGF-b production. Thus, although the TNFs directly inhibit the proliferation and differentiation of hematopoietic cells, they can also indirectly stimulate them, with varying results, depending on cell type and culture conditions (204,205).

Chemokines: Stromal Cell–Derived Factor-1a, Monocyte Chemoattractant Protein-1, Macrophage Inflammatory Protein-1a and 1b

Several chemokines have been shown to regulate hematopoietic cells. Many of them are synthesized by bone marrow stromal cells and can exhibit increased expression in response to inflammatory cytokines. Stromal cell–derived factor-1a (SDF-1a) stimulates the growth of pre-B lymphocytes, is a chemoattractant for primitive multipotent hematopoietic cells, and augments the action of TPO on megakaryocytopoiesis. SDF-1a–deficient mice die *in utero* or within 1 hour of birth. They exhibit severely reduced fetal liver B lymphocytopoiesis and bone marrow myeloid progenitor cell numbers (206,207). Monocyte chemoattractant protein-1 (MCP-1) induces the monocyte integrin expression necessary for chemotaxis and attracts and regulates several other lymphohematopoietic cell types. MIP-1a and MIP-1b attract and activate neutrophils and monocytes and attract $CD8^+$ (MIP-1a) or $CD4^+$ (MIP-1b) T cells (208). MCP-1 and MIP-1a and other chemokines inhibit multipotent hematopoietic cell proliferation and differentiation *in vitro* and also hematopoiesis *in vivo* (207).

Jagged and Notch

Notch is a membrane-spanning protein known to control fate decisions in *Drosophila melanogaster* and *Caenorhabditis elegans.* Evidence suggests that the mammalian paralogs of Notch and its ligands are involved in the regulation of hematopoiesis. Primitive hematopoietic cells have been shown to express Notch, and a Notch ligand, Jagged-1, is expressed by bone marrow stromal cells (209). Stromal cells expressing Jagged enhance primitive multipotent hematopoietic progenitor cell proliferation, and activation of Notch in a myeloid cell line inhibited granulocyte differentiation and increased cell proliferation (209,210). A gene broken at the t(7;9) breakpoint in several T-cell lymphomas is a mammalian *Notch* homolog, *Tan-1*(211).

PATHOLOGIC CONDITIONS INVOLVING HEMATOPOIETIC CYTOKINES

The bases of several hematologic conditions can be attributed to alterations in the expression of cytokines and their receptors or to mutations in the genes encoding them. Some of these conditions are summarized in Table 17.2. Analysis of the pathologic roles of cytokines and their receptors is in its infancy, and in many disease states not summarized in Table 17.2, a role for cytokines has been suggested. For example, several studies suggest that in the anemia of chronic disease, overproduction of IL-1 and TNF-a may lead to increases in other cytokines such as IFN-g and MCP-1 that can suppress erythropoiesis. In addition, in studies with mice, elevated levels of circulating CSF-1 before the development of frank leukemia have been shown to be associated with autocrine regulation of acute myeloid leukemic cells by CSF-1 (212). Table 17.2 also does not list conditions resulting from alterations in postreceptor signaling pathways (213,214,215,216,217,218,219,220,221,222,223,224 and 225).

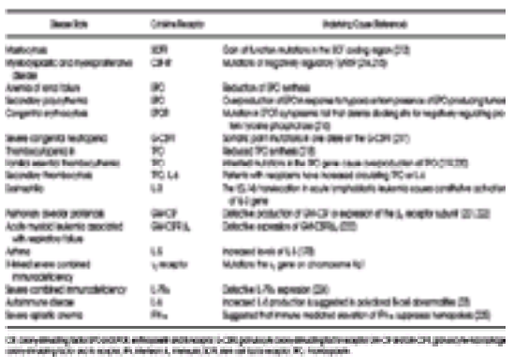

TABLE 17.2. Hematopoietic Cytokines and Receptors in Human Disease

CLINICAL APPLICATIONS AND POTENTIAL

Several hematopoietic cytokines, including EPO, TPO, IL-11, GM-CSF, and G-CSF are used clinically. EPO is used to correct the anemia of chronic renal disease. TPO and IL-11 are used to correct thrombocytopenic conditions. The most successful application of GM-CSF and G-CSF has been in reducing infections in patients with congenital and cyclic neutropenias, whereas their widespread application has been to accelerate white cell recovery and to reduce infections in patients receiving chemotherapy for solid tumors or in patients receiving hematopoietic stem cell transplants (226,227). In particular, the use of peripheral blood cells from donors previously injected with G-CSF to mobilize primitive hematopoietic cells has resulted in the increased use of peripheral blood rather than bone marrow for transplantation, in a decreased incidence of posttransplantation infection, and in a decreased requirement for platelet transfusions (228). Clearly, the hematopoietic cytokines will have extensive application in the future as we learn more about their regulation and mechanisms of action.

18 T-LYMPHOCYTE EFFECTOR ACTIVITY

Thomas J. Braciale, M.D., Ph.D., and Steven M. Varga, Ph.D.

The vertebrate immune system has evolved to counter infestation and invasion by foreign prokaryotic and eukaryotic microorganisms. The immune system is composed of two distinct but related components, the innate and the adaptive immune systems. The *innate immune system* consists of effector cells and soluble effector molecules present both in the blood and in tissues. These effectors are poised to respond rapidly to a variety of insults and use recognition mechanisms with broad specificity to distinguish self from nonself. The activity of these effector mechanisms typically is unaltered by prior exposure to an infectious agent and is therefore not adaptive. Cells of the innate immune system are both hematopoietic (e.g., monocytes and macrophages and neutrophils) and nonhematopoietic (e.g., fibroblasts and epithelial cells) in origin. The soluble mediators of the innate immune system range from the complex of interacting blood proteins comprising the complement and clotting systems to small, highly potent lipid mediators such as arachidonic acid metabolites. The cells and products of the innate immune system can be viewed more precisely as effectors of the vertebrate inflammatory system.

The *adaptive immune system*, by contrast, consists of two highly specialized and highly specific lymphocyte cell types, the B- and T-lymphocytes. These cells display receptors that have exquisite specificity for foreign antigen and that are clonally distributed among individual cells of the B- or T-lymphocyte lineage. Engagement of the antigen receptors on specific B- or T-lymphocytes leads to expression of the lymphocyte effector activities. Figure 18.1 illustrates the major adaptive immune effectors: antibodies produced by activated B-lymphocytes; lymphokines, the cytokines secreted by activated $CD4^+$ and $CD8^+$ T-lymphocytes; and cytolytic T-lymphocytes, activated T-lymphocytes capable of killing other cells by direct cell-to-cell contact. Unlike the cells of the innate immune/inflammatory system, which are constitutively active or rapidly induced, B- and T-lymphocytes exist before contact with foreign antigen as small “resting” cells that lack effector activity. Engagement of the antigen receptor on specific B- and T-lymphocytes by antigen results in the selective activation and differentiation of these resting cells into large blast-like cells that now exhibit effector activity. Adaptive immune cells exert their effector function directly as well as by orchestrating the effector mechanisms of the cells and products of the innate immune system. In the case of the antibody molecule, the Fc portion of the molecule interacts with the soluble proteins of the complement system and with Fc receptors on cells of the innate immune system (e.g., neutrophils and macrophages). In like manner, activated T-lymphocytes mobilize and orchestrate the response of the innate immune/inflammatory system by the release of soluble lymphokine and chemokine mediators. The usual outcome of this interplay between the adaptive and innate immune systems is the elimination of an invading microorganism and the establishment of an adaptive response (i.e., immunologic memory by the B- and T-lymphocytes responding to the organism). An abnormal response to self-molecules or an exaggerated (or inappropriate) response to foreign molecules by the adaptive immune system can lead to immunologic disease. This chapter deals with the effector activities of T-lymphocytes and the manifestations of these effector activities through the interplay of T-lymphocytes with the innate immune system.

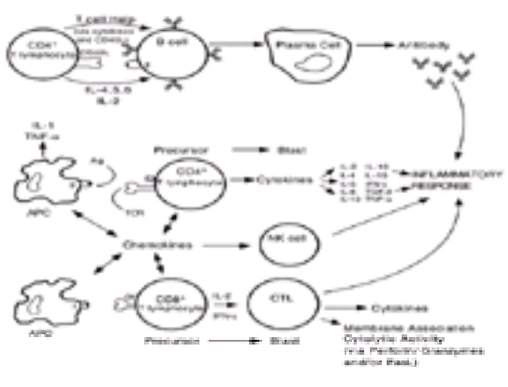

Figure 18.1. Cells of the adaptive immune system and their products. This diagram depicts the major cells types comprising the adaptive immune system, that is, T-lymphocytes and B-lymphocytes. The B-lymphocyte effector cell is the plasma cell. The primary effector product of the plasma cell is the antibody molecule. The T-lymphocyte effector cells are the $CD4^+$ and $CD8^+$ T-lymphoblasts. These blast cells produce cytokines in response to antigen. The $CD8^+$ T-lymphoblast also goes by the designation CTL (cytolytic T lymphocyte) because this cell exhibits cytolytic activity that depends on direct contact of the CTL with the antigen bearing cell. Both T- and B-lymphocytes start out as small resting cells that undergo activation and blast transformation after contact with antigen. See text for abbreviations.

EVENTS IN THE INDUCTION AND EXPRESSION OF T LYMPHOCYTE EFFECTOR ACTIVITY

The hallmark of the T-lymphocyte response to injury or invasion by foreign microorganisms is antigen specificity. The T-lymphocyte antigen receptor (TCR) must be engaged to activate the resting T-lymphocyte and to initiate cell proliferation and the differentiation program leading to the clonal expansion and the expression of lymphocyte effector activity by the progeny cells. This requirement for antigen recognition in the development of T-lymphocyte effector function is demonstrated both by primary (virgin) T-lymphocytes, which take days to transit through this activation and differentiation program, and by clonally expanded memory T-lymphocytes, which can rapidly express effector activity (within 12–24 hours of contact with antigen).

The antigen receptor on T-lymphocytes recognizes a complex between fragments of foreign antigens and major histocompatibility complex (MHC) molecules on cell surfaces. The TCRs must be engaged not only for primary and memory T-lymphocytes to activate but also for activated T-lymphocytes to express effector activity. Thus, the effector activity of T-lymphocytes is usually local, that is, focused on the antigen-bearing cell and its immediate environment. When antigen load is high or when activated T-lymphocytes encounter so-called superantigens, like the bacterial toxins producing toxic shock syndrome (1), however, systemic effects of T-lymphocyte effector activity are observed.

In response to TCR engagement, effector T-lymphocytes secrete soluble products, cytokines and chemokines, which function to recruit and activate cells of the innate and inflammatory systems. Major cellular targets of soluble effector molecules include leukocytes (i.e., granulocytes and monocytes or macrophages), vascular endothelial cells, tissue fibroblasts, and mast cells. Once activated, these cells can secrete cytokines and chemokines, which in turn amplify the local inflammatory response initiated by effector T-lymphocytes.

A second effector mechanism used by activated T-lymphocytes is the killing of antigen-bearing cells by direct cell-to-cell contact. This function is the most highly evolved and specific form of T-lymphocyte effector activity because it uses only the activated T-lymphocyte and requires both antigen receptor engagement and direct cell-to-cell contact.

T-LYMPHOCYTE RECOGNITION AND ACTIVATION

The primary functions of T-lymphocytes are to help B-lymphocytes produce antibodies, to interact with the inflammatory system and enhance the activity of inflammatory cells through the release of soluble mediators, and to act as antigen-specific cytotoxic effectors. The central event in this process is the recognition of antigen by the TCR (2). Like the antibody molecule, this receptor is a heterodimer and has characteristic N-terminal variable regions and C-terminal constant regions. The variable regions are generated by somatic rearrangement and diversification of a fixed number of germline genes (3). Unlike the antibody molecule, the TCR recognizes small peptide fragments of foreign and self-proteins expressed on cell surfaces in association with the highly polymorphic specialized cell-surface molecules, the MHC class I and class II molecules. Class I and II MHC molecules capture peptide fragments of proteins within the cells expressing the MHC molecule (see Chapter 6 for detailed discussion). MHC class I molecules primarily capture peptides during the synthesis of MHC class I molecules in the endoplasmic reticulum. These peptides are derived from a peptide pool generated by proteolysis of self- or foreign proteins in the cell cytoplasm. Cytosolic peptides are transported to the

endoplasmic reticulum, where peptides can bind to the nascent MHC class I molecule (4,5). In most instances, self- or foreign proteins must gain access to the cell cytoplasm to undergo the proteolytic fragmentation necessary for peptide capture by MHC class I molecules, although several alternative pathways for fragmentation and presentation of endocytosed extracellular proteins to class I molecules have been described (6,7 and 8). These alternative pathways of peptide presentation by MHC class I molecules may represent important mechanisms for the presentation of peptides from phagocytosed self- and foreign proteins produced by damaged and dead cells (9). MHC class I molecules are constitutively expressed at varying levels on most cells of the body, but the level of class I expression on cells can be upregulated through the action of certain cytokines, particularly the type I interferons (10,11).

The MHC class II molecules primarily capture peptides formed by proteolysis of endocytosed self- and foreign proteins in the endosome/lysosome compartment of MHC class II-expressing cells (12). In contrast to MHC class I molecules, the MHC class II molecules are constitutively expressed primarily on cells of reticuloendothelial origin that serve as antigen-presenting cells (APCs) (13). The expression of these molecules can be induced on other cell types (e.g., epithelial cells) by the action of cytokines, particularly type II interferon (IFN-g). MHC class I and II molecules must have a peptide bound to their peptide-binding cleft to form a stable molecule at the cell surface (4,5). Because MHC molecules are normally expressed at the surface of body cells before infection or injury, peptides derived from self-proteins make up most peptides complexed with MHC molecules on cell surfaces (14,15). These self-peptides are the presumed targets of the autoreactive T-lymphocytes responsible for tissue destruction in several autoimmune diseases.

One APC type, the dendritic cell, has been recognized as the critical cell for presenting peptide–MHC complexes to primary (naïve) T-lymphocytes (16). Dendritic cells not only constitutively express high levels of MHC class II and I molecules but also express ligands for coreceptors on T-lymphocytes that are necessary for the activation of primary (virgin) T-lymphocytes. Dendritic cells are strategically arrayed at epithelial surfaces and at sites of antigen accumulation in lymphoid tissues, that is, the lymph nodes and spleen, where they can capture foreign antigens for processing and presentation as peptides to T-lymphocytes (17).

The progenitors of effector T-lymphocytes are small, quiescent lymphocytes in the G_0 phase of the cell cycle present in the blood, lymphoid tissues, and epithelial surfaces. These resting small lymphocytes must activate, proliferate, and differentiate to give rise to activated effector cells (18). Engagement of T-lymphocyte antigen receptor by the appropriate peptide MHC complex displayed on an APC is necessary but not sufficient to complete this process. For $CD4^+$ T-lymphocytes, the cell-surface CD4 molecule serves as a coreceptor by binding to a nonpolymorphic (structurally conserved) region of the MHC class II molecule. This interaction serves to strengthen and stabilize the interaction of the antigen receptor with the peptide MHC complex and also concentrates at the site of antigen receptor engagement intracellular signaling molecules associated with the CD4 molecules, for example, the kinase *lck*, which is necessary for T-lymphocyte activation (19). The CD8 molecule is believed to play a corresponding role in $CD8^+$ T-lymphocyte activation by binding to conserved regions of the MHC class I molecule (20). This role of the CD4 and CD8 molecules as coreceptors for the TCR explains why $CD4^+$ T-lymphocytes preferentially recognize antigenic peptides bound to MHC class II molecules and $CD8^+$ T-lymphocytes primarily recognize peptide MHC class I complexes.

Although the CD4 and CD8 coreceptors must bind to their ligands (the MHC class II and I molecules, respectively) for activation of most quiescent T-lymphocytes, costimulatory receptors displayed on the surface of the resting T-lymphocyte also must be engaged for primary cells to differentiate into activated effector T-lymphocytes (21). The costimulatory molecules CD28, CD2, and lymphocyte function-associated antigen (LFA)-1 play a critical role in T-lymphocyte activation (22). Engagement of these receptors by their ligands [i.e., CD80/CD86, LFA-3, intercellular adhesion molecule (ICAM)-1/ICAM-2] on APCs leads to signal transduction events within the T-lymphocytes, which, along with antigen receptor–coreceptor engagement, initiate the cascade of gene activation events that are necessary for the antigen-dependent activation and differentiation of effector T-lymphocytes (23,24,25,26 and 27). As indicated, dendritic cells express high levels of these costimulating ligands and therefore serve as potent APCs for T-lymphocyte activation.

Engagement of the antigen receptor and costimulatory receptor on the resting T-lymphocyte leads to lymphocyte activation, that is, blast transformation and progression of the cell from G_0 to the G_1 state of the cell cycle. Early in the course of lymphocyte activation, a number genes will become transcriptionally active (28), including genes encoding transcription factors that control the expression of early cell-surface markers of lymphocyte activation, such as CD69, as well as the production of several lymphokines and the expression of lymphokine–cytokine receptors. Interleukin-2 (IL-2) is the principal lymphokine responsible for progression of the activated lymphoblast from the G_1 state to the S phase of the cell cycle and subsequent proliferation (29,30). This T-lymphocyte growth factor is produced by T-lymphocytes early (24–48 hours) after activation. Although produced by both $CD4^+$ and $CD8^+$ T-lymphocytes, $CD4^+$ T cells generally secrete higher levels of IL-2 than $CD8^+$ T cells and sustain the production of IL-2 during the subsequent proliferation and differentiation of the activated T-lymphocyte. IL-2 is both an autocrine and paracrine T-lymphocyte growth factor that functions both on the cell producing it and on neighboring activated $CD4^+$ and $CD8^+$ T-lymphocytes. These cells must express the high-affinity heterotrimeric IL-2 receptor to respond to IL-2. This receptor complex, which itself is upregulated on T-lymphocytes after activation and blast transformation, transduces the proliferative signal mediated by IL-2 (29). Other cytokines, such as IL-4 and IL-7, either alone or in combination, also can deliver an IL-2-independent proliferative stimulus to activated T-lymphocytes, but the physiologic significance of these growth factors for early T-lymphocyte activation is uncertain.

Once cell division commences, the activated T-lymphocyte and its daughter cells undergo a series of differentiation steps, culminating in the formation of activated effector T-lymphocytes that have the same antigen specificity (i.e., express an antigen receptor identical to that of their quiescent small lymphocyte progenitor). The differentiation program set in motion by antigen receptor engagement is not fixed. In the case of $CD4^+$ T-lymphocytes, the precursor lymphocyte can give rise to effector cells with one of several distinct patterns of cytokine production. The classic cell-mediated immune response (e.g., cutaneous delayed-type hypersensitivity) is an example of a type 1 or proinflammatory response and is orchestrated by effector $CD4^+$ T-lymphocytes of the T-helper cell-1 (Th1) subset. The response of these effectors is characterized by the preferential production of IFN-g and tumor necrosis factor-b (TNF-b) in response to antigen. Atopic dermatitis and allergic asthma exemplify type 2 responses mediated by effector $CD4^+$ T-lymphocytes of the Th2 subset. In response to antigen, these effector cells preferentially produce IL-4, IL-5, and IL-13.

During the differentiation of an activated $CD4^+$ T-lymphocyte and its daughter cells into effectors, the cells may activate the genes encoding type 1 or type 2 cytokines or both. Many factors appear to influence the commitment of activated $CD4^+$ T-lymphocytes to differentiation along the Th1 or Th2 pathway, including antigen dose and form (31,32 and 33), the APC type stimulating the resting $CD4^+$ precursor cell (34), and, most importantly, the cytokine milieu in which the lymphocyte activation and differentiation occur (35,36,37,38,39,40,41 and 42). As discussed elsewhere (Chapter 10 and Chapter 11), the commitment of effector $CD4^+$ T-lymphocytes to a type 1 or 2 cytokine response can affect profoundly the magnitude and character of the host response and immune-mediated injury. $CD8^+$ T lymphocytes can also differentiate into effector cells exhibiting a type 1 (Tc1) or type 2 (Tc2) cytokine profile (43,44). In most circumstances, however, $CD8^+$ T-cell differentiation is along the type 1 pathway, yielding Tc1 IFN-g-secreting effector $CD8^+$ T-lymphocytes.

Activated effector $CD4^+$ and $CD8^+$ T-lymphocytes have less stringent requirements for stimulation than their quiescent small lymphocyte progenitors. Although the TCR/coreceptor complex on effector cells must be engaged for the cells to secrete cytokines and kill antigen-bearing cells, engagement of costimulatory receptors (e.g., CD28) is not required. This is an important evolutionary adaptation by T-lymphocytes in dealing with invading microorganisms because most cells in the body that are susceptible to infection do not express the costimulatory ligands constitutively displayed by professional APCs. Effector T-lymphocytes, however, do display unique cell-surface adhesive molecules that are not present on small resting lymphocytes. These molecules facilitate the entry of effector cells into sites of inflammation and antigen deposition (as discussed subsequently).

An important outcome of the activation and differentiation of resting primary T-lymphocytes is the generation of an expanded population of memory T-lymphocytes directed to the stimulating antigen. Memory T-lymphocytes display characteristic cell-surface markers (e.g., the CD45RO molecule, a 180-kd isoform of the leukocyte common antigen (45,46,47 and 48)), which distinguish memory cells from primary (virgin) T-lymphocytes. Whereas the generation of effector cells from primary T-lymphocyte precursors requires 3 to 6 days, memory T-lymphocytes rapidly undergo blast transformation and cell division. Memory cells can express effector activity soon after exposure to the stimulating antigen, that is, within 24 to 48 hours (49). These cells and their progeny daughter cells are the predominant cell types involved in the expression of the cutaneous delayed-type hypersensitivity reaction.

TRAFFICKING OF LYMPHOCYTES INTO INFLAMMATORY SITES

The trafficking of lymphocytes to sites throughout the body is mediated by adhesion molecules on the cell surface of lymphocytes, which bind to their complementary ligands on the surface of endothelium (50,51). The expression level of various adhesion molecules on the cell surface of a lymphocyte depends on the activation state of the cell, and it is the differential expression of these various adhesion molecules that controls the migration of lymphocytes from the blood into peripheral tissues of the body (52). naïve T lymphocytes circulate through the blood and secondary lymphoid tissues, such as lymph nodes, Peyer patches, tonsils, and spleen. naïve lymphocytes display this restricted trafficking pattern because of their expression of high cell-surface levels of the carbohydrate binding lectin-like molecule, L-selectin (CD62L), the lymph node homing receptor for lymphocytes (53). CD62L expressed on the surface of a T-lymphocyte interacts with its carbohydrate ligand displayed by specialized vascular structures known as *high endothelial venules*, resulting in the extravasation of naïve, resting lymphocytes from the blood into lymphoid tissues (54). Constitutively high expression of CD62L on naïve T cells serves to keep naïve T cells circulating through the lymphoid tissues (55). Thus, the primary locations for the activation of naïve T-lymphocytes and subsequent differentiation into activated effector lymphocytes are the lymph node and the spleen, where there is an environment rich in professional APCs, such as dendritic cells.

In contrast to naïve T-lymphocytes, activated effector T-lymphocytes are able to exit the secondary lymphoid tissues through efferent lymphatics and to enter the

vascular compartment. Effector T-lymphocytes leave the bloodstream and enter peripheral tissues at sites of inflammation. This ability of effector lymphocytes to deviate from the normal recirculation pattern of naïve T-lymphocytes is the result of the differential expression of several distinct cell-surface adhesion molecules as a consequence of T-lymphocyte activation and differentiation (55,56 and 57). Lymphocyte activation, as discussed, induces a large number of genes to become transcriptionally active, including genes that encode various adhesion molecules. Activated effector T-lymphocytes express increased levels of the integrins LFA-1 and very late antigen-4 (VLA-4) as well as carbohydrate ligand for selectin. Thus, effector lymphocytes differ from naïve lymphocytes by expressing increased (e.g., CD44, LFA-1, and VLA-4) or decreased (e.g., CD62L) cell-surface levels of several adhesion molecules. The activation-dependent upregulation of several of these adhesion molecules (e.g., CD44) is often used as a marker for activated effector T-lymphocytes.

Besides their use as activation markers, several cell-surface adhesion molecules also contribute to the distinct homing preference for peripheral tissues exhibited by activated effector T-lymphocytes (55). The expression of CD44, LFA-1, and VLA-4, combined with the downregulation in the cell-surface expression of CD62L that occurs after lymphocyte activation, facilitates the migration of activated effector T-lymphocytes from lymph nodes via the blood to enter peripheral tissues such as the lung, gut mucosa, skin, and joints. For activated T-lymphocytes to enter tissues, they must bind to vascular endothelium. Only activated vascular endothelium expresses the appropriate combination of adhesion receptor ligands and the chemotactic proteins (termed *chemokines*) to induce the extravasation of activated effector T-lymphocytes into tissues (58,59). This requirement ensures that activated T-lymphocytes preferentially extravasate into tissues at sites of antigen deposition (i.e., inflammation).

The vascular endothelium is activated through the release of cytokines and chemokines by tissue phagocytes, particularly macrophages. Phagocytosis of foreign antigen by tissue macrophages leads to activation of the macrophages and release of TNF-a, a potent activator of vascular endothelium. Activation of vascular endothelial cells by cytokines such as TNF-a results in the upregulation of several different types of adhesion receptors (60,61). One of the earliest cell-surface molecules upregulated is the endothelial cell adhesion molecule E-selectin; this lectin-like carbohydrate-binding protein interacts with its carbohydrate ligand displayed on the surface of activated T cells (62,63). It is the T-lymphocyte's interaction with E-selectin that causes rolling along the endothelium. Firm adhesion of lymphocytes to endothelium is mediated by integrins. Two integrins important in lymphocyte/endothelial cell interactions are LFA-1, which binds to ICAM-1, and VLA-4, which binds to vascular cell adhesion molecule 1 (VCAM-1). These two integrin ligands, ICAM-1 and VCAM-1, are also induced on vascular endothelium activated by TNF-a. In addition, activated vascular endothelium is induced to express certain chemokines, such as IL-8, as well as to accumulate other chemokines produced by cells of the innate immune system via the binding of chemokines to the extracellular matrix of endothelial cells (64). Once the lymphocyte has become firmly adhered to the vascular endothelial cell, chemokines are required to induce the transition of integrins into a high-avidity state that is necessary to complete the extravasation of the activated lymphocyte into the inflamed tissue (Fig. 18.2).

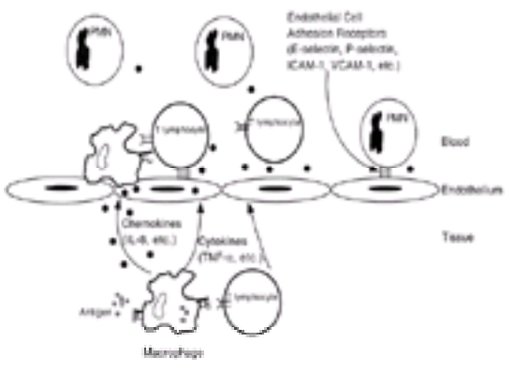

Figure 18.2. Recruitment of lymphocytes into areas of inflammation. Uptake of antigen in a tissue by resident macrophages leads to macrophage activation and the production of chemokines (e.g. IL-8) and proinflammatory cytokines [e.g., tumor necrosis factor-a (TNF-a)], which activate the vascular endothelium. Activation of the vascular endothelium by cytokines results in the upregulation of adhesion receptors such as E-selectin and P-selectin on the surface of endothelial cells. Additional macrophages, polymorphonuclear cells (PMN), and T-lymphocytes are recruited to the inflammatory site by following a chemokine gradient in the bloodstream. Interaction of these newly recruited cells with the adhesion molecules displayed on the surface of activated endothelium results in the extravasation of the cells into the inflammatory site.

Once lymphocytes reach these peripheral tissues, they probably interact with proteins and carbohydrates within the extracellular matrix, which, along with a chemokine gradient, regulates their migration through tissues. Activated effector lymphocytes express elevated levels of VLA-4, VLA-5, and VLA-6. These integrin receptors bind extracellular matrix proteins, such as fibronectin (a ligand for VLA-4 and VLA-5) and laminin (a ligand for VLA-6) (65). This interaction between effector T-lymphocyte integrins and the extracellular matrix likely aids in the movement of activated effector T-lymphocytes through tissues (66).

The events involved in the movement of effector T-lymphocytes from the vascular compartment at sites of inflammation to the sites of antigen deposition in tissues are beginning to be understood in molecular terms. Lymphocyte adhesion to the endothelium is a multistep process (52,67). Initially, lymphocytes are retarded in the blood flow by the transient binding of selectins to their carbohydrate ligands, a process termed *rolling*. The next step in the extravasation process, termed *activation*, is not well understood. It is thought that chemokines, which bind to seven transmembrane-spanning G-protein-coupled receptors expressed on target cells, mediate integrin activation and transition into a high-avidity state. Integrin activation leads to strong adhesion, or *tethering*, to endothelium, followed by transmigration into tissue. The entire spectrum of leukocyte cell types may enter a tissue during different stages of an inflammatory reaction, controlled by the action of various cytokines and chemokines that regulate expression of adhesion ligands (and receptors) on vascular endothelium.

Activated macrophages and endothelial cells secrete cytokines, and chemokines have chemotactic properties for various leukocytes. Chemokines represent a family of small basic chemotactic proteins that play a critical role in the movement of leukocytes during inflammation (68). Lymphocyte movement is directed toward an increasing concentration gradient of the chemokines. Chemokines usually are produced at the site of inflammation, where the concentration is the highest, and diffuse away from the site. A single chemokine can bind more than one receptor, and, conversely, a given chemokine receptor can bind several structurally distinct chemokines. A range of chemokines is known to induce lymphocyte chemotaxis, including IL-8, inhibitory protein (IP)-10, macrophage chemotactic protein (MCP)-1, macrophage inflammatory protein (MIP)-1a, and RANTES (regulated on activation, normal T-cell expressed and secreted). Chemokine receptors were shown to be differentially expressed on T-lymphocyte subsets. The chemokine receptors CCR3 and CCR4 are expressed on Th2 cells, whereas CCR5 and CXCR3 are expressed on Th1 cells, providing a possible mechanism by which Th subsets can be preferentially recruited into distinct inflammatory sites (69,70 and 71). Thus, lymphocytes follow a chemokine gradient toward the tissue involved in the inflammatory response.

The recruitment and extravasation of activated T-lymphocytes constitute a highly regulated series of interactions between the lymphocytes and vascular endothelial cells. Vascular endothelial cells express constitutive levels of MHC class I and II molecules, which can be upregulated by cytokines such as IFN-g. Therefore, vascular endothelial cells can present antigens to T-lymphocytes and further amplify T-lymphocyte responses at inflammatory sites. Cytokines such as IL-1, IL-4, IL-13, and TNF-a activate endothelial cells and upregulate the expression of adhesive receptors on the endothelial cell surface. TNF-a is produced by macrophages and activated T-lymphocytes (72). Thus, macrophages that have ingested antigen at a peripheral site can secrete TNF-a to initiate an inflammatory response, which later can be further amplified by TNF-a produced by activated effector T-lymphocytes that have migrated to the inflammatory site. The TNF-a produced by T-lymphocytes in turn further activates the vascular bed and recruits and activates monocytes and macrophages at the site of antigen deposition. The morphologic manifestations of a delayed-type hypersensitivity response reflect this interplay between the cells of the innate and adaptive immune systems.

T-LYMPHOCYTE EFFECTOR ACTIVITY MEDIATED BY LYMPHOKINES

As discussed, after initial stimulation with antigen, naïve lymphocytes secrete primarily IL-2. After additional exposures to antigen, IL-2-secreting T-lymphocytes will differentiate into effector cells capable of secreting multiple cytokines (73,74). Cytokines are small pleiotropic molecules that often have both autocrine and paracrine activity and mediate many diverse biologic effects (75). Most of the primary effector functions of activated T-lymphocytes are mediated by the cytokines that they secrete (39,76). Many of the later chapters in this text discussion detail the functionally distinct subsets (i.e., Th1 versus Th2) of T-lymphocytes that produce different types of cytokines. The type of cytokines released by effector T-lymphocytes exposed to foreign antigen can have important consequences for successful host defense.

Lymphokines have three important functions in the expression of T-lymphocyte effector activity: (a) They regulate lymphocyte activation, proliferation, and differentiation; (b) they activate inflammatory cells of the innate immune system (e.g., monocytes, neutrophils) and amplify the inflammatory response of cells of the innate immune system; and (c) they stimulate the production of inflammatory cells from precursors in the bone marrow and direct the recruitment of inflammatory cells from the bone marrow to sites of inflammation.

Four lymphokines—IL-2, IL-4, IL-15, and transforming growth factor-b (TGF-b)—directly regulate lymphocyte activation and growth. As discussed, IL-2 is produced by

newly activated T-lymphocytes and can serve as both an autocrine or paracrine growth factor to drive antigen-activated T-lymphocytes through the cell cycle (77). In addition, IL-2 also enhances the production of many other cytokines by activated effector T-lymphocytes. Thus, the primary role of IL-2 is to promote the proliferation and expansion of antigen-specific T lymphocytes. IL-2 also can stimulate the proliferation of natural killer (NK) cells and enhances their ability to secrete IFN-g. Finally, IL-2 serves as an important regulator of T-lymphocyte death by inducing the upregulation of several antiapoptotic genes such as bcl-2 (78). Therefore, IL-2 produced by effector T-lymphocytes can amplify the cellular immune response by supporting further effector T-lymphocyte proliferation and sustain the response through its antiapoptotic effects.

Although it is less well studied than IL-2, IL-15 shares a number of biologic activities with IL-2, including the stimulation and proliferation of antigen-activated T-lymphocytes. IL-15 also stimulates the proliferation of NK cells and, in concert with IL-12 made by macrophages, enhances the production IFN-g (79). In addition to these functions, IL-15 can enhance the cytotoxic activity of NK cells and also act as a strong chemoattractant for T-lymphocytes (80,81). In contrast to IL-2, however, the main source of IL-15 is macrophages, not T-lymphocytes.

Interleukin-4 is produced mainly by $CD4^+$ T-lymphocytes, although, as noted, some $CD8^+$ T-lymphocytes may make IL-4 under certain conditions. IL-4 serves as an autocrine growth factor for type 2 CD4 T-lymphocytes (82). IL-4 synergizes with stimuli provided by CD40 engagement on B cells to drive B-cell activation, proliferation, and differentiation, thus strongly enhancing antibody production by B cells, especially antibody of the immunoglobulin G4 (IgG4 isotype, IgG1 in mice). IL-4 also has a number of activities that promote allergic inflammation, including stimulating basophil recruitment and production, eosinophil chemotaxis, mast cell activation, and the production of IgE by B cells (83,84,85 and 86). Finally, IL-4 also plays an important role in the development of granulomatous inflammation by stimulating the morphologic transformation of macrophages into epitheloid cells and the formation of giant cells characteristic of granulomas.

The fourth regulatory cytokine, TGF-b is produced by many different cell types, including platelets, macrophages, and T and B cells; it has many diverse and sometimes opposing effects. TGF-b has several antiinflammatory activities, including the suppression of hematopoiesis, the reduction in the production of proinflammatory cytokines, and the inhibition of leukocyte adhesion to endothelium (87). A newly recognized subset of $CD4^+$ T-lymphocytes, termed *Th3 cells*, was proposed as $CD4^+$ T-lymphocytes that produce high amounts of TGF-b. Thus, through the production of the immunosuppressive cytokine TGF-b, these cells may play important roles in downregulating immune responses and may represent the suppressor T-cell population, the presence of which has long been suggested in the literature (87,88).

Interleukin-10 and -13 are two other effector cytokines made by Th2 cells. Both IL-4 and IL-13 induce human B cells to undergo Ig isotype switching to IgE, and both cytokines regulate inflammatory responses by suppressing TNF-a and IL-1 production by monocytes and macrophages (89). Unlike IL-4, however, IL-13 cannot induce T-cell proliferation. IL-10 is made by macrophages and T-lymphocytes, and it inhibits the production of proinflammatory cytokines and downregulates antigen presentation by macrophages (90,91). In addition, both IL-4 and IL-10 inhibit the synthesis of Th1 cytokines and the cell proliferation of Th1 cells (92).

Interferon-g is produced by type 1 $CD4^+$ and $CD8^+$ T-lymphocytes as well as NK cells and is an important mediator of inflammatory cell activation. IFN-g increases the generation of highly reactive oxygen species, such as superoxide anion and hydrogen peroxide in macrophages, increasing their phagocytic and microbicidal activity. IFN-g selectively inhibits the cytokine production and proliferation of Th2 cells as well as IgG1 and IgE production by B cells. IFN-g, however, is the major switch factor for antibodies of the IgG1 isotype (IgG2a in mice). In addition, IFN-g enhances the production of cytokines such as IL-1 and TNF-a by macrophages as well as the expression of MHC class I and II molecules on macrophages, B cells, and endothelial cells (93,94). These effects serve to amplify further an inflammatory response. Finally, IFN-g stimulates NK cell activity and plays a critical role in antiviral defense. This product of activated T-lymphocytes serves as a critical effector molecule involved in activating cells of the innate immune system.

The stimulation of bone marrow–derived leukocyte precursors is one last important effector function mediated by a group of cytokines. The cytokines IL-3, IL-5, macrophage colony-stimulating factor (M-CSF), and granulocyte macrophage–colony-stimulating factor (GM-CSF) stimulate immature hematopoietic precursor cells in the bone marrow (95). IL-3 is a growth factor for hematopoietic stem cells and mast cells. IL-5 stimulates the production of eosinophils from immature precursors in the bone marrow. In addition, IL-5 promotes the recruitment and activation of eosinophils. M-CSF and GM-CSF, secreted by T cells and macrophages, induce the growth, differentiation, and activation of precursor and mature granulocytes (GM-CSF) and macrophages (both M-CSF and GM-CSF). All these cytokines play a key role in signaling the bone marrow to increase the production of leukocytes to replenish those innate immune cells turning over at inflammatory sites. Thus, these cytokines act as a positive feedback mechanism to ensure that any leukocytes lost during an immune response can be quickly replaced. Because activated T-lymphocytes are an important source of these hematopoietic growth factors, the production of innate immune effector cells is regulated by TCR engagement and therefore by antigen availability.

Cells of the immune system must make several important decisions, including not only what is foreign to the host but also how best to respond to foreign antigen to mediate its removal from the host. The regulation of the type of T-cell response and other effector mechanisms chosen during an immune response can have important consequences for successful host defense. As described, many of the effector functions of T-lymphocytes are mediated by the cytokines they secrete. Effector T-lymphocytes that have differentiated into type 1 or type 2 cells (a process described in detail in Chapter 10 and Chapter 11) are capable of mediating quite different (and often directly opposing) immune responses.

The classic delayed-type hypersensitivity response is a manifestation of the response of $CD4^+$ T-lymphocytes of the Th1 type. The morphologic manifestations of the delayed-type hypersensitivity response are an intense infiltration of the site of antigen deposition with mononuclear cells, primarily monocytes/macrophages and lymphocytes. This response can be understood in terms of the cells and soluble factors that orchestrate it. Memory $CD4^+$ T-lymphocytes encounter antigen that has migrated to the regional draining lymph node either as free antigen or as processed antigen presented by the dendritic cells. Memory $CD4^+$ T-lymphocytes in the lymph node give rise to effector cells that migrate to the site of antigen deposition. Activated effector T-lymphocytes transit from the vascular compartment into tissue spaces through activated vascular endothelium at the site of antigen deposition. When these activated effector T-lymphocytes contact antigen, they release proinflammatory cytokines and chemokines that promote the recruitment and activation of mononuclear phagocytes into the site of antigen deposition.

The characteristic features of an allergic response include eosinophil accumulation in tissues, mast cell activation, and production of IgE antibodies. These features of the allergic response reflect the activity of T lymphocytes secreting a Th2 type cytokine profile. These Th2 type $CD4^+$ T lymphocyte effectors produce IL-3, IL-5, and GM-CSF, which promote the recruitment and activation of eosinophils at the site of inflammation. IL-4 produced by these T lymphocytes promotes B cell activation and the differentiation of B lymphocytes into IgE-secreting plasma cells. IgE binds to high-affinity receptors on eosinophils and mast cells. Cross linking of the IgE on these cells by antigen leads to eosinophil and mast cell degranulation. Various inflammatory mediators are released by the activated eosinophils, including leukotrienes, platelet-activating factor, and cationic proteins. The rapid degranulation of IgE-armed cells by antigen results in the classic immediate-type hypersensitivity response. The activation and recruitment of type 2 $CD4^+$ T-lymphocytes with the subsequent recruitment of eosinophils into sites of antigen deposition are characteristic of a more prolonged and sustained atopic response.

CELL-MEDIATED CYTOLYSIS BY CYTOLYTIC T LYMPHOCYTES

The second major strategy used by effector T-lymphocytes to eliminate antigens is to destroy, by direct contact, cells expressing the peptide MHC complex to which their antigen receptors are directed. This activity, called *cell-mediated cytolysis* or *cell-mediated cytotoxicity*, is carried out by cytolytic (or cytotoxic) T-lymphocytes (CTLs). Contact-dependent killing is a property of many cell types, ranging from unicellular protozoa to the cells of the vertebrate innate and adaptive immune system. Contact-dependent cell-mediated cytolysis by activated T-lymphocytes likely evolved as an effector mechanism to eliminate intracellular pathogens, in particular intracellular parasitism by viruses and certain bacteria. This effector activity of T-lymphocytes also may play a role in allograft rejection and tumor cell elimination.

Most CTLs express the cell-surface CD8 coreceptor and primarily recognize peptide MHC class I complexes displayed on cell surfaces (2). Because MHC class I molecules are ubiquitously displayed on most body cells, $CD8^+$ CTLs are particularly suited to survey the body for “abnormal” cells (i.e., allografts, tumors, infected cells) displaying peptide MHC complexes specific for the CTL antigen receptor. Although $CD8^+$ T cells and CTLs are frequently used synonymously, $CD4^+$ effector T-lymphocytes in certain instances (as discussed later) can exhibit CTL activity (96). Also, the antigen receptor engagement events resulting in the trigging of cytolytic activity by $CD8^+$ CTLs typically leads to the synthesis and secretion of cytokines by these activated effector cells. For this reason, $CD8^+$ Tc1 and Tc2 CTLs, both of which exhibit cell-mediated cytolytic activity, can be distinguished by the production of IFN-g by Tc1 CTLs and IL-4 and IL-5 by Tc2 CTLs in response to antigenic stimulation (43).

Cytolysis mediated by $CD8^+$ CTLs has been defined and characterized primarily through *in vitro* assays of target cell killing. CTLs use two distinct *in vitro* cytolytic pathways: the perforin-dependent granule exocytosis pathway and the FasL/Fas pathway (Fig. 18.3). As discussed subsequently, each pathway uses distinct effector molecules expressed by the CTLs to trigger killing, and each pathway requires the expression of distinct ligands by the antigen-bearing target cell to induce destruction of the target cell. Typically, both killing pathways are activated simultaneously by engagement of the antigen receptor on the CTLs. Under certain experimental conditions [e.g., suboptimal stimulation of the antigen receptor by the target antigen or by structural variants of the stimulatory antigenic peptide termed *altered peptide ligands* (97)], the perforin/granzyme or the FasL/Fas killing pathways can be selectively triggered (98,99). Engagement of costimulatory adhesive receptors normally displayed on the surface of activated CTLs, such as CD2 and the B-integrin LFA-1, leads to enhanced killing of target cells by CTLs. The ligands for these adhesive receptors need not be constitutively expressed on target cells for target-cell recognition and destruction by CTL. Many of these ligands, such as the LFA-1 ligand CD54

(ICAM-1), can be induced or upregulated on target cells through the action of proinflammatory cytokines produced by cells of the innate immune system. Consequently, at sites of inflammation or injury, cells displaying the appropriate peptide MHC class I complex can also express these adhesive ligands. This ensures the efficient recognition and selective destruction of these target cells by CTL.

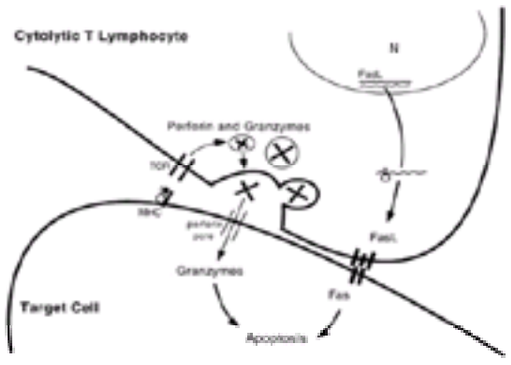

Figure 18.3. Mechanisms of T-lymphocyte-mediated cytolysis. Activated $CD8^+$ T lymphoblasts (CTLs) kill target cells by at least two distinct mechanisms: granule exocytosis and ligand receptor interaction. The T-cell antigen receptor (TCR) must be engaged for these killing mechanisms to be triggered. Engagement of the TCR on a mature CTL by peptide major histocompatability complex (MHC) on the target cell leads to the movement of granules containing perforin and granzymes to the site of TCR engagement and release of granule contents onto the surface of the target cell. Here the process of pore formation and apoptosis of the target cell is initiated. TCR engagement also leads to the transcriptional activation of the FasL gene and upregulation of FasL on the CTL surface. Engagement of Fas receptor on the target cell surface by FasL also triggers the cascade of events leading to apoptosis of the target cell.

Cell destruction mediated by CTLs occurs by triggering programmed cell death or apoptosis in the target cell. Apoptosis is a unique type of cell death distinguishable from other types of lethal cellular injury, for example, hypoxia, by characteristic morphologic and biochemical changes in the dying cell. Cells undergoing apoptotic cell death exhibit plasma membrane ruffling and vesicle blebing from the plasma membrane, mitochondrial swelling with alterations in mitochondrial membrane potential, and nuclear disintegration resulting in chromatin condensation and fragmentation of DNA into nucleosome sized pieces (100). The induction of apoptotic cell death is not unique to CTL. Apoptosis can be triggered by a variety of stimuli, such as ionizing radiation. Apoptosis is the mechanism used by most multicellular eukaryotic organisms to eliminate cells during tissue remodeling throughout development. The apoptotic process is mediated by a family of cytoplasmic cysteine proteases: the caspases. Members of this protease family exist as inactive proenzymes in all mammalian cells. They function in a cascade fashion with initiator procaspases (e.g., procaspases 8 and 10) undergoing autocatalytic proteolytic cleavage and activation in response to an apoptotic stimulus and terminal effector procaspases (e.g., procaspases 3 and 7) serving as substrates for the activated initiator enzymes. On activation, these caspases trigger the terminal events in the cell nucleus, mitochondria, and cytoplasm, resulting in the morphologic changes of apoptotic death. The cellular residue of this type of cell death, the apoptotic body, is susceptible to uptake by phagocytic cells, particularly macrophages. Phagocytosis of the apoptotic body is believed not to trigger macrophage activation, however (9).

PERFORIN/GRANZYME GRANULE EXOCYTOSIS KILLING PATHWAY

Quiescent naïve $CD8^+$ T-lymphocytes do not exhibit cell-mediated cytolytic activity, as already discussed. On engagement of the $CD8^+$ T-cell antigen receptor and costimulatory receptors by the appropriate peptide MHC class I complex and costimulatory ligands on an APC, the $CD8^+$ CTL precursors activate, proliferate, and differentiate into activated effector CTLs. During this differentiation process, the genes encoding products associated with CTL-mediated killing become transcriptionally active (101,102,103,104 and 105). The products include the pore-forming protein perforin, a family of serine proteases, the granzymes; and the lysosomal enzyme cathepsin C. These proteins accumulate in discrete secretory granules bound to a proteoglycan matrix in the cytoplasm of the differentiating $CD8^+$ lymphoblast. The presence of these lytic granules is a hallmark of the activated $CD8^+$ effector T-lymphocyte, the CTL. Exposure of the differentiating $CD8^+$ T cell to cytokines, particularly IL-2 and IL-7 (106,107), enhances the generation of effector CTL. Whereas these lytic granules are not present in naïve $CD8^+$ T-lymphocytes, they can be observed in circulating $CD8^+$ T cells expressing the $CD45RO^+$ memory phenotype (108). Granules that contain perforin/granzyme are also present in NK cells and in some T-lymphocytes of the g/d lineage.

Perforin/granzyme-dependent killing by CTL is through the process of granule exocytosis, described briefly later [for a more detailed description, see Henkart (109)]. In the mature effector CTLs, lytic granules are distributed throughout the cell cytoplasm. When the CTL encounters a cell displaying the appropriate peptide MHC class I complex, the CTL antigen receptor is engaged. The receptor-mediated signal transduction events result in rapid reorganization of the CTL cytoskeleton (within minutes) with polarized movement of granules (and other cellular organelles) to the site of CTL/target-cell contact resulting in release of the granules and their contents into the extracellular space at the contact interface between the two cells (101,102,104). The perforin molecule is liberated from the extruded granule into the extracellular space in a monomeric form. This 65- to 75kd glycoprotein monomer has several unique structural features, including a distinct domain with structural homology to the complement proteins constituting the pore-forming complement membrane attack complex (110), and a lipid-binding domain (111). In the presence of extracellular calcium, perforin monomers insert into the lipid bilayer of the target cell and polymerize to form structural and functional pores in the target cell membrane. Perforin pore formation can lead to target cell lysis, presumably because of the loss of intracellular macromolecules through these pores. Perforin pore formation alone does not induce the apoptotic death characteristic of CTL killing. Apoptotic death requires granzymes. The formation of perforin pores is believed to provide the granzymes access to the target cell cytoplasm.

At least eight members of the lymphocyte granzyme family of serine proteases (granzymes A–H) have been identified in the human (112,113). Two of these granzymes, A and B, have been directly implicated in CTL-mediated killing through the granule exocytosis pathway (114). Granzymes exist as proenzymes in the acid pH environment of the secretory granule. During degranulation, the proenzyme form of the granzymes is cleaved and activated by cathepsin C in the extracellular space at the site of CTL contact with the target cell. Although direct transfer of active granzymes into target cells has not been demonstrated, it is likely that the active enzymes enter cells through perforin pores. Granzymes are believed to trigger the DNA damage characteristic of the apoptotic process in the target cell by at least two mechanisms. Activated granzymes can bind directly to chromatin and cleave nuclear membrane constituents (115), thereby initiating nuclear damage and DNA fragmentation by a caspase-independent mechanism. Granzyme B also has been shown to cleave and activate both initiator and effector caspases (116). Therefore, granzymes may trigger apoptosis by activating the caspase-dependent cell death pathway. *In vitro* studies of CTL-mediated lysis with caspase inhibitors used to block killing or CTL effectors genetically deficient in specific granzymes also implicate caspase activation by granzymes as an important step in target cell killing by CTL through the granule exocytosis pathway (109).

Definitive information on the contribution of the perforin/granzyme killing pathway to $CD8^+$ T-lymphocyte effector activity *in vivo* has come from studies of mice rendered genetically deficient in perforin or specific granzymes by targeted gene disruption (reviewed in 109). In most instances, mice deficient in perforin or granzymes demonstrate normal resistance to viral and bacterial infections (117,118,119,120,121 and 122), reject allografts and tumors normally, and show no enhanced resistance or susceptibility to autoimmune injury (123), although exceptions have been noted under certain conditions (124). These findings are perhaps not surprising because $CD8^+$ T-lymphocytes also express their effector activity by cytokine and chemokine release and by killing through the Fas/FasL pathway.

THE FASL/FAS PATHWAY

The second major pathway used by CTL to kill cells is engagement of the 43-kd Fas (CD95) molecule on target cells by FasL (CD95L) displayed on activated T-lymphocytes (125). Fas is a member of the nerve growth factor (NGF) receptor superfamily. This receptor family also includes the TNF receptor types I and II (TNFRI and TNFRII) and the CD40 molecule. The Fas monomer is readily detected *in vitro* on cell lines of many different lineages and normally is expressed at the cell surface *in vivo* at high levels on lymphocytes and at varying levels on the surface of cells of other tissue types. The Fas molecule has in its cytoplasmic tail a novel “death” domain. Ligation of the extracellular domain of the Fas monomer by FasL results in the formation of a Fas trimer and activation of the cytosolic death domain. Trimerization of Fas triggers the activation of the caspase-dependent apoptotic pathway and death of the target cells (100). A structurally homologous death domain is also present in the cytoplasmic tail of other members of the NGF receptor family, including the TNFRI. The trimerization of the TNFRI receptor on cell surfaces by TNF also can lead to caspase activation and cell death. The presence of a cytoplasmic death domain on both Fas and TNFRI reflects the role of these molecules as inducers of cell death.

FasL is a member of the NGF superfamily and, like other members of this growth factor superfamily, it is a type II membrane glycoprotein. The molecule is present at low or undetectable levels on primary (resting) T-lymphocytes. The activation and differentiation of a resting T lymphocyte after TCR engagement also results in transcriptional activation of the Fas L gene and its expression on the surface of activated T-lymphocytes. FasL exists on the cell surface as a homotrimer. It is this property of the molecule that allows it to trimerize and activate Fas molecules when this ligand encounters its receptor on target cells. Unlike perforin and granzymes, which are exclusively expressed in cells of the lymphocyte lineage, FasL has been reported to be constitutively or inducibly expressed *in vivo* on nonlymphoid cells in

the eye, testes, and lungs (126).

The expression of FasL on activated lymphocytes is under tight control at both the transcriptional and the posttranslation levels. Expression of the FasL gene in effector lymphocytes requires TCR engagement by antigen, and sustained cell surface expression of the FasL trimers on effector T lymphocytes appears to require continuous antigenic stimulation. The FasL trimer on the surface of activated T-lymphocytes is also susceptible to cleavage by extracellular metaloproteases (127). The proteolytically cleared FasL trimer has been reported to be functional, that is, capable of engaging Fas and inducing apoptosis, but the soluble FasL more likely serves as a competitive inhibitor of cell-associated FasL, which blocks the interaction of membrane-bound FasL with the Fas receptor. The tight control of FasL expression on the surface of effector T cells ensures that FasL will preferentially engage Fas on cells displaying the appropriate peptide MHC complex.

The FasL/Fas killing pathway differs from the perforin/granzyme pathway in several respects. Although both killing pathways are normally simultaneously activated by engagement of the CTL antigen receptor, the intracellular signaling requirements for granule release and FasL expression may differ (98,99). Also, whereas perforin/granzyme-dependent killing requires extracellular Ca^{2+}, killing through FasL/Fas interaction is Ca^{2+} independent. In addition, FasL-dependent target cell lysis *in vitro* is slower than perforin-mediated killing, presumably reflecting the need for *de novo* expression of FasL. Finally, engagement of Fas by FasL does not always lead to apoptotic cell death. Different Fas-expressing cell types vary in their susceptibility to this killing mechanism. This represents the balance of proapoptotic and antiapoptotic mechanisms within the target cell regulating Fas-dependent cell death.

To date, little evidence suggests a primary role for the FasL/Fas killing pathway in T-lymphocyte effector activity against infectious agents or in graft rejection. The interaction between FasL and Fas on lymphocytes appears to be crucial for lymphocyte homeostasis. As discussed later, both humans and mice with genetic defects in the expression of functional Fas or FasL suffer from lymphoproliferative disorders and immune dysfunction, leading to autoimmune disease.

CELL-MEDIATED CYTOLYTIC ACTIVITY BY $CD4^+$ T-LYMPHOCYTES

Although the expression of contact-dependent killing is a characteristic of differentiated effector $CD8^+$ T-lymphocytes, $CD4^+$ T-lymphocytes also can express killing activity in certain circumstances. $CD4^+$ cytolytic effector T cells usually are detected when T-lymphocyte populations are maintained in long-term culture (128,129) or after exposure of resting T-lymphocytes to high levels of IL-2 during the stimulation of the $CD4^+$ T cells *in vitro*. During the normal process of $CD4^+$ T-cell activation and differentiation *in vivo*, the genes for perforin and granzymes are not transcriptionally active (130), suggesting that the expression of the granule-based killing pathway is not a typical property of $CD4^+$ effector T-lymphocytes. Under experimental conditions where $CD8^+$ T lymphocytes are eliminated, $CD4^+$ T-lymphocytes can differentiate *in vivo* into effector cells with lytic activity (131). The significance of $CD4^+$ CTL as effector cells is presently not clear. These cells have been proposed to play a role in regulating immune responses by eliminating antigen-bearing MHC class II positive APC and B-lymphocytes (128,132,133 and 134).

RESOLUTION OF THE EFFECTOR T-LYMPHOCYTE RESPONSE

Antigen drives both the induction and expression of T-lymphocyte effector activity. Once effector T-lymphocytes have responded and the stimulating antigen is eliminated, this expanded pool of antigen-specific effector T-lymphocytes is no longer needed. Most of these cells are eliminated from the lymphoid compartment. Without such a mechanism to remove effector T-lymphocytes from the lymphoid compartments (e.g., the lymph nodes and spleen as well as peripheral sites such as the gut, skin, and respiratory tract), these sites would rapidly fill with effector cells. In addition, new populations of effector cells entering these compartments in response to another unrelated pathogen ultimately would be crowded out by accumulated effector cells from prior infections (135,136).

During the resolution of the cellular immune response, activated effector T-lymphocytes in lymphoid tissues and sites of inflammation are eliminated by several related mechanisms, resulting in the apoptotic death of the T-lymphocyte effector cells. Engagement of the TCR on activated T-lymphocytes leads not only to the expression of lymphocyte effector activity but also to the transient expression by the T-lymphocytes of genes encoding antiapoptotic proteins (e.g., members of the bcl-2 gene family) as well as the transient synthesis and release of lymphocyte growth factors such as IL-2. Activated T-lymphocytes require the growth factor IL-2 to sustain their viability, and IL-2 interaction with its high affinity receptor on activated T-lymphocytes in turn also induces the expression of antiapoptotic proteins. After antigen is eliminated, the genes encoding growth factors and antiapoptotic proteins are no longer active and the effector T-lymphocytes undergo programmed cell death as a result of growth factor withdrawal. Activated effector T-lymphocytes also are eliminated by a mechanism operating at the level of TCR engagement through a process called *activation-induced cell death*. As mentioned, engagement of the TCR on activated T-lymphocytes results in the upregulation of FasL. Activated T lymphocytes are particularly sensitive to Fas-mediated apoptotic death. There is now compelling evidence that activated T-lymphocytes (particularly $CD4^+$ T-lymphocyte effectors) are in part eliminated during the resolution phase of the cellular immune response by FasL/Fas-mediated activation-induced cell death (137). Humans (and experimental mice) lacking functional FasL or Fas molecules suffer from lymphoproliferative syndromes that frequently are associated with autoimmune diseases. The T-lymphocytes that accumulate in the lymphoid tissues of these patients no longer express the CD4 (or CD8) coreceptor molecule (138). These “CD4/CD8 double-negative” lymphocytes are believed to be accumulated T-effector cells that were not eliminated during the resolution phase of past immune responses as a result of a defective FasL/Fas interaction. The TNF/TNFR pathway also has been suggested to play a role in activation-induced cell death, particularly in the elimination of activated $CD8^+$ T-lymphocyte effectors (139).

19 NATURAL KILLER CELLS

Lewis L. Lanier, M.D.

Natural killer (NK) cells were first identified as a population of leukocytes from humans or experimental animals without known or deliberate immunization that were able to kill certain tumor cell lines in *in vitro* cytotoxicity assays (reviewed in 1). The initial characterization of the cells mediating this activity indicated that they had a lower buoyant density than most B or T cells and were predominantly "large granular lymphocytes" (2). Most NK cells are slightly larger than the average lymphocyte, and they display prominent azurophilic granules in the cytoplasm. However, morphology alone is inadequate to distinguish these cells from cytotoxic T lymphocytes, which look quite similar. Moreover, a subset of NK cells is small and agranular, and thus morphologically indistinguishable from other lymphocytes (3). A precise classification of NK cells requires a detailed analysis of their expression of cell-surface leukocyte differentiation antigens.

Lymphocytes comprise three distinct lineages: B cells, T cells, and NK cells. B and T lymphocytes are defined by the rearrangement and expression of their immunoglobulin (Ig) and T-cell antigen receptor (TcR) genes, respectively. NK cells do not rearrange Ig or TcR genes and are identified by their characteristic cell-surface antigenic phenotype (4). In humans, all mature NK cells bear the phenotype $CD3^-$, $CD56^+$, and most of these cells also coexpress CD16 (a low affinity receptor for IgG), CD94, and CD161 [natural killer receptor (NKR)-P1], although subsets lacking these other antigens have been described (reviewed in 5). Classification of these lymphocytes as NK cells requires that they be CD3 negative because minor populations of $CD3^+$ T cells express CD16, CD56, CD94, and CD161. Although rodent NK cells do not express CD56, in mice they can be identified as $CD3^-$, $DX5^+$ (or $NK1.1^+$ in certain mouse strains) lymphocytes, and in rats, as $CD3^-$, $NKR\text{-}P1^+$ lymphocytes.

NK cells have been implicated not only in the lysis of certain tumors, but also in innate immunity against intracellular bacteria, viruses, and parasites and in the regulation of hematopoiesis and adaptive immune responses (6,7). In many cases, these effector functions are mediated by their ability to secrete rapidly many different cytokines in response to stimulation. The origin, development, and function of NK cells are reviewed in this chapter.

ORIGIN AND DEVELOPMENT

Like all hematopoietic cells, NK cells arise from a bone marrow–derived hematopoietic stem cell. Studies tracing NK cell development along the branching paths of hematopoietic differentiation indicate that these cells share a common progenitor with lymphoid cells but do not develop from myeloid precursors (reviewed in 8). NK cells share a common progenitor with T lymphocytes (8). However, unlike T cells, NK cells do not require a thymus for their development; they develop normally in athymic nude mice. Moreover, NK cells also are present in mice lacking the recombinase enzymes, encoded by the *RAG-1* and *RAG-2* genes, necessary for the maturation of B and T lymphocytes. Thus rearrangement of somatic genes apparently is not required for assembling the receptors used by NK cells for antigenic recognition. Studies from the *in vitro* culture of NK/T-cell progenitors have indicated that their development is promoted by stem cell factor, interleukin (IL)-7, IL-2 (or IL-15), and unknown factors contributed by stromal feeder cells (reviewed in 8 and 9). How this relates to the physiologic conditions *in vivo* is uncertain.

Studies from gene "knock-out" mice have revealed that NK cell development requires IL-15 and the receptor for IL-15 (comprising the IL-15 receptor-a, IL-2 receptor-b, and IL-2 receptor-g subunits), the IRF-1 transcription factor (necessary for the production of IL-15), Jak3 (necessary for IL-15 receptor signaling), and the Ets-1 and Ikaros transcription factors (affecting unknown pathways; reviewed in 9). Disruption of other cytokine genes or their receptors [e.g., interferon-g (IFN-g, IL-2, IL-7] has a minimal effect on NK cell development. Because of the close developmental relationship between NK and T cells, all of the genetically deficient mice that lack NK cells also have T-cell abnormalities. Therefore conclusions about the role of NK cells in immune responses based on studies of these animals must be interpreted with caution.

In humans NK cells arise very early during ontogeny, being detected in the fetus by 8 weeks of gestation, before to the appearance of T cells at ~16 weeks. NK cells are abundant in the fetal liver, spleen, and blood and express a phenotype similar to that of NK cells in the adult (8). In contrast, NK cell development in mice occurs more slowly. The NK cells in newborn mice lack many of the NK cell receptors (e.g., Ly49) and are generally less functional, requiring 4–6 weeks for their complete maturation (10). The lifespan of NK cells was originally considered to be quite short (i.e., a few days or weeks); however, recent studies are challenging this view and indicating that at least some NK cells might have long lives.

TISSUE DISTRIBUTION

NK cells are abundant in the blood (comprising 5%–20% of circulating lymphocytes) and are present in spleen, liver, and bone marrow at a frequency of a few percentage of the total lymphocytes (1). They also are found in lower numbers in the thymus, lung, and gut lymphoid tissues. However, unlike B and T lymphocytes, NK cells are rarely encountered in lymph nodes and do not recirculate in the lymphatics. In mice certain viral infections result in the recruitment of NK cells from the bone marrow into infected liver tissues by a process that involves interferon-a/b (7).

The decidual tissues of the placenta contain maternally derived lymphocytes and macrophages. Most of these lymphocytes are NK cells, which were initially referred to as uterine granular lymphocytes or granulated metrial gland cells (11). The uterus is the only anatomic location in the body where NK cells predominate over other types of lymphocytes. What attracts and maintains NK cells in this site is not known. The phenotype of decidual NK cells also differs from that of the mother's peripheral blood NK cells (11). The physiologic significance of maternal NK cells in the decidua has not been determined, although a role in fetal sustenance and protection of the fetus against pathogens has been proposed (12).

EFFECTOR FUNCTIONS

The effector functions of NK cells are quite similar to those of $CD8^+$ cytotoxic T lymphocytes (CTLs). As their names imply, both cells mediate cell-mediated cytotoxicity. Killing of target cells by NK cells involves predominantly the directional secretion of perforin (a protein related to the C9 subunit of complement) and granzymes (a class of proteases) (13). In addition, NK cells and CTLs express Fas ligand and membrane or soluble tumor necrosis factor (TNF) that also can lyse susceptible cells. Unlike naive, resting $CD8^+$ T cells that require activation before synthesizing perforin or TNF, mature NK cells constitutively express these molecules. Hence, NK cells do not require proliferation, transcription, or protein synthesis before mediating cytotoxicity. This provides a rapid response, the hallmark of innate immune reactions. Mice lacking *perforin* genes fail to reject certain transplantable tumors, indicating a role for cytotoxicity in tumor immunity (14,15).

The cytokines secreted by activated NK cells are similar to those made by $CD4^+$ and $CD8^+$ T cells. Abundant IFN-g is produced by activated NK cells, and this has been shown to be essential in innate immunity against several intracellular bacteria (e.g., *Listeria monocytogenes*) (16,17), parasites (e.g., *Toxoplasma gondii*) (18,19), and viruses (e.g., mouse cytomegalovirus) (7). Whereas T cells also produce IFN-g, the kinetics of this response are slower than those of NK cells and require clonal expansion of antigen-specific T cells. IL-12 and IL-18 produced in inflammatory sites are required for the induction of IFN-g by NK cells. The prevailing view is that activated macrophages produce IL-1, IL-6, IL-12, IL-15, and TNF, which may augment NK cell synthesis of IFN-g. In turn, IFN-g potentiates macrophage stimulation that promotes their antimicrobial functions. Although innate immunity alone may be unable to eradicate these pathogens, it buys time for the development of a sterilizing adaptive immune response and the generation of immune memory.

Although NK cells predominantly produce cytokines characteristic of Th1 and $CD8^+$ T cells (including lymphotoxin, TNF-a, and IFN-g), under certain conditions, they can also secrete IL-5 and IL-13, typically made by Th2 cells (20,21). Activated NK cells synthesize granulocyte-macrophage colony-stimulating factor (GM-CSF), macrophage colony-stimulating factor (M-CSF), and several different chemokines that may influence the migration and differentiation of other hematopoietic cells (1,7). However, unlike T cells, NK cells do not produce IL-2 or IL-4. Cytokines produced by NK cells also may promote a subsequent Th1-dominated T-cell response, affect the isotypes of antibodies generated, and influence bone marrow hematopoiesis (1).

RECEPTORS AND RECOGNITION

NK cells discriminate between normal and transformed or pathogen-infected tissue by a complex process that involves both activating and inhibitory receptors. Unlike B or T cells, no single receptor provides for self- versus non–self-discrimination. Rather, NK cells apparently use many different activating receptors to initiate cell-mediated cytotoxicity and cytokine production (reviewed in 5 and 22). The best-defined activating receptor on NK cells is CD16, a low-affinity receptor for the Fc region of IgG. CD16 allows NK cells to kill IgG-coated targets by antibody-dependent cellular cytotoxicity (ADCC). CD16 has no intrinsic signaling capacity but is noncovalently associated with the membrane adaptor proteins CD3z and the high-affinity Fc receptor for Ige (FceRIg). These adaptors have immunoreceptor tyrosine-based activation motifs (ITAMs) that, on CD16 binding to IgG, result in tyrosine phosphorylation of the ITAM in CD3z or FceRIg and subsequent stimulation through the protein tyrosine kinases Syk or ZAP70 (22). CD3z and FceRIg also are associated with the 1C7 (NKp30) and NKp46 NK cell receptors (23,24); however, the ligand specificities of these receptors are not known. DAP12, another ITAM-bearing adaptor protein on NK cells, is associated with several different NK cell receptors, some of which recognize classic or nonclassic major histocompatibility complex (MHC) class I ligands. For example, the Ly49D/DAP12 complex on mouse NK cells recognizes H-2D^{d}, the human CD94–NKG2C/DAP12 complex binds human leukocyte antigen (HLA)-E, and the human KIR2DS/DAP12 complex recognizes HLA-C ligands (22).

NK cells also express a receptor, designated NKG2D, for the human nonclassic MHC class I chain–related A and B molecules, MICA and MICB (25) (Fig. 19.1). The NKG2D receptor associates with DAP10, another membrane adaptor protein with a YxNM motif in its cytoplasmic domain that permits recruitment and activation of the p85 subunit of phosphatidylinositol 3 (PI3)-kinase (26). The NKG2D/DAP10 receptor complex is expressed on all NK cells, CD8^{+} T cells, and gd-TcR^{+} T cells (25). MICA and MICB are not expressed in substantial amounts on normal tissues but are overexpressed on carcinomas (27). NK cells are able to kill MICA/B-bearing tumors, suggesting a role for the NKG2D/DAP10 receptor complex in immune surveillance. In addition to these multisubunit receptor complexes linked to the Syk/ZAP70 or PI3-kinase signaling pathways, activation of NK cells also may involve other adhesion molecules, integrins, and costimulatory receptors [e.g., CD2, lymphocyte functional antigen (LFA)-1, 2B4, DNAM-1, CD44, CD28, and others) (reviewed in 5,22,28).

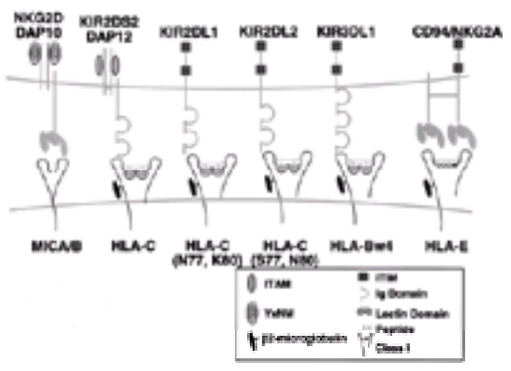

Figure 19.1. Activating and inhibitory natural killer (NK) cell receptors for major histocompatibility complex (MHC) class I. Diagrammatic representation of activating and inhibitory NK cell receptors and their MHC class I ligands. Killer cell Ig-like receptor (KIR)2DL1 and KIR2DL2 are inhibitory members of the KIR family that express two immunoglobulin (Ig)-like domains (2D) in the extracellular region and have a long (L) cytoplasmic domain containing two immunoreceptor tyrosine-based inhibition motif (ITIM) sequences. These receptors recognize a polymorphism of human leukocyte antigen (HLA)-C at residues 77 and 80 in the a1 domain. Peptides within the HLA-C binding groove can affect KIR recognition. KIR3DL1 is an inhibitory receptor with three Ig-like domains (3D) in the extracellular region and two ITIMs in the long (L) cytoplasmic tail. KIR3DL1 recognizes the Bw4 serologic motif in the a1 domain of the HLA-B heavy chain. The C-type lectin-like CD94 protein is disulfide-bonded to NKG2A, which has an ITIM in its cytoplasmic domain. This heterodimer binds HLA-E. Expression of HLA-E on the cell surface requires that it contain nine amino acid peptides derived from the leader segments of certain HLA-A, -B, and -C molecules in its peptide-binding groove. The KIR2DS2 receptor has two Ig-like domains (2D) in its extracellular region, but a short cytoplasmic domain without intrinsic signaling capacity. It noncovalently associates with the DAP12 membrane adaptor protein, which is a disulfide-bonded homodimer containing an IT activation motif (ITAM) in the cytoplasmic region of each subunit. KIR2DS2 interacts with HLA-C, but the precise specificity has not been defined. DAP12 also associates with the activating CD94/NKG2C receptor for HLA-E and with the activating isoforms of the rodent Ly49 receptor family (not shown). NKG2D is a C-type lectin-like receptor that associates noncovalently with DAP10. DAP10 is a membrane adaptor protein, expressed as a disulfide-bonded homodimer that contains a YxNM sequence in its cytoplasmic domain that can recruit and activate the p85 subunit of phosphatidylinositol-3 (PI3) kinase. NKG2D bind the nonclassic class I proteins MICA and MICB. Nomenclature for the KIR molecules and their ligand specificities are described at http://www.ncbi.nlm.nih.gov/prow/guide/679664748g.htm.

Because many of the ligands for these activating NK cell receptors are present on normal cells but are overexpressed in infected, inflamed, or transformed tissues, it is important to prevent NK cells from causing autoimmune destruction. This function is achieved by the presence of inhibitory receptors on NK cells that oppose the action of the activating receptors. In particular, NK cells express inhibitory receptors that recognize self MHC class I molecules and prevent or dampen NK cell attack against cells that express normal or elevated levels of class I. In humans, the killer cell Ig-like receptor (*KIR*) gene family on chromosome 19q13.4 encodes about ten receptors, many of which recognize polymorphic HLA-B or HLA-C ligands (Fig. 19.1) (29). *KIR* genes apparently do not exist in rodents; however, in mice, the Ly49 gene family, encoding receptors for H-2D and H-2K, serve the same function as the KIR molecules in primates. In addition, both human and rodent NK cells express heterodimeric receptors, composed of CD94 and NKG2A subunits, that recognize the nonpolymorphic human HLA-E molecule or the mouse counterpart called Qa1^{b} (Fig. 19.1). NKG2A and several receptors in the *KIR* family contain immunoreceptor tyrosine-based inhibition motifs (ITIMs) in their cytoplasmic domains. When NK cells expressing these inhibitory receptors encounter potential target cells bearing the relevant MHC class I ligand, the ITIMs are tyrosine phosphorylated, resulting in the recruitment of the cytoplasmic protein tyrosine phosphatases Src-homology 2 domain–containing tyrosine phosphatase (SHP-1) or SHP-2 (29). These phosphatases are responsible for inactivation of the NK cells.

Within the KIR, Ly49, and NKG2 families, some of these receptors do not have ITIMs in their cytoplasmic domains but instead associate with the membrane adaptor protein DAP12 and activate NK cells (Fig. 19.1). Therefore both activating and inhibitory receptors exist for MHC class I. To understand this complex system of regulation, it is important to appreciate that an individual NK cell clone within the total population expresses only a subset of these receptors. For example, within the NK cell population are cells that express an activating receptor (e.g., KIR2DS/DAP12) for HLA-C and an inhibitory receptor (e.g., CD94/NKG2A) for HLA-E. Because normal tissues express both HLA-C and HLA-E, the inhibitory receptor dominates and prevents autoimmunity. However, if on infection or transformation, expression of HLA-E, but not HLA-C, were downregulated, NK cells would be able to recognize this HLA-E–negative, HLA-C–positive cell as abnormal and eliminate it. Therefore, by differentially expressing arrays of these various NK cell receptors within the total population, it is possible to generate a very diverse repertoire for the detection of abnormal cells. The process by which repertoire diversity is achieved is not understood. However, it appears that every NK cell clone has at least one inhibitory receptor (and sometimes more) for a self class I ligand, probably to prevent autoimmunity (30,31).

The ability to detect loss of MHC class I has likely evolved to protect against viruses, and possibly transformed cells. Many viruses [including adenovirus, herpes simplex virus, cytomegalovirus, human immunodeficiency virus (HIV), and others] have devised mechanisms to block MHC class I synthesis (reviewed in 32). For example, the Nef gene product of HIV preferentially downregulates HLA-A and HLA-B, but spares HLA-C, possibly attempting to evade T-cell recognition and at least partially avoid NK cell attack (33). Expression of MHC class I is often abnormal in tumors (34), again suggesting the possibility of immune evasion.

NATURAL KILLER CELLS IN TRANSPLANTATION

The classic laws of transplantation state that tissue grafts from either parent (A and B) to an (AxB) F_1 offspring will not be rejected by the recipient. Whereas this fact is generally true for solid organs, it does not apply to bone marrow transplantation. In this case, there is not only the problem of graft-versus-host disease if mature lymphocytes are transferred into an incompatible recipient, but also a host-versus-graft reaction that can result in failure of the stem cells to engraft. One component of the host-versus-graft response is the rejection of the parental bone marrow by radiation-resistant NK cells in the F_1 recipient. In the (AxB) F_1 recipient, some NK cells will coexpress inhibitory receptors for both parental A and B MHC class I haplotypes; however, a substantial proportion will have an inhibitory receptor for only A or only B. This situation presents no problem for the host because all tissues will codominantly express A and B. However, stem cells from the parent expressing only A or only B will be rejected by the subset of NK cells that is not inactivated. This mechanism of parental bone marrow rejection was originally observed in mouse studies, where it was called “hybrid resistance” (35). As allogeneic stem cell transplantation becomes a more frequently used therapy in humans, the potential for hybrid resistance must be considered.

NATURAL KILLER CELL IMMUNODEFICIENCIES AND DISEASES

Immunodeficiency patients totally lacking NK cells are quite rare. However, several cases of this disease have been reported, and the clinical features invariably involve an inability to resolve certain viral infections (36,37). The genetic basis for the absence of NK cells has not been determined in these patients; however, they have normal B and T lymphocytes, implying a lineage-specific defect. Most viruses, such as influenza and adenovirus, are resolved efficiently in these patients; however,

herpesviruses cause life-threatening disease in these individuals. There are similar findings in mice depleted of NK cells, in which control of mouse cytomegalovirus is compromised, but responses to mouse influenza and lymphocytic choriomeningitis virus are apparently normal (reviewed in 7).

Malignancies of NK cells also are infrequent, unlike the situation with lymphomas and leukemias of the B- and T-cell lineages. The clinical disorder known as “large granular lymphocyte lymphoproliferative disease” is used to describe abnormal expansions of either NK cells (with a phenotype $CD3^-$, $CD56^+$), or T cells (typically with a phenotype $CD3^+$, $CD8^+$, and $CD56^-$ or $CD56^+$) (38). Although this disease is often benign, it can be associated with severe neutropenia and anemia.

NK cells (as well as other leukocytes) are affected in the Chediak–Higashi syndrome (39). In this disease, normal numbers of NK cells are present but are characterized by the presence of one large granule in the cytoplasm, and the cytolytic activity of these cells is therefore impaired.

20 NEUTROPHILS

Helene F. Rosenberg, M.D., and John I. Gallin, M.D.

Neutrophils are the most abundant of the leukocytes, comprising about two thirds of the circulating white blood cell pool. They are short-lived cells whose major physiologic role is the destruction of invading microorganisms. Mature neutrophils are highly motile cells; they respond to a variety of specific chemotactic stimuli and contain cell-surface antigens that mediate transfer and adherence to other cell surfaces. Neutrophils engulf microbial targets by a process known as phagocytosis; they contain numerous storage granules with antimicrobial peptides and oxidative enzymes that participate in the destruction of ingested microinvaders. Neutrophils also secrete products that modulate the inflammatory process. This chapter reviews the development and physiology of neutrophils; Chapter 29 discusses the pathophysiology and disorders of neutrophil function.

HISTORY

In 1882 Metchnikoff conceived the phagocytic theory of host defenses on observing that motile cells from starfish larvae clustered around a foreign body inserted under its skin. Although Metchnikoff was not the first to note this association between host cells and bacteria—in 1880 Koch and others described cells filled with anthrax bacilli—his experiments were the first to suggest a role for them. Metchnikoff also discovered that motile host cells were capable of engulfing, or phagocytosing, certain fungal pathogens, thereby rendering them benign. In contrast, fungi that were not attacked by these phagocytic cells caused disseminated fatal disease. From these and other studies, Metchnikoff predicted that defects in these phagocytic cells would result in a compromised host; his work provided the basis for many of our current concepts of host defense.

NEUTROPHIL STRUCTURE AND DEVELOPMENT

Neutrophils develop from undifferentiated precursors into cells capable of responding to and destroying a variety of microbial pathogens. Neutrophilic precursors proliferate and differentiate in the bone marrow; 55%–60% of the hematopoietic cells in the marrow are dedicated to the neutrophil lineage (1). Although differentiation is believed to be a continuous process, a number of distinct neutrophil precursors have been identified both morphologically and biochemically. The process of differentiation is mediated by growth factors, or cytokines, and also is influenced by bone marrow stromal elements.

Pluripotent hematopoietic stem cells are defined as cells capable of unlimited self-renewal and the generation of all hematopoietic lineages. For many years, this cell population was believed to exist in theory, but today, a stem cell population has been defined biochemically by the presence of the cell-surface protein known as CD34 (2). CD34 is a 110-kd glycosylated protein of unknown function; isolated $CD34^+$ cells can generate numerous hematopoietic lineages (including neutrophils) *in vitro* (3) and can reconstitute all hematopoietic lineages in lethally irradiated hosts (4). This observation has taken on recent clinical significance, as $CD34^+$ progenitor cells circulating in the blood are now in use in bone marrow transplantation and in gene therapy trials for chronic granulomatous disease, a genetic aberration of neutrophil oxidative metabolism (5,6; see Chapter 29).

In the current model of hematopoiesis, the CFU-GEMMs (colony-forming unit–granulocyte/erythrocyte/macrophage/megakaryocytes) are the first committed precursor cells of the myeloid lineage (Fig. 20.1). CFU-GEMM cells are no longer $CD34^+$; they express the cell-surface antigen CD33 (67-kd glycoprotein) and thus can be distinguished biochemically from both stem cell precursors and the terminal deoxynucleotidyl transferase (TdT)–positive precursors of the lymphoid lineages. CFU-GEMM cells generate CFU-GM cells (colony-forming unit–granulocyte-macrophages), which express additional surface antigens (CD13 and CD15) and are committed to the granulocyte and macrophage lineages.

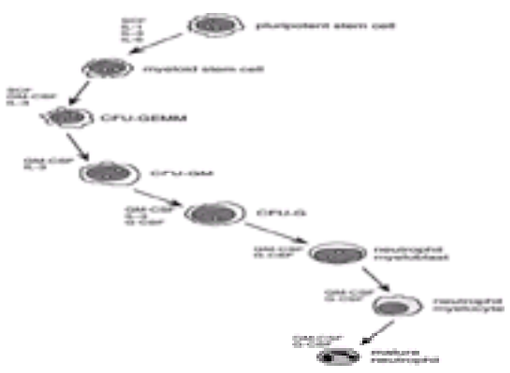

Figure 20.1. Differentiation of the pluripotent stem cell to the mature neutrophil. The cytokines listed are those shown to support the growth of the specific neutrophil progenitors and are described further in the text. Although distinct stages of differentiation have been recognized and defined, hematopoiesis is believed to be a continuous, rather than a stochastic, process. See text for abbreviations.

The myeloblast is the first morphologically distinct cell type of the neutrophil lineage. The process by which the myeloblast differentiates into a mature neutrophil is shown in Fig. 20.2. The myeloblast has a large nucleus, multiple nucleoli, prominent rough endoplasmic reticulum and Golgi apparatus, and numerous mitochondria, all characteristics of a biosynthetically active cell. The myeloblast matures to the promyelocyte. The first granules to appear are synthesized at the promyelocyte stage and are called azurophil, or primary, granules. The azurophil granules contain peroxidase, are rich in acid hydrolases and in the important host defense proteins, defensins, and are classic intracellular lysosomal granules. The azurophil staining characteristic of primary granules is normally observed only in immature cells in the bone marrow.

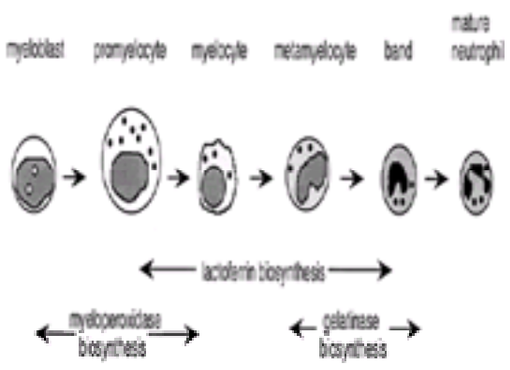

Figure 20.2. Maturation from myeloblast to mature neutrophil in the bone marrow. *Large black circles*, the azurophil granules appearing in the promyelocyte stage; *dark shading*, the specific granules, which first appear in the myelocyte stage. The stages during which myeloperoxidase, lactoferrin, and gelatinase are synthesized are indicated by the *arrows*.

The second group of granules to appear, called specific, or secondary, granules, are formed during the subsequent myelocyte stage. Specific granules contain a number of distinct proteins, including lactoferrin, vitamin B–binding protein, and collagenase, but lack acid hydrolases. The secondary granule membrane serves as a storage pool for several neutrophil plasma membrane proteins, including the adhesion protein Mac-1, the immunoglobulin Fc receptor, the chemotactic f-Met-Leu-Phe (fMLF) receptor, and the reduced nicotinamide adenine dinucleotide (NADPH) oxidase component cytochrome *b*-558, all of which are brought to the cell surface on neutrophil activation. Recent results from several laboratories suggest that the two-granule-populations view of neutrophil granules is somewhat oversimplified. Borregaard and Cowland (7) reviewed these findings and suggested that there are actually four populations of neutrophil cytoplasmic granules. Two additional populations of granules, gelatinase granules and secretory granules, have been identified. Although there is some overlap in protein content, the gelatinase and secretory granules form during the later stages of neutrophil development (Fig. 20.1). Gelatinase granules are defined by their high content of gelatinase, and secretory granules, as the intracellular storage site for alkaline phosphatase. The (overlapping) contents of each of the four distinct populations of neutrophil cytoplasmic granules are listed in Table 20.1.

Azurophil Granules	Specific Granules	Gelatinase Granules	Secretory Granules
Lysozyme	Lysozyme	Lysozyme	Alkaline phosphatase
Myeloperoxidase	Lactoferrin	Gelatinase	Albumin
BPI	Cytochrome b-558	Cytochrome b-558	Cytochrome b-558
Defensins	Procollagenase	Formyl peptide receptor	CD11b
Azurocidin	Mac-1/CR3 receptor	CD11b	CD14
Acid phosphatase	Formyl peptide receptor		CD16
β-Glucosaminidase	B_{12} binding protein		Formyl peptide receptor
α-Mannosidase	Histaminase		
Arylsulfatase	CD11b		
α-Fucosidase			
Cathepsin G			
Cathepsin D			
Elastase			
Phospholipase A			
Deoxyribonuclease			
5′-Nucleotidase			
Collagenase			
β-Glycerophosphatase			
β-Glucuronidase			

* See reference 1 for greater detail.
BPI, bactericidal permeability-increasing protein.

TABLE 20.1. Components of Neutrophil Azurophil, Specific, Gelatinase, and Secretory Granules*

There are no further cell divisions after the myelocyte stage. Primary granules are diluted by cell divisions during the myelocyte stage, and thus mature neutrophils are left with 200 to 300 granules, at a ratio of 1:2 azurophil to specific granules (1,8).

The final stages of neutrophil maturation in the bone marrow include the metamyelocyte and band neutrophil, preceding the mature neutrophil. Differentiation from the myeloblast to the band form requires ~7 days; maturation of the band form to the mature neutrophil requires another 7 days. The mature neutrophil is incapable of cell division and has a segmented, condensed nucleus, no nucleoli, and few mitochondria. Several studies have addressed the mechanism of formation of the condensed, multilobed nucleus of the neutrophil (reviewed in 9). The current working model describes nuclear filaments and filament control factors that interact specifically and hierarchically with distinct regions of genomic DNA. These interactions result in alterations in transcription and ultimately in the observed pattern of nuclear condensation.

Growth factors, or cytokines, interact with one or several of these hematopoietic precursor cells; they induce proliferation and support growth and differentiation (Fig. 20.1). A number of cytokines act on early hematopoietic progenitors; these cytokines include interleukin (IL)-1, IL-6, and stem cell factor (SCF)/*c-kit* ligand (10,11 and 12). Some of their actions with respect to neutrophil growth and development are indirect; for instance, IL-1 induces the production of granulocyte-macrophage and granulocyte colony-stimulating factors (GM-CSF, G-CSF), cytokines with direct effects on neutrophil precursors (13).

Three cytokines have direct effects on neutrophils and their precursors: G-CSF, GM-CSF, and IL-3 (14).

1. *G-CSF* is a 19-kd glycoprotein with actions that are specific for the neutrophil lineage (15,16). G-CSF is produced by macrophages, endothelial cells, and fibroblasts and binds to a single class of high-affinity receptors on neutrophils, normal neutrophil precursors, and leukemic blasts (16,17). Administration of G-CSF results in expansion of the myeloblast compartment, more rapid maturation time, and a dose-dependent increase in circulating neutrophils (18). Mutations leading to structural abnormalities of the G-CSF receptor on neutrophils result in a severe form of congenital neutropenia (19,20 and 21). Signal-transduction pathways through the G-CSF receptor have been elucidated, and include the protein tyrosine kinase families JAK, Src, and Akt. Most recently, G-CSF has been used clinically in combination with antibiotic therapies to combat various infectious diseases in both neutropenic and nonneutropenic individuals (22,23). Betsuyaku et al. (24) showed recently that neutrophils from G-CSF receptor–deficient mice have markedly reduced chemotactic responses to IL-8 both *in vitro* and *in vivo*, despite a normal number of IL-8 receptors, suggesting an otherwise unrecognized interaction between these two signaling systems.
2. *GM-CSF* is a 22-kd glycoprotein produced and secreted by activated T lymphocytes, macrophages, fibroblasts, and epithelial cells (25). In addition to its numerous effects on mature neutrophils (11), GM-CSF enhances survival and proliferation of hematopoietic precursors committed to neutrophil and macrophage lineages. Two distinct classes of GM-CSF receptor have been identified (26). Mature human neutrophils express class I receptors (26), which are downregulated by GM-CSF and also bind IL-3. Class II receptors (not downregulated by GM-CSF, no IL-3 binding) have been detected on leukemic blasts; normal neutrophil progenitors express both receptor classes (15,26).
3. *IL-3* (multi-CSF) is produced by activated T lymphocytes and natural killer (NK) cell, and supports the growth and development of mixed myeloid/erythroid cultures *in vitro*. The actions of IL-3 are directed by high-affinity receptors on early progenitor cells (27). The overlapping biologic activities of GM-CSF and IL-3 led to the discovery that the GM-CSF receptor and the IL-3 receptor, each containing two distinct subunits, have identical b chains (28).

In addition to the soluble growth factors, bone marrow stromal cells play crucial roles in neutrophil development (29,30). The association of maturing neutrophil precursors with bone marrow reticular cells and adherent macrophages has been described. Bone marrow stromal cells not only secrete but can also sequester cytokines into defined hematopoietic microenvironments (31).

The bone marrow serves as a storage pool for ~90% of the total pool of mature neutrophils; the signals initiating release of mature neutrophils from the marrow are not well characterized, although it is believed that IL-1 and a low-molecular-weight cleavage fragment from the third complement component (C3e) (32,33) may participate in this process. Mature neutrophils are more deformable and have lower affinity for the bone marrow adhesion protein hemonectin than do their precursors (34); mature neutrophils leave the bone marrow by passing between discontinuous adventitial cells lining the venous sinuses and between endothelial cells into the circulation. Fever and metabolic stress can enhance the rate of release of mature neutrophils from the bone marrow.

In the steady-state condition, neutrophils circulate in the bloodstream for a brief period ($t_{1/2}$ = 6 hours) before entering tissues. The half-life of neutrophils is shortened greatly in settings of acute inflammation, such as infection. Little is known of the fate of aged neutrophils remaining in circulation; evidence suggests that they leave the circulation primarily via the gastrointestinal tract (35). Senescent neutrophils also are cleared by tissue macrophages in the lung and spleen.

Although homogeneous in appearance, peripheral blood neutrophils have been shown to be heterogeneous by several structural and functional parameters (36). Mature neutrophils differ from one another in the expression of cell-surface receptors, in their ability to produce superoxide, in membrane potential, and in their ability to carry out protein synthesis. Although monoclonal antibodies have been developed that recognize distinct subsets of peripheral blood neutrophils (37,38), the significance of neutrophil heterogeneity remains unclear.

At the molecular level, the intracellular events resulting in the development of the neutrophil phenotype are controlled at the level of transcription by several specific families of transcription factors (reviewed in 39,40,41 and 42). Prominent among the factors involved in the regulation of neutrophil gene expression are members of the Myb, CDP, GATA, AML, Ets, and C/EBP families of transcription factors. None of these factors functions independently to define neutrophil lineage commitment, but the interplay among them functions in the coordinate regulation of genes expressed during neutrophil hematopoiesis. The roles of the C/EBPs (CCAAT enhancer-binding proteins) in neutrophil differentiation have been the best characterized to date (43,44 and 45). Smith et al. (46) and Zhang et al. (47) have reported that C/EBPa expression is critical for the upregulation of G-CSF receptors during normal hematopoiesis, and Zhang et al. reported impaired neutrophil development secondary to loss of G-CSF signaling in engineered C/EBPa-null mice. Similarly, Yamanaka et al. (49) reported that C/EBP-e-null mice were unable to generate

functionally mature neutrophils. Lekstrom-Himes et al. (50) recognized this abnormality as phenotypically and functionally analogous to the human disease syndrome known as neutrophil specific granule deficiency (see Chapter 29).

NEUTROPHIL FUNCTIONS

Several structures and functions distinguish the mature peripheral blood neutrophil in its role as a “professional” phagocytic cell. Neutrophils contain cell-surface receptors that sense signals in their immediate environment. These extracellular signals are translated into intracellular messages that mediate neutrophil motility, adherence, phagocytosis, degranulation, and production of superoxide. The functions of the activated neutrophil are shown in Fig. 20.3.

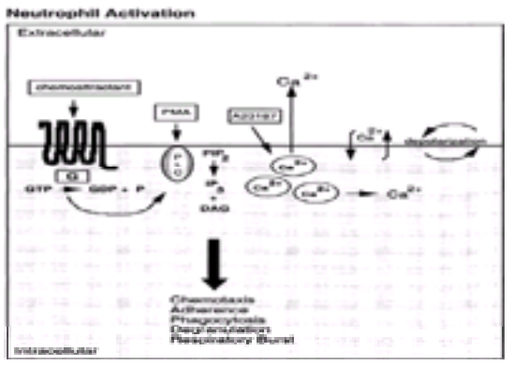

Figure 20.3. Events involved in activation of the peripheral blood neutrophil. Activation begins with binding of a chemoattractant to its specific G protein–coupled receptor. It results in the activation of phospholipase C (*PLC*) and production of inositol triphosphate (*IP*) and diacylglycerol (*DAG*), calcium flux, and membrane depolarization. Phorbol myristic acid (*PMA*) can bypass the receptor by activating PLC directly. The calcium ionophore A23187 likewise causes calcium flux in the absence of receptor-mediated activation. Neutrophil chemotaxis, adherence, phagocytosis, degranulation, and production of toxic oxygen metabolites occur as a result of neutrophil activation.

Neutrophil Chemoattractants

Neutrophils are chemotactic cells; they can respond with directed movement along concentration gradients of specific chemoattractant substances. They respond to a number of chemoattractant agents; among the best characterized of these ligands is the formylated peptide fMLF. This peptide and other similar formylated peptides are by-products of bacterial metabolism. Other agents include complement factor C5a, a proteolytic product of the complement cascade, leukotriene B_4 (LTB_4), and platelet-activating factor (PAF), the latter two being lipids released by neutrophils and platelets, respectively. Neutrophils also recognize peptides from the intecrine families, which include IL-8 and its homologs neutrophil-activating peptide 2 (NAP-2) and GRO-a, as well as macrophage inflammatory peptides (MIP-1a, MIP-1b) (51,52). Neutrophils also synthesize and secrete a significant quantity of IL-8 (53,54).

The neutrophil chemoattractant agents exert their effects by binding to specific cell-surface receptors. The mechanism by which the extracellular binding event translates into intracellular signaling has been a subject of intensive investigation. Initial studies with several of these receptors suggested the involvement of guanine nucleotides (55). The cDNA sequences of PAF (56,57), fMLF (58), IL-8 (59,60 and 61), and C5a receptors (62) are members of a extensive family of seven-transmembrane heterotrimeric guanosine triphosphate (GTP)-binding protein (G protein)-coupled receptors. The members of this receptor family all have guanine nucleotide binding sites, GTPase activity, with specificity (albeit with significant promiscuity) for a given ligand. The ligand-receptor-G protein complex initiates a cascade of events beginning with the activation of membrane-bound phospholipase C (55). Phospholipase C hydrolyzes a specific phospholipid, phosphoinositide-4,5-diphosphate (PIP_2), to inositol 1,4,5-triphosphate (IP_3) and diacylglycerol (DAG). IP_3 and DAG are themselves second-messenger molecules; IP releases calcium from intracellular storage organelles (calciosomes) into the cytoplasm, and DAG is an activator of protein kinase C, which activates the neutrophil respiratory burst (see Neutrophil Antimicrobial Systems, later). Chemoattractant stimulation also results in changes in the plasma membrane potential (depolarization followed by hyperpolarization), which are likely to play an essential role in signal transduction.

Several of the receptors for the intecrine family of signaling molecules, which are primary agents responsible for differential trafficking of leukocytes, are expressed by human neutrophils. Most prominent of this group are CXCR1 and CXCR2, which are receptors for the ligand IL-8, and CCR1, the receptor for the ligands MIP-1a, RANTES, and MCP-2 and -3 (reviewed in 63, 64).

Cytoskeletal Responses

One immediate result of neutrophil activation by these agents is the chemotaxis of neutrophils toward the source of the attractant. The neutrophil travels by “crawling” across a surface; broad lamellopodia are seen at the leading edge and a short tail, or uropod, at the rear. Retraction fibers projecting from the rear of the cell are often broken off as the neutrophil moves forward (65).

On a subcellular level, the neutrophil cytoskeleton must respond to the chemoattractant signals by making structural alterations that result in net movement of the cell in a given direction. The neutrophil cytoskeleton is composed of actin filaments; cytochalasin B, a fungal product that interferes with actin polymerization and inhibits filament formation and likewise neutrophil chemotaxis and phagocytosis (66,67). The mechanism by which a chemoattractant signal is transmitted to the cytoskeleton is not clear; however, a number of actin-binding proteins can actively alter the cytoskeletal structure. Profilin (68) is a protein in leukocytes that binds to actin monomers and thus prevents their polymerization into filaments; the phosphoinositol metabolite PIP_2 reduces the affinity of profilin for actin. Cofilin and destrin also are actin-binding proteins that bind phosphoinositides (65,69) and may be linked to neutrophil activation. Gelsolin is yet another actin-binding protein that binds to and blocks the growing end to polymerizing actin filaments and severs actin–actin bonds in preexisting filaments (65,70). Intracellular calcium promotes the interaction of gelsolin with actin (71), whereas PIP_2 (72) inhibits it, suggesting a way in which the cytoskeleton might respond to neutrophil activation. Witke et al. (73) reported that mice with a targeted disruption of the gelsolin gene exhibited delayed neutrophil migration both *in vitro* and into peritoneal exudates *in vivo*.

Neutrophil Adherence

For neutrophils to leave the peripheral bloodstream and enter the site of active tissue inflammation, they must first pass through the endothelial cell layer lining the postcapillary venule. Neutrophil adherence to endothelial cells is mediated by two distinct families of cell-surface receptors: the leukocyte integrins and the selectins (Fig. 20.4).

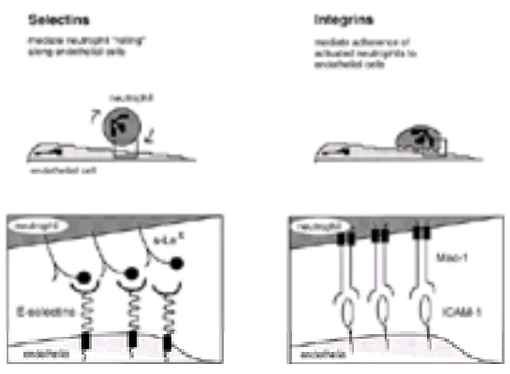

Figure 20.4. Comparison of the features characteristic of selectins and integrins. The areas within the boxes in the upper two panels are “magnified” in the lower two panels. Endothelial cell selectins bind to the sialylated Lewis X (*s-Le*^{x}) antigen on the neutrophil cell surface, thereby mediating neutrophil “rolling” along endothelial cells. In contrast, the adherence of activated neutrophils is mediated by the integrin Mac-1 (CD11b/CD18) and its ligand intercellular adhesion molecule-1 (ICAM-1) on endothelial cells.

Leukocyte Integrins

The leukocyte integrins represent a subclass of a large family of proteins that mediate interactions between cells and their extracellular environment. The leukocyte integrins—known as leukocyte function–associated antigen 1 (LFA-1) (CD11a/CD18), Mac-1 (CD11b/CD18 or CR3), and p150, 95 (CD11c/CD18)—mediate the interactions of leukocytes with each other, with extracellular particles, and with endothelial cells. Each of the three leukocyte integrins is a heterodimeric cell surface protein that contains a distinct alpha chain (CD11a, CD11b, or CD11c) and a common beta chain (CD18) (74,75,76 and 77). The alpha and beta chains each have an extracellular, a transmembrane, and a cytoplasmic domain; distinctive features include an extracellular cysteine-rich repeated motif on the beta chain and a putative cation-binding site on each alpha chain. Intact leukocyte integrins are absolutely crucial for neutrophil function; individuals with leukocyte adhesion deficiency (LAD) have recurrent bacterial and fungal infections associated with defects in neutrophil motility and adherence (78) (see Chapter 29).

The leukocyte integrin Mac-1 plays a major role in neutrophil-mediated activities. The complete, glycosylated heterodimer is stored in the specific granule compartment; on stimulation with any one of a variety of inflammatory mediators, Mac-1 is translocated along with the specific granule membrane to the neutrophil cell surface. In addition to mediating neutrophil adherence to endothelial cells, Mac-1 binds to the complement component IC3b (79) and directs phagocytosis and intracellular lysis of complement-opsonized microorganisms. Mac-1 also recognizes fibrin and fibrinogen and can mediate neutrophil adherence to the extracellular matrix (80). In addition, monoclonal antibodies to Mac-1 can block neutrophil aggregation and adhesion-dependent chemotaxis (80) and peroxide production (81,82). A number of these monoclonal antibodies can block a single Mac-1 function while leaving the other functions unaffected; it is believed that Mac-1 is a modular protein, with different domains subserving a variety of independent activities. Lu et al. (83) described a strain of Mac-1–deficient mice obtained by disruption of the CD11b gene. Neutrophils from Mac-1–deficient mice demonstrated defects in adherence, phagocytosis, and aggregation *in vitro*, although neutrophil accumulation *in vivo* in response to peritoneal thioglycollate proceeded normally.

The leukocyte integrin LFA-1, which is crucial to lymphocyte adherence, also is present on the neutrophil surface and plays a role in antibody-dependent killing (75,84). In contrast to Mac-1–deficient mice, LFA-1–deficient mice exhibited marked reduction in neutrophil extravasation in response to TNF-a, leading the authors to conclude that the contributions of LFA-1 to the adhesion process were more prominent than those of Mac-1 (85). Given these findings, it is curious to note that Mac-1–deficient mice develop spontaneous infections, whereas LFA-1–deficient mice do not. The third leukocyte integrin, p150, 95 is also found in neutrophils, also binds to complement component IC3b (86), and appears to play a role in neutrophil–endothelial interactions (75,80). Intracellular signaling through integrin-initiated pathways mediates virtually all “downstream” neutrophil functions (87). These signaling cascades proceed by the Src family of tyrosine kinases, with specific kinases Hck, Fgr, and Lyn identified through studies with specific gene-deleted mice (88).

Intercellular cell-adhesion molecule (ICAM)-1 has been characterized as a ligand for Mac-1 and LFA-1 on the endothelial cell surface. ICAM-1 is a member of the immunoglobulin gene family and contains five extracellular immunoglobulin-like domains (74,75,76 and 77). Endothelial ICAM-1 expression is upregulated by a number of cytokines, including IL-1, tumor necrosis factor-a (TNF-a), and interferon-g (IFN-g). Similar to the results with LFA-1–deficient mice, neutrophils from mice deficient in ICAM-1 display reduced neutrophil migration (89,90). However, Eppihimer et al. (91) have shown that deficiency of ICAM-1 alters expression of several other adhesion molecules, suggesting that these data must be interpreted with caution.

Selectins

The selectin proteins are similar to the integrins in that they too are transmembrane proteins that mediate cell–cell interactions; however, unlike the leukocyte integrins, selectins are uniquely leukocyte proteins. They function independent of the activation state of the neutrophil, and they recognize carbohydrate, rather than protein, ligands on their target cells (92,93). Three unique selectins have been characterized. L-selectin (MEL-14, LAM-1, Leu-8) was first described as a “homing receptor” on lymphocytes but has since been detected on all leukocytes. E-selectin (ELAM-1) is a cell-surface antigen on activated endothelial cells that mediates adhesion of neutrophils (94). P-selectin (PADGEM, CD62, GMP-140) is found in the membranes of both platelet and endothelial cell storage granules and mediates adhesion of neutrophils to each of these cell types (95,96).

All selectins have a similar multidomain structure. The structural components include an extracellular region with features similar to C-type animal lectins, a second domain with an epidermal growth factor (EGF)-like repeat, and a third domain containing a motif common to complement regulatory proteins; similar to the integrin a and b subunits, the selectins also contain a single transmembrane region and short cytoplasmic tail.

The endogenous ligand of E-selectin is a sialylated form of the myeloid specific carbohydrate known as the Lewis X antigen (97,98); this distinct carbohydrate moiety is commonly found in both glycolipids and N- and O-linked glycoproteins of myeloid cells. P-selectin also recognizes the sialylated Lewis X antigen (99). Although the endogenous ligand of the L-selectin has not yet been determined, it has been shown that L-selectin itself contains a sialylated Lewis X glycosyl group and binds through this moiety to the E- and P-selectins on endothelial cells (100,101). Interestingly, with activation *in vitro*, neutrophils shed L-selectin; and *in vivo*, exudative neutrophils have no L-selectin (102). Shedding of L-selectin may be an important requirement for neutrophil detachment from the endothelium during diapedesis.

Evidence suggests that selectins play a role in neutrophil “rolling,” a process in which blood-borne neutrophils slow before adhering to endothelial cells. Two cases of putative selectin dysfunction secondary to the absence of the sialylated Lewis X antigen have recently been described (103) (see Chapter 29).

Several groups have generated specific selectin gene–deleted mice (reviewed in 104). In P-selectin–deficient mice have more circulating neutrophils than are observed in wild-type mice, but there is no leukocyte rolling early in the inflammatory response (105). In contrast, neutrophils from L-selectin–deficient mice exhibit normal rolling early in inflammation but reduced rolling responses at later times (106), suggesting complementary functions for these two proteins. The inflammatory responses of E-selectin–deficient mice appeared to be normal at baseline (107), although aberrant responses to TNF-a have been reported (108).

Phagocytosis

Phagocytosis is the process by which neutrophils engulf invading pathogens and isolate them in membrane-bound compartments, or phagosomes (Fig. 20.5) (109). Neutrophil cytoplasmic granules containing toxic and cytolytic agents (described in later sections) fuse with the phagosome and mediate the destruction of the ingested material.

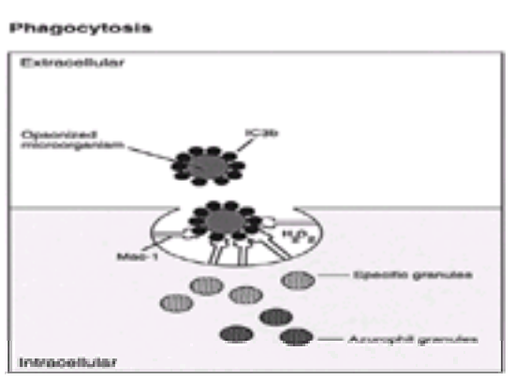

Figure 20.5. Ingestion, or phagocytosis, of a foreign particle by an activated neutrophil. The microorganism is coated, or opsonized, by a proteolytic product of the complement cascade known as IC3b. The complement receptor CR3 (Mac-1) recognizes the IC3b ligand and mediates formation of the phagosome around the opsonized particle. Peroxide within the phagosome results from activation of the respiratory burst (see text). Specific and azurophil granules fuse with the phagosome and release their contents of microbicidal enzymes and proteins (see Table 20.1).

Most invading pathogens or foreign particles are labeled, or “opsonized” by a coating of IgG or metabolites of complement component 3 (C3) known as C3b and IC3b. IgG-opsonized particles can interact with three distinct types of Fc receptors (RI, RII, RIII), all of which recognize the non–antigen-binding (Fc) end of the IgG molecule (110,111). The cDNA sequences of these receptors indicate that they belong to the Ig superfamily (112). Cross-linking of cell-surface Fc receptors (FcRII) by polyvalent immune complexes activates the neutrophil, resulting in phagocytosis and triggering of the respiratory burst. Although the signaling mechanism has not been clarified, receptor cross-linking also results in an increase in intracellular calcium and the production of inositol phosphates. The signal appears to be transmitted via the cytoplasmic tail of the Fc receptors (113). Neutrophils also have receptors for IgA-coated particles (114) and are capable of ingesting some nonopsonized particles,

such as latex beads.

Activation of the complement cascade by either classic (immunoglobulin-dependent) or alternative (immunoglobulin-independent) pathways results in the covalent binding of C3 to the surface of the target particle. As part of the binding process, C3 undergoes cleavage to become C3b, which is recognized by complement receptor 1 (CR1; CD35). C3b can then undergo proteolytic cleavage to become IC3b, which is recognized by complement receptor 3 (CR3). [Note that CR3 is the same as Mac-1 (CD11b/CD18), described earlier as a leukocyte integrin.]

CR1 is found on neutrophils, monocytes, and macrophages and exists in four distinct allelic forms in the human population. All forms have short cytoplasmic tails, a single transmembrane region, and a long extracellular region consisting of multiple small consensus repeats (SCRs) that in combination form long homologous repeats (LHRs); the allelic forms differ in their numbers of LHRs. The SCRs are interesting in that they are shared by a variety of related proteins, including a number of complement-related proteins, the IL-2 receptor, and, as mentioned briefly earlier, E-selectin (115,116); their functional significance is not yet clear.

CR3, as noted earlier, is a multifunctional protein that subserves several neutrophil functions and recognizes at least two distinct ligands. CR3, in its role as an adhesion protein and member of the integrin family, has been discussed earlier; with respect to phagocytosis, CR3 recognizes particles coated with IC3b (but not C3b). Experiments with blocking peptides suggested that CR3 recognizes the sequence arginine–glycine–aspartate (RGD) within the sequence of IC3b (117); recognition of the RGD sequence is a feature shared by other members of the integrin family of proteins.

The engulfment step of phagocytosis proceeds as the neutrophil extends cytoplasmic processes, or pseudopodia, along the edges of the opsonized target. Actin filaments appear locally at the site of engulfment. Pseudopodia can extend only so long as the leading edge encounters cell surface–bound ligand; incompletely opsonized particles cannot be engulfed (118). The pseudopodia meet, fuse, and thus isolate the particle in (plasma) membrane-bound organelles known as phagosomes. The specific granules are the first to fuse with the phagosome and release their contents. After specific granule discharge, primary granules fuse with the phagosome and release microbicidal peptides and myeloperoxidase. The individual components of both types of granule are described in more detail in the following section.

NEUTROPHIL ANTIMICROBIAL SYSTEMS

The two major antimicrobial systems of neutrophils can be classified as oxygen dependent and oxygen independent. The oxygen-independent systems rely on the antimicrobial activities of the cationic peptides and proteins that are released from azurophil and specific granules into the phagosome. The oxygen-dependent systems produce reactive oxygen metabolites that are toxic to invading microorganisms.

Oxygen-dependent Antimicrobial Activity

Baldridge and Gerard (119) were the first to describe the effect known as the “respiratory burst” when they noted that phagocytes incubated with microorganisms used oxygen at a more rapid rate than did their resting counterparts. Others noted that hypoxic conditions reduced (but did not eliminate) the antimicrobial activity of neutrophils (120,121 and 122). The respiratory burst is a process by which neutrophils reduce molecular oxygen to superoxide; superoxide is ultimately converted to hydrogen peroxide and other toxic oxygen metabolites. The respiratory burst is crucial to host defense; defects in any one of several components result in a life-threatening disorder known as chronic granulomatous disease of childhood (see Chapter 29).

The individual components catalyzing the respiratory burst have become the subjects of intensive investigation (Fig. 20.6) (123,124). Two of these components comprise the membrane-bound heterodimer known as cytochrome *b*-558, which contains a 91-kd glycosylated b subunit found in a noncovalent complex with a 22-kd a subunit (125,126). The low midpoint potential of this cytochrome (–245 mV) enables it to perform the direct single-electron reduction of molecular oxygen (127). The 91-kd subunit contains a binding site for the electron donor NADPH and a region homologous to FAD-binding domains of other proteins (128,129 and 130). There are two heme groups per heterodimer, which are thought to be coordinated jointly by both polypeptides (131,132). In the resting neutrophil, cytochrome *b*-558 is found primarily within the membrane of the specific granule (133,134). On neutrophil activation, the vesicles containing membrane-bound cytochrome *b*-558 fuse with the emerging phagolysosomes and with the plasma membrane (135).

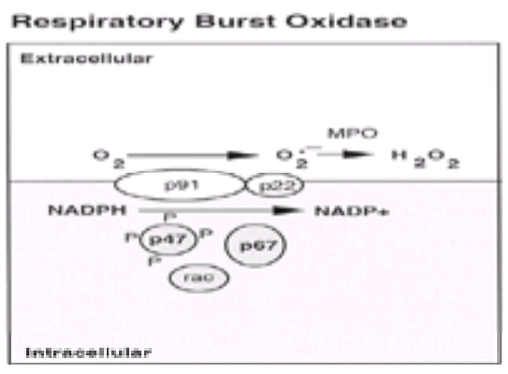

Figure 20.6. Components of the respiratory burst oxidase include two membrane-bound proteins (p91 phox and p22 phox) and three cytoplasmic proteins (p47 phox, p67 phox, rac). Neutrophil activation results in translocation of the cytoplasmic components to the membrane; together, these components catalyze the reduction of molecular oxygen to superoxide at the expense of reduced nicotinamide adenine dinucleotide phosphate (NADPH). The precise location at which the superoxide is produced is not known. Superoxide is then converted to the toxic oxygen metabolite hydrogen peroxide.

The respiratory burst requires the activity of three independent cytosolic components known as p47 phox (phagocyte oxidase) (136), p67 phox (137), and a low-molecular-weight G (GTP-binding) protein known as rac (138,139 and 140). Neutrophil activation results in phosphorylation of p47 phox (141) and the translocation of both p47 phox and p67 phox to the plasma membrane (141,142 and 143). The 91-kd membrane component contains a carboxyl-terminal domain essential for interaction with the translocated p47 phox (143,144). Although both of these cytosolic components are crucial for superoxide production, their mechanism(s) of action remains unclear. The third cytosolic component, rac, has been isolated from neutrophils as a complex with an inhibitory protein known as rho-GDI (145). The role played by rac/rho-GDI in the production of superoxide is likewise unclear.

Another source of oxygen-dependent toxicity is the peroxidase–peroxide–halide system (146,147 and 148). Myeloperoxidase, a major component of the primary neutrophil granules, catalyzes the conversion of hydrogen peroxide (derived primarily from the respiratory burst) and hydrogen chloride to hypochlorous acid, molecular chlorine, and chloramines. Native myeloperoxidase is composed of two glycosylated identical heavy subunits (55–63 kd) and two identical light (10–15 kd) subunits, with two iron (Fe^{3+})-containing heme groups covalently linked to each of the heavy subunits.

The production of nitric oxide by nitric oxide synthase is another oxygen-dependent antimicrobial system. Nitric oxide synthase has been characterized primarily in mouse macrophages (149,150 and 151), but nitric oxide also may function as an antimicrobial agent in human neutrophils (152). Nitric oxide plays an important role in the macrophage-mediated killing of intracellular parasites and may assist in neutrophil-mediated bacterial killing. Although there seems to be more support in the literature documenting nitric oxide synthesis by human neutrophils (153,154 and 155), Holm et al. (156) reported that indicators such as nitrate and nitrite are produced by human neutrophils in response to appropriate stimuli, but that there is no production of nitric oxide itself.

Oxygen-independent Antimicrobial Activity

The azurophil and specific granules store a number of antimicrobial proteins, including lysozyme, lactoferrin, and a number of distinct cationic proteins, as described later and in Table 20.1. The contribution of each individual granule component to the overall antimicrobial activity of the neutrophil is difficult to measure, as single protein defects (analogous to CGD) have not yet been identified; the activities described later result from experiments done with purified proteins *in vitro*. More details on neutrophil granule proteins can be found in references 7 and 157,158 and 159.

Lysozyme

Lysozyme is a small (14–15 kd) hydrolytic enzyme whose target is bacterial cell wall peptidoglycan. Lysozyme has been found in both primary and secondary granules of the human neutrophil, as well as in numerous tissues and secretions (e.g., saliva). Although lysozyme can destroy bacterial cell wall peptidoglycan *in vitro*, its role as

an antibacterial agent *in vivo* is unclear for two reasons. First, other antimicrobial proteins released simultaneously with lysozyme activate endogenous bacterial muramidases that are equally if not more effective at hydrolyzing their own cell-wall peptidoglycan; second, neutrophils from several nonhuman species lack lysozyme with no apparent ill effect.

Lactoferrin

Lactoferrin is a large (78 kd) glycosylated protein, is a member of the transferrin family of iron-binding proteins, and is found in neutrophil specific granules as well as in other body tissues as secretions (160,161 and 162). The antibacterial properties of lactoferrin may be due in part to its ability to bind free iron, which is necessary for bacterial viability; high concentrations of plasma lactoferrin may contribute to the anemias associated with chronic inflammatory diseases. Two of the three known isoforms of lactoferrin have ribonuclease activity, which may or may not be related to its antipathogen functions. Lactoferrin has antiviral activity against RNA viruses (163), a striking parallel to the antiviral activity described for the otherwise unrelated ribonucleases present in human eosinophils (164). Individuals with a condition known as neutrophil specific granule deficiency (see Chapter 29) have neutrophils that are devoid of lactoferrin and are subject to recurrent bacterial infections (165,166); however, the absence of a number of other granule proteins (including defensins; see later) precludes any conclusions as to the significance of lactoferrin as an antibacterial agent *in vivo* from these findings.

Cationic Proteins

The neutrophil primary granule contains a number of cationic antimicrobial proteins. They include defensins, cathepsin G, azurocidin/CAP37, and bacterial permeability–increasing protein/CAP57 (167).

Bacterial Permeability–Increasing Protein

Bacterial permeability–increasing protein (BPI) is a single-chain protein (50–60 kd) with potent antibacterial activity *in vitro* (168); other isolates include CAP57 (169), which is identical to BPI. In contrast to the other primary granule cationic proteins that are arginine rich, BPI has an elevated lysine content. There are two interesting features of BPI: (a) its toxicity is remarkably specific for gram-negative bacteria; and (b) all the antibacterial activity resides in the cationic amino-terminal half of the protein. The mechanism of BPI's toxicity has been delineated: BPI inserts into the outer bacterial membrane, resulting in permeabilization of the bacterial cell and subsequent growth arrest. This event results in activation of bacterial enzymes, which eventuates in autolytic destruction of bacterial cell wall peptidoglycan and phospholipids (157).

Defensins

The defensins human neutrophil proteins (HNPs) are a group of small (29–34 amino acids) antimicrobial cyclic peptides that are rich in arginine and contain six cysteines in three invariant disulfide bonds (170,171,172,173 and 174). Defensins are active against a variety of gram-positive and gram-negative bacteria as well as against some fungi and viruses. HNP-1, HNP-2, and HNP-3 differ by only a single N-terminal amino acid; the amino acid sequence of HNP-4 differs at many points, but the cysteine components are conserved. Defensins comprise ~50% of the total primary granule protein content. Experiments with purified proteins have shown that defensins form voltage-gated ion channels in artificial lipid membrane systems (175). This finding suggests that, similar to BPI, the antimicrobial activity of the defensins likely begin with a membrane-perturbation event. Defensins also function as monocyte and T-cell chemoattractants (176,177).

Cathepsin G

Cathepsin G is a serine protease (25–29 kd) with activity primarily against gram-negative bacteria. Cathepsin G has significant sequence homology to neutrophil elastase and to a serine protease from cytotoxic T lymphocytes (178). The antibacterial activity of cathepsin G appears to be unrelated to its serine protease activity; elevated temperatures, protease inhibitors, and proteolysis of cathepsin G itself did not alter its bactericidal properties (179). One group has shown that short peptides derived from isolated regions of cathepsin G have antibacterial activity and may in part account for the antibacterial activity of the protein as a whole (180).

Azurocidin/CAP37

Azurocidin/CAP37 is a member of the group of proteins known as serprocidins. It is similar in structure to a serine protease, but it has mutations in the catalytic site precluding serine protease activity (181,182). Similar to cathepsin G and elastase, azurocidin/CAP37 is highly cationic owing to a high content of arginine residues and, similar to BPI and the defensins, probably acts by interfering with intact bacterial membranes. This protein is also a monocyte and T-cell chemoattractant (176,183).

PRO- AND ANTIINFLAMMATORY MEDIATORS PRODUCED BY NEUTROPHILS

The assumption that neutrophils are terminally differentiated, biosynthetically inactive cells has been shown to be incorrect; stimulated neutrophils synthesize and secrete a variety of inflammatory mediators that affect the activity of neutrophils themselves as well as that of other inflammatory cells (184). Cassatella (185) recently published an extensive review of this subject. In brief, a variety of external stimuli, including bacteria and bacterial products, fungi, protozoa, viruses, and some cytokines and growth factors (including TNF-a, IL-1b, IL-2, IL-15, and IL-13) and chemotactic agents (fMLF, C5a, and PAF) can induce the production of both pro- and antiinflammatory mediators. There have been reports documenting the production of the proinflammatory cytokines TNF-a, IL-1b, IL-1b, IL-12, and interferon-g, the antiinflammatory cytokines IL-1 receptor agonist and TGF-b; and numerous CC and CXC chemokines (including IL-8) and hematopoietic growth factors. Future research will be needed to elucidate the various independent and interdependent pathways leading to production of these immunomodulatory proteins as well as to determine the biologic significance of these findings in given physiologic settings and conditions.

21 MONOCYTES AND MACROPHAGES

Iain P. Fraser, M.B., Ch.B, and R. Alan B. Ezekowitz, M.B., Ch.B.

Ilya Metchnikoff's description of ameboid cells in starfish larvae ingesting a rose thorn led to the realization that there exist specialized hematopoietic cells that are able to recognize and ingest foreign material. This fundamental cellular process of phagocytosis is a feature of a specialized lineage of myeloid cells that originates in the bone marrow. During embryogenesis at the time circulation is established, macrophages populate tissues where they reside for the life of the animal. A circulating pool of precursor cells, the monocytes, continually renews these resident macrophages. Macrophages are among the body's most versatile cells in that they adapt to different roles according to their local milieu and play distinct roles at different stages of development. During development, they clear apoptotic cells, an essential process that allows the developing embryo to proceed to the next stage of maturation. In the fully developed animal or human, macrophages play a key role in tissue remodeling and in first-line host defense, and they are an essential interface between innate and adaptive immunity. Macrophages secrete >100 biologically active metabolites, thereby instructing the homeostatic cascades of the clotting and complement systems as well as interfacing with vital functions of the organs in which they reside. Our focus is the origins of mononuclear phagocytes and their role in innate immunity.

ORIGIN AND DEVELOPMENT OF MONOCYTES AND MACROPHAGES

In the mammalian embryo, the monocytes and macrophages that are destined to make up the mononuclear phagocyte system appear first in the fetal yolk sac and then subsequently derive from fetal liver precursors. In the mammalian adult, monocytes are produced from precursors in the hematopoietic bone marrow. Circulating monocytes provide a cellular pool that can be mobilized to deliver large numbers of inflammatory cells on demand to sites of inflammation. This circulating pool also gives rise to the more stable, long-lived populations of resident tissue macrophages scattered throughout the body. This population of resident cells acts as a first line of host defense against invading pathogens.

The cells that make up the mononuclear phagocyte system are in a continual state of differentiation and adaptation. The extensive repertoire of cell-surface receptors expressed by these cells facilitates their interaction with the extracellular environment (other cells, pathogens, humoral factors, and substrates). Some of the receptors are coupled to the cytoskeleton in a way that enables these cells to internalize particles (i.e., >0.5 µm diameter) with great efficiency from the extracellular environment. These transcriptionally active cells are also endowed with a prodigious array of secretory products, ranging from signaling molecules (such as cytokines and chemokines) to effector molecules able to destroy invading pathogens (such as reactive species of oxygen and nitrogen).

In the adult, monocytes originate in the bone marrow. Monocytes and neutrophils are thought to share a common progenitor, known as the colony-forming unit, granulocyte-macrophage (CFU-GM) (1). Morphologically identifiable members of the monocytic lineage in the bone marrow include monoblasts and promonocytes, which in turn give rise to mature monocytes. The newly formed mature monocytes remain in the bone marrow for £24 hours before entering the peripheral blood, where they distribute between a circulating and a marginating pool (2,3). In normal human adult peripheral blood, monocytes account for ~1%–6% of the total leukocytes. The half-life of these cells in the circulation has been estimated at ~17 hours under resting conditions in the adult mouse (4) and £70 hours in normal human adults (5).

Monocytes are recruited from the peripheral blood under two broadly defined circumstances. The first is a poorly understood, low-level, constitutive process that gives rise to mature resident macrophages that populate most tissues. One old idea is that this process is a random one that signals the tissues to entice the passing cells to adhere and take up residence. It seems likely, at least in higher animals, that constitutive expression of chemokines in organs plays an instructive role in the baseline coaxing of monocytes from the circulation into the tissues. The egress of monocytes from the blood to the tissue is greatly amplified in the context of acute inflammation. This amplification response is clearly orchestrated by a number of chemokines that serve not only to regulate chemotaxis and transmigration, but also to modify cell function. This latter process is manifest by both an increase in bone marrow monocytopoiesis and by a decrease in the monocyte circulating half-life (6). The molecular signals mediating this process of recruitment are well known and are discussed further later.

The majority of resident tissue macrophages are thought to derive from circulating monocytes (7,8). A minority of these mature cells, however, may be produced by local division of precursor cells within the tissues themselves (9,10).

Resident Macrophage Populations

Mature tissue macrophages may be found embedded in the connective tissues and interstitia of many organs (often referred to as histiocytes in this setting). Additionally, they may be located in prominent subendothelial locations (e.g., hepatic sinusoidal Kupffer cells, adrenal sinusoidal macrophages), subepithelial locations (choroid plexus macrophages, salivary gland macrophages), or freely within tissue spaces (e.g., pulmonary alveolar macrophages, synovial macrophages, resident peritoneal macrophages) (reviewed in 11,12). Early histologists described many of these cells before their hematopoietic origins became known; and thus they carry unique names, including the microglia of the brain, the osteoclasts of bone, and the Kupffer cells of the liver.

The phenotypes of these resident cells vary greatly and are influenced by the microenvironment. The ability of macrophages to respond to the local milieu imparts a heterogeneity and plasticity. The versatility of macrophages to adapt and modify their phenotypes has sometimes led to the mistaken premise that there are subsets of macrophages that are predetermined in the bone marrow. Macrophages represent a single lineage of bone marrow–derived cells that are capable of undergoing extensive regional differentiation, and this capacity accounts for their marked heterogeneity.

The strategic subepithelial and subendothelial locations of resident macrophages suggest a critical role in first-line host defense. Resident macrophages are adorned with a wide array of cell-surface receptors that might be considered pattern-recognition receptors. Prototypic examples include the mannose receptor, which is able to recognize directly a broad range of carbohydrates that adorn infectious agents. Pathogen recognition may involve cooperation between receptors. Receptor ligation triggers release of a variety of antimicrobial molecules either extracellularly or into the nascent phagosome. The ability of these resident cells to limit the infection depends on the susceptibility of the microbe to this repertoire of antimicrobial products that compose the cells' armamentarium. For example, a certain gram-positive bacterium that is susceptible to lysozyme, a product of resident macrophages, would be killed, whereas other gram-positive bacteria or gram-negative organisms might not be killed. Resident macrophages therefore have a limited armamentarium and lack the full array of microbicidal capabilities characteristic of their inflammatory and activated counterparts (13,14).

However, the ability of resident macrophages to contain an infection is augmented by their ability to initiate vasodilatation and to increase blood vessel permeability. These processes facilitate the egress of serum factors and active inflammatory cells that act as rapidly deployed reinforcements in restricting the infectious nidus. Another example is a murine model of listeriosis, in which Lepay et al. (15) showed that resident Kupffer cells were incapable of generating reactive oxygen intermediates (ROIs), and that the total hepatic production of H_2O_2 could be accounted for by recently recruited monocytes. In another study of murine listeriosis, Rosen et al. (16) demonstrated that inhibition of myelomonocytic cell recruitment interfered with the ability of the mice to resist the infection. These data indicate that the resident macrophage populations lacked the ability to adequately contain serious infectious challenges, and that successful resistance to these infections was contingent on the host's ability to recruit an inflammatory cell population containing monocytes. This same population of Kupffer cells has been shown, however, to play a significant role in hepatic cytokine secretion and liver regeneration, indicative of a trophic rather than a microbicidal role. In a rat model, selective ablation of Kupffer

cells before partial hepatectomy resulted in impaired liver regeneration and was accompanied by reduced hepatic cytokine secretion (17).

Homeostatic functions have been ascribed to resident macrophage populations, but with a few notable exceptions, they remain poorly understood. Mature macrophages are found in the bone marrow where they interact with developing erythroid and myeloid precursors, forming a functional unit within the bone marrow (18,19 and 20). In this setting, the central mature macrophage contributes to a variety of hematopoietic functions (21), including erythroblast iron and ferritin metabolism (22), phagocytosis of extruded erythroid nuclei (23), phagocytosis of effete erythrocytes (24), and production of hematopoietic growth factors (25 and 26,27). In the central nervous system, the resident microglial population undergoes metabolic changes after physiologic stress (such as water deprivation) that are clearly different from those seen in response to infections (28), again suggesting a role in tissue homeostasis.

Cytokines, Colony-Stimulating Factors, and Monocyte Maturation

The colony-stimulating factors (CSFs) play critical roles in hematopoiesis by virtue of their ability to support the survival, proliferation, differentiation, and end-cell functions of myeloid cells (29,30 and 31) (see Chapter 17). Two CSFs thought to be critical to the monocyte/macrophage lineage are macrophage colony-stimulating factor (M-CSF) (also known as CSF-1), and granulocyte-macrophage colony-stimulating factor (GM-CSF). Several studies, many of them using mice genetically deficient in one or more CSFs, have contributed greatly to our understanding of the physiologic contributions made by these CSFs.

The osteopetrotic (op/op) mouse is a naturally occurring mutant animal that has congenital osteopetrosis secondary to a severe osteoclast deficiency. Early studies of these mice established that they lack the ability to produce M-CSF (32). These mice were found to be severely lacking in a variety of macrophage populations: decreased CFU-GM, decreased circulating monocytes, and decreased serosal cavity and tissue macrophages. Resident macrophage populations of the liver, spleen, and thymus appeared to be less severely affected by this deficiency (33). The residual macrophages in the op/op mice were capable of normal phagocytic function *in vivo* but appeared to be less competent to release cytokines in response to inflammatory stimuli such as lipopolysaccharide (LPS) (34). Studies such as these have given rise to the concept of M-CSF–dependent and –independent populations of macrophages.

In an extension of these observations, Witmer-Pack et al. (35) used immunohistochemistry to identify subpopulations of macrophages and dendritic cells in the M-CSF–deficient mice. They found that in addition to osteoclasts, macrophage populations from the peritoneal cavity, splenic marginal zone, and subcapsular sinuses of lymph nodes were particularly affected by the absence of M-CSF. Macrophage populations in the thymic cortex, splenic red pulp, lymph node medulla, intestinal lamina propria, liver (Kupffer cells), lung (alveolar macrophages), and brain (microglia) were less affected and reached significant levels even in the absence of M-CSF. Cells of the dendritic cell lineage were not morphologically affected in the mutant mice. Additional studies have confirmed these observations and have further reinforced the concept of M-CSF–dependent and –independent macrophage subpopulations (36,37). Endogenous levels of GM-CSF, and interleukin (IL)-3 are elevated in the op/op mice and are thought to compensate partially for the M-CSF deficiency in the animals. The administration of exogenous GM-CSF to op/op mice corrected the macrophage deficiency, but not the osteoclast deficiencies in these animals, indicating an absolute requirement of osteoclasts for M-CSF (38).

Functions ascribed to GM-CSF include enhancement of antigen presentation (39), phagocytosis (40,41), microbicidal activity (42), and leukocyte adhesion (43).

The effects of GM-CSF on macrophage development and activity were demonstrated dramatically in a study in which transgenic mice were made to express the GM-CSF gene under the control of a retroviral promoter (44). Elevated levels of GM-CSF were detected in the serum, urine, peritoneal cavity, and eyes of these animals. Massive accumulations of macrophages in the eyes led to ocular opacity and retinal damage, and similar accumulations of macrophages were found in the peritoneal and pleural cavities, as well as in skeletal muscle. Additionally, these macrophages had an activated phenotype. A more refined analysis of the physiologic functioning of GM-CSF became possible with the advent of gene-targeting techniques in mouse embryonic stem cells.

In the first study of GM-CSF–deficient mice to be published, a critical and unexpected role for GM-CSF in pulmonary homeostasis was described (45). The mice deficient in GM-CSF developed a progressive accumulation of surfactant lipids and proteins within their alveolar spaces (similar to that in the human disease, alveolar proteinosis) but had no appreciable reduction in alveolar macrophage number. No abnormalities in steady-state hematopoiesis were detected. In a second study published by another group, the pulmonary phenotype and normal hematopoiesis were confirmed, and the additional finding of focal areas of subclinical lung infections in some animals was noted (46). Longer-term follow-up of these animals revealed a modest impairment in their reproductive capacity as well as a propensity to develop pulmonary and soft tissue infections (47).

More recent studies with these mice have further defined a role for GM-CSF in host defense. When infected with the intracellular pathogen *Listeria monocytogenes*, GM-CSF–deficient mice were less capable of containing the infection, had severely depleted levels of bone marrow hematopoietic cells, and demonstrated deficient peritoneal cavity inflammatory responses when compared with their wild-type counterparts (48). In an alternative model, LeVine et al. (49) studied a model in which GM-CSF–deficient mice were challenged with intratracheally inoculated group B streptococci. The clearance of these organisms from the lungs was reduced in mice deficient in GM-CSF compared with that in wild-type controls. This decreased clearance was not associated with a decrease in phagocytosis in the GM-CSF–deficient mice but was associated with a marked decrease in production of ROIs by alveolar macrophages. These studies suggest that GM-CSF may play a more significant role as an activator of monocyte-macrophage functions than as a mediator of monocyte-macrophage growth and differentiation.

Chemokines and Monocyte Development, Chemotaxis, and Recruitment

A diverse array of stimuli have been reported to induce the chemotaxis of monocytes and other leukocytes (see Chapter 16). These mediators include formylated bacterial peptides (50), cleaved complement components such as C5a (51), platelet-activating factor (PAF) (52), and leukotrienes (53). In addition, many cytokines and other biologically active molecules have been described to mediate chemotaxis of monocytes. These include fragments derived from extracellular matrix components such as elastin (54), fibronectin (55), and collagen (56); cytokines such as platelet-derived growth factor (PDGF) (57), GM-CSF (58), and transforming growth factor type b (TGF-b) (59); and collectins such as pulmonary surfactant protein A (60). The physiologic importance of the *N*-formylpeptide receptor (FPR) in host defense was defined by Gao et al. (61), who deleted the gene encoding this receptor to create FPR-null animals. These mice developed normally and did not develop infections when housed under specific pathogen-free conditions. Challenge of these mice with the intracellular pathogen *Listeria monocytogenes* resulted in increased mortality rates, however, and was associated with increased hepatic and splenic bacterial burdens (61).

The most recent attention has focused on the chemokines, a large family of peptides that control leukocyte migration (62,63) and that have been implicated in the development, homeostasis, and functioning of the immune system (64). Chemokines reported to act on monocytes and/or macrophages include the monocyte chemoattractant proteins (MCP) -1, -2, -3, -4, and -5; macrophage inflammatory proteins (MIP)-1a and -1b, I309, hemofiltrate CC chemokines (HCC) -1 and -4; fractalkine; growth-related oncogenes (GRO)-a, -b, and -g; IFN-inducible protein (IP)-10; leukotactin 1 (Lkn-1); lymphocyte and monocyte chemoattractant (LMC); macrophage-derived chemokine (MDC); monokine induced by IFN-g (MIG); myeloid progenitor inhibiting factor 1 (MPIF-1); regulated on activation normal T-cell expressed and secreted (RANTES); stromal cell-derived factor (SDF-1); and platelet factor 4 (PF4). The molecular diversity of chemokines and their promiscuity of receptor–ligand interactions poses challenges in clearly identifying the precise role for each of these molecules in macrophage/monocyte homeostasis, although clues do exist (see later).

MCP-1 is a CC chemokine that is capable of attracting monocytes, memory T cells, and natural killer (NK) cells (65). Studies of its activity in transgenic mice overexpressing the chemokine attest to its monocyte-recruitment capabilities (66,67 and 68). More recent investigations with MCP-1 knock-out mice have defined further the physiologic role of this chemokine. Lu et al. (69) demonstrated normal levels of circulating leukocytes and of resident macrophage populations in their studies of MCP-1–null mice. These knock-out mice demonstrated decreased recruitment of monocytes to the peritoneal cavities of animals injected locally with thioglycollate broth and showed a decreased accumulation of monocytes in experimentally induced delayed-type hypersensitivity reactions. These data indicate a unique role for MCP-1 in the inflammatory recruitment of monocytes, and suggest that this chemokine does not play an essential role in baseline monocytopoiesis or in the baseline recruitment of resident macrophage populations.

MIP-1a is another CC chemokine with monocyte chemoattractant activity (70). Studies using neutralizing anti-MIP-1a antiserum to block the activity of this chemokine *in vivo* in mice showed that it plays a critical role in the recruitment of monocytes to sites of wound injury (71). These studies also demonstrated that appropriate tissue repair (as assayed by local collagen production and angiogenic activity) after wound injury was critically dependent on MIP-1a–mediated monocyte recruitment. The role of MIP-1a in viral infections was analyzed in the first report describing the phenotype of the MIP-1a knock-out mouse (72). These mice, unable to make MIP-1a, demonstrated decreased levels of mononuclear cell infiltrates in the heart after infection by coxsackievirus and in the lung after infection by influenza virus. In a neutropenic mouse model of invasive pulmonary aspergillosis, MIP-1a was depleted by means of antibody before intratracheal instillation of *Aspergillus fumigatus* conidia (73). The mice in whom the chemokine had been depleted demonstrated a six-fold increased mortality rate, which was associated with a 12-fold increase in lung fungal burden. Taken together, these data point to a critical role in host defense for MIP-1a, and indicate that this chemokine mediates unique activities that cannot be compensated for by other chemokines.

MDC was identified by random sequencing of cDNA clones from human monocyte-derived macrophages (74). This CC chemokine was found to be highly expressed in macrophages and monocyte-derived dendritic cells but not in monocytes or cell lines. Studies with purified MDC revealed it to be chemotactic for monocyte-derived dendritic cells, and for NK cells, as well as for monocytes. The activity of MDC has recently been extensively investigated in a murine cecal ligation and puncture model (75). Exogenously administered MDC protected the mice from death, whereas blockade of endogenous MDC activity with neutralizing antibodies resulted in decreased

survival in this model. Furthermore, MDC induced respiratory burst activity and stimulated the release of lysosomal hydrolases from peritoneal macrophages exposed to this chemokine *in vitro*. These data indicate that chemokines can modulate monocyte/macrophage end-cell functional activities in addition to inducing cellular recruitment from the circulation.

PF4 is a CXC-chemokine (76) that is one of three chemokines known to be released by activated platelets. Whereas most CXC chemokines act predominantly on the polymorphonuclear cell lineage, PF4 acts on a wide range of cell types. In addition to its activity on mature cell lineages, PF4 also sustains the survival of hematopoietic progenitor cells (77). Recently, purified human PF4 was shown to prevent peripheral blood monocytes from undergoing spontaneous apoptosis, and it was also able to induce the differentiation of macrophages from monocytes (78). In these studies, the phenotype of PF4-induced macrophages differed from that of GM-CSF–induced macrophages in that major histocompatibility complex (MHC) class II molecules were not upregulated on the macrophage cell surface in the presence of PF4. These findings suggest a means by which platelets are able to modify the cellular phenotype of recently recruited inflammatory cells such as monocytes and provide an example of how macrophage phenotypes may be differentially regulated, depending on the cellular environment to which they are recruited.

Reverse Transmigration of Monocytes and the Formation of Dendritic Cells

After granulocytes are recruited to extravascular inflammatory sites, they undergo apoptosis and are cleared locally by macrophages by means of a mechanism that does not result in a proinflammatory response (79,80,81 and 82). The fate of recruited monocytes has been less well defined. Studies using adoptive transfer of macrophages have shown that these cells emigrate from sites of inflammation to draining lymphoid organs in a nonrandom fashion (83,84). In the *in vitro* studies with human umbilical vein endothelial cells cultured on amniotic tissue, the majority of monocytes that migrated transendothelially into the amniotic tissue subsequently emigrated back across the endothelium in a basal-to-apical direction (85). This process of reverse transmigration was mediated in part through the P-glycoprotein (MDR-1) transmembrane transporter (86), and by transmembrane tissue factor (87). In contrast, the initial (i.e., forward) transmigration of leukocytes is mediated by leukocyte integrins of the CD11/CD18 family (88,89) and by CD31 on both leukocytes and endothelial cells (90,91).

Transendothelial migration may be an important determinant in the differentiation of members of the mononuclear phagocyte system. Human monocytes can be differentiated into functional, immunostimulatory dendritic cells when cultured *in vitro* in the presence of IL-4 and GM-CSF (92,93). In an *in vitro* model of monocyte transendothelial migration, Randolph et al. (94) showed that monocytes cultured with endothelium (in the presence of serum, but without supplemental cytokines) differentiated into dendritic cells. Of the $CD14^+$ monocytes that migrated through the endothelium and into the underlying collagen matrix, those that remained in the subendothelial matrix differentiated into macrophages, whereas those that transmigrated out of the matrix developed into dendritic cells. The differentiation and transmigration of dendritic cells in this system were significantly enhanced if phagocytosable foreign material (latex beads or yeast cell walls) was present in the subendothelial matrix (94).

These studies were further extended to an *in vivo* model in which latex microspheres were injected into mouse skin sites (95). The monocytes contained in the resultant inflammatory infiltrate phagocytosed all of the locally injected particles, with a majority differentiating into mature macrophages. Approximately 25% of the monocytes that had phagocytosed the injected particles migrated out of the injection sites and localized in the T-cell areas of the draining lymph nodes, where they exhibited a phenotype characteristic of dendritic cells and not of macrophages (95). These authors have postulated that dendritic cells that derive from monocytes may play a unique role in the acquisition and presentation of particulate (as opposed to soluble) antigens, and that they therefore occupy a unique niche in host defense.

Taken together, these findings indicate that the fate of monocytes after their migration from the circulation is significantly more complex than previously believed, and that these cells retain a high degree of developmental plasticity even after they have left the circulation. Although many data have implicated cytokines in this differentiation process, the physical acts of phagocytosis and cellular transmigration are clearly also important factors, although their exact mechanism(s) of action remains to be determined.

Genes That Regulate the Differentiation of Monocytes and Macrophages

The development of monocytes and macrophages is determined by the expression of lineage-specific transcription factors that cooperate with more ubiquitously expressed factors. Some of the transcription factors that are thought to play a key role in myeloid cell development include PU.1, CCAAT displacement factors, AML-1B, Sp-1, GATA-1 and -2, and c-jun. Of these, the role of PU.1, which is a member of the Ets family of transcription factors, has been particularly informative, as it seems to form a focal point for the assembly of transcription factors that specify myeloid cell differentiation. PU.1 is expressed in a hematopoietic-specific fashion in B cells and myeloid cells, where it is required for the development of these lineages. Its DNA recognition sequence is purine rich with a core motif of 5'-GGAA/T-3'. The amino terminus serves as the activation domain. The molecule also contains a PEST [region rich in proline (P), glutamate, (E), serine, (S) and threonine,(T)], which is an instability sequence, and a carboxyl terminus that contains Ets homology winged helix-turn-helix motif that binds DNA. Numerous PU.1 target genes have been identified, including those encoding the M-CSF receptor (96), the GM-CSF receptor (97), class A scavenger receptors (98), the CD11b leukocyte integrin (99), the macrophage mannose receptor (100), FcgR1b (101), phagocyte oxidase (phox) subunits (102,103), c-*fes*(104), and serine proteases (105).

PU.1 appears to play an important role in macrophage differentiation. A proposed paradigm for the role of PU.1 as a bridging factor emerged from studies on CD11b, FcgR1b, and macrophage mannose receptor promoters. A consensus from this work indicates that PU.1 interacts with the ubiquitous transcription factor, Sp-1, and that this complex is able to interact with the basal transcription machinery. Of interest is that most macrophage-restricted genes lack a classic TATA box and that the preinitiation complex is specified by a so-called transcription initiator (Inr). The relative strength of the Inr and the absence of a TATA box, in conjunction with PU.1 and enhancers like the interferon (IFN)-g response elements, all appear to be key variables in directing macrophage-specific gene expression.

Gene-targeting experiments revealed that PU.1 is a critical factor for the expression of genes associated with terminal myeloid development and also affects other hematopoietic lineages. The first report characterizing PU.1–knock-out mice demonstrated that PU.1-null embryos died at a late gestational age (embryonic days 16.5–18), and that the mutant embryos were unable to generate progenitors for monocytes, granulocytes, and T and B lymphocytes (106). These embryos were also anemic because of impaired maturation of erythroblasts (in the face of normal erythroblast numbers), but demonstrated normal megakaryocytopoiesis. Other investigators independently generated PU.1–knock-out mice and reported the birth of homozygous null animals that then died of severe septicemia within 48 hours of birth (107). Analysis of these mice confirmed the absence of mature macrophages, neutrophils, and B and T lymphocytes, as in the earlier study. When these neonatal mutant mice were maintained with prophylactic antibiotics, they were able to develop T lymphocytes and neutrophil-like cells, but failed to develop B lymphocytes or macrophages.

These PU.1-null animals have now been used extensively in further studies of hematopoiesis and have helped to refine our understanding of the physiology of this important transcription factor. Tondravi et al. (108) demonstrated that the development of both macrophages and osteoclasts is defective in PU.1-null mice, and that the resultant defect in osteoclastogenesis gives rise to an osteopetrotic phenotype. These authors also showed that PU.1 mRNA accumulated in bone marrow–derived macrophages as they matured to osteoclasts *in vitro*. More recent studies have shown that PU.1 is also essential for the production of myeloid-derived, but not lymphoid-derived, dendritic cells (109).

Although PU.1-null mice were described to develop neutrophil-like cells, these cells were subsequently shown to be arrested in their differentiation and incapable of becoming functionally competent (110). This finding suggested that PU.1 was not required for neutrophil lineage commitment but was essential for neutrophil development, maturation, and end-cell function. Hematopoietic cells derived from PU.1-null mice failed to proliferate *in vitro* in response to M-, G-, or GM-CSF, and this finding correlated with minimal expression of the receptors for G- and GM-CSF, and absence of receptor for M-CSF (111). Subsequent transfection of cDNAs for the receptors for M-CSF or GM-CSF into PU.1-null cells allowed the cells to survive and grow in the relevant growth factor, but failed to rescue the cells sufficiently to give rise to mature macrophages (112). In an extension of these findings, Henkel et al. (113) reported that PU.1-null hematopoietic progenitors were able to commit to the monocytic lineage, but their differentiation was arrested at a stage before mature macrophage development (113). In a recently published study, DeKoter and Singh (114) demonstrated that low intracellular concentrations of PU.1 protein induced a B-lymphocyte fate on the hematopoietic progenitor cell, whereas high concentrations of PU.1 promoted macrophage development and blocked B-lymphocyte differentiation. These studies demonstrate how the graded expression of a transcription factor is able to specify hematopoietic cell fate in a mammalian model of differentiation.

Lichanska et al. (115) published a comprehensive analysis of macrophage differentiation in the mouse embryo, using a number of differentiation markers, including PU.1 and the M-CSF receptor (also known as c-*fms*). A striking finding was the presence of normal numbers of phagocytically active, c-*fms*–positive embryonic macrophages at embryonic day 11.5 in mice lacking PU.1. Furthermore, they showed that PU.1-null embryonic stem cells gave rise to macrophage-like cells when cultured *in vitro*. These data confirm that fetal macrophages (i.e., those derived from the yolk sac before the initiation of fetal liver hematopoiesis) are ontologically and functionally distinct from macrophages arising later in life. The authors of this study suggested that the PU.1-independent macrophages could represent the same population as the M-CSF–independent macrophages described in the op/op mouse.

The specification of myeloid cells clearly involves the interplay of a number of transcription factors that are not necessarily myeloid restricted in their expression but, when titrated with other factors, provide unique complexes that instruct stem cells to commit to the myeloid lineage. Superimposed on this commitment is the regulation of genes in response to external regulators like cytokines and chemokines that confer the functional heterogeneity that is the hallmark of macrophages.

EFFECTOR FUNCTIONS OF MONOCYTES AND MACROPHAGES

Macrophages secrete >100 biologically active substances. These substances include natural proteinases, lysosomal enzymes, all the components of the alternative pathway of complement, tissue factor, plasminogen activator, and plasminogen activator inhibitor. The secretion of this vast array of substances allows macrophages to respond to and influence their local environments. One such example is that macrophages are able to secrete the third complement component (C3), which is cleaved by an alternative pathway convertase that is also macrophage derived. This macrophage production of complement allows for local opsonization of particles, which may then be recognized by macrophage complement receptors (116).

The generation of ROIs is a specialized function of myeloid cells and a key component of their host defense armamentarium. For this reason, we focus on this aspect of macrophage secretion.

Reactive Oxygen Intermediates and Reactive Nitrogen Intermediates as Effector Molecules

Much of the ability of phagocytes to mediate antimicrobial and tumoricidal activity resides in their ability to generate large amounts of toxic molecular species such as ROIs and RNIs (reviewed in 117). Macrophages and neutrophils are the key phagocytic cells able to generate these intermediates at high enough levels to mediate their host defense functions.

REACTIVE OXYGEN INTERMEDIATES

ROIs result from the activity of phagocyte NADPH oxidase (phox), a molecular complex assembled at the plasma membrane after translocation of its constituent cytoplasmic components (118). This enzyme complex reduces molecular oxygen to the superoxide free radical by the addition of a single electron (119). The antimicrobial effects of ROIs were suggested by the observation that activation of macrophages to enhance their antimicrobial activity was accompanied by an increased macrophage capacity for respiratory burst activity (120).

The physiologic significance of this effector pathway was elucidated well before the advent of gene targeting in mice. In this case, naturally occurring human mutations in the genes encoding the subunits of the NADPH oxidase lead to the disease known as chronic granulomatous disease (CGD) (see Chapter 29). In CGD, the inability of phagocytes to kill ingested microorganisms causes recurrent infections with abscess formation in the liver, lungs, and lymph nodes of affected individuals. Histologically, these lesions contain characteristic granulomas. The most common human mutations (in two thirds of all patients with CGD) affect the X-linked $gp91^{phox}$ subunit (121). It is clear that some patients with CGD retain some oxidase activity and have a less severe clinical phenotype. Interestingly, as little as 5%–10% of normal respiratory burst capacity may be sufficient to generate a normal phenotype (122). Mouse models in which the genes encoding either the $gp47^{phox}$ (123) or $gp91^{phox}$ (124) subunits of the NADPH oxidase are deleted accurately recapitulate the human CGD phenotype, and these animals have been used to define further the roles played by NADPH oxidase in host defense (125,126 and 127).

REACTIVE NITROGEN INTERMEDIATES

Nitric oxide synthases (NOSs) catalyze the reaction of L-arginine plus molecular oxygen to form L-citrulline and the short-lived, but highly biologically active gas nitric oxide (NO). Three major isoforms of NOS have been identified. Two, NOS1 (also known as nNOS, or neuronal NOS) and NOS3 (also known as eNOS, or endothelial NOS), are constitutively expressed in the appropriate cell types and generate low levels of NO. The third isoform, NOS2 (also known as iNOS, inducible NOS, or independent NOS) is inactive under resting conditions and is induced in macrophages with the appropriate cytokine or microbial stimulation to produce large quantities of NO (reviewed in 128). The antimicrobial activity of NO has been most convincingly demonstrated by genetic deletion of NOS2 from mice (see later).

For some years, the inducible NOS pathway was thought to be restricted to the phagocytes of rodents and thought not to be present in human cells (see 129 for example). This view was reinforced by the ready detection of inducible NOS activity in rodent tissue and inflammatory macrophages and by the apparent lack of inducible NOS activity from monocytes prepared from the peripheral blood of healthy humans. In retrospect, it seems apparent that this situation arose in part from the lack of studies (for technical reasons) with monocytes derived from the blood of healthy mice or with tissue or inflammatory macrophages derived from humans. Such studies have since been conducted, and the existence of the inducible NOS pathway in human cells is no longer in question. For example, Nicholson et al. (130) demonstrated the presence of NOS2 activity in alveolar macrophages of humans with tuberculosis. The evidence for NOS2 activity in human cells is reviewed in (131).

Deletion of the murine gene encoding NOS2 to create NOS2–knock-out mice has been reported independently by several groups (132,133 and 134). In one of these mutant mouse strains, the intended NOS2 deletion did not occur, and an alternative NOS2 transcript was expressed (133). Reanalysis of these animals showed that functional NOS2, albeit at low levels, was indeed expressed (135), suggesting that some of the conclusions drawn from infectious models using these particular animals may need to be reevaluated. To date, no NOS2 mutations have been described in humans, but polymorphisms detected in the NOS2 promoter have been associated with susceptibility to more severe forms of malaria (136).

In NOS2-null mice, macrophage activation and ROI production were unimpaired; and both lymphocyte ontogeny and leukocyte migration were comparable to those of wild-type control animals. When these animals were used in a variety of infectious models by these and other authors (reviewed in 117,137), they showed decreased survival (frequently associated with increased microbial burdens) for a number of pathogens, including Ectromelia virus, *Chlamydia pneumoniae*, coxsackievirus, *Listeria monocytogenes*, *Mycobacterium tuberculosis*, and *Trypanosoma cruzi* [this list does not include experiments with the mutant mouse strain created by Wei et al. (133)]. Infection of mice with influenza A virus resulted in protection from pneumonitis in the mice lacking functional NOS2 activity (138), suggesting that NO production in response to infection is not always of ultimate benefit to the host. It should be noted that although NOS2-null mice are poorly equipped to deal with many exogenous infectious challenges, they have not (over several generations) developed spontaneous infections by endogenous bacterial flora (such as enteric gram-negative bacteria) (139).

The traditional concept of NO mediating antimicrobial and cytotoxic effects in the immune system continues to undergo reevaluation, and more activities are being attributed to this effector molecule (reviewed in 117). NOS2-derived NO affects the production of several cytokines, including IL-1, IL-6, IL-8, IL-10, IL-12, IFN-g, tumor necrosis factor (TNF)-a, and TGF-b (reviewed in 140). The differentiation of Th1 lymphocytes is also influenced by NOS2-derived NO (135). Diefenbach et al. (141) demonstrated the activity of NO as an immune signaling molecule. These authors showed that NO derived from NOS2 was required for IL-12 or IFN-a/-b–induced activation of NK cells and documented the NO dependence of IL-12 responsiveness *in vivo* (141). Thus NO may play an important role very early in the host response to pathogens (i.e., before the generation of specific immunity) and may thus be considered an effector of innate immunity. Other examples of nonmicrobicidal activities for NOS2-derived NO include liver regeneration (142), induction of apoptosis through inhibition of the proteosome (143), and induction of T-cell receptor (TCR)-mediated apoptosis in T lymphocytes (144). The ability of NO to inhibit caspase activity may protect macrophages from undergoing apoptosis and also prevents the release of soluble IL-1 and IL-18 from macrophages, thereby reducing the circulating levels of these cytokines in NOS2-null mice and leading in turn to decreased IFN-g levels (145).

REACTIVE NITROGEN INTERMEDIATE AND REACTIVE OXYGEN INTERMEDIATE DOUBLE KNOCK-OUT MICE

The availability of the knock-out mice mentioned earlier has facilitated breeding of strains to produce “double knock-outs”—mice lacking the means to generate both ROIs (i.e., $gp91^{phox}$ –/–) and RNI (i.e., NOS2 –/–) (146). The prevailing view before the publication of this study was that these two pathways were biochemically parallel and functionally nonredundant (i.e., single-gene knock-out mice lacking either one of the two pathways are markedly more susceptible to a variety of infections, in spite of the preservation of the other pathway). However, the double–knock-out mice proved to be significantly more susceptible to infection with endogenous microorganisms than were mice singly deficient in either of the pathways. Indeed, the roles of these two pathways are at least partially redundant, and preservation of one pathway in the absence of the other provides some host defense capability. The double–knock-out mice showed evidence of some macrophage-mediated killing, indicating that NOS2- and phox-independent microbicidal mechanisms are present, albeit at functionally low levels.

In a detailed analysis of peritoneal macrophages derived from $gp91^{phox}$ –/– and NOS2 –/– single- and double–knock-out mice, Vazquez-Torres et al. (147) demonstrated that these two effector pathways act sequentially, are functionally distinct, and are essential for limiting the growth of *Salmonella typhimurium in vitro.* NADPH oxidase activity peaked shortly after phagocytosis of the bacteria and was required for an initial, rapid antibacterial phase. In contrast, NOS2-dependent pathways provided a subsequent, more sustained bacteriostatic effect. In their model, IFN-g augmented macrophage antibacterial activity primarily via the NOS2-dependent pathway (147). In an extension of these studies, Mastroeni et al. (148) studied the course of *Salmonella* infection *in vivo* in the same knock-out mice. Their findings demonstrated that both the NADPH oxidase and the NOS2-dependent pathways were required for host resistance to infection by *Salmonella*, but that each pathway acted at different temporal stages of the infection. In the $gp91^{phox}$ –/– mice, increased bacterial burdens were present as early as the first day after infection, and all mice had died by the fifth day after infection. In contrast, the NOS2 –/– mice demonstrated increased bacterial burdens only after the first week of infection (148). The implication of these studies is that the NADPH oxidase acts early in an infectious challenge, helping to keep bacterial burdens low from the outset, whereas the NOS2-mediated pathway comes into force later, providing a more sustained antibacterial response.

Other Antimicrobial Effector Mechanisms of Monocytes and Macrophages

PHAGOSOMAL ACIDIFICATION

Phagocytosis of a number of microorganisms by macrophages leads to phagosomal acidification that coincides with killing of the internalized organisms. This mechanism has been demonstrated for pathogens as diverse as *Escherichia coli* (149), *T. gondii* (150), and *Candida albicans* (151). Several microorganisms have evolved mechanisms to evade host defenses by inhibiting phagosomal acidification. Examples include *Legionella pneumophila* (149), *T. gondii* (150), and *Mycobacterium avium-intracellulare* (152). *M. avium-intracellulare* acts to exclude vesicular proton–adenosine triphosphatase (ATPase) from the maturing phagosome (152); but in macrophages that have been immunologically activated, this evasion mechanism is overcome by the host, and phagosomal acidification and microbicidal activity are restored (153).

RESTRICTION OF IRON

Most microorganisms require iron for various essential functions and have evolved mechanisms to chelate iron actively from the extracellular environment (154). Host cells such as macrophages correspondingly actively control iron availability during infections in an attempt to deprive pathogens of an essential element (155). For example, immunologically activated human macrophages can limit the intracellular multiplication of *L. pneumophila* by limiting the availability of iron (156). At least two mechanisms for host-mediated iron restriction have been described: a downmodulation of transferrin receptors, restricting intracellular iron delivery (156), and destruction of ferritin by IFN-g–activated macrophages (157). Deprivation of iron by host phagocytes may be detrimental to host defense functions, as both phox and NOS2 activity are in part iron-dependent processes; and this situation may represent an important predisposition to infection in patients receiving long-term iron chelation therapy (158). A critical balance between host cell iron requirements and exclusion of iron from pathogens therefore must be maintained.

NATURAL RESISTANCE–ASSOCIATED MACROPHAGE PROTEIN 1, IRON, AND MACROPHAGE-MEDIATED RESISTANCE TO INFECTION

One of the best-characterized mouse host resistance loci is that which encodes the protein known as natural resistance–associated macrophage protein 1 (Nramp1) (reviewed in 159). Studies that led to the identification of this gene product were initiated >25 years ago, when inbred mice were shown to segregate into resistant and susceptible strains, based on their ability to contain an infectious challenge with *Salmonella typhimurium* (160). Subsequent studies reported similar susceptibility/resistance segregation for a number of additional pathogens including *Leishmania donovani* (161), *Mycobacterium bovis* BCG(162), and *Mycobacterium lepraemurium* (163). In each case, the resistant phenotype behaved as a dominant trait encoded by a single gene named independently *Bcg* (162), *Ity* (160), and *Lsh* (161). The ability of these mice to resist infection was expressed as the ability of macrophages to contain intracellular replication of the respective pathogens.

This genetic locus was ultimately cloned and sequenced in 1993 and was predicted to encode an integral membrane protein (now called Nramp1) with characteristics suggestive of an ion transporter/channel (164). This protein is macrophage-restricted (165), is localized to the membranes of phagosomes (166), and mediates resistance to infection in mice (167,168). Although the molecular mechanism of action of Nramp 1 remains to be fully defined, recently discovered additional Nramp proteins are providing clues. *Nramp2* is another mammalian *Nramp* gene that encodes a protein that shares 78% similarity with *Nramp1*, but is expressed by a number of different cell types (169). The Nramp2 protein is able to transport vectorially Fe^{2+}, Mn^{2+}, Zn^{2+}, and other divalent cations (excluding Ca^{2+} and Mg^{2+}). Studies suggest that Nramp2 acts as an iron-acquisition mechanism, both in the cell where it is able to transport iron from endosomes into the cytoplasm, and in the intestine, where it acts as a transferrin-independent iron-import system (170,171 and 172). A number of investigators have therefore postulated that Nramp1 may function in host defense by providing macrophages with the intracellular iron required for processes such as generation of ROIs and RNIs, while simultaneously depriving microbes within the phagosome of the iron that is essential for their growth and survival.

MACROPHAGES AND APOPTOSIS

The removal of apoptotic cells and microorganisms requires phagocytosis. Phagocytes express pattern-recognition receptors that recognize, on the one hand, pathogen-associated molecular patterns and, on the other, apoptotic cell-associated molecular patterns. The clearance of apoptotic cells is a major phagocytic, noninflammatory function of macrophages (173,174). Thus we have postulated that the primary role for primordial phagocytic receptors is the removal of apoptotic cells during development and that the recognition of microorganisms is a later adaptive function. Findings with model organisms like *Caenorhabditis elegans* and *Drosophila melanogaster* have indicated that some of the recognition pathways are conserved between invertebrates and vertebrates. A good example is the remarkable conservation of the phosphatidylserine receptor between mammals, worms, and flies. Ligating this receptor by apoptotic cells results in an antiinflammatory rather than a proinflammatory response such as that more often associated with macrophage phagocytosis of microorganisms. Some of macrophage pattern-recognition receptors implicated in this process *in vitro* include the following: CD14 (81), complement receptors (175), class A scavenger receptors (176), class B scavenger receptors such as SR-BI (177), CD36 (178), and croquemort (a CD36-like molecule identified in *Drosophila* macrophages) (179,180), vitronectin receptor (79), phosphatidylserine receptor (82,181), and the ATP-binding cassette transporter (182). Evidence for the phagocytic function of these receptors in the clearance of apoptotic cells *in vivo* comes from studies on the *ced* genes in *C. elegans* and of croquemort in *Drosophila*. In mammals, the redundancy of the system has been illustrated by an analysis of mice genetically lacking class A scavenger receptors (SR-A) (183). These mice failed to demonstrate any failure to clear apoptotic cells *in vivo* (184), in spite of convincing evidence for the ability of class A scavenger receptors to mediate clearance of apoptotic cells *in vitro* (176).

The close proximity of macrophages to cells undergoing apoptosis during the tissue remodeling that occurs during embryogenesis has led to speculation that macrophages may be involved in inducing apoptosis in bystander cells, and not simply phagocytosing those cells that have already undergone apoptosis (185). Experimental evidence for this process in mammals is confined to a pupillary membrane model in the developing rodent eye, which fails to undergo apoptosis when local macrophages are eliminated by means of a locally expressed toxic transgene (186) or by local injection of toxic liposomes (187). Recent evidence from this research group indicates that the ability of macrophages to induce apoptosis is in part dependent on the cell-cycle phase of the target cell (188). These authors have suggested that macrophages may induce apoptosis by subverting the external signals that normally promote cell-cycle progression. Although the evidence for macrophages playing a role in the induction of apoptosis in this model system is clear, this mechanism has not been validated in other situations of physiologic apoptosis, and caution should be applied when generalizing this mechanism to other situations in the body.

Macrophages undergo apoptosis after infection by a range of bacterial pathogens *in vitro* (reviewed in 189). Whether this may be classified as a host defense mechanism remains to be determined. This mechanism could be viewed as depriving the pathogen of an intracellular niche from which it would otherwise replicate secluded away from the rest of the immune system. Additionally, this mechanism could facilitate antigen processing by the host, and assist in the generation of an enhanced specific immune response against the pathogen. Alternatively, this apoptotic process could be viewed as a pathogen-induced mechanism to kill the host cells that would otherwise act to destroy the pathogen. The demonstration of pathogen-expressed antiapoptotic mechanisms (e.g., 190) supports the view that host cell apoptosis after infection is primarily a host defense mechanism.

MONOCYTE AND MACROPHAGE ACTIVATION AND DEACTIVATION

The modern concept of macrophage activation as an acquired cellular resistance to intracellular parasites was expounded in the 1960s by Mackaness (191), who demonstrated a requirement for sensitized lymphocytes (later shown to be T cells) in this process. Subsequent studies showed that activating macrophages in this fashion (i.e., to enable killing of pathogens) also activated the ability of the cell to kill tumor cells (192). These concepts evolved into a step-wise model of activation in which certain products from T-cell supernatants could confer an inflammatory and an activated phenotype on homogeneous populations of resident macrophages (193,194). This work paved the way for the characterization of the responsible cytokines, most notably macrophage-activating factor, later identified as IFN-g (195,196). The activated state has been characterized by enhanced phagocytosis, processing and presentation of extracellular antigens, and an increased ability to lyse intracellular parasites and to destroy tumor cells (197). Many of these concepts still hold true today, although much more is now known about the molecules that mediate these events.

Interferon-g

Many studies with gene knock-out mice and some with naturally occurring human mutations have contributed to our understanding of the mechanisms of macrophage activation. IFN-g (originally described as macrophage-activating factor) is the major responsible cytokine. IFN-g is a dimeric glycoprotein that is produced in immune responses predominantly by activated T lymphocytes and NK cells, although macrophages also make this cytokine in an autocrine fashion (198). The cell-surface receptor complex for IFN-g is composed of two chains, a and b. Although the b chain does not bind the ligand directly, it is required for IFN-g–mediated signaling as well as for formation of the receptor complex (199).

Disruption of the gene encoding IFN-g in mice did not interfere with their development and did not give rise to spontaneous infections when the mice were housed in the absence of pathogens (200). These mice, however, were deficient in their production of macrophage antimicrobial products, had reduced expression of MHC class II antigens, and succumbed to ordinarily sublethal doses of *Mycobacterium bovis* BCG. In particular, macrophages isolated from these mice after infection with BCG produced very little NO in response to LPS stimulation, but were able to produce some ROIs, albeit at low levels when compared with wild-type littermates. These mice

are unable to contain infection with *Mycobacterium tuberculosis*, in association with a failure of their macrophages to produce RNIs (201,202). Similar studies with these mice have indicated that IFN-g is essential for the resolution of enteric *Salmonella* infections (203). A similar overall phenotype was observed when the receptor for IFN-g (IFN-g-Ra, or -R1) was knocked out in mice, this mouse strain demonstrated susceptibility to infection with both *L. monocytogenes* and vaccinia virus (204). Likewise, knock-out of the IFN-g-Rb (or -R2) gene resulted in severe immune defects and susceptibility to infection by *L. monocytogenes* (205). Taken together, these results indicate that IFN-g is not essential for embryogenesis or for development of the immune system, but that a variety of immune cell functions are significantly impaired when this cytokine is absent, rendering affected animals very susceptible to certain infections. Furthermore, these results suggest that priming for generation of RNIs (i.e., via NOS2 activity) is more dependent on IFN-g than is priming for ROI production.

After the description of the knock-out mice discussed earlier, human mutations in the IFN-g receptor axis began to be delineated. The initial clinical description was of six children who developed disseminated infections with atypical mycobacteria, three of whom died of the infection (206). Laboratory analysis showed that their production of IFN-g and TNF-a was defective. The molecular defect responsible for this phenotype was identified by means of a genetic screen involving four of the affected children, their unaffected family members, and healthy control individuals (207). All four affected children had mutations in the gene encoding IFN-g-R that resulted in an absence of receptors from the cell surface; this absence was associated with a functional defect in macrophage activation *in vitro*. At the same time as this report, another group reported a similar mutation in the IFN-g-receptor gene in a child who had died at age 10 months from idiopathic disseminated *M. bovis* BCG infection (208). The demonstration that affected humans and knock-out mice have otherwise preserved Th1-type immune responses (with normal delayed-type hypersensitivity responses in the humans) suggests strongly that this locus mediates susceptibility to infection largely by its effect on macrophage activation. Furthermore, in a model of experimental influenza virus infection with the IFN-g knock-out mice, IFN-g was not required for the development of effective humoral or cellular immune responses (209).

Since the initial reports of human mutations in the IFN-g-receptor gene, several novel mutations with variable phenotypes have been uncovered. Jouanguy et al. (210) reported a mutation that gave rise to a partial receptor deficiency in a child with disseminated BCG infection, whose younger sister had pulmonary tuberculosis after having had BCG vaccination withheld in infancy. Cells from these patients responded functionally to IFN-g *in vitro*, but only if high concentrations of the cytokine were used. Dorman and Holland (211) described a patient with disseminated atypical mycobacterial infection who was shown to have a truncating mutation in the gene encoding the IFN-g-receptor signaling chain (IFN-g-Rb or -R2). Most recently, Jouanguy et al. (212) described four cases of novel mutations in the IFN-g-receptor ligand-binding chain (IFN-g-Ra, or -R1) in which normal numbers of receptors could be detected at the cell surface by antibodies. Radiolabeled IFN-g failed to bind to these receptors, and cells expressing these receptors were unable to respond functionally to exogenous ligand. An important implication of this study is that demonstration of immunoreactive IFN-g-receptors at the cell surface does not preclude the diagnosis of complete functional receptor deficiency.

Interleukin 12

IL-12 is a heterodimeric cytokine composed of 35-kd and 40-kd subunits known as p35 and p40, respectively. It is produced by a variety of cells (predominantly macrophages and dendritic cells) and is thought to mediate resistance to intracellular organisms by virtue of its ability to induce IFN-g production by NK and T cells, as well as by promoting the generation of specific Th1 immune responses (213,214 and 215). Production of this key cytokine by mononuclear phagocytes is thought to be an early event in the generation of an immune response, and IL-12 is therefore regarded as a central mediator of innate immune responses. Because IL-12 acts upstream of IFN-g and is a major inducer of IFN-g, it might be predicted that deficiency of IL-12 would give rise to a phenotype similar to that seen for IFN-g-deficiency. Knock-out mice in which the genes encoding either the p35 subunit (216) or the p40 subunit (217) of IL-12 develop normally are fertile and have no obvious abnormalities. These IL-12–deficient mice were, however, unable to contain infections with *Leishmania major* and were unable to mount *Leishmania*-specific delayed-type hypersensitivity responses. When lymph node cells derived from these mice were stimulated with *Leishmania* antigen *in vitro*, decreased levels of IFN-g and increased levels of IL-4 were produced. IL-12 was therefore confirmed to be essential for the production of IFN-g in response to infections and for the facilitation of Th1-type immune responses. In an alternative model of IL-12 deficiency, mice were treated with a neutralizing anti–IL-12 monoclonal antibody and then infected with *S. typhimurium* (218). As expected, these mice were unable to contain the infection and were found to have impaired upregulation of MHC class II molecules, decreased NOS2 activity, decreased IFN-g production, impaired granuloma formation, and upregulated IL-10 activity. Administration of recombinant IFN-g to these mice reversed these defects, confirming that IL-12 indeed acts upstream of IFN-g in the immune response (218). Mice generated with a deficiency in the b1 chain of the IL-12 receptor yielded a similar immunologic phenotype; their ability to produce IFN-g in response to a variety of stimuli was significantly impaired (219).

In 1998, Altare et al. (220) reported the finding of human IL-12 receptor deficiency in four children with disseminated mycobacterial infections (either BCG or *Mycobacterium avium*), two of whom had also had non-typhi *Salmonella* infections (220). Mutations in IFN-g, its receptor, and in IL-12 itself were all excluded during the evaluation of these individuals. Mutations in the b1 chain of the IL-12 receptor resulting in IL-12 receptor deficiency were found in these patients, with resultant IFN-g deficiency. At the same time as this report, three other unrelated individuals (aged 19, 22, and 26 years) with severe mycobacterial and *Salmonella* infections were found to lack expression of the IL-12 receptor b1 chain, with resultant lack of IL-12–mediated signaling and IFN-g production (221). In another individual with disseminated *M. bovis* BCG and *Salmonella enteritidis* infections, a large homozygous deletion was found in the gene encoding the IL-12 p40 subunit, with resultant absence of functional IL-12 activity (222). Taken together, the results of these investigations involving both humans and mice demonstrate that IL-12 is a critical mediator of resistance to infection by both mycobacteria and *Salmonella*, that IFN-g is a key downstream mediator of IL-12 function, and that impaired macrophage function is the major determinant of susceptibility to infection by these organisms (223).

Interleukin 18

IL-18 was originally identified as an IL-12–independent IFN-g–inducing cytokine expressed by a range of cells including macrophages (224). Although it shares considerable biologic activity with IL-12, IL-18 is structurally unrelated and has additional biologic functions (225). Whereas IL-18 alone is not able to induce IFN-g from naive T cells (because of their lack of IL-18 receptors), IL-18 and IL-12 act synergistically in IFN-g induction (226). This finding has been confirmed with IL-12– and IL-12–receptor-deficient mice, which have minimal ability to produce IFN-g in the face of normal IL-18 production and activity. IL-18 does, however, appear to play a role in host defense mediated by macrophages. The administration of recombinant IL-18 to mice infected with highly virulent *Cryptococcus neoformans* resulted in enhanced host defense against this pathogen, in a manner that was reversible by administration of IFN-g neutralizing antibodies (227).

Mice deficient in IL-18 have been generated and have confirmed a role for IL-18 in IFN-g production, NK cell activity, and the induction of Th1-type responses (228). The defects in these IL-18–deficient animals were not so severe as those in their IL-12–deficient counterparts; however, mice deficient in both cytokines demonstrated a more severe phenotype than that in either single–knock-out animal (228). When challenged experimentally with mycobacteria, these IL-18–deficient mice developed higher mycobacterial burdens than did their wild-type counterparts, but did not progress to acutely disseminated disease (229). Although their IFN-g levels were reduced when compared with those of wild-type mice, their IL-12 levels were similar, confirming an independent function for IL-18 in the induction of IFN-g and demonstrating that IL-12 does not appear to compensate for the lack of IL-18 in these animals.

Tumor Necrosis Factor a

TNF-a is a proinflammatory and immunomodulatory cytokine produced predominantly, and in large quantities, by activated macrophages (reviewed in 230,231). This cytokine is also the chief mediator of septic shock induced by bacterial LPS or superantigens. In contrast to the cytokines mentioned earlier, TNF-a is an effector molecule produced by activated macrophages, rather than an activator of macrophages. The ability of macrophages to release TNF-a depends in part on the differentiation state of the macrophage (recruited cells being more competent than resident macrophage populations) and in part on the nature of the signals inducing the activating response (232).

Recently there has been an explosion of interest in the signal-transduction pathways that couple pathogen recognition to host-cell responses (particularly focusing on production of TNF by macrophages) (233,234). The mammalian Toll-like receptors (named for their homology to a receptor first described in *Drosophila*) are the critical cell-surface molecules involved in the initial recognition of pathogens, and they initiate the subsequent signaling cascade that leads ultimately to activation of the transcription factor nuclear factor-kB (NF-kB) (235,236 and 237). Although many of the details of the recognition events mediated by the Toll-like receptors remain to be elucidated, it appears that they are able to confer some degree of pathogen-specific recognition (238), which may direct the subsequent innate and adaptive immune responses in the appropriate directions.

TNF-b (also known as lymphotoxin b, or LT) is structurally related to TNF-a but is produced primarily by lymphocytes rather than by monocytes or macrophages. A mouse knock-out model in which the TNF-b gene was disrupted (with preservation of that encoding TNF-a) demonstrated a critical role for TNF-b in lymphoid organogenesis rather than in host defense (239), and this cytokine is not discussed further here.

The first knock-out mice involving TNF-a had deletions of the receptor rather than of the cytokine itself. The biologic effects of TNF are mediated by two receptor chains, a 55-kd chain (TNFRp55 or TNFR1) and a 75-kd chain (TNFRp75 or TNFR2). Pfeffer et al. (240) targeted the gene encoding the p55 chain to generate mice that lacked detectable p55 protein but expressed normal levels of p75. These TNFRp55-null animals developed normally, but their cells lost the capacity to respond to TNF *in vitro*. In addition, these mice were resistant to the toxic effects of LPS and bacterial superantigen but were severely compromised in their ability to deal with experimental *L. monocytogenes* infection. Rothe et al. (241) generated independently a mouse strain lacking TNFRp55 and found essentially the same defect in host defense as that reported by Pfeffer et al. In addition, this group reported that although the mutant mice were resistant to the effects of low doses of LPS after

D-galactosamine sensitization, they remained sensitive to high doses of LPS.

Mice lacking the TNFRp75 were subsequently generated and shown to exhibit wild-type sensitivity to low-dose LPS challenge after D-galactosamine sensitization, but were relatively resistant to the effects of high doses of TNF and to local cytotoxicity mediated by TNF (242). The ability of these mice to clear *L. monocytogenes* was slightly impaired relative to that of wild-type mice, but was not so severely affected as the ability of the mice lacking TNFRp55. Subsequent studies with these mice have assessed their ability to handle infection with *C. albicans* (243). Mice lacking TNFRp55 were highly impaired in their ability to clear this infection and died readily of it. Mice lacking TNFRp75 were also deficient in their ability to clear the yeast from their tissues but did not have increased mortality rates.

TNF-a knock-out mice (i.e., those unable to produce the cytokine) were fertile, viable, and without obvious phenotypic abnormality, but they were particularly susceptible to infection with *L. monocytogenes*, confirming a role for TNF-a in antibacterial host defense (244). Additional immunologic features of these mice included a relative resistance to LPS-mediated septic shock, reduced delayed-type hypersensitivity responses, and disordered development and architecture of splenic follicles.

Although there is ample evidence to suggest that TNF is a prime effector in septic shock in humans, the use of TNF antagonists (monoclonal antibodies or soluble receptors) in this clinical setting has not been shown to be of benefit (245). These reagents are, however, finding a therapeutic niche in chronic inflammatory diseases such as rheumatoid arthritis and inflammatory bowel disease (246). Reports of an increased incidence of bacterial infections in some patients receiving these agents concern us (247) but are not surprising in view of the role that TNF plays in the host antimicrobial response as demonstrated in mice.

Macrophage Deactivation

Just as the host must be able to activate cellular defense mechanisms rapidly in the face of a pathogenic challenge, so must the host be able to limit the physical extent and temporal duration of the activation; otherwise, unwanted inflammatory consequences may arise. Similarly, microbes and tumor cells have evolved mechanisms for inhibiting the activation of cellular defense mechanisms, this time as a means of ensuring their survival.

The transforming growth factors (TGF-b1 and TGF-b2) were among the first macrophage-deactivating factors described (248). Subsequently, IL-10 was found to potently suppress the ability of mouse macrophages to release TNF-a, to produce oxidase-generated ROIs, and to weakly inhibit the NOS2-mediated generation of RNIs (249,250). This cytokine, a product of Th2 lymphocytes, monocytes, and macrophages (among other cells), downregulates a number of monocyte and macrophage activation-dependent functions (reviewed in 251). In a review of the information gained from studies with IL-10 knock-out mice, Rennick et al. (252) concluded that IL-10 acts to protect the host from the harmful side effects of an “overly zealous” immune/inflammatory response. A not unexpected consequence of this activity is that the presence of excess IL-10 is associated with an increased susceptibility to a number of infectious organisms, including *C. albicans* (253), *Klebsiella pneumoniae* (254), *M. avium* (255), and *S. pneumoniae* (256).

Intracellular pathogens such as *M. avium* have evolved mechanisms that both interfere with routine cellular activities and promote the functional deactivation of their macrophage hosts. Macrophages infected with *M. avium* increased their production of TGF-b, which reduced the microbicidal activity of the cells after stimulation with IFN-g (257). Likewise, infection of macrophages with *M. avium* resulted in a downregulation of cellular receptors for IFN-g, which in turn led to decreased expression of IFN-g–inducible genes and a decreased ability of the host cells to kill their invading pathogens (258). Similarly, macrophages infected with *M. avium* produce increased amounts of IL-10, which in turn inhibits the production of TNF-a by macrophages, and also induces the release of soluble TNF-a receptors by macrophages, leading to inactivation of the already reduced amounts of TNF-a that are produced (259).

Recent studies have implicated the peroxisome proliferator-activated receptor g (PPARg) as an important regulator of macrophage function, particularly in macrophage deactivation (reviewed in 260). These receptors are ligand-dependent transcription factors of the nuclear hormone receptor superfamily and have well-documented roles in the regulation of adipocyte differentiation and in glucose homeostasis. These receptors are known to be expressed at high levels in macrophages (261), are induced in monocytes exposed to oxidized low-density lipoprotein (oxLDL), and are expressed at high levels in the macrophage-derived foam cells present in atherosclerotic lesions (262,263). These observations have been followed by studies suggesting that PPARg agonists mediate macrophage deactivation. Ricote et al. (264) reported that PPARg activity was markedly upregulated on activation of monocyte-derived macrophages *in vitro* and that PPARg agonists inhibited macrophage expression of NOS2, gelatinase B, and class A scavenger receptors. This group also reported that activation of PPARg resulted in antagonism of the transcription factors AP-1, STAT, and NF-kB (which are all implicated in the transcription of proinflammatory genes). At the same time, Jiang et al. (265) reported that PPARg agonists inhibited the production of proinflammatory cytokines by monocyte-derived macrophages activated *in vitro*. A more recent study with novel PPARg agonists failed to show any inhibition of proinflammatory cytokine production by human monocytes, human monocyte-derived macrophages, or murine macrophage-like cell lines, calling into question the “deactivating” capabilities of PPARg-mediated stimulation (266). Further studies are needed to delineate the true physiologic functioning of this receptor in monocyte and macrophage biology.

Interleukins-4 and -13: Alternative Activation States of Macrophages

Although macrophage activation and deactivation have traditionally been conceived as relating to the acquisition and loss of macrophage ability to kill tumor cells or microorganisms, alternative states of macrophage “activation” are possible. IL-4, which is produced predominantly by Th2-type lymphocytes, inhibits the production of proinflammatory cytokines and ROIs by macrophages (i.e., “deactivation”), while simultaneously upregulating MHC class II expression and upregulating the expression and function of the macrophage mannose receptor (i.e., “activation”) (267). When mouse macrophages were treated with IL-13, the release of NOS2-mediated RNI and proinflammatory cytokines was suppressed, whereas MHC class II and macrophage mannose receptors were significantly upregulated (268). These authors reported a preservation of oxidase-mediated ROI production in macrophages treated with IL-13. Whereas IFN-g decreases fluid-phase pinocytosis and receptor-mediated endocytosis by macrophages, IL-4 and IL-13 enhance both of these processes in actin-dependent and -independent fashions (269). IL-4 and IFN-g both independently and in combination act to upregulate mannose receptor–mediated phagocytosis by macrophages, even though these cytokines have divergent activities on mannose-receptor expression levels (270).

Data such as these have suggested that individual macrophage activities may be selectively upregulated (i.e., activated) in a fashion distinct from that mediated classically by IFN-g. Additionally, cytokines such as TGF-b, usually thought of as promoting macrophage deactivation, do have monocyte/macrophage activating ability that is in part mediated by the physiologic state of the target cell (271). It may therefore be more appropriate to refer to the specific phenotypic characteristics or activities of a given monocyte or macrophage, than to use the blanket terms “activated” or “deactivated.”

CONCLUSIONS

The mononuclear phagocyte system is part of an essential framework of tissue homeostasis. The versatility and plasticity of monocytes and macrophages reveal that the role of these cells extends well beyond gatekeepers that guard the portals by which pathogens may enter. The idea that model systems like *Drosophila* may be a fertile ground to dissect out necessary genes that may be involved in fundamental myeloid cell processes like phagocytosis and the application of gene-array technology to delve further into the interplay between pathogen and macrophage are examples of the work that may lie ahead.

22 EOSINOPHILS

Peter F. Weller, M.D.

Eosinophils are a distinct class of bone marrow–derived granulocytes that normally are present in low numbers in the blood. After leaving the circulation, eosinophils preferentially localize in tissues with mucosal epithelial surfaces. Increased numbers of eosinophils in the blood or tissue eosinophilia typically accompany allergic diseases and helminth parasite infections and may occur with various other, often idiopathic, disorders (see Chapter 35). Because eosinophils are terminally differentiated after leaving the marrow, the more acute, “effector” functions of these end-stage granulocytes have historically been the focus of studies of eosinophil function, including the means by which eosinophils participate in the immunopathogenesis of allergic diseases and the activities of eosinophils as helminthotoxic cells. In addition to these conventional effector responses, pertinent to diseases commonly marked by eosinophilia, other findings indicate that eosinophils have functional roles in host responses not conventionally associated with eosinophilia, such as wound healing (1,2), fibrosis (3), and graft rejection (4). Eosinophils express receptors for a multitude of cytokines and other immunologic mediators and contain in their cytoplasmic granules preformed stores of diverse cytokines. Eosinophils can engage in cognate cell–cell interactions with other cell types, including lymphocytes (5), and may function as class II major histocompatibility complex (MHC)-dependent antigen-presenting cells to elicit responses of $CD4^+$ T cells (6). Eosinophils, as recently reviewed (7,8,9 and 10), therefore, are more than end-stage effector cells and can participate in host immune and inflammatory responses not necessarily distinguished by quantitatively extensive eosinophil infiltration.

DEVELOPMENT AND MATURATION OF EOSINOPHILS

Eosinophils arise in the bone marrow from interleukin (IL)-5–responsive $CD34^+$ progenitor cells. Allergen challenge of sensitive asthmatic patients elicits the expression of the IL-5 receptor a chain on human marrow $CD34^+$ cells (11). The signal for this IL-5–receptor expression may well be IL-5 itself, because it induces a change in the expression of IL-5 receptors on progenitor cells from a soluble, antagonistic isoform to a functional membrane-associated isoform (12). In addition to IL-5, two other cytokines, granulocyte-macrophage colony-stimulating factor (GM-CSF) and IL-3, also can stimulate eosinophilopoiesis. In contrast to IL-3 and GM-CSF, which principally promote the development of other lineages, IL-5 in humans uniquely promotes the early development and terminal differentiation of eosinophils (and basophils). [In mice, IL-5 also regulates B-1 cell development (13)]. Although IL-5 may be produced by $CD8^+$ T cells, natural T cells, natural killer (NK) cells, mast cells, eosinophils themselves, and bone marrow endothelial cells, IL-5 is a prototypical cytokine elaborated by Th2 $CD4^+$ T cells. IL-5 production by Th2 lymphocytes accounts for the lymphocyte dependence of eosinophil production presciently demonstrated by Baston and Beeson (14) in experimental animals and for the eosinophilia accompanying Th2 T-cell–mediated immune responses characteristic of allergic diseases and helminth infections.

Receptors for GM-CSF, IL-3, and IL-5 are composed of distinct cytokine-specific, low-affinity a chains, which combine with a common b chain to constitute high-affinity ab receptors for each of these cytokines (15). Mice with genetic deletions of IL-5, the IL-5 receptor a chain, or the common receptor b chain fail to develop augmented eosinophilia in response to allergic or helminthic challenges (13,16,17 and 18). Nevertheless, each of these three genetic knock-out mice still exhibits basal eosinophilia, indicating that other cytokines or mediators also contribute to normal eosinophilopoiesis.

Eosinophil maturation within the marrow develops over about a week to generate a pool of mature, yet marrow-retained, eosinophils. IL-5 alone and in concert with the chemokine eotaxin can release this pool of already developed eosinophils from the marrow into the circulation to immediately increase blood eosinophilia and facilitate eosinophil recruitment to sites of specific inflammation (19,20). This process that releases intramedullary eosinophils involves the migration of eosinophils from marrow sinusoids into the sinus lumen. During this transmigration, eosinophils shed L-selectin and increase b_2-integrin expression. Eosinophil a_4 integrins promote retention of eosinophils within medullary sinusoids, whereas b_2 integrins facilitate eosinophil release from the marrow (19). Eotaxin also promotes the release from the marrow of eosinophil progenitor cells (20). Sites of allergic inflammation, such as the bronchial mucosa, have been shown to contain $CD34^+$ eosinophil progenitor cells (21). Whether these cells arise from the marrow or from circulating progenitor pools is unknown (22).

TISSUE DISTRIBUTION OF EOSINOPHILS

Eosinophils released into the blood circulate with a half-life of ~8–18 hours. Eosinophils normally leave the circulation to localize in tissues, especially those with mucosal interfaces with the external environment, notably the respiratory, gastrointestinal, and lower genitourinary tracts. Although the mechanisms governing this normal localization of eosinophils to mucosal tissues are not fully known, the chemokine eotaxin is involved in the homing of eosinophils to the gastrointestinal, but not respiratory, tract (23). Eosinophils are principally tissue-dwelling cells, and for every eosinophil present in the circulation, there are estimated to be 300 to 500 in the tissues (24). Eosinophils live longer than neutrophils and persist in tissues for at least several days, if not several weeks. The eosinophilopoietic cytokines, GM-CSF, IL-3, and IL-5, also act on mature eosinophils to prolong their longevity and prevent their apoptosis (25).

Eosinophil Adherence Mechanisms

In addition to the normal homing of eosinophils to mucosal tissues, in specific forms of inflammation, eosinophils accumulate in tissue sites in relatively greater abundance than do neutrophils. Contributing to this eosinophil localization are multiple adherence molecules expressed on eosinophils that help regulate their egress from the marrow, their circulation through the bloodstream, and their subsequent entry into tissues. As for other leukocytes, the recruitment of eosinophils into tissue sites of inflammation uses the combinatorial interactions involving specific adhesion molecules (via their expression and altered affinity states) that mediate cellular interactions with the vascular endothelium and the actions of chemoattractant molecules (26,27). Eosinophils express several adhesion molecules broadly shared with other leukocytes that mediate their initial rolling and subsequent adherence to endothelial cells. Similar to neutrophils, eosinophils can adhere via CD11/CD18 heterodimeric b_2 integrins to intercellular adhesion molecules (ICAM)-1 and -2. Likewise, specific sialoglycoproteins mediate adherence between eosinophils and endothelial E-selectin and P-selectin. Eosinophils express less of the E-selectin ligand, sialyl-Lewis X, than do neutrophils, perhaps explaining the weaker binding of eosinophils to E-selectin (27). Eosinophils express the P-selectin glycoprotein ligand-1 (PSGL-1) (28) and exhibit greater binding to P-selectin than do neutrophils, especially at lower P-selectin densities and under shear-flow conditions (29,30 and 31). Unlike neutrophils, but similar to lymphocytes, eosinophils are able to bind to vascular cell adhesion molecule (VCAM)-1. Eosinophils express two a_4 integrins, very late activation antigen (VLA)-4 (a_4b_1) and a_4b_7, that bind to VCAM-1 (32). Moreover, a_4b_7 can bind to the mucosal addressin, mucosal addressin cell adherence molecule (MadCAM), that is principally expressed in vascular beds in the gut (32). Another b_2 integrin, a_db_2, which binds ICAM-3 and is expressed on other leukocytes, is an additional integrin that preferentially mediates eosinophil adhesion to VCAM-1 (33). Both IL-4 and IL-13 enhance expression of VCAM-1 and P-selectin on human endothelial cells (26,31). Eosinophils, but not neutrophils, adhere to human umbilical vein endothelial cells under shear stress, using both the P-selectin–PSGL-1 and VLA-4–VCAM pairs of receptors (31,34). Thus IL-4 or IL-13 stimulation of the endothelium may participate in contributing to the preferential localization of eosinophils in specific sites of inflammation (26).

Eosinophil adherence molecules, by their interactions with extracellular matrix components, also modulate the activities of eosinophils that have exited the bloodstream (35). Eosinophil VLA-6, a_6b_1, binds laminin. Both a_4b_1 and a_4b_7 interact with specific domains of tissue fibronectin, and these interactions can enhance eosinophil functional responses (32). Eosinophils express CD44, which binds hyaluronic acid (36). Siglec-8, a sialic acid–binding immunoglobulin-like lectin, is expressed on eosinophilic leukocytes, as well as basophils and mast cells, and mediates binding to sialoglycoconjugates (37,38).

Eosinophil Chemoattractants

Mobilization of eosinophils into tissues, in addition to involving interactions with vascular lining cells, is governed by specific receptor-mediated chemoattractant stimuli. Chemoattractants promote the directed migration of eosinophils, and some chemoattractants may also enhance the adhesion of eosinophils and subsequent migration through the vascular endothelium. Many compounds have been identified as eosinophil chemoattractants (39), including humoral immune mediators like platelet-activating factor (PAF) and the complement anaphylatoxins, C5a and C3a; certain cytokines; and several chemokines, most notably the eotaxins. None of these is specific solely for eosinophils, but eotaxin and the more recently recognized eotaxin-2 and eotaxin-3 exhibit the most restricted specificity for eosinophils (40,41 and 42). Each of these eotaxins signals through the CCR3 chemokine receptor that is expressed on eosinophils as well as on basophils, some Th2 cells, and some mast cells (43,44 and 45). Other chemokines that attract eosinophils include RANTES (regulated on activation normal T-cell expressed and secreted), which signals via CCR3 and CCR1 receptors, and macrophage inhibitory protein 1a (MIP-1a), which signals through CCR1 (46,47). Thus the mobilization and recruitment of eosinophils to sites of immunologic reactions are governed by both (a) the responsiveness of eosinophils to chemoattractants (chemokines, cytokines, and other mediators) that facilitate eosinophil emigration from the vasculature and elicit directed migration of eosinophils, and (b) the expression and functional states of eosinophil adherence molecules and the differential expression of endothelial cell adherence ligands.

STRUCTURE OF EOSINOPHILS

The human eosinophil, unlike the neutrophil, typically has a bilobed nucleus. The distinguishing morphologic feature of the eosinophil is its content of large, distinctive cytoplasmic granules (48). These specific granules are morphologically unique because each contains one or more crystalloid cores. This crystalloid core, present only in the specific granules of eosinophils, is recognizable by transmission electron microscopy and usually appears electron dense. Both the core and the surrounding matrix of these granules contain a number of cationic, positively charged, proteins that provide the basis for their staining with eosin. Eosinophils at sites of inflammatory responses can exhibit morphologic changes in their specific granules, including loss of either the matrix or core components from within intact granules, compatible with the mobilization and extracellular release of these major granule components (48).

A second population of cytoplasmic granules, the primary granules, arises early in eosinophil maturation. These granules are present in eosinophilic promyelocytes and may persist in lesser numbers in mature eosinophils (48). Another distinct population of smaller cytoplasmic granules has been delineated morphologically with cytochemical identification of acid phosphatase and arylsulfatase B in these granules (48). The cytoplasm of eosinophils participating in inflammatory reactions in tissues has increased numbers of these smaller granules as well as increased numbers of vesicular and membranovesicular structures (48).

Lipid bodies are cytoplasmic structures distinct from granules (48). Lipid bodies are roughly globular in shape and range in size from minute to the size of large cytoplasmic granules; by electron microscopy, they appear dark with osmium fixation due to their lipid content. Lipid bodies lack a delimiting membrane but contain an internal honeycomb-like membranous structure that is often obscured by the overlying lipid. Lipid bodies are found in neutrophils and other cells, especially in association with inflammation, but eosinophils typically contain more lipid bodies than do neutrophils (49) Whereas normal blood neutrophils contain approximately one lipid body per cell, normal eosinophils contain from approximately five to ten; eosinophils in inflammatory reactions may contain approximately two dozen lipid bodies (50). Lipid body formation in eosinophils is rapidly inducible within minutes (51). Both exogenous PAF and endogenous PAF, elicited by stimuli such as IL-5, activate signaling pathways that lead to lipid body formation (52,53). In eosinophils, key enzymes involved in eicosanoid formation, including prostaglandin H synthase, the 5- and 15-lipoxygenases, and leukotriene (LT) C_4 synthase are localized, in part, at lipid bodies (54,55).

CELL-SURFACE RECEPTORS AND PROTEINS

Eosinophils express cell-surface receptors for a multitude of immunologic ligands (Table 22.1) (9). Receptors for immunoglobulins include those for IgG, IgE, and IgA. The receptor for IgG on eosinophils is principally the low-affinity FcgRII (CD32) (56), whereas neutrophils have FcgRII and FcgRIII (CD16), and monocytes have FcgRI (CD64) and FcgRII. Human eosinophils, unlike murine eosinophils, do not usually express CD16. Exposure of human eosinophils to interferon-g and other stimuli, including PAF and C5a, however, can elicit expression of a phosphatidylinositol-linked form of CD16 on eosinophils (56,57). CD16 may be expressed on eosinophils from some patients with eosinophilic disorders.

TABLE 22.1. Eosinophil Plasma Membrane Proteins and Receptors

Eosinophils also have three potential receptors for IgE. Human, but not murine (58), eosinophils may express the high-affinity IgE receptor, FceRI, typically found on basophils and mast cells (59). Although the FceRI a-chain protein is clearly detectable within eosinophils, its surface expression can be low or undetectable (60). Moreover, whether engagement of eosinophil FceRI can elicit degranulation of eosinophils, as it does on basophils and mast cells, remains the subject of controversy among investigators because of conflicting experimental findings (59,60 and 61). Thus the functional roles of eosinophil FceRI remain to be fully delineated. Eosinophils express FceRII, the low-affinity IgE receptor, like CD23 found on lymphocytes, monocytes, and other cells (62). Eosinophils also express a lectin-like protein, eBP/Mac-2, which binds IgE with low affinity (63).

Eosinophils express FcaRI (CD89), which, because of its greater glycosylation, has a greater molecular weight than does FcaRI on neutrophils (64). In addition, eosinophils, like neutrophils, may contain both splice variants and alternative isoforms of FcaR, although the functional roles of these alternative FcaRs are not certain (65,66). Eosinophil FcaRI binds secretory IgA more potently than other forms of IgA, and engagement of FcaRI triggers eosinophil release of granule proteins (67).

Eosinophils have receptors for complement components including C1q (CR1), C3b/C4b (CR1), iC3b (CR3), C3a, and C5a (68,69 and 70). Eosinophil C5a receptors differ in posttranslational modification and ligand affinity from neutrophil C5a receptors (70). The C3a and C5a receptors are members of the G-protein–coupled seven transmembrane–spanning family (71). Both C3a and C5a are eosinophil chemoattractants and stimulate oxygen radical production by eosinophils. Eosinophils express selected receptors for chemokines. CCR1 is a receptor for MIP-1a, macrophage chemotactic protein (MCP)-3, and RANTES, whereas CCR3 is a receptor for eotaxin, eotaxin-2, eotaxin-3, MCP-3, and RANTES (43). Macrophage-derived chemokine (MDC) induces eosinophil chemotaxis via an as yet unidentified receptor, different from CCR3 or CCR4 (72). Although eosinophils from atopic patients or eosinophils stimulated with IL-5 have been reported to respond to IL-8 (73,74), neither normal nor cytokine-stimulated eosinophils appear to express functional IL-8 receptors (75). Eosinophils also express CXCR4 and can respond (e.g., migration, calcium fluxes) to the ligand for this receptor, stromal cell–derived factor-1a (SDF-1a) (76).

Mature eosinophils, like their immature precursors, express functional heterodimeric receptors for the three cytokines, GM-CSF, IL-3, and IL-5, which promote eosinophilopoiesis and stimulate functioning of mature eosinophils. In addition to these eosinophil-active cytokines, eosinophils have receptors for a broad range of other cytokines (Table 22.1), including IL-1a (77), IL-2 (78), IL-4 (79), IL-12 (80), IL-13 (81), interferons (IFNs) a and g (77,82), tumor necrosis factor a (TNF-a) (83), stem cell factor (c-*kit*) (84), and IL-16 (which signals via CD4 on eosinophils) (85). Thus eosinophils are potentially stimulated by a considerable diversity of cytokines, although the consequences of these cytokine receptor–mediated responses for the functioning of eosinophils is yet to be fully established.

Of potential importance to cognate interactions between eosinophils and B and T lymphocytes is the fact that eosinophils can express several relevant plasma membrane proteins. Class II MHC proteins are generally absent on blood eosinophils, but their expression is inducible *in vitro* (86). Moreover, eosinophils recruited into tissues sites of inflammation exhibit *in vivo* induction of human leukocyte antigen (HLA)-DR expression as a consequence of their recruitment from the bloodstream (87). Eosinophils can express CD40 (88), CD154 (CD40 ligand) (89), CD153 (CD30 ligand) (90), CD28 (B7-2), and CD86 (91).

Eosinophils have receptors for several lipid mediators, although whether these receptors are intracellular as well as surface expressed is not known. These lipid mediator receptors include those for PAF and LTB_4, which are chemoattractants for eosinophils and stimulate eosinophil degranulation and respiratory burst activity (9). Both IL-5R– and FcgR-mediated stimulation of eosinophils elicit endogenous generation of PAF, which signals via PAF receptors to augment eosinophil functions,

including the enhancement of LTC_4 generation (52). Eosinophils have receptors for prostaglandin E_2 (although the subtypes have not been defined) (9) and for both currently recognized cysteinyl leukotriene receptors (92,93). The functions of the cysteinyl leukotriene receptors have not been fully defined, although these leukotrienes can augment eosinophil functioning and prolong eosinophil viability (94). Eosinophils have intracellular estrogen (95) and glucocorticoid receptors (9).

CONSTITUENTS OF EOSINOPHILS

Eosinophils are granulocytes, and as such, their granules are stores of proteins packaged and ready for extracellular release. The specific granules of eosinophils contain a range of proteins that include both specific cationic proteins and, as more recently demonstrated, preformed stores of diverse cytokines and chemokines.

Cationic Granule Proteins

Four cationic granule proteins of eosinophils have been extensively studied, in part because of their abundance in the specific granules and their capacities to exert multiple effects on host cells and microbial targets (96). Major basic protein (MBP), named on the basis of its quantitative predominance in the granule and its markedly cationic (basic) isoelectric point of ~11, is a 13.8- to 14-kd protein derived by proteolytic processing from a translated 23- to 25-kd preproMBP precursor. In addition to MBP, a homolog of MBP has been identified that is somewhat smaller (13.4 kd) and less basic (pI 8.7) (97). The activities of the MBP homolog (which was present in prior preparations of MBP), in comparison with MBP itself, have not yet been defined. MBP lacks any enzymatic activity and likely exerts its effects on the basis of its markedly cationic nature.

A second granule protein is eosinophil peroxidase (EPO), an enzyme distinct biochemically and physicochemically from the myeloperoxidase of the neutrophil and monocyte. EPO, which is also cationic (pI 10.8), uses hydrogen peroxide and halide ions to catalyze the formation of hypohalous acids, which are toxic for parasites, bacteria, and tumor and host cells. EPO uses bromide in preference to chloride and is even more active with a pseudohalide, thiocyanate (98,99). Thus EPO synthesizes several oxidant products, including hypobromous acid and hypothiocyanous acid.

The other dominant cationic granule proteins are eosinophil cationic protein (ECP; 18 kd, pI 10.8) and eosinophil-derived neurotoxin (EDN) (18–19 kd, pI 8.9). EDN, not as yet demonstrated to be neurotoxic for humans, is named because it, when injected intracerebrally into test rabbits, elicits a characteristic neuropathologic response termed the “Gordon phenomenon,” which is identical to the response initially elicited by the injection of tissues containing human eosinophils (100). Both ECP and EDN share sequence homology with pancreatic ribonuclease (RNase) (101). EDN expresses 100-fold more RNase activity than does ECP (102), although their toxic effects on bacterial, parasitic, and mammalian target cells apparently are not principally due to their RNase catalytic activities.

In the specific granule, MBP is uniquely localized to the crystalloid core, whereas ECP, EDN, and EPO are localized in the matrix of the granule around the core. MBP also is found in low amounts (~3% of eosinophil levels) in basophils, but whether this reflects endocytosis or endogenous synthesis is not known. Uptake of MBP and EPO into mast cells occurs by endocytosis. Small amounts of EDN and ECP also are found in neutrophils. Because neutrophils contain mRNA transcripts for them, EDN and ECP are likely synthesized by neutrophils (103). Thus eosinophils are the dominant source of these four markedly cationic proteins. The properties of these proteins and their numerous biologic effects have been reviewed (96) because these proteins have major effects not only in potential roles of the eosinophils in host defense against helminthic parasites but also in their contribution to tissue dysfunction and damage in eosinophil-related allergic and other diseases. Because MBP lacks enzymatic activity, one mechanism by which this highly cationic polypeptide may exert its activities is through interactions with lipid membranes. MBP associates with acidic lipids and disrupts liposomes prepared from such lipids (104). Such interactions might contribute to its wide range of toxicity.

The large, specific granule of the eosinophil contains a variety of acid and neutral hydrolases similar to the hydrolytic enzymes in neutrophil granules, although the content of enzymes in eosinophil granules has never been thoroughly studied. Eosinophils are a major source of a 92-kd metalloproteinase, a gelatinase (105).

Cytokines and Chemokines

Eosinophils elaborate diverse cytokines and chemokines (Table 22.2) (106). The potential activities of eosinophil-derived cytokines are protean. Eosinophil-derived cytokines include those with potential autocrine growth factor activities for eosinophils and those with potential roles in acute and chronic inflammatory responses. A notable feature of eosinophils as sources of cytokines is that eosinophils contain preformed stores of these cytokines in eosinophil–specific granules, as first demonstrated by immunogold ultrastructural localization of TNF-a in eosinophil–specific granules (107). Thus, in contrast to most lymphocytes, which must be induced to synthesize *de novo* cytokines destined for release, eosinophils [like natural T cells (108)] can immediately release preformed cytokine and chemokine proteins into the milieu proximate to themselves. Although levels of preformed cytokines in eosinophils may be lower than those of specifically stimulated lymphocytes, local and rapid release of eosinophil-derived cytokines in tissues could readily effect responses of adjoining cell types.

Cytokines	Chemokines
TGF-α, TGF-β1	RANTES
IL-1α	MIP-1α
IL-2	IL-8
IL-3, IL-5, GM-CSF	MCP-3
IL-4	Eotaxin
IL-6	
IL-10	
IL-12	
IL-16	
IFN-γ	
TNF-α	
VEGF	
PDGF-β	
HB-EGF	
MIF	
LIF	
NGF	

GM-CSF, granulocyte-macrophage colony-stimulating factor; HB-EGF, heparin-binding epidermal growth factor; IFN, interferon; IL, interleukin; LIF, leukemia inhibitory factor; MIF, macrophage migration inhibitory factor; NGF, nerve growth factor; PDGF, platelet-derived growth factor; RANTES, regulated on activation normal T-cell expressed and secreted; TGF, transforming growth factor; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor.

TABLE 22.2. Cytokine and Chemokine Products of Human Eosinophils

Eosinophils synthesize each of the three cytokines that have growth factor and function-enhancing activities for eosinophils, GM-CSF, IL-3, and IL-5 (109,110,111,112 and 113). Eosinophils contain mRNA transcripts for GM-CSF, IL-3, and IL-5. Evidence for active cytokine production by eosinophils includes the demonstration that eosinophil viability-sustaining activities of IL-3 and GM-CSF were present in supernatant fluids of stimulated eosinophils. *In situ* hybridization studies of lesional and elicited eosinophils have documented that eosinophils participating in allergic and other responses in tissues contain transcripts for these cytokines. Thus eosinophils can elaborate three cytokines that promote the survival of eosinophils, antagonize apoptosis, and enhance effector responses of these cells. Roles for adhesion proteins and specific integrins in mediating the enhanced release of GM-CSF in eosinophils have been evidenced by findings that eosinophils adherent to fibronectin have enhanced survival *in vitro* and increased production of GM-CSF and IL-3 proteins, as well as enhanced effector responses (114,115). The increased eosinophil survival was inhibited by antibodies to either IL-3 or GM-CSF, as well as by blocking antibodies to fibronectin and a_4 and b_7, implicating a_4b_1 and a_4b_7 integrins expressed on eosinophils in transducing signals for heightened eosinophil release of IL-3 and GM-CSF (114,115).

Other cytokines elaborated by human eosinophils that may have activities in acute and chronic inflammatory responses include IL-1a (116), IL-6 (117,118), IL-8 (119), TNF-a (120), and MIP-1a (120). Human eosinophils can elaborate other “growth” factors, including transforming growth factor (TGF)-a (121), TGF-b1 (122,123), vascular endothelial growth factor (VEGF) (124), platelet-derived growth factor-b (PDGF-b) (125), and heparin-binding epidermal growth factor (126). These cytokines may contribute to epithelial hyperplasia and fibrosis, as well as have other activities. In addition, eosinophils are recognized as sources of specific cytokines and chemokines capable of stimulating or inhibiting lymphocyte responses, including IL-2 (127), IL-4 (128,129), IL-10 (130,131), IL-12 (80), IL-16 (132), RANTES (133,134), and TGF-b1 (122,123).

ACTIVATED EOSINOPHILS

Blood and tissue eosinophils, in conjunction with eosinophilic diseases or inflammation, may exhibit morphologic, biochemical, or functional alterations indicating that they have been “activated” (135). Morphologically, these activated eosinophils may have cytoplasmic vacuolizations with diminished numbers or sizes of their large specific granules, and often they contain heightened numbers of lipid bodies and extensive numbers of membranovesicular structures in their cytoplasm (48). Electron microscopy of eosinophils can demonstrate absence of the normal electron density of either the crystalloid cores or the matrices in specific granules, indicating that contents of the core or matrix have been released (48,136). “Activated” circulating blood eosinophils are metabolically more active than are unstimulated cells, with increased hexose monophosphate shunt activity and increased superoxide anion production *in vitro* (137). Activated eosinophils centrifuged over density-gradient media are less dense (“hypodense”) than are normal eosinophils (138). Increased numbers of such circulating hypodense eosinophils have been associated with various diseases, including asthma. Activated eosinophils may exhibit enhanced plasma membrane expression of some proteins, including CD69, HLA-DR, and CD25

(139).

The morphologic, biochemical, and functional attributes associated with eosinophils activated *in vivo* can be elicited in part by exposure of eosinophils to specific stimuli, particularly the three eosinophil active growth factor cytokines. GM-CSF, IL-3, and IL-5 activate eosinophils *in vitro*, prolonging their survival in culture, rendering them hypodense, and enhancing their capacity for LTC_4 formation and parasite killing (140,141 and 142). Thus the effector functions of mature eosinophils can be stimulated in tissue sites by these three cytokines and likely by other mediators acting on the many eosinophil-expressed receptors. In addition, interactions with the extracellular matrix components can further contribute to eosinophil activation. Eosinophil activation, however, is not a singularly binary process, and some attributes of activation may be elicited without other attributes by mediators and mechanisms that remain to be fully delineated. In contrast to earlier reports, which suggested that activated eosinophils release an altered form of ECP (detectable with the EG2 monoclonal antibody) that reflected eosinophil activation, staining with this antibody is now known not to reflect a state of eosinophil activation (143,144,145 and 146).

PRODUCTS OF EOSINOPHILS

Eosinophils release a broad range of products (147), including oxidative products and newly formed lipid mediators, as well as the preformed granule-derived cationic proteins and cytokines (Table 22.2) noted earlier.

The oxidative products released by eosinophils include hydrogen peroxide, superoxide anion, hydroxyl radical, and singlet oxygen. In addition, eosinophil peroxidase, as noted earlier, may catalyze the formation of longer-lived hypohalous oxidants, including brominating oxidants (148,149).

When stimulated, eosinophils form and release biologically active lipids. The oxidative metabolism of arachidonic acid by the 5-lipoxygenase pathway in human eosinophils leads to the intracellular production and subsequent release of LTC_4 (150). The elaboration of this eicosanoid by eosinophils differs from the predominant formation of LTB_4 from neutrophils. Neutrophils contain an epoxide hydrolase that forms LTB_4 from LTA_4, but eosinophils possess a specific LTC_4 synthase, which conjugates glutathione to the intermediate LTA_4 to produce LTC_4 (151) (see Penrose and Austen, Chapter 27). Eosinophils also elaborate products from the 15-lipoxygenase pathway of arachidonic acid metabolism (152). Arachidonic acid metabolism via cyclooxygenase pathways in eosinophils forms predominantly prostaglandin (PG) E_2 and thromboxane B_2 (147,153). In addition to perinuclear membranes, sites of eicosanoid formation include lipid bodies in eosinophils; lipid body domains likely contribute to the augmented formation of lipoxygenase and cyclooxygenase products in primed eosinophils (54). Increased numbers of eosinophil lipid bodies correlate with increased capacities to release LTC_4 and PGE_2 (54). Moreover, lipid bodies in eosinophils have been shown to be sites of specific LTC_4 formation in eotaxin- and RANTES-primed and stimulated cells (154). In addition to their roles as paracrine mediators, cysteinyl leukotrienes also have autocrine effects antagonizing eosinophil apoptosis (94).

Eosinophils are a source of PAF, 1-*O*-alkyl-2-acetyl-3-phosphocholine, a potent paracrine mediator with a wide range of biologic activities (147,155). PAF also functions in autocrine signaling in eosinophils, including in pathways stimulated by IL-5R and FcgR engagement (52).

MECHANISMS OF EOSINOPHIL DEGRANULATION

Because eosinophil–specific granules contain four major cationic proteins as well as many preformed cytokines and chemokines (Table 22.2), the processes by which eosinophils selectively mobilize these granule constituents for their extracellular release are fundamental to the regulated functioning of these cells. Unlike mast cells or basophils that undergo acute exocytotic degranulation in response to cross-linking of their high-affinity FcgRI, a comparable physiologic mechanism to elicit comparable exocytotic degranulation of eosinophils has not been identified. Cross-linking of eosinophil IgG or IgA FcR can stimulate release of eosinophil cationic proteins, but this rapid FcR-mediated acute “degranulation” process is not physiologic and is actually cytolytic for eosinophils (156). In contrast to the acute degranulation that can be elicited *in vitro*, electron microscopic observations of tissue samples demonstrate that specific eosinophil granule contents are mobilized and released by mechanisms not involving the wholesale exocytosis of specific granules (48). The ultrastructure of lesional eosinophils provides compelling evidence that eosinophil specific granule contents are mobilized *in vivo* by selective incorporation into small vesicles that traffic to the cell surface and release these granule contents [i.e., by a process of “piecemeal” degranulation based on vesicular transport (48)]. By this process, for instance, interferon-g can rapidly stimulate the extracellular release of eosinophil RANTES and its focal deposition in the microenvironment surrounding viable eosinophils (157,158). How this process of vesicular transport is regulated and functions to selectively mobilize specific eosinophil granule–derived cytokines or cationic proteins is under investigation.

In addition to regulated release of granule contents from viable eosinophils, a common, but often overlooked and enigmatic, occurrence is the apparent lysis of eosinophils. Both cutaneous and pulmonary biopsy specimens from individuals with eosinophil-associated diseases contain free, extracellular, but still membrane-bound, core-containing eosinophil granules. The mechanism of cytolysis in such reactions is undefined and occurs more commonly than heretofore recognized (159,160). Whether this process releases biologically active granule-bound proteins *in vivo* is uncertain.

FUNCTIONS OF EOSINOPHILS

Conventional considerations of the roles that eosinophils may play have been guided by quantitative considerations, so that those diseases characteristically marked by more prominent eosinophilia have occasioned the most interest. Thus studies have focused on roles eosinophils play in host defense against helminth infections and in the immunopathogenesis of allergic and other eosinophilic diseases (Chapter 35). In addition, roles of eosinophils must be considered in immune or inflammatory responses not conventionally recognized to involve abundant eosinophils. Conventional hematoxylin and eosin stains are not always sufficiently distinctive or sensitive to recognize tissue eosinophils. Moreover, in some diseases, morphologically intact eosinophils may not be present, although immunostaining for eosinophil proteins in involved tissues can provide evidence that eosinophils were present during the evolution of the disease (161). Thus eosinophils may be involved in the pathogenesis of some inflammatory and immune responses even without prominent lesional eosinophilia.

As end-stage effector cells, eosinophils can have roles in host defense and disease pathogenesis that are beneficial and detrimental, respectively, to the host. In addition, eosinophils may have roles in immune responses based on their collaborative interactions with other cells.

Roles in Host Defense

In contrast to unicellular protozoan parasites, multicellular helminth parasites characteristically stimulate Th2-mediated blood or tissue eosinophilia (162). In such infections, which are often associated with augmented IgE antibody formation, eosinophils can have a role in killing helminthic parasites, especially during their larval stages. Examples of parasites that may be killed *in vitro* by eosinophils include *Trichinella* and schistosomes, organisms too large to be phagocytosed (163). The initial adherence of eosinophils to the surface of the parasite surface may be mediated by eosinophil CR1 binding to C3b deposited on the surface of the worm and/or by FcgR- or FceR-mediated binding with antiparasite IgG or IgE, respectively (163). *In vitro*, deposition of eosinophil cationic granule contents onto the surface of the parasite follows, accompanied by a tighter binding of the eosinophil to the parasite. Cell products that can contribute to the death of the parasite include MBP, ECP, EDN, and EPO. Oxidative products such as hydrogen peroxide also may contribute to parasite cytotoxicity (163).

More recent studies, in which the administration of neutralizing antibody to IL-5 or infections in IL-5 gene knock-out mice have been used to abrogate the development of eosinophilia in helminth-infected mice, have caused the role of eosinophils as helminthotoxic effector cells to be reevaluated [reviewed in (164,165)]. In these eosinophil-depleted mice, the intensities of primary and secondary infections with some helminths have not been uniformly greater than in eosinophilic mice, nor have IL-5 transgenic mice consistently exhibited increased resistance to infection with some helminth species. Nevertheless, these studies performed in mice must be interpreted with caution. Some helminth infections elicit Th1-biased responses in mice, which differ from the known Th2-biased responses in humans or rats. Differences between killing of adults or larvae and of responses in tissues or the gastrointestinal tract must be considered. Many of the experimental infections involve introducing unnatural helminth infections into mice, in which innate immune responses may be prominent. Natural human infections are usually a consequence of repeated exposures, during which acquired and not innate immunity becomes prominent. Moreover, murine eosinophils, unlike human eosinophils, lack FceRI (58). With these caveats, the mixed results evaluating eosinophil helminthotoxicity in murine models need not simply negate a role for eosinophils in parasite host defense. In humans, eosinophilia has been correlated with protection against schistosome infections (165). Moreover, helminths characteristically coexist in infected hosts for prolonged periods, and helminths have evolved a diversity of mechanisms to modulate innate and acquired immunity in their natural hosts (166). Thus the apparent ambiguities of studies of the roles of eosinophils in experimental murine systems may reflect more on the complexities of helminth–host interactions. Eosinophils likely have roles in killing infective larval stages, but not adults, of most helminth parasites (164); but given that helminths persist in the face of eosinophilia even in naturally infected hosts, eosinophil helminthotoxicity does not totally protect hosts against these parasitic infections.

Eosinophils do not have major roles in host defense against bacteria and most other small microbial pathogens. With most bacterial and viral infections, eosinopenia, rather than eosinophilia, develops (Chapter 35). Eosinophils can phagocytose and kill bacteria *in vitro*, but eosinophils are not effective *in vivo* against infections with small microbial pathogens when neutrophil function is impaired. One viral infection in which eosinophils may play a role is that due to respiratory syncytial virus (RSV). RSV infections elicit eosinophilia and associated bronchial hyperreactivity (167). The eosinophil granule proteins EDN and ECP, on the basis of their RNase activities,

can exert antiviral activity for this single-stranded RNA virus (168,169).

Roles in Disease Pathogenesis

The capacities of eosinophils to release biologically active lipids as paracrine mediators of inflammation and to degranulate and release their preformed cationic and cytokine granule constituents enable eosinophils to contribute to the immunopathogenesis of various diseases. As noted earlier, eosinophils form several classes of biologically active lipids. Eosinophils, like other cells, may liberate PAF. The potent, diverse activities of PAF can be mediated directly or by stimulating other cells to release leukotrienes, prostaglandins, and complement peptides. Stimulated eosinophils also release LTC_4. LTC_4 and its derivative cysteinyl leukotrienes have bronchoconstrictor activity, constrict terminal arterioles, dilate venules, and stimulate airway mucus secretion (170). Thus eosinophils are potential sources of two major types of mediator lipids, the cysteinyl leukotrienes and PAF.

Oxidants released by eosinophils, including superoxide anion, hydroxyl radical, and singlet oxygen, and EPO-catalyzed hypothiocyanous acid and other hypohalous acids have the potential to damage host tissues (148).

Released eosinophil granule proteins are immunochemically detectable in fluids, including blood, sputum, and synovial fluids, and in tissues, including the respiratory and gastrointestinal tracts, skin, and heart, in association with various eosinophil-related diseases (96). The eosinophil cationic proteins, including MBP, ECP, and EPO, can damage various cell types (96). Release of mediators of inflammation from other cell types also may follow stimulation by eosinophil granule cationic proteins. For instance, MBP can activate basophils, mast cells, and neutrophils to release their inflammatory mediators (96). Thus extracellular release of eosinophil granule proteins, by degranulation or cytolysis of eosinophils, could contribute to local tissue damage by causing dysfunction and damage to adjacent cells.

Other Eosinophil Functions

Other functional roles for the eosinophil are likely, but as yet not fully delineated. In addition to the acute release of lipid, peptide, and cytokine mediators of inflammation, eosinophils likely contribute to chronic inflammation, including the development of fibrosis. Eosinophils are the major source of the fibrosis-promoting cytokine TGF-b in nodular sclerosing Hodgkin's disease and idiopathic pulmonary fibrosis (171). Additional roles of the eosinophil in modulating extracellular matrix deposition and remodeling are suggested by studies of normal wound healing. During dermal wound healing, eosinophils infiltrate into the wound sites and sequentially express TGF-a early and TGF-b1 later during wound healing (1). Depletion of eosinophils with anti–IL-5 monoclonal antibody accelerates skin wound closure (172).

Additional functions for the eosinophil are suggested by the findings that eosinophils may be induced to express class II MHC proteins and can function as antigen-presenting cells. Blood eosinophils lack HLA-DR expression, but eosinophils recovered from the airways 48 hours after segmental antigen challenge express HLA-DR (87). Cytokines, including GM-CSF, IL-3, IL-4, and interferon-g, induce eosinophil HLA-DR expression (116). Both murine and human eosinophils can function as HLA-DR–dependent, MHC-restricted, antigen-presenting cells in stimulating proliferation of T cells (116,173). *In vivo*, murine eosinophils can process exogenous antigens in the airways, traffic to regional lymph nodes, and function as antigen-specific antigen-presenting cells to stimulate responses of $CD4^+$ T cells (6). For potential interactions with lymphocytes, human eosinophils express relevant membrane proteins, including CD40 (88), CD28, and CD86 (91), and express receptors for cytokines, such as IL-2, as noted earlier.

Because eosinophils normally become resident in submucosal tissues, they likely have functional roles in ongoing homeostatic immune responses at these sites. Moreover, broader functional contributions are suggested by the multitude of cytokine receptors expressed on eosinophils and by their potential to release cytokines that are stored preformed in their granules. Interactions of eosinophils with other cells, including lymphocytes, are feasible, but not yet fully investigated. Thus eosinophils likely have functions that extend beyond their currently more defined roles as effector cells contributing to allergic inflammation.

23 BASOPHILS

Bruce S. Bochner, M.D., and John Schroeder, Ph.D.

In 1877, while experimenting with various basic aniline dyes, Paul Ehrlich (1) first described the existence of tissue elements that exhibited metachromasia, staining reddish after treatment with blue–violet dyes. The term “mast cell,” from the German word *mästen* (to fatten), was used to describe the extensive granularity of these cells. Ehrlich (2) subsequently detected the presence of similar metachromatically staining cells in the blood of humans and called them blood mast cells or basophils, even though he suspected that these cells had an independent origin. After its discovery, the importance and function of the basophil remained a mystery for many years. Not until the mid-1950s was the basophil even considered to be a possible source of histamine (3); conclusive demonstration that basophils released histamine (4) and contained essentially all of the histamine in circulating cells (5) occurred years later. Since these discoveries, a great deal of experimentation has occurred with basophils, often viewed as a convenient circulating substitute for the study of the role of tissue mast cells in allergic diseases. Besides the obvious similarities that both cell types contain histamine and histamine can be released through immunoglobulin E (IgE)-dependent mechanisms, this concept was supported by several studies (reviewed in 6,7). For example, a striking correlation was seen between histamine-release responses of basophils exposed to various allergens *in vitro* and the severity of allergic respiratory symptoms experienced by the basophil donor. However, when methods were developed in the 1980s to isolate and purify human mast cells from a variety of tissues, it became clear that the basophil could no longer be viewed as a mast cell surrogate. Indeed, accumulated information suggests that the basophil in many ways may instead be more closely related to the eosinophil.

This chapter focuses on human basophil biology, with a review of information on basophil growth and differentiation, morphology, and phenotype. Particular attention is given to mediator release, as it is now known that basophils secrete immunomodulatory cytokines in addition to histamine and leukotrienes. Many advances also have been made in understanding the signal-transduction mechanisms involved in the release of these mediators. Finally, information is presented to emphasize the evidence that basophils infiltrate allergic lesions, along with other inflammatory cells, under the influence of specific cytokines. Although both the mast cell and the eosinophil are subjects of their own chapters, the important similarities and differences between these cells and the basophil are discussed.

GROWTH AND DIFFERENTIATION

The conditions for human basophil growth and differentiation have been extensively studied *in vitro* and have been reviewed (8). Initial studies demonstrated that metachromatically staining, histamine-containing leukocytes can be grown from immature precursors present in peripheral blood, bone marrow, fetal liver, and cord blood in the presence of various soluble stimuli. Among these stimuli, interleukin (IL)-3 has been identified as the primary growth and differentiation factor for the basophil (9,10), although cytokines including granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-5, and other tissue factors also may participate. *In vitro* studies show that mature basophils retain responsiveness to IL-3, which has a remarkable ability not only to modulate mediator release but also to maintain basophil viability even after weeks in culture (11). Although relatively little is known about basophil hematopoiesis *in vivo*, it has been demonstrated that treatment of nonhuman primates with IL-3 results in increased numbers of circulating basophils, eosinophils, and their progenitors (12).

In recent years, the relationship between the growth and differentiation of basophils and mast cells has become clearer with the demonstration of common progenitor cells for eosinophils and basophils and unique precursors for mast cells (8,10,13). Human basophils are derived from a common hematopoietic stem cell from which eosinophils also originate (13,14). Increased numbers of basophil precursors have been identified in the blood of patients with allergic rhinitis, nasal polyposis, and asthma, disorders associated with eosinophilia (15). In rare diseases in which strikingly increased numbers of circulating basophils are observed or functional and structural abnormalities in basophils are seen, similar eosinophil abnormalities are often identified, whereas mast cell abnormalities are not (16,17). Likewise, in diseases associated with increased numbers of mast cells, such as systemic mastocytosis, no increases in the circulating numbers of basophils are found. Finally, basophils in peripheral blood have never been shown to be capable of cell division or of conversion into mast cells. Thus basophils in many ways are related to eosinophils, and it seems likely that both circulating basophils and tissue-dwelling mast cells represent separate lineages of terminally differentiated cells.

Human basophils also appear to resemble eosinophils with respect to their duration of bone marrow maturation and half-life in the circulation, where they remain for several days (18). In association with certain myeloproliferative diseases, such as acute and chronic granulocytic leukemia, extensive blood basophilia may occur (19,20). Usually, however, the basophil is the least common blood cell and represents <1% of the total number of circulating leukocytes (21). Increased numbers of basophils have been identified in blood and nasal secretions of individuals with allergic rhinitis and in blood and bronchial secretions of individuals with asthma (22,23 and 24). The circulating numbers of both eosinophils and basophils are extremely sensitive to glucocorticoids, showing profound and prolonged suppression after exogenous glucocorticoid administration (25). Unlike the eosinophil or mast cell, the basophil is not normally a tissue-dwelling cell, although the recruitment of basophils from the circulation into tissues and their subsequent participation in various inflammatory responses is well documented.

MORPHOLOGY

With light microscopy and appropriate dyes, human basophils can be readily identified in most biologic specimens. The metachromatic staining of the intracytoplasmic granules of both mast cells and basophils is seen by light microscopy after the cells have been exposed to dyes such as toluidine blue or Alcian blue. This staining is a characteristic property of both types of cells and continues to be among the standard methods for their identification (26,27). Staining results from the ability of the dyes to bind intracellular proteoglycans. To facilitate the study of the biology of human basophils, methods have been developed for their isolation and purification. Because basophils have a specific gravity similar to that of monocytes and lymphocytes (1.070–1.080 g/mL), purification techniques involving density-gradient centrifugation can be used to separate basophils from most granulocytes and erythrocytes, which have higher densities (28). These methods yield basophil preparations with purities ranging from 1% to 20%. To achieve higher purity, additional steps, such as elutriation, affinity purification, negative selection after antibody labeling, or cell sorting can be used (29).

To ensure consistency in their identification and analysis, specific criteria have been established for the delineation of basophils and mast cells (30). Several basophil-specific monoclonal antibodies have now been developed that recognize intracellular or surface structures unique to basophils (31,32). Although these antibodies have proved useful in detecting basophils in tissue sections (33), the function of these molecules remains to be delineated. The morphologic features of basophils can be examined with transmission electron microscopy (Fig. 23.1) (27). Basophils are typically 5–7 μm in diameter, with a segmented nucleus that exhibits marked chromatin condensation. Multiple irregular, short, thick projections are present on the cell surface. In the cytoplasm, basophils have fewer and larger electron dense granules than do mast cells and lack the typical scroll-like appearance of mast cells. Histamine and chondroitin sulfate, the predominant basophil proteoglycan, are stored in these electron dense granules; quantities of these and other mediators are listed in Table 23.1. In various regions of the cell, major basic protein (34), Charcot–Leyden crystal protein (35), glycogen, lipid bodies, and other substances and structures have been identified (27). On degranulation, basophils appear to undergo direct granule extrusion, an event associated with a number of changes in cell-surface configuration (27,36). Extensive basophil surface membrane ruffling and shedding is often seen, in association with detectable alterations in the expression of various cell-surface markers.

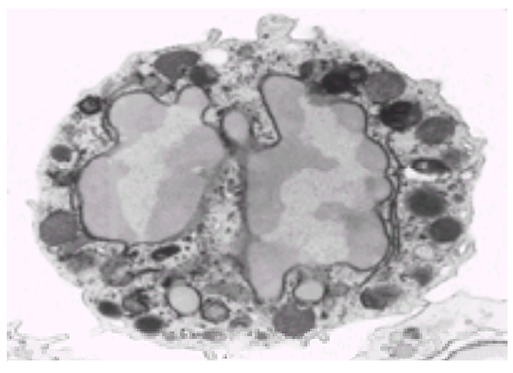

Figure 23.1. Transmission electron micrograph of a basophil isolated from the peripheral blood of a normal donor. The cell is round with short surface processes, is

fully granulated, and has a polylobed nucleus. Small aggregates and individual dense particles of glycogen are present in the cytoplasm, along with smooth, membrane-bound vesicles, either appearing empty or containing dense particles. Golgi areas are poorly developed, and free and membrane-bound ribosomes are minimal. (Reproduced from Dvorak AM, Warner JA, Kissell S, et al. F-met peptide-induced degranulation of human basophils. *Lab Invest* 1991;64:234–253, with permission.)

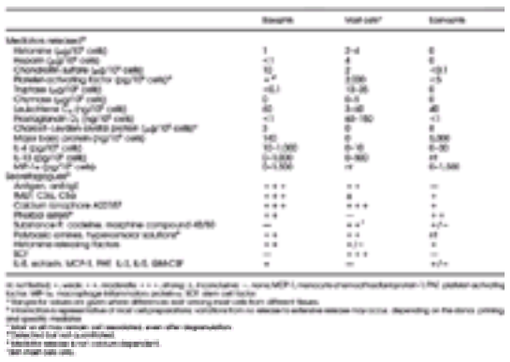

TABLE 23.1. Comparison of Selected Human Basophil, Mast Cell, and Eosinophil Mediators and Secretagogues

SURFACE PHENOTYPE

In addition to evaluation by electron microscopy, basophils have recently undergone extensive phenotypic analysis with respect to the expression of a variety of surface membrane structures. Immunocytochemistry, immunofluorescence and flow cytometry, and binding studies have been used to characterize their surface structures (reviewed in 37,38). Documented similarities and differences among the surface phenotypes of basophils, mast cells, and eosinophils are displayed in Table 23.2. For example, both basophils and mast cells express receptors for IgE that bind Fce with high affinity (so-called FceRI, K_a $<10^{10}$/M). This receptor, which has been cloned, consists of three different subunits (a, b, g), in which two g subunits associate with each a and b subunit; it is the a subunit that binds IgE (39). The active binding site on IgE recognized by the a2 region of the FceRIa subunit is a region in the C3 domain of the epsilon heavy chain (40). Neither basophils nor mast cells express low-affinity IgE receptors (FceRII, CD23). Basophils from different donors express a wide range of IgE-receptor densities (from 10^3 to 10^6 per basophil), which are much greater than those reported for mast cells (typically $<10^4$ per cell) (41). Many years ago, a correlation was found between the number of FceRI receptors per basophil and serum levels of IgE (42). This issue has now been explored in greater detail in recent studies *in vitro* and *in vivo*, including those with humanized anti-IgE antibody in clinical trials. IgE positively and reversibly influences the level of its own receptor (reviewed in 41,43). Although the mechanisms responsible for this action are not yet clear, it requires direct binding of IgE to FceRI (44). In addition, despite the extremely slow rate of dissociation of IgE from its receptor, it appears that a relatively consistent number of unoccupied FceRI receptors exist on basophils (45), thereby permitting passive sensitization of basophils from many donors by incubation with IgE *in vitro*. IgE can be removed *in vitro* by treating the basophils with low-pH solutions, such as lactic acid (46).

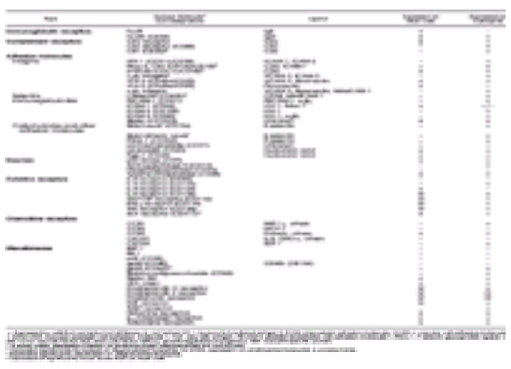

TABLE 23.2. Various Surface Structures On Human Basophils and Their Expression On Mast Cells and Eosinophils

Basophils also express receptors for IgG as well as receptors for complement components, cytokines, chemokines, and other soluble stimuli including lipids, histamine, and low-molecular-weight peptides (Table 23.2). Many more of these characteristics are shared by eosinophils than by mast cells. Basophils express several peptidases of unknown functions. They also express a wide variety of adhesion molecules with biologic functions, including members of the integrin, selectin, and immunoglobulin gene superfamilies.

BIOLOGIC FUNCTIONS

Mediator Release

The ability of human basophils (as well as mast cells) to secrete preformed and newly synthesized mediators underscores their important role in allergic and other inflammatory responses. Several preformed mediators, such as histamine, proteoglycans, and other substances, have been identified in human basophils (Table 23.1), and their rapid release has been documented. Basophils activated with certain stimuli also synthesize and release leukotriene C_4 (LTC_4), which is derived from the metabolism of arachidonic acid. Basophils do not, however, synthesize prostanoid products such as prostaglandin D_2 (PGD_2), whereas mast cells do (47). Basophils generate, *de novo*, large quantities of IL-4 and IL-13, cytokines that play a pivotal role in allergic inflammation (48,49,50,51,52 and 53). Although studies with immunohistochemistry and other methods have identified cytokines in human mast cells (and eosinophils), the quantities appear low, and the parameters involved in their synthesis from these cells are poorly understood (54,55,56 and 57). In contrast, a vast amount of information has been obtained about the generation of IL-4 and IL-13 in basophils. Most notable is the considerably longer time (hours) required for the secretion of these cytokines relative to the time required for the release of histamine and LTC_4 (Fig. 23.2).

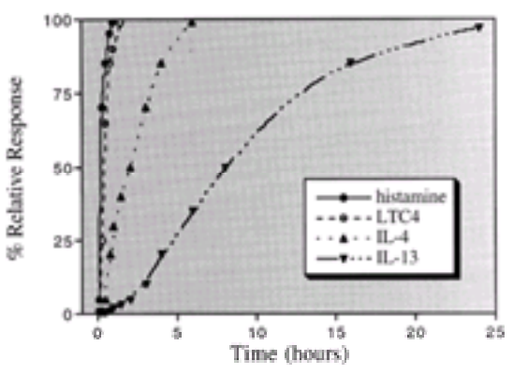

Figure 23.2. Kinetics of mediator and cytokine release from human basophils. Shown is a representative time course of secretion of histamine, leukotriene C_4 (LTC_4), interleukin 4 (IL-4), and IL-13 after immunoglobulin E (IgE)-dependent activation of the cells *in vitro*.

The excitability of the basophil is illustrated, in part, by the fact that it releases histamine concentrations of anti-IgE 100-fold lower than those required to release histamine from most mast cells. This increased sensitivity is not due simply to differences in cell-surface IgE density (58). Basophils also are far more responsive to IgE-independent secretagogues, such as complement products, formylated bacterial products [e.g., f-Met-Leu-Phe (fMLP)] cytokines, chemokines, low-molecular-weight peptides, hyperosmolar solutions, and lipids (Table 23.1) (6,7,59). Although basophils respond to many different stimuli, their activation generally results in the release of histamine and LTC_4. In contrast, their generation of IL-4 and IL-13 seems far more dependent on activation with specific stimuli (50). Both cytokines are made in response to FceRI cross-linking, induced either by a specific interaction with antigen or nonspecifically by anti-IgE or anti-FceRI antibodies. Optimal secretion of IL-4 and IL-13 in response to these stimuli occurs at concentrations nearly 10-fold less than that necessary for optimal histamine release. Surprisingly, most IgE-independent stimuli, such as fMLP, C5a, and various chemokines [e.g., the monocyte chemoattractant protein (MCP) family], although capable of inducing histamine release, fail to induce IL-4 and IL-13 secretion when used alone. Some do appear to synergize or enhance the secretion of these cytokines if combined with other stimuli (60,61 and 62). Two cytokines that activate basophils for cytokine production independent of cross-linking are the histamine-releasing factor (HRF, formerly known as the IgE-dependent HRF) and IL-3. Recombinant HRF directly induces IL-4 secretion and histamine release from basophils isolated from a subset of allergic donors (63,64). It does not appear to stimulate IL-13 release from these cells (unpublished observations). In contrast, IL-3 is an excellent inducer of IL-13 generation in cells from most donors (61,65). However, it does not generally induce the secretion of IL-4 nor does it commonly cause histamine release, unless used at high concentrations and, if so, only from cells of selected donors (66). Basophils treated for just 15 minutes with either HRF or IL-3 secrete increased amounts of IL-4, IL-13, histamine, and LTC_4 on subsequent activation with a cross-linking stimulus (49,50,67,68). For IL-3, this “priming” effect is mediated through binding of its receptor, which, as noted earlier, is expressed at high levels on basophils. Other nonphysiologic agents, such as D_2O and cytochalasin B, also enhance mediator release from human basophils (69).

Compared with the mast cell, the basophil is activated by more types of artificial stimuli such as calcium ionophores (e.g., ionomycin and A23187, both of which increase intracellular calcium), polybasic amines, and the tumor-promoting phorbol esters [which activate protein kinase C (PKC)]. Although all these agents induce degranulation, which results in histamine release, the phorbol esters do so independent of changes in cytosolic calcium (70,71). Changes in cytosolic calcium seem to play an important role in the secretion of IL-13 and IL-14, evidenced by the fact that calcium ionophores are the most potent activators of these cytokines. This statement is particularly true for IL-4. For instance, phorbol myristate acetate (PMA) alone is capable of inducing large quantities of IL-13 but does not activate basophils for IL-4 secretion (65). In fact, when added with ionomycin, PMA inhibits by 70% the IL-4 produced in response to the ionophore alone (72). This finding is surprising in view of the prosecretory effects that PMA and ionomycin have on many cell types, including IL-4 secretion from primary lymphocyte cultures. Inhibitors of PKC activation, like the bisindolymaleimides (Bis), reverse the effect that PMA has on IL-4 secretion while blocking the phorbol from inducing IL-13 secretion in basophils. Thus PKC activation appears to play a pivotal role in regulating the generation of these cytokines in basophils by acting as an inducer of IL-13 and an inhibitor of IL-4.

The basophil secretagogues that are most likely to be clinically important in allergic diseases are those that interact with surface IgE. A great deal of effort has been focused on attempts to elucidate the mechanisms involved in IgE-dependent degranulation of basophils. These secretagogues are multivalent and induce cross-linking of surface IgE, which then triggers calcium-dependent degranulation. Essential to the induction of degranulation is the establishment and maintenance of a critical number of IgE cross-links on the cell surface, estimated to range between 200 and 500, depending on the donor (73,74). Because much of the information pertaining to this sensitivity has been derived from studies of basophil histamine release, it is difficult to say at this time whether similar parameters will apply for the generation of LTC_4 and cytokines. However, studies suggest that there are subtle differences with regard to sensitivity for the release of cytokines as opposed to histamine (75). Thus it seems that the number of receptor aggregates necessary for a half-maximal response of histamine also produces a 50% response in cytokine and LTC_4 secretion.

A substantial amount of information has been obtained in recent years about the sequence of intracellular biochemical events after FceRI cross-linking and how these events relate to mediator release and cytokine generation. Many factors play a role, including tyrosine kinases and phosphatases, phospholipases, guanosine triphosphate (GTP)-binding proteins, PKC, cyclic nucleotides, and calcium (76,77). In human basophils, as in rodent mast cell lines, specific tyrosine kinases are involved in the early events after FceRI aggregation. Both p53/p56lyn (a member of the src family of kinases) and p72syk kinases are expressed in basophils, and both are phosphorylated within minutes after activation (78). These phosphorylation events induced by anti-IgE are blocked by the PP1 and PP2 tyrosine kinase inhibitors, as is the secretion of histamine, LTC_4, IL-4, and IL-13 (79). In contrast, PP1 and PP2 fail to prevent the rapid release of histamine and LTC_4 by fMLP, which is thought to signal through a receptor coupled to a pertussis toxin–sensitive (GTP)-binding protein (80,81).

Despite the presence of IgE on the surface of basophils from every donor, ~10%–15% of individuals fail to release histamine after extensive cross-linking of their basophil surface IgE (82,83). The exact defect responsible for this “nonreleaser” phenomenon is unknown, but it has been suggested that syk kinase is deficient in cells isolated from these donors (84). Another interesting *in vitro* observation is that cross-linking of IgE in the absence of calcium leads to a state referred to as desensitization, in which subsequent rechallenge of basophils with an appropriate IgE-dependent stimulus, even in the presence of calcium, fails to elicit degranulation. This phenomenon is stimulus specific (e.g., antigen desensitizes to anti-IgE but not to fMLP) and is not due to irreversible cross-linking or internalization of surface IgE (73). This approach is often used to demonstrate that a particular histamine-releasing stimulus is acting on the basophil through IgE-dependent or IgE-independent mechanisms (so-called cross-desensitization studies).

Some of the intracellular mechanisms that regulate histamine, LTC_4, and cytokine release from basophils diverge from one another in downstream events (85). The generation of LTC_4 depends on cytosolic phospholipase A_2 ($cPLA_2$) activity, which provides the arachidonic acid substrate through its ability to metabolize phospholipids. The so-called extracellular signal–regulated kinases (ERKs; ERK1 and ERK2), which are downstream of p21ras, can target $cPLA_2$ for activation. Phosphorylation of these ERKs and $cPLA_2$ was found to correlate with IgE-dependent (and -independent) release of LTC_4 from basophils. An inhibitor of ERK phosphorylation, PD098059, prevents the subsequent activation of $cPLA_2$, which results in the inhibition of LTC_4 release (86,87). Both histamine and IL-4 are unaffected, suggesting that the intracellular events regulating the release of these mediators occur independent of the ERK1/ERK2 pathway. Other studies show that phosphatidylinositol-3-(PI3)-kinase activation likely plays a role in the secretion of cytokines as well as histamine and LTC_4. This enzyme initiates signaling pathways that are important for ribosomal activity in the translation of some proteins. Both wortmannin and LY294002 inhibit PI3-kinase, and both compounds also prevent the secretion of all three classes of mediators released in response to IgE-mediated activation (87).

The activation of PKC has long been implicated in the prodegranulatory events that follow IgE-mediated activation, particularly those involved in mediator release. However, much of this belief is derived from studies performed in rodent cell lines, which may not fully translate to human cells. Recent studies show no evidence that the PKC isozymes identified in human basophils, which include b1, b2, and d, are activated after cell stimulation with anti-IgE (88). In contrast, these isozymes are activated after cell stimulation with PMA or fMLP. Although early studies did suggest a prodegranulatory role for PKC activation in the signaling events after FceRI cross-linking in human basophils, these conclusions were derived from experiments with staurosporine. This compound was initially reported to be an inhibitor of PKC but is now known also to inhibit the early and late tyrosine kinase activity associated with FceRI aggregation. Thus pharmacologic studies with staurosporine are difficult to interpret. More selective inhibitors of PKC (e.g., Bis II) show no inhibitory effect on histamine release induced by anti-IgE and, in many instances, enhance mediator release by this stimulus (89). As alluded to earlier, the same is true for IL-4, thereby suggesting that PKC activity in basophils may play a more antagonistic role in FceRI-mediated secretion.

Changes in cytosolic calcium responses play a critical role in the prosecretory events occurring in basophils, and these responses are likely initiated, in part, from the formation of triphosphates, particularly IP_3. Whereas both IgE-dependent and IgE-independent stimuli can induce a calcium response sufficient for degranulation, the duration and magnitude of the response likely determines whether cytokine generation is initiated. Several lines of evidence support this belief. First, the levels of IL-4 secreted in response to anti-IgE are remarkably enhanced with increases in extracellular calcium (50); chelators of this ion [e.g., ethyleneglycol-bis-(b-aminoethylether)-*N,N,N*',*N*', tetraacetic acid (EGTA) completely ablate all generation of IL-4, including the accumulation of its mRNA. As noted, ionophores, which sustain increases in cytosolic calcium, stimulate the secretion of large quantities of IL-4 and IL-13 from basophils. Finally, the concentrations of cross-linking stimuli (i.e., anti-IgE) that are optimal for cytokine secretion, yet suboptimal for histamine release, generally induce prolonged calcium responses in basophils (90). Similar calcium responses are not observed with univalent stimuli (e.g., fMLP or C5a) (68,91), nor is cytokine generated under these conditions.

Pharmacologic studies suggest that a calcium-dependent calcineurin pathway is involved in the IgE-mediated secretion of IL-4 and IL-13. Both FK506 and cyclosporin A (CsA), which are relatively specific inhibitors of calcineurin phosphatase activity, prevent the generation of these cytokines in basophils stimulated by anti-IgE (65). Although FK506 and CsA also inhibit mediator release induced by anti-IgE (92), they are 50- to 100-fold more potent at blocking the secretion of IL-4 and IL-13, and inhibit these cytokines at subpicomolar concentrations. Because calcineurin plays a pivotal role in regulating the nuclear factor of activated T cell (NFAT) family of transcription factors, which are important for cytokine generation in many types of immune cells, members of this family may regulate cytokine generation in basophils.

As noted earlier, the release of IL-13 from basophils, unlike that of IL-4, does not necessarily depend on FceRI cross-linking. IL-13 generation is linked neither to IL-4 nor to histamine. At least three pathways are involved in the generation of IL-13 in basophils, all of which appear pharmacologically distinct (93). Unlike that generated in response to FceRI aggregation or to calcium ionophores, the IL-13 produced after basophil activation with either IL-3 or PMA is completely resistant to FK506. As expected, the IL-13 generated with PMA is blocked with inhibitors of PKC, but these agents have little to no effect on the IL-13 made in response to IL-3 or anti-IgE. Glucocorticoids, which have proven efficacy in the treatment of allergic disease, rapidly inhibit the IL-4 and IL-13 made in response to many different stimuli (94,95).

However, the existence of multiple pathways for IL-13 is supported by the finding that dexamethasone differentially inhibits the secretion of this cytokine. The IL-13 made in response to IL-3 is most affected, being inhibited at subnanomolar concentrations. Nearly 30-fold greater amounts of drug are required to block the release of IL-13 induced by anti-IgE. This finding is unexpected, given that IL-3 lessens the inhibitory effects that glucocorticoids have on histamine and LTC_4 release (96).

Information from the study of many cell types, including basophils and eosinophils, suggests a previously unrecognized state of intermediate activation that has been referred to as *priming*. Basophils exposed to priming stimuli, especially various cytokines, become more sensitive to functional activation through traditional mechanisms such as those mediated through FceRI or complement receptors. As noted earlier, human basophils incubated with IL-3 (or HRF) release markedly greater quantities of IL-4, IL-13, LTC_4, and to a lesser extent histamine, during a subsequent challenge with anti-IgE. IL-3 also primes cells subsequently stimulated with fMLP or C5a for histamine and LTC_4 release (96,97). This priming response occurs with very low concentrations of IL-3. It has recently been proposed that cells from allergic individuals are in a primed state, as assessed by their release to thapsigargin (an agent that increases intracellular calcium) (98). Higher spontaneous or stimulus-induced basophil histamine release occurs in individuals with food allergy and other allergic conditions (99,100,101,102 and 103). Whether these findings result from cytokine-induced priming *in vivo* remains to be determined.

Recent studies have produced information about the mechanisms underlying the early and late effects of IL-3 priming. For example, a transient phosphorylation of $cPLA_2$ is detected in basophils exposed for 15 minutes to IL-3, and this event is associated with increased LTC_4 release from basophils activated with both IgE-dependent and IgE-independent stimuli (104). After 2 hours, $cPLA_2$ is no longer phosphorylated nor is there increased LTC_4 released on activation. $cPLA_2$ is once again phosphorylated by the cells after 18 hours of incubation in IL-3, and LTC_4 release is augmented on activation. An inhibitor of protein synthesis, such as cycloheximide, prevents this late effect of IL-3 (105). Likewise, cycloheximide prevents IL-3, but not anti-IgE, from inducing IL-13 mRNA expression (95). These findings suggest that the late effects of IL-3 on IL-13 and LTC_4 are mediated through the synthesis of as-yet-unidentified proteins.

A great deal of information also has accumulated about the pharmacologic regulation of mediator release. Substances including b_2 agonists (106), H_2 agonists (107), adenosine (108), cyclosporine (109), glucocorticoids (110), and cyclic adenosine monophosphate (AMP)-active agents (111) all prevent *in vitro* mediator release from basophils induced by some but not necessarily all stimuli. Finally, b_2 and H^2 agonists also inhibit cytokine secretion from basophils (112).

Role in Diseases and Recruitment Mechanisms

A major difference between basophils and mast cells is their compartmentalization in the body. Whereas mast cells reside in virtually every organ, basophils are not normally tissue-dwelling cells but instead remain in the circulation. However, during certain inflammatory responses, basophils (like eosinophils) emigrate from the vasculature to the extravascular space. Basophils have been identified in the skin at tissue sites of contact hypersensitivity, bullous pemphigoid, cutaneous basophil hypersensitivity, and late-phase allergic responses (6,22,113 and 114) and also have been identified in the upper and lower airways of patients with allergic rhinitis and asthma (23,24,33,114). Basophils increase in number after localized antigen challenge of the skin or airways in allergic individuals (33,115,116). The numbers of blood basophils correlate with bronchial responsiveness as well as with changes in bronchial reactivity over time (117,118).

The importance of basophils at inflammatory sites has been elucidated by recent studies comparing mediator concentrations with histology and cytology. For example, the short-term release of histamine in the cutaneous antigen challenge model is accompanied by evidence of mast cell degranulation, including the release of PGD_2 and tryptase (119,120). In contrast, during the late-phase response, the number of metachromatic cells increases 30- to 50-fold, and this increase correlates with a second increase in histamine. This event occurs at time points typically beyond 4 hours and is not accompanied by the reappearance of PGD_2 or tryptase, strongly suggesting that the basophil (and not the mast cell) is the source of histamine in the late phase. Various microscopic, functional, and phenotypic analyses reveal that most of the metachromatic cells at these sites are basophils and not mast cells; the same is true of similar studies in the airways (115,121). Glucocorticoids administered systemically or locally are particularly effective in reducing the appearance of mediators along with a dramatic reduction in the influx of basophils (122,123 and 124).

The fact that basophils are found in certain inflammatory sites at percentages that are vastly greater than their percentages in peripheral blood suggests that they are preferentially activated and recruited to these locations. The mechanism traditionally thought to be involved in leukocyte emigration is the local release of chemoattractants that promote adherence and chemotaxis. Cytokines [e.g., interferon (IFN)-g, IL-3, IL-5], complement fragments, chemokines (especially those such as eotaxin that act through the chemokine receptor CCR3), and other factors are chemoattractants for human basophils (reviewed in 59,114,125). However, results of studies examining the *in vitro* binding of purified leukocyte subtypes to cultured human vascular endothelial cells suggest that the endothelium can play an active role in the recruitment of granulocytes (126,127). These responses are the result of interactions between cell-surface structures on both the endothelial cell and the leukocyte. Leukocyte adherence to endothelium and other substrates is mediated through adhesion molecules on the basophil that include the b_2 integrins, leukocyte functional antigen 1 (LFA-1), and Mac-1 (Table 23.2). Agents such as chemotactic factors, IL-3, and IgE-dependent secretagogues directly stimulate divalent cation-dependent adhesiveness of basophils to the vascular endothelium (128,129 and 130). Such events are associated with the upregulation of the expression of b_2 integrins and the intracytoplasmic granule marker CD63, along with the reduced expression of L-selectin and P-selectin glycoprotein ligand 1 (PSGL-1), the major ligand for P-selectin (130,131,132 and 133). The changes in expression of CD11b and L-selectin are identical in basophils extravasated into the lower airways after allergen challenge *in vivo* (134). Neither IL-3 nor IgE-dependent secretagogues have the same effects on neutrophils. For basophils, these effects occur at concentrations of stimulus below the threshold required to induce histamine release. Therefore, the exposure of circulating basophils to low levels of these agents *in vivo* may contribute to their selective adhesion and recruitment during certain inflammatory responses.

The endothelium also plays an active role during the process of leukocyte adherence by expressing adhesion molecules and secreting substances that promote transmigration. For example, the cytokines IL-1, tumor necrosis factor (TNF), and IL-4 can stimulate cultured endothelial cells to acquire adhesive properties, rendering them extremely effective in binding basophils (and other leukocyte subtypes) *in vitro* (128,135,136). With respect to the potential role of adhesion molecules and the preferential recruitment of basophils, recent data suggest that there are differences in adhesion-related responses among granulocytes (137,138). Basophils and eosinophils, but not neutrophils, adhere to the cytokine-inducible endothelial vascular cell adhesion molecule 1 (VCAM-1) (135,136). This circumstance is due to the fact that basophils and eosinophils, unlike neutrophils, express counterreceptors for VCAM-1 (the a_4b_1 and a_4b_7 integrins) and MadCAM-1 (a_4b_7 integrins) (135,137). Because human basophils are capable of interacting with other endothelial adhesion molecules such as P-selectin and E-selectin (133,137), several similarities and differences exist in the recruitment mechanisms used by basophils and other leukocytes. It is not yet known whether the same adhesion molecules or other, as yet unidentified structures are responsible for basophil transendothelial migration or whether there are factors derived from endothelial cells or other tissues (e.g., chemokines) that selectively promote basophil recruitment.

CONCLUSION

Our knowledge of the human basophil has expanded tremendously. The basophil is most closely related to the eosinophil with respect to several characteristics such as growth and differentiation. Both cell types have a remarkably similar pattern of surface markers, and they seem to be recruited and to participate in a parallel way during various disease processes such as allergic inflammation. Nevertheless, the basophil clearly resembles the mast cell in terms of its morphology, mediator profile, and involvement in FceRI IgE-mediated responses. It is anticipated that future studies will shed additional light on the relationships among basophils, mast cells, and eosinophils, and on their respective roles in the pathophysiology of inflammatory responses.

24 BIOLOGY OF THE MAST CELL

Joshua A. Boyce, M.D., and K. Frank Austen, M.D.

Mast cells are morphologically and histochemically distinct cells of hematopoietic origin that are widely distributed throughout mammalian tissues. They are particularly abundant in a perivascular distribution in connective tissues and at mucosal surfaces (1). When stained with basic dyes such as toluidine blue, mast cells are easily recognizable under light microscopy by their prominent cytoplasmic granules (Fig. 24.1A). Mast cells have diverse effector functions that are firmly implicated in the pathophysiology of allergic disease (2,3 and 4). Classic mast cell–mediated hypersensitivity (allergic) reactions are initiated by the binding of multivalent allergen to membrane-bound immunoglobulin E (IgE) that is coupled to the tetrameric high-affinity Fc receptor for IgE (FceRI) on mast cells. IgE-dependent activation of mast cells results in their release of preformed inflammatory mediators that are stored in their secretory granules, including histamine, neutral proteases, preformed cytokines, and proteoglycans. Additionally, mast cells activated by FceRI secrete newly synthesized lipid mediators that are the products of endogenous arachidonic acid metabolism, such as prostaglandin D_2 (PGD_2) (5), leukotriene B_4 ($LT\ B_4$) (6), and LTC_4, the parent molecule of the cysteinyl leukotrienes (7). Finally, activated mast cells synthesize and secrete a host of proinflammatory cytokines (8,9 and 10). The net result of tissue mast cell activation thus includes the rapid development of plasma extravasation, tissue edema, bronchoconstriction, leukocyte recruitment, and persistent inflammation, with the clinically recognizable syndromes of anaphylaxis, urticaria, angioedema, and acute exacerbations of asthma. The importance of mast cells and their products in allergic diseases is supported by the finding that pharmacologic pretreatment of susceptible persons with cromolyn, an inhibitor of mast cell exocytosis, attenuates bronchoconstriction in response to allergen challenge (11). The additional recognition that mast cell–derived products regulate fibroblast proliferation (12,13), collagen synthesis (13,14), and angiogenesis (15,16) reflects a likely role for mast cells in wound healing and tissue remodeling (17). Moreover, hyperplasia of mast cells within lesional tissue is a recognized histopathologic feature of rheumatoid arthritis (18), fibrotic lung diseases (19,20), rapidly progressive glomerulonephritis (21), multiple sclerosis (22), and hepatic fibrosis (23). Finally, the findings that mast cells undergo exocytosis and generate lipid inflammatory mediators when these cells are activated by low-affinity Fc receptors for IgG (FcgR) (24) and are activated directly by cell wall proteins of gram-negative bacteria in experimental models of bacterial peritonitis (25,26) indicate potential salutary roles for mast cells in both innate and adaptive immune responses.

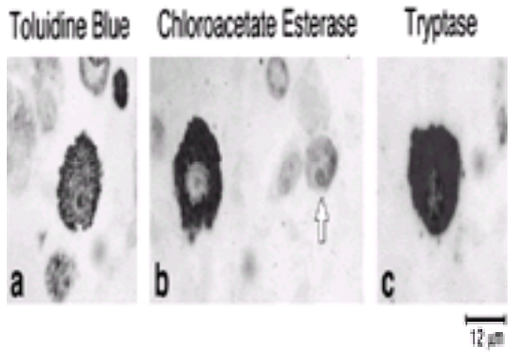

Figure 24.1. Mast cells. Staining and immunohistochemical features of human mast cells in the stroma of an excised nasal polyp. Sections show prominent granule metachromasia with toluidine blue **(A)** and red reaction indicative of chloroacetate esterase **(B).** Neutrophils *(arrow)* also react for chloroacetate esterase activity but much less intensely than mast cells. All human mast cells show immunoreactivity with an antitryptase antibody **(C).** (Photomicrograph courtesy of Daniel S. Friend, M.D., Harvard Medical School, Boston.)

This chapter deals with the current understanding of mast cell development, their effector capabilities, and the relevance of these findings to disease and immunity.

MAST CELL DEVELOPMENT

Mouse

Current knowledge about the molecular basis of mast cell development has come mainly from mouse studies. A mast cell–deficient mouse strain, *W/Wv*(27), proved to have a mutation at the white-spotting (W) locus that encodes the membrane receptor tyrosine kinase, c-*kit* (28). The ligand for c-*kit,* stem cell factor (SCF), also known as KIT ligand or Steel factor (29,30), is a growth factor that is constitutively and abundantly expressed by fibroblasts and stromal cells and exists in both membrane-bound and secretory form. The Sl locus that encodes SCF (31) is mutated in a second strain of mast cell–deficient mice (*Sl/Sld* strain) (32). These observations thus provide molecular evidence that the intact functions of both c-*kit* and SCF are absolutely required for normal mast cell development *in vivo* in mice. The transplantation of normal bone marrow cells from a histocompatible strain populated the tissues of the *W/Wv* mice with normal-appearing mast cells (27), a finding reflecting correction of the defective c-*kit* receptor in the *W/Wv* recipients and confirming the hematopoietic origin of mast cells. Moreover, the finding that recombinant soluble SCF stimulated the growth of mast cells from mouse bone marrow cells *in vitro* further validates the importance of the SCF/c-*kit* interaction in mast cell development from hematopoietic precursors (33).

Although the profound defects in all tissue mast cells in *W/Wv* and *Sl/Sld* mice support the absolute necessity for SCF and c-*kit* in normal mast cell development, other growth factors derived from T lymphocytes are crucial for a mast cell subpopulation that arises in the intestinal mucosa under conditions of helminth-induced inflammation. Athymic nude mice that were infected experimentally with *Trichinella spiralis* failed to mount a reactive intestinal mucosal mast cell hyperplasia, an expected and essential feature of adaptive immunity to helminthic infections (34). These same T-cell–deficient mice had normal numbers of mast cells in the adjacent intestinal submucosal connective tissue. Thus, T-cell–derived growth factors are required for the selective development of “reactive” mast cells in the intestinal mucosa, but not for the development and maintenance of the “constitutive” mast cells of the submucosa. A conditioned medium derived from activated T lymphocytes stimulated primitive mast cells (termed persisting or P cells) to grow from cultures of mouse bone marrow cells or dispersed spleen cells (35,36). The same conditioned medium also elicited the growth of primitive mouse mast cells from cultures of “lymphocyte-like” cells that were isolated from dispersed intestinal mucosa (37), a finding indicating the presence of mast cell–committed progenitors in the mucosal compartment of the intestine. The mast cell growth-stimulating bioactivity of T-cell–conditioned medium was subsequently largely attributed to a hematopoietic cytokine, interleukin-3 (IL-3). Purified IL-3 proved capable of inducing mast cell proliferation from dispersed intestinal mucosa (38), as well as from unfractionated mouse bone marrow (39,40 and 41). The importance of IL-3 for reactive mouse

intestinal mucosal mast cell hyperplasia was confirmed by two *in vivo* studies. In the first, blocking antibodies against IL-3 (or another T-cell–derived cytokine, IL-4) inhibited the hyperplastic mucosal mast cell response in a mouse model of helminth infection (42). In the second, mice with a targeted disruption of the IL-3 gene showed a markedly blunted (but not completely eliminated) reactive intraepithelial intestinal mast cell hyperplasia after they were infected with the nematode *Nippostrongylus brasiliensis* (43), without an effect on constitutive mast cell numbers, including those in the intestinal submucosa. When the IL-3 deficiency was expressed in mice with the c-*kit*-deficient *W/Wv* genetic background, mast cells were lacking in both the intraepithelial and submucosa compartments, and no mast cells developed in response to the infection (43). Taken together, these data support a model of mast cell development in mice that proceeds from bone marrow–derived committed progenitors that traffic to peripheral tissues. In the intestine, these progenitors give rise to constitutive mast cells that reside mostly in the submucosal connective tissues and are c-*kit* /SCF-dependent, but are independent of T-lymphocyte–derived growth factors. Such progenitors also give rise to reactive mast cells in an intraepithelial distribution in the jejunum. These reactive mast cells also require c-*kit* for their derivation *in vivo,* but unlike constitutive mast cells, they are expanded in response to T-cell–derived growth factors, particularly IL-3, in reaction to a mucosal inflammatory stimulus.

The characteristics of the committed precursors of mast cells in mice remained elusive for several decades. The lymphocyte-like cells derived from the intestinal mucosa that gave rise to mast cells *in vitro* were positive for the Thy-1 antigen, a membrane marker that is generally associated with thymocytes (37). Rodewald and colleagues isolated a population of committed mouse mast cell progenitors by sorting rare cells from fetal blood that expressed high levels of c-*kit* and low levels of Thy-1 (44). The c-*kit*^{hi}/Thy-1^{lo} fetal blood cell population, termed promastocytes, lacked FceRI and did not respond to cytokines active for the differentiation of lymphocytes, monocytes, and granulocytes in colony-forming assays; however, they gave rise to pure colonies of primitive FceRI-positive mast cells when they were cultured in the presence of recombinant SCF and IL-3. Both cytokines were necessary for optimal mast cell colony formation, a finding reflecting the apparent synergy between SCF and IL-3 for amplified mast cell growth from their committed progenitors (44). Fetal blood–derived promastocytes injected intraperiteonally into *W/Wv* mice induced the local development of mature mast cells. The failure of promastocytes to engraft bone marrow when injected intravenously likely reflected their commitment to the mast cell lineage. That the derivation of c-*kit*^{hi}/Thy-1^{lo}/ FceRI-negative promastocyte-like cells from uncommitted bone marrow progenitors depends on SCF was subsequently established in an *in vitro* model (45). Mouse bone marrow cells that were selected for their expression of Sca-1 (a membrane marker of uncommitted hematopoietic progenitor cells) developed into promastocyte-like cells and, subsequently, into primitive FceRI-positive mast cells (metamastocytes) when they were cultured in the presence of SCF in combination with two costimulatory growth factors, IL-6 and IL-10 (45). In contrast, the same Sca-1–positive uncommitted progenitors failed to develop a promastocyte-like phenotype in response to IL-3, whereas FceRI-positive mast cells (but not a promastocyte-like population) grew vigorously in response to IL-3 from bone marrow that was depleted of the uncommitted Sca-1–positive fraction. Thus, promastocytes derive from uncommitted hematopoietic precursors in response to SCF, acting through c-*kit.* Unlike IL-3, SCF and its receptor are both necessary and sufficient to provide normal numbers of tissue mast cells *in vivo* in mice. IL-3 serves as a cofactor for mast cell development from SCF-dependent committed progenitors and as a central T-cell–derived factor for mast cell hyperplasia at mucosal surfaces in mice.

Human

The finding that human patients with T-cell immunodeficiencies lack mast cells in the intestinal mucosa but not the adjacent submucosa suggested substantial developmental parallelism for mast cells in mice and humans, with T-cell–dependent and T-cell–independent mast cell subpopulations in both species (46). Recombinant human SCF, like its mouse homolog, supports mast cell growth *in vitro* (47,48 and 49). Furthermore, a gain-of-function mutation in the c-*kit* receptor is associated with an aggressive form of systemic mastocytosis (50). Thus, as in the mouse, SCF and c-*kit* are important for mast cell development in humans. In contrast to the mouse, however, recombinant human IL-3 failed to mediate mast cell growth *in vitro* when it was provided as a single exogenous growth factor to human progenitor cells; instead, it elicited the growth of basophils and eosinophils (51,52 and 53). Furthermore, mature mast cells that were dispersed from human lung tissue lacked binding sites for IL-3 (54). Based on these observations, it was assumed that the capacity for IL-3 alone to expand lineage-committed mast cell progenitors *in vivo* had been deleted during the evolution of higher primates. The potential contribution of IL-3, and of other T-cell–derived factors in human mast cell development, remained unknown until the identification and characterization of human mast cell progenitors and the delineation of their growth factor requirements and responses.

Speculation that human tissue mast cells derived from circulating basophils or monocytes was refuted by the failure of these lineages to give rise to mast cells under a variety of conditions *in vitro* (55,56). Based on cytofluorographic analysis of cell membrane markers, CD34-positive populations of human mononuclear cells identified in peripheral blood (56,57) and bone marrow (58) were found to have mast cell growth potential *in vitro,* based on colony formation in response to recombinant SCF. Although lacking visible secretory granules, these progenitor cells could be distinguished from monocytes by their expression of c-*kit* (56,57,58 and 59), as well as by their lack of CD14 (56), a component of the lipopolysaccharide (LPS) receptor that is considered a marker of the monocyte-macrophage lineage. The mast cell–producing potential of c-*kit*/CD34–positive cells was later shown to be restricted to the subfraction that also expressed CD13 (59), the human homolog of a membrane aminopeptidase previously demonstrated on mouse metamastocytes (45). When cultured *in vitro* with a combination of SCF and IL-6, the c-*kit*/CD34/CD13–positive cell fraction gave rise to mast cells and, to a much lesser extent, monocytes, whereas the c-*kit*/CD34–positive, CD13-negative cell fraction gave rise to multiple lineages under the same conditions (59). Thus, a circulating population of mast cell progenitors in humans has some monocytic growth potential as well. Whether a human promastocyte equivalent, with no monocytic potential, like that of the mouse, also exists is unknown. Nonetheless, the finding that progenitors of mast cells *in vitro* are sorted from peripheral blood of humans, as in mice, is consistent with the origins of tissue mast cells from circulating progenitors in both species. Because mature mast cells are not found in the circulation, these progenitors must acquire their distinctive functional and morphologic characteristics *in situ,* with tissue-specific mast cell features being a function of local microenvironmental factors.

Although human lung mast cells reportedly lack IL-3 receptors, and IL-3 alone fails to stimulate human mast cell growth, SCF-dependent growth of human mast cells *in vitro* from CD34-positive peripheral blood cells was strongly augmented by the addition of IL-3 in one study (57). The apparent disparity was resolved by a study of mast cell progenitors derived *in vitro* from umbilical cord blood mononuclear cells (60). When cultured for 4 weeks in the presence of SCF, IL-6, and IL-10, the cord blood cells gave rise initially to a mononuclear cell population lacking the characteristic metachromatic staining properties of mature mast cells, but with uniform membrane characteristics similar to those reported for human mast cell progenitors of bone marrow or peripheral blood (c-*kit*–positive/CD13-positive/CD14-negative) (56,57,58 and 59). As detected by flow cytometry, these mast cell progenitors expressed the receptor for IL-3, and recombinant IL-3 promoted their proliferation when provided in combination with SCF. With longer periods (9 weeks) of culture, the c-*kit*–positive/CD13-positive mast cell progenitors developed into cytologically mature mast cells, accompanied by a disappearance of the IL-3 receptor from the cell surface, consistent with the reported lack of this receptor on mature human tissue mast cells (54). However, the mature cultured mast cells became IL-3 receptor positive again when they were exposed to either recombinant IL-3 or recombinant IL-5 in conjunction with SCF. Furthermore, although the mature mast cells did not proliferate in response to IL-3 alone, they proliferated vigorously in response to IL-3 when they were provided with SCF (comitogenic response). Thus, even though IL-3 fails to promote mast cell growth by itself, the IL-3 receptor is constitutively expressed by human mast cell progenitors, is inducible on mature mast cells, and mediates an SCF-driven comitogenic effect on human mast cells and their progenitors *in vitro.* Thus, as in the mouse, IL-3 may amplify SCF-dependent mast cell development in humans despite its lack of activity alone as a human mast cell growth factor *in vitro.*

In addition to IL-3, certain other T-cell–associated growth factors augment the SCF-dependent proliferation of mast cells *in vitro* from both human and mouse progenitors (Table 24.1). In mice, IL-4, IL-10 (61), and IL-6 (45) share this property. Mice with tissue-specific overexpression of an IL-9 transgene display hyperplasia of mast cells in the intestinal (62) and lung (63) epithelium, findings suggesting a comitogenic effect. SCF-driven mast cell development from human cord blood–derived pluripotent progenitors is augmented by IL-6 (64); human cord blood–derived c-*kit*–positive/CD13-positive mast cell progenitors and their mature counterparts exhibited SCF-dependent comitogenic responses to IL-5 and IL-6 as well as IL-3 and lesser comitogenic responses to IL-9 and granulocyte-macrophage colony-stimulating factor (GM-CSF) (60). IL-5, previously considered a selective growth factor for human eosinophils (65), was particularly potent as a comitogen with SCF for mast cells originally derived from cord blood with SCF, IL-6, and IL-10. IL-5 was also potently costimulatory with SCF and IL-6 for mast cell development *in vitro* directly from CD34-positive/c-*kit*–positive/CD13-positive human mast cell progenitors sorted from bone marrow and peripheral blood (59). Mature mast cells dispersed from surgically resected human intestines proliferated in response to IL-4 when SCF was present, but not in response to IL-4 alone (66). Furthermore, many of the same T-cell–derived cytokines that support comitogenic responses from human mast cells, such as IL-3, IL-4, IL-5, and IL-6, also attenuate their apoptosis *in vitro* independently of SCF (67).

Cytokine[a]	Mouse		Human	
	Alone	Comitogenic	Alone	Comitogenic
SCF	+	N/A	+	N/A
IL-3	+	+	−	+
IL-4	−	+	−	+
IL-5	−	N/D	−	+
IL-6	−	+	−	+
IL-9	−	+	−	+/−
IL-10	−	+	−	−
GM-CSF	−	−	−	+/−

GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; N/A, not applicable; N/D, not done; SCF, stem cell factor.
[a] SCF is absolutely required *in vivo* in mice and *in vitro* in human models of mast cell development. Although comitogenic effects are observed for GM-CSF (human only) and IL-4 for mast cell growth *in vitro* from committed progenitors, both these cytokines inhibit mast cell derivation from uncommitted progenitor cell sources.

TABLE 24.1. Cytokines Active for Mast Cell Development

Taken together, the development of mast cells and of their committed progenitors is SCF dependent in the human, as in the mouse. Both intestinal mucosal mast cell hyperplasia *in vivo* and SCF-driven mast cell proliferation *in vitro* are augmented by a range of T-cell–derived cytokines that are similar, if not identical, in the two species (Table 24.1). The activity of T-cell–derived cytokines as cofactors for mast cell development and viability *in vivo* may help to explain the prominence of mast cells at sites of allergic inflammation in humans (68,69), as well as in the intestines of mice experimentally infected with nematode parasites (70), in which these T-cell–associated cytokines are abundant. Because mast cell subpopulations in both mice and humans are functionally, morphologically, and biochemically heterogeneous, regional differences in mast cell characteristics and numbers may reflect regional differences in available levels of SCF, the local repertoire of T-cell–derived cytokines, or both. Moreover, the lack of intestinal mucosal mast cells in T-cell immunodeficiencies in both mice and humans likely reflects the requirement for T-cell–derived cytokines in mast cell development at these mucosal surfaces in both species (34,46). Because of the evident parallelisms in mast cell development in mice and humans, the remaining sections of this chapter discuss human mast cell biology unless otherwise specified.

HOMING DETERMINANTS FOR MAST CELLS AND THEIR PROGENITORS

Chemoattractants

Although mast cell development in tissues is regulated by SCF and local T-cell–derived growth factors acting on committed progenitors, the mechanisms involved in the recruitment and distribution of the circulating pool of committed mast cell progenitors, and the movement of mast cells in tissues, have only been recently explored. Several chemoattractants with activity on mast cells have been identified using *in vitro* model systems. Recombinant soluble SCF is chemotactic for a transformed human mast cell line, HMC-1 (71). The chemotactic complement fragments, C5a and C3a, also elicit migration of HMC-1 (72). That complement fragments may support mast cell migration *in vivo* is upheld by the expression of the C5a receptor, CD88, by human mast cells in the synovium of patients with rheumatoid arthritis (73). Several angiogenic growth factors are chemotactic for mouse mast cells (74), a finding potentially relevant to the observed accumulation of mast cells at sites of new blood vessel formation.

The structurally homologous low-molecular-weight chemotactic cytokines known as chemokines are also likely involved in mast cell progenitor homing and in mast cell activation (75). In mice, the intramuscular injection of the recombinant chemokine RANTES (regulated on activation, normal T cell expressed and secreted) resulted in the accumulation of mast cells at the injection site (76). Antibody neutralization suggested that the chemokine macrophage inflammatory protein-1a (MIP-1a) was involved in mast cell degranulation in an *in vivo* mouse model of contact hypersensitivity (77). Although reagents that detect receptors for mouse chemokines are lacking, the development of antibody reagents that recognize human chemokine receptors (CCRs) has facilitated their study on human mast cells and their progenitors. Human mast cell progenitors derived *in vitro* from cord blood with SCF, IL-6, and IL-10 express at least four chemokine receptors based on cytofluorographic and functional analyses (ligand-induced calcium flux or chemotaxis): CCR3, the receptor for eotaxin, monocyte chemotactic proteins (MCP) 2 to 4, and RANTES; CCR5, a receptor for MIP-1a, MIP-1b, and RANTES; CXCR2, a receptor for IL-8, granulocyte chemotactic protein-2 (GCP-2), growth-related oncogene (GRO), epithelial neutrophil-activating peptide-78 (ENA-78), neutrophil-activating peptide-2 (NAP-2), and LPS-induced CXC chemokine (LIX); and CXCR4, a receptor for stromal cell–derived factor-1a (SDF-1a) and SDF-1b (75). The CCR3/CCR5/CXCR2/CXCR4-positive profile of chemokine receptors is unique to human mast cell progenitors from among hematopoietic cells on which these receptors are characterized. The transition of these progenitors into cytologically mature mast cells *in vitro* was accompanied by the disappearance of CXCR2, CXCR4, and CCR5, but the retention of CCR3 (60). The finding that mature human mast cells express CCR3 *in vivo* was recognized by immunohistochemistry, and its function was validated by a chemotactic response of human mast cells dispersed and purified from tissues to recombinant eotaxin (78). In this study, the mast cells expressing CCR3 were primarily those in the submucosa of the airway, whereas mast cells closest to the airway epithelium did not express CCR3; these findings suggest that chemokine receptor expression by mast cells may be regulated by microenvironmental factors. In a study with immunogold electron microscopy, human mast cells dispersed from skin expressed both CXCR2 (localized to their granule membranes) and another IL-8 receptor, CXCR1 (localized to their microplicae) (79). Both CXCR1 and CXCR2 were also expressed on the surface of HMC-1 cells (79), and recombinant IL-8 elicited both chemotaxis and calcium mobilization in HMC-1. Thus, composite evidence holds that mast cells and their committed progenitors express several chemokine receptors, and the profile of chemokine receptors is modified by both the microenvironment and by cell maturation, likely reflecting changes in their requirements for migration or retention. Because SDF-1 is constitutively expressed at multiple tissue sites, the expression of CXCR4 by mast cell progenitors suggests that SDF-1 may be important for their basal homing. The ligands for CCR3, CCR5, and CXCR2 are expressed in a variety of inflammatory circumstances; thus, these receptors are potentially relevant to the accumulation of mast cells in diverse inflammatory diseases (18,19,20,21,22 and 23).

Adhesion Receptors

The process of cell recruitment involves not only specific chemoattractants such as chemokines but also specific adhesive interactions between the trafficking cells and their microenvironment. Mature human mast cells dispersed from several tissues reportedly lack b_2 integrins (80), which are necessary for transendothelial migration of blood-borne leukocytes. Low levels of one b_2 integrin family member, aMb_2 (MAC-1), were expressed by mouse peritoneal mast cells (81). The finding that a targeted disruption of the aM subunit in mice resulted in reduced basal numbers of mast cells in several tissues suggested the potential relevance of MAC-1 as a homing determinant for mast cells and their progenitors, at least in rodents (81). Unlike the b_2 integrins, mast cells of both humans and mice abundantly and constitutively express several b1 integrins, many of which are counterligands for extracellular matrix proteins (82). The major fibronectin receptor of both mouse and human mast cells, a_5b_1, is highly expressed by mast cells dispersed from several human tissue sources (80,82). Dispersed mature human mast cells also express two receptors for laminin, a_3b_1 and a_6b_1 (80). A vitronectin receptor, avb_3, is absent from human mast cell progenitors derived *in vitro* from cord blood, but it is acquired as a feature of mast cell maturation *in vitro* (60), and it is expressed by mature human mast cells dispersed from tissues (80). Thus, mast cells express several receptors that likely facilitate their interactions with extracellular matrices and basement membranes *in vivo* under basal conditions, and at least one of these, avb_3, is acquired during maturation.

Along with lymphocytes, eosinophils, and basophils, mast cells express the a_4b_1 heterodimer (very late antigen-4; VLA-4) (80,82), which is especially important for the recruitment of other effector cells to sites of allergen-induced inflammation in experimental models (83). For blood-borne cells, VLA-4 serves as the major receptor for vascular cell adhesion molecule-1 (VCAM-1), which is induced on endothelial cells with priming by IL-4, IL-1, and other proinflammatory cytokines (84). The VLA-4/VCAM-1 interaction permits the rolling, firm adhesion, and transmigration of leukocytes across the endothelium. Additionally, lymphocytes and eosinophils, and likely mast cells, use VLA-4 as a receptor for fibronectin in the tissues. The functional importance of VLA-4 is supported by studies with the systemic administration of either monoclonal antibodies or small molecule inhibitors that block VLA-4/VCAM-1 and VLA-4/fibronectin interactions. These perturbations substantially attenuate allergen-induced pulmonary inflammation in rats, sheep, and guinea pigs (83,85,86,87 and 88). These studies support the role of VLA-4 not only in inflammation-based leukocyte homing but also in the activation of mast cells, because mast cell degranulation in a mouse model of passive cutaneous anaphylaxis was inhibited by antibody blockade of VLA-4 (89). Furthermore, the administration of an anti–VLA-4 antibody before allergen challenge attenuated immediate increases in pulmonary resistance, as well as several biochemical indices of early-phase mast cell activation (histamine and tryptase levels in bronchoalveolar lavage fluid, and biliary concentrations of *N*-acetyl-LTE_4) in sensitized brown Norway rats (90). Thus VLA-4 integrin may be particularly pertinent to mast cell function.

Finally, additional integrins that are lacking on mast cells constitutively may be induced by the cytokines available during inflammatory responses. For example, aLb_2, also known as lymphocyte function antigen-1 (LFA-1), is induced on the surfaces of mature cultured human mast cells by their incubation with IL-4 (91). The aE integrin is induced on mouse mast cells by transforming growth factor-b (TGF-b) (92). The induction of aLb_2 and aEb_7 on mast cell surfaces may facilitate their interaction with their counterligands on epithelial cells: intercellular adhesion molecule-1 (ICAM-1) and E-cadherin (93), respectively. Thus, the repertoire of mast cell–associated adhesion molecules is modified not only during cell maturation in tissues but also likely by microenvironmental factors encountered under inflammatory conditions.

MORPHOLOGIC AND FUNCTIONAL FEATURES OF MAST CELLS

Cytochemical and Immunochemical Heterogeneity

The unique staining characteristics of mast cells led to their identification by Ehrlich in the late 1800s (94). Mature tissue mast cells have abundant secretory granules with avidity for anionic stains, such as Alcian blue or toluidine blue, readily permitting their identification in tissue sections. Such stains elicit conversion to purple in mast cell granules, a property known as metachromasia (Fig. 24.1A). In all mouse mast cells and in most human mast cells, the granules also react with a substrate for chloroacetate esterase (a substrate for chymotryptic proteases), which results in a bright red color that is restricted to mast cells (Fig. 24.1B) and, to a lesser extent, neutrophils, which react less strongly. In humans, immunoreactivity with an antitryptase antibody (Fig. 24.1C) provides a reliable marker for mature mast cells.

The histochemical heterogeneity of mast cells was first studied by Enerback (95,96 and 97), who recognized that rat mast cells at different anatomic locations had different staining properties. The trivial terms “mucosal mast cells” (defined only for the small intestine) and “connective tissue mast cells” were adopted to designate anatomically and histochemically distinct populations in rodents. Mucosal mast cells in the gastrointestinal lamina propria and near and within the epithelial cell layer were identifiable by their metachromatic staining with Alcian blue dye, but not with safranin dye, and were rendered invisible by formalin fixation (95). Large numbers of mast cells with these mucosal features appeared in the small intestinal epithelium of mice infected experimentally with helminths and were absent in athymic mice, a finding implying T-cell dependence for their derivation as reactive mast cells (34). Connective tissue mast cells, exemplified by those in the mesentery and submucosa of the intestine and in the skin, were formalin-tolerant, safranin-positive cells (95,96 and 97), and they developed in normal numbers (constitutive mast cells) even in

athymic mice (34). The concept of mast cell heterogeneity has since encompassed histamine content, capacity for arachidonic acid metabolism in response to immunologic stimulation, and composition of neutral proteases, and it is likely to reflect several patterns of phenotypic behavior in different tissues. Indeed, as determined by neutral protease composition of their secretory granules, several tissue-related phenotypes of mast cells exist in mice (98). Although human mast cells do not counterstain with safranin, differences in the functional, ultrastructural, and biochemical features of the mast cells in different tissues support the concept of mast cell phenotypic heterogeneity in humans as well as in rodents.

The observed differences among mast cells at different locations fueled a debate on whether distinct mast cell populations arose from different progenitor cell sources. However, committed mast cell progenitors derived *in vitro* from bone marrow with IL-3 gave rise to both connective tissue and intestinal mucosal mast cells when they were infused into mast cell–deficient *W/Wv* mice (99), a finding supporting a common lineage. The concept that all mast cells arise from a single source was further supported by the observation that the injection of clonally derived peritoneal cell colonies from +/+ littermates restored the mast cells of all anatomic compartments in *W/Wv* mast cell–deficient mice with the appropriate tissue-specific mast cell phenotypes as defined by histochemical stains for the secretory granule proteoglycan class (100). Furthermore, the progeny of an immature, transformed mast cell line (V3-MC) injected into histocompatible BALB/c mice also acquired distinct tissue-specific patterns of protease expression that required both the acquisition and the deletion of proteases relative to the parent cell line (101). Finally, clonally derived, hyperplastic mast cells from patients with systemic mastocytosis exhibit tissue-specific phenotypic variations similar to the mast cells of normal individuals (102). Taken together, these observations support the conclusion that mast cells are derived *in vivo* from a single lineage of committed progenitors both in rodents and in humans, and the ultimate phenotype of the mature mast cells arising from these progenitors is the composite result of tissue-specific and regional differences in microenvironmental factors.

Ultrastructural Features

Mast cells can be readily identified in tissues on the basis of their ultrastructural features. Mast cells range between 7 and 20 µm in diameter, with 1- to 2-µm processes (microplicae) emanating from their plasma membranes (103,104 and 105) (Fig. 24.2A). The cytoplasm of mast cells is dominated by secretory granules. The secretory granules of human mast cells contain electron-dense material that is either amorphous or crystalline. The crystalline granules contain one of three structural arrangements: scrolls (Fig. 24.2B), gratings (parallel, electron-dense lines separated by lucent areas) (Fig. 24.2C), or lattices (two sets of parallel, electron-dense lines running in different directions) (Fig. 24.2D). All three patterns of crystal may be present in a single granule (104). When the cell is stimulated by IgE-dependent mechanisms, the crystalline structures become amorphous, and only amorphous granule material is discharged from the granules as they fuse with the plasma membrane (104). The mast cells in the bronchial epithelial layer of humans with asthma contain sparse, amorphous material, a finding indicating likely ongoing degranulation *in vivo* in the asthmatic state (68).

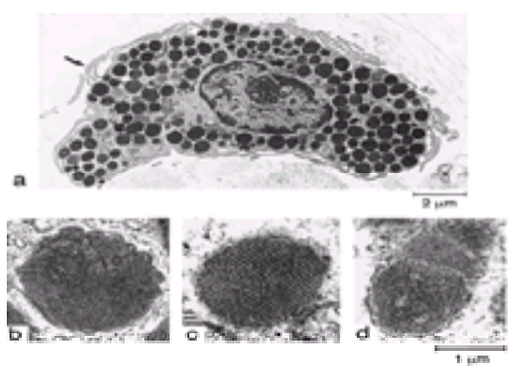

Figure 24.2. Ultrastructural features of mast cells from human skin. **A:** Transmission electron micrograph showing a mast cell containing many prominent electron-dense granules. Note 1- to 2-µm processes (microplicae) emanating from the plasma membrane *(arrow).* Higher magnification of electron-dense granule crystals shows three structural arrangements: scrolls **(B),** gratings **(C),** and lattices **(D).** (Photomicrograph courtesy of Daniel S. Friend, M.D., Harvard Medical School, Boston.)

The relative amounts of these granule structures differ among the mast cells at different tissue locations in humans. For example, the granules of mast cells in breast parenchyma, skin, axillary lymph nodes, and bowel submucosa contain relatively few scrolls (“scroll-poor” granules) but are rich in gratings and lattices (105,106 and 107), whereas mast cells in the lung alveoli and in the bowel mucosa contain many scrolls (“scroll-rich”) but relatively few gratings and lattices (103,104,106,107). The differences in ultrastructural features of human mast cell granules probably reflect corresponding differences in protease and proteoglycan content (see later). The findings that the induction of heparin proteoglycan biosynthesis in mouse IL-3–driven mast cells by 3T3 fibroblast coculture is accompanied by changes in granule ultrastructure (108,109) and that the induction of chymase expression in cultured human mast cells by recombinant IL-4 is accompanied by the appearances of grating and lattice-type granule crystals (110) support the correlation between granule content and ultrastructural appearance, as well as a flexible developmental program for both these mast cell features.

The ultrastructural flexibility of mast cell granule phenotype is illustrated by experimental *Trichinella spiralis* infection in BALB/c mice (111). The mast cells in the jejunal muscle and submucosa of infected mice exhibited spheric, electron-dense granules without crystals before infection and remained unchanged throughout the course. The reactive mast cells that appeared in the jejunal mucosa had fewer, larger granules, which were irregularly shaped, owing to their content of lattice-rich crystals. During the resolution of the intestinal mastocytosis, the numbers of intraepithelial mast cells declined, and those remaining showed fragmentation and dissolution of their crystals. Some of the mast cells in the lamina propria during resolution (but not the onset) of the mast cell hyperplasia contained fragmented crystals with a lattice structure similar to those in the intraepithelial mast cells during the peak of the hyperplasia. These alterations in granule ultrastructure are accompanied by sequential changes in the protease phenotype of the mast cells (111). That the ultrastructural and immunohistochemical phenotype of mast cell granules changes with the evolution and resolution of a T-cell–dependent intraepithelial jejunal hyperplasia highlights the plastic nature of mast cells.

Mast Cells and FceRI

FceRI is the major activating receptor on the mast cells of both humans and rodents (112), and its high-level expression is a hallmark of mast cells. When occupied by monomeric allergen-specific IgE and cross-linked by a multivalent allergen, FceRI transduces signals that result in immediate granule fusion and exocytosis, arachidonic acid metabolism, and induction of cytokine and chemokine gene transcription. IgE-mediated activation of mast cells occurs exclusively through FceRI and is thought to account for the clinical manifestations of rhinitis, conjunctivitis, urticaria, angioedema, and bronchoconstriction that immediately follow allergen challenge in susceptible hosts. Additionally, FceRI is a target of autoantibodies produced by a subset of patients with chronic urticaria (113).

The FceRI of mast cells and basophils is a tetrameric receptor composed of one Fc-binding a subunit with a single transmembrane domain, a pair of identical g subunits with short extracellular domains and long cytoplasmic tails, and a single b subunit that possesses two extracellular loops, four transmembrane domains, and two long cytoplasmic tails (Fig. 24.3) (112). The a subunit is required for binding to the Fc portion of IgE but has no intrinsic signaling properties, because deletion of its cytoplasmic tail does not abrogate FceRI-mediated cell activation (114). Conversely, the two g subunits and b subunit of FceRI have no intrinsic ligand-binding activity but associate as a functional subunit in FceRI-mediated signal transduction after receptor activation. Both the b and g subunits possess immunoreceptor tyrosine activation motifs (ITAM) in their cytoplasmic tails, which are conserved among multiple receptors involved in the initiation of diverse immune responses. The b subunit is especially important for amplification of FceRI-mediated signaling (114,115). Although FceRI can exist as an ag2 heterotrimer on human monocytes, dendritic cells, and other hematopoietic cell types (116,117,118 and 119), its signaling efficiency is markedly attenuated compared with the tetramer on mast cells and basophils. The amplifying capacity of the b subunit may be pertinent to the genetics of human atopic disease, because polymorphisms in the chromosome 11 locus that encodes this subunit are associated with an increased risk of asthma and bronchial hyperreactivity in some, but not all, human populations (120,121 and 122).

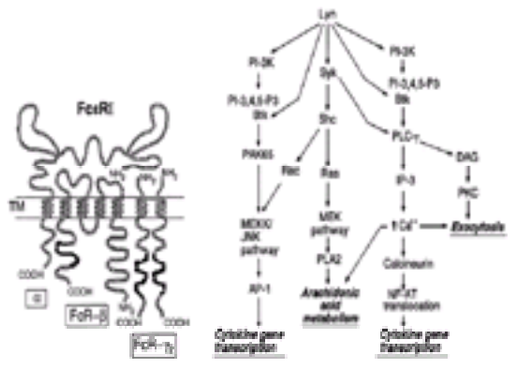

Figure 24.3. Left: Schematic representation of the tetrameric FceRI structure. The functional receptor is composed of single FceRIa (a) and FcR-b subunits and a pair of FcR-g subunits. The a and FcR-g subunits possess single transmembrane domains (TM), whereas FcR-b has four. The immunoreceptor tyrosine activation motifs of the b and g subunits are represented in bold. (From Kinet JP. The high-affinity IgE receptor (FceRI): from physiology to pathology. *Annu Rev Immunol* 1999;17:931–972. With permission from the *Annual Review of Immunology,* Vol. 17, © 1999, by Annual Reviews www.AnnualReviews.org.) **Right:** After FceRI cross-linkage, Lyn and Syk initiate a cascade of signal transduction pathways that couple to mast cell effector responses (bold type). See text for abbreviations.

The antigen-induced clustering of IgE-bound tetrameric FceRI results in several downstream signaling events that couple to mast cell effector systems (Fig. 24.3) (112). The Lyn tyrosine kinase, which is constitutively bound to the b subunit, is phosphorylated and, in turn, phosphorylates and activates the ITAMs on the b and g subunits of adjacent receptors. Two phosphorylated tyrosines on the FcRg ITAM serve as the membrane-targeting signal for the tandem SH-2 domains of Syk tyrosine kinase and bring it into proximity with Lyn. Lyn then phosphorylates Syk on tyrosine residue 518, resulting in autophosphorylation of Syk on other residues. Syk phosphorylates phospholipase C-g (PLC-g), which generates inositol 1,4,5-trisphosphate (IP_3), essential for the mobilization of calcium that is necessary for degranulation and nuclear import of calcineurin-dependent nuclear factor of activated T-cell (NFAT) transcription factors, leading, in turn, to the transcription of cytokine genes. Syk also phosphorylates Shc, leading to activation of Rac and Ras, and their downstream pathways (MEKK/JNK and MEK, respectively). Lyn activates phosphatidylinositol-3-kinase, which generates phosphatidylinositol-3,4,5-P3 in the vicinity of the signaling cluster. The phosphatidylinositol-3,4,5-P3 becomes the membrane targeting signal for the PH domains of the Tec family kinases, which includes Bruton tyrosine kinase (Btk), bringing them into proximity so that Lyn can phosphorylate them at tyrosine residue 551. Tec kinases then become further autophosphorylated and provide an additional or alternative route for the activation of PLC-g. Btk also phosphorylates and activates PAK65, leading to activation of the MEKK/JNK pathway, with activation of activator protein-1 (AP-1) transcription factors. Based on studies with mast cells derived from Btk-deficient mice, Btk is especially important for the transcription of cytokine genes after FceRI-mediated mast cell activation (123,124), and it is less important for exocytosis. More comprehensive discussions of FceRI-mediated signal transduction pathways appear in published reviews (112,125).

Although the high-level expression of FceRI on mast cells implies a potentially important physiologic role, such a function has been elusive. Mice rendered genetically deficient in FceRI by targeted disruption of the FceRIa or the Fcb subunits are developmentally and immunologically normal (126). When infected experimentally with the nematode *Schistosoma mansoni,* FceRIa-deficient mice normally eliminate worms from the intestine but develop an increased volume of hepatic granulomas and a greater degree of hepatic fibrosis than their FceRIa-sufficient littermates (126). In the FceRIa-deficient mice infected with *Schistosoma mansoni,* a splenic non-B, non-T cell population of unclear origin (possibly an innate natural killer [NK] cell–related population) did not secrete in IL-4 *in vitro* compared with the same cell population extracted from their normal similarly infected littermates. Thus, although FceRI is not required for elimination of *Schistosoma mansoni,* it does appear to modify the extent of hepatic disease that occurs in response to this infection. An additional role for FceRI has been proposed in the host response to *Haemaphysalis longicornis* ticks, because deficiencies in either mast cells or IgE markedly impair the ability of mice to eliminate the parasite (127,128).

Regulation of Mast Cell FceRI Expression and Function

The recognition that serum IgE levels correlate with the numbers of IgE binding sites on circulating human basophils prompted speculation that IgE and its receptor share a common regulatory control mechanism (129). Incubation of transformed rat basophilic leukemia (RBL) cells *in vitro* with monomeric IgE increased their surface levels of FceRI (130,131). This IgE-mediated upregulation of FceRI was attributed to stabilization of existing receptors at the cell membrane, because it was insensitive to the protein synthesis inhibitor cycloheximide. Later, mast cells from an IgE-deficient strain of mouse were found to be profoundly deficient in surface FceRI (132). This condition was corrected *in vivo* by the injection of exogenous IgE into the mice. Furthermore, FceRI expression by IL-3–driven mast cells derived from the bone marrow of these mice could be upregulated by incubation with IgE *in vitro.* Incubation of mast cells with IgE enhanced not only their FceRI expression but also signal transduction and mediator release in response to FceRI cross-linking. These observations confirmed that IgE regulates the surface levels of its own receptor, with associated incremental functional effects, and that decreased IgE concentrations *in vivo* lead to decreased levels of membrane expression of FceRI. The finding that administration of a humanized murine antihuman IgE antibody to atopic individuals markedly decreased the levels of FceRI on the surfaces of their circulating basophils (133) validates these observations in humans.

Locally derived cytokines may also serve a regulatory role in FceRI expression and signaling. Human mast cells derived *in vitro* from cord blood mononuclear cells that were cultured in the presence of SCF and IL-6 responded to the addition of exogenous IL-4 with dose- and time-dependent enhancement of their surface FceRI expression (134). Similarly, human mast cells purified from dispersed intestinal tissue responded to recombinant IL-4 *ex vivo* with upregulated FceRI expression and priming for IgE-dependent activation (66). Unlike the effect of IgE, IL-4 caused an increased steady-state level of mRNA encoding FceRIa (134). Given that they act by separate mechanisms, it is not surprising that IL-4 and IgE are synergistic for FceRI expression and FceRI-mediated mast cell activation *in vitro* (135).

Mast Cells and FcgRIII

Although IgE-dependent mast cell activation and anaphylaxis absolutely require the intact FceRI (136), anaphylaxis can also occur, at least in rodents, through IgG-dependent mechanisms. Rodent mast cells bear the low-affinity receptor for IgG, FcgRIII (137), which has not yet been identified on human mast cells. When ligated *in vitro* by antibody, FcgRIII induces mouse mast cells to degranulate and release LTC_4, similar to their responses through FceRI (137), whereas mast cell activation by FcgRIII *in vivo* can mediate anaphylaxis in mice (138,139). Furthermore, FcgRIII-mediated mast cell activation plays a dominant role in an experimentally induced Arthus reaction by facilitating the deposition of immune complexes (140). Both FceRI and FcgRIII are multimeric receptors that share the b and g subunits essential for signal transduction (136,137). FcgRIII-mediated anaphylaxis is amplified in mice that are deficient in FceRIa, a finding reflecting competition between the distinct a subunits of FceRI and FcgRIII for a limited number of shared b and g subunits (139). The common g subunit also participates in heterodimeric or homodimeric arrangements with other multimeric immune receptors, such as the T-cell antigen receptor, FcgRI, and the Fc receptor for IgA (FcaR), depending on the cellular context (141,142 and 143).

Mast Cell Activation through Non-Fc Receptors

Stimulation of mouse (144) and human (145) mast cells with recombinant soluble SCF promotes their exocytosis and arachidonic acid metabolism through c-*kit,* with kinetics that are similar to IgE-dependent activation. Mast cells release histamine in response to the anaphylactogenic complement fragments, C3a and C5a (146). These complement fragments act through pertussis toxin–sensitive, G protein–linked receptors (147). Some chemokines, whose receptors are also G protein linked, can also induce exocytosis and arachidonic acid metabolism by mast cells, as demonstrated for MIP-1a (77) and MCP-1 (148) in *in vivo* models.

Inhibitory Receptors of Mast Cells

The recognition of receptors that bear a common immunoreceptor tyrosine-liked inhibitory motif (ITIM) has led to increased understanding of the regulation of immune cell activation responses (149). Mouse mast cells possess two closely related low-affinity Fc receptors for IgG, FcgRIIb1 and FcgRIIb2 (150,151), that emanate from alternative splicing events of mRNA from the FcgRIIb gene. Both bear an ITIM motif in their cytoplasmic tails (152). When coligated with FceRI, FcgRIIb1 and FcgRIIb2 inhibit mast cell exocytosis by recruiting *src*-homology inositol phosphatase-1 (SHIP-1), which results in the inhibition of sustained calcium flux and downstream events (152). The relevance of this inhibitory function for FcgRIIb isoforms in the modulation of mast cell function is supported by the finding that mice deficient in the FcgRIIb gene exhibit an augmented experimentally induced IgE-dependent anaphylactic response *in vivo* (153). Although these findings reveal a mechanism by which mast cell activation in a mouse adaptive immune response can be counterregulated, these inhibitory Fc receptors have not yet been reported for human mast cells.

Another inhibitory receptor expressed by mouse mast cells is gp49, named for its molecular size (154). gp49b1 contains two extracellular immunoglobulin-like domains and a pair of cytoplasmic ITIM motifs. gp49b1 shares homology with a group of NK cell–related receptors with immunomodulatory functions known as killer immunoglobulin-like receptors (KIR) (155). As with FcgRIIb, experimental cocross-linkage of gp49b1 and FceRI inhibits mast cell exocytosis, as well as LTC_4

generation (154). Unlike FcgRIIb, however, the ITIM motifs of gp49b1 associate with *src*-homology-2 domain-containing phosphatase-1 (SHP-1) and SHP-2 (156), and coligation of gp49 with FceRI inhibits both transient and sustained calcium flux in mouse mast cells. Human genes that are closely related to gp49 and are localized to human chromosome 19 (termed leukocyte immunoglobulin-like receptors or LIRs) have been cloned (157,158 and 159), and their mRNA transcripts have been detected in human mast cells by reverse transcriptase–polymerase chain reaction (157).

MAST CELL–ASSOCIATED MEDIATORS AND EFFECTOR FUNCTIONS

Histamine

Histamine is present in the granules of both human and rodent mast cells in all tissue compartments. Human mast cells typically contain 1 to 2 pg of histamine per cell (160), similar to the histamine content of mast cells in rodent intestinal mucosa and about 10-fold lower than the content of mast cells in rodent connective tissue (161). Histamine has a positive charge and associates with carboxyl groups of proteoglycans in mast cell granules. After exocytosis, histamine dissociates from the mast cell proteoglycans at neutral pH (see later). Histamine acts through three classes of receptors (162) to mediate several functions, including bronchial and gastrointestinal smooth muscle contraction, vasodilatation and vasopermeability, secretion of gastric acid, and induction of cutaneous pruritus. Histamine also exerts both stimulatory and inhibitory effects on immune cells, including the following: enhancement of NK cell activation; stimulation of IL-6 synthesis by B cells; inhibition of mitogen- and antigen-mediated T-cell proliferation; inhibition of neutrophil activation; and inhibition of tumor necrosis factor (TNF)-a, IL-1, interferon-g, and IL-2 production by monocytes and T cells (163). Thus, histamine has both proinflammatory and immunomodulatory functions.

Mast Cell Proteases

Granule-associated trypsin-like (tryptases) (164) and chymotrypsin-like (chymases) (165) proteolytic enzymes are hallmarks of mast cells in all mammalian species studied. Two distinct patterns of protease composition in human mast cells were initially reported by Irani and colleagues (166). Using immunocytochemical techniques with antibodies directed against tryptases and chymase, these investigators recognized that human mast cells expressed either both tryptase and chymase or tryptase alone (designated TC and T mast cells, respectively). Mast cells with these two immunohistochemical patterns were found to have different anatomic distributions, with TC mast cells predominating in the skin and submucosa of the small intestine and T mast cells predominating in the intestinal and bronchial mucosa and in the alveoli of the lung (166). Later, this same group reported that the TC subset of human mast cells possessed two additional proteases based on immunolocalization: a carboxypeptidase A (CPA) (167) and a cathepsin G–like chymotryptic protease (168). The anatomic distributions for T and TC mast cells, combined with the observation that T mast cells were depleted at the gastrointestinal tract mucosal surface in humans with acquired T-cell immunodeficiencies (with normal numbers of submucosal TC mast cells in the same specimens) (46), raise the possibility that human intestinal T mast cells are a T-cell–dependent phenotype, analogous to the intraepithelial mast cells in the mouse jejunum, whereas the TC subset is the human equivalent of the constitutive, SCF-dependent rodent mast cells found in the connective tissues. The T versus TC mast cell dichotomy in the human, however, likely does not reflect the true diversity of the human mast cell proteases. A cluster composed of at least five distinct human tryptase genes has been identified (169). It is possible that each human tryptase gene is differentially regulated, and their respective expression patterns may depend on anatomic site, locally available growth factors, and the presence or absence of disease. If so, T mast cells of human lung may not be functionally or immunohistochemically equivalent to T mast cells of other tissues and may express different tryptases in allergic inflammation than under basal conditions. Furthermore, no data are available regarding the number and phenotype of lung mast cells in humans with T-cell immunodeficiencies; thus, the expression of tryptases or chymase could be regulated differently from that in the mast cells of the intestine.

The original studies of human mast cell protease expression used immunohistochemical probes that distinguished the known tryptases and chymase. Two highly homologous human tryptase cDNAs, tryptase a (170) and tryptase b (171), also known as tryptase II (172), encode functionally distinctive and well-characterized enzymes. Studies with specific monoclonal antibodies that distinguish between immunoreactive a and b/II tryptases revealed that a tryptase was present in human plasma and reflected the total body mast cell burden (173). In contrast, b/II tryptase is not found in plasma under normal conditions but is released by mast cells on activation (174). Thus, the measurement of these tryptases in human plasma is clinically useful in the diagnosis of systemic mastocytosis and anaphylaxis, respectively. Although a and b/II tryptases are highly homologous, structural dyshomology exists in their putative substrate-binding domains and accounts for differences in substrate specificity (175). Both a and b/II tryptase genes reside on human chromosome 16, within the previously mentioned cluster containing four additional tryptase genes that have been mapped (169,176). A cDNA encoding one of these novel human tryptases has been cloned in both human and mouse and encodes a tryptase with a novel transmembrane domain (176). Thus, each of these tryptase genes likely arose from a single ancestral gene to encode enzymes with distinct functions. To date, antibody reagents and molecular probes have not been developed or used for the full characterization of the expression patterns for the additional human tryptases.

The putative effector functions of the mast cell tryptases, as defined by *in vitro* assays or by pharmacologic studies *in vivo,* are diverse. In addition to the transmembrane tryptase (176), mouse mast cells have two homologous granule-associated tryptases, designated mouse mast cell protease-6 (mMCP-6) and mMCP-7 (177,178). mMCP-7 is released into the circulation of mice after experimentally induced anaphylaxis (179), where it potently and selectively degrades plasma fibrinogen, even in the presence of plasma protease inhibitors (180). In contrast, mMCP-6 is not detected in plasma after anaphylaxis but is retained along with the exocytosed secretory granule core in connective tissues. Unlike mMCP-7, mMCP-6 does not degrade fibrinogen; but when mMCP-6 is instilled as a recombinant protein into the peritoneal cavity of mice, it elicits a marked, selective, and sustained influx of neutrophils (181), which is attributed to mMCP-6–mediated induction of IL-8 expression by endothelial cells. This property of endothelial cell stimulation for IL-8 production *in vitro* is shared with recombinant human tryptase b/II, which also induces expression of IL-1b by endothelial cells (182). Human tryptase b/II also stimulates the formation of vascular tubes *in vitro,* a finding suggesting a role in angiogenesis (15), and it elicits fibroblast (14) and epithelial cell (183) proliferation *in vitro,* thus implying a role in remodeling and repair after neutrophil-mediated tissue injury. The activating effects of tryptases on multiple cell types of stromal derivation suggest the possibility that tryptases act through specific cell-surface receptors. Indeed, both human a and b/II tryptases activate protease-activated receptor-2 (PAR-2) (184), a 7-transmembrane–spanning receptor expressed by several stromal cell types that requires proteolytic modification of its extracellular domain for its activation (185). Finally, human tryptases have been proposed to potentiate bronchoconstriction in response to histamine (186), an effect ascribed to the enzymatic cleavage of inhibitory airway neuropeptides. The finding that pretreatment of sensitized sheep with specific inhibitors of tryptase activity attenuates the pathobiologic consequences of allergen exposure (187) may reflect inhibition of each of these actions *in vivo.*

Only one mast cell–specific chymase gene has been identified in humans (188), in sharp contrast to the mouse, in which at least nine mast cell chymase genes exist (189). Human mast cell chymase, like other members of the chymase family, cleaves angiotensin I to form angiotensin II (190,191), a function that is potentially germane to the homeostatic role of mast cells in the local regulation of vascular tone and perfusion. A dog mast cell chymase cleaves and activates a 92-kd gelatinase (192,193), a member of the matrix metalloproteases implicated both in the migration of leukocytes and in tumor metastasis. A role for mast cell chymases in the extracellular cleavage and activation of angiogenic factors has been proposed as a determinant of tumor invasiveness (194). Recombinant human chymase cleaves type 1 procollagen and initiates collagen fibril formation (195). Human mast cell chymase cleaves SCF (196), and it yields a product that retains activating and mitogenic functions (197). Moreover, human chymase stimulates secretion by bronchial mucus glands (186). Thus, chymase may be involved in wound repair, extracellular matrix turnover, angiogenesis, mucus secretion, and the local modulation of vascular caliber and tone.

As noted earlier, tryptase and chymase are distributed differently in human mast cells, with both tryptase a and tryptase b/II expressed by the mast cells of all human tissue distributions and chymase limited to the mast cells in connective tissues and the perivascular regions (167). As determined by monoclonal antibodies that recognize both tryptase a and tryptase b/II, mast cells differ in their quantities of these tryptases. For example, the mast cells dispersed from the epithelial layer of nasal polyps contained fivefold less tryptase than submucosal mast cells from the same specimens (198). Dispersed human intestinal mucosal mast cells contained threefold less tryptase than dispersed skin mast cells (160). Basophils also contain minute quantities of tryptase (199); and mRNA encoding tryptase a, but not tryptase b, is detected in basophils by reverse transcriptase–polymerase chain reaction (200). Circulating metachromatic cells that would otherwise have been characterized as basophils but stained immunocytochemically for tryptase, chymase, and CPA were found in the peripheral blood of patients with allergy, asthma, and drug reactions, respectively, but not in the blood of healthy subjects (201). The finding that several patterns of protease expression and differences in tryptase content have been identified in subsets of mast cells makes it likely that tissue and microenvironment-specific factors regulate their patterns of protease expression.

The finding that patterns of protease expression by mast cells reflect microenvironmental influences is supported by extensive studies *in vitro* with mouse mast cells. IL-3–driven bone marrow–derived mouse mast cells from BALB/c mice express both protein and steady-state levels of RNA encoding two tryptases (mMCP-6 and mMCP-7) (176,177), a chymase (mMCP-5) that is highly homologous to human chymase (202), and CPA (203). Mouse mast cells derived in the presence of SCF, rather than IL-3, express a different protease profile that includes another chymase, mMCP-4 (204). The expression of two additional chymases, mMCP-1 and mMCP-2, both of which are associated with mouse mucosal mast cells *in vivo,* was induced by exposure of IL-3–driven bone marrow–derived mast cells to IL-10 (205) or IL-9 (206) *in vitro.* Nuclear run-on analyses revealed that multiple protease genes were constitutively transcribed in these mast cells, but the steady-state levels of mRNA encoding mMCP-1 and mMCP-2 depended on mRNA stabilization mediated by IL-10 (207). Thus, multiple protease genes are transcribed simultaneously by mast cells, but only some are expressed at the steady state. This mechanism may permit mast cells to change their repertoire of bioactive proteases rapidly *in vivo* under appropriate inductive circumstances, as reflected by tissue-specific differences in protease expression in mouse mast cells *in vivo* (98,208), as well as the changes in protease expression in the mast cells at a single tissue site during the onset and resolution of helminth-induced reactive mast cell hyperplasia (111). The finding that exogenous recombinant IL-4 induced chymase immunoreactivity in a population of cord blood–derived human mast cells *in vitro* that were initially positive for tryptase alone suggests that human mast cells also alter their protease composition in response to the microenvironment (110).

Mast Cell Proteoglycans

Like all granulated hematopoietic cells, mast cells have proteoglycans in their secretory granules. All secretory granule proteoglycans contain a common peptide core (209,210 and 211), called serglycin for its repetitive serine and glycine residues that allow glycosaminoglycans to attach to every second and third serine residue. This structure also likely accounts for the resistance of proteoglycans to degradation by bound proteases that are freed from their activating peptide. The secretory granules of mast cells contain biochemically distinct species of proteoglycans that differ in sulfation of their respective glycosaminoglycan side chains. Mast cells dispersed from human tissues contain proteoglycans that are rich in heparin (heparin proteoglycans) (212,213) and proteoglycans that are rich in chondroitin sulfate E (214,215). Mouse and rat mast cells also contain both species of proteoglycans, and the mast cells of their connective tissue are especially rich in heparin proteoglycans (216). Conversely, the mast cells of the rat intestinal mucosa contain lesser amounts of heparin, and chondroitin sulfate E or di-B proteoglycans predominate (217,218). These differences in proteoglycan content account for striking histochemical differences between these two populations in rodents; the heparin-rich content of rat connective tissue mast cells permits their uptake of safranin or berberine sulfate dyes. In contrast, the relative lack of heparin in mouse intestinal mucosal mast cells and in mast cells derived *in vitro* with IL-3 renders them safranin negative.

As is the case with the mast cell proteases, the proteoglycan content of rodent mast cells is not a fixed feature of their phenotype. Mouse bone marrow–derived, IL-3–driven mast cells cocultured with a monolayer of fibroblasts convert to a heparin-positive phenotype (108,219,220). This same culture condition also sustains the viability of the mouse mast cells in the absence of exogenous growth factors (219); it markedly augments their IgE-dependent exocytosis, production of PGD_2, LTB_4, and LTC_4 (220), and it promotes the development of electron-dense granules. Rat peritoneal mast cells (221), human lung-derived mast cells (222), and human cord blood–derived mast cells (223) also survive on fibroblast monolayers and acquire augmented IgE-dependent activation responses *in vitro.* These changes in functional, biochemical, and ultrastructural phenotype of mast cells that are elicited by fibroblast coculture suggest that mast cell–fibroblast interactions, mediated by the c-*kit* receptor (224), help to determine the biochemical and functional phenotype of mast cells in connective tissues.

Intracellular functions of proteoglycans include the storage and packaging of mast cell granule constituents. The acidic (negatively charged) proteoglycans form the basic structural components of large, macromolecular complexes that are stored and released from mast cell granules during exocytosis (225,226 and 227). These complexes are composed of highly acidic proteoglycans associated with basically charged proteases, as well as histamine and b-hexosaminidase. With exocytosis and release into the extracellular environment at neutral pH, histamine and b-hexosaminidase dissociate from the complex. The relative charges of the protease and the proteoglycans determine the destiny of the proteases after exocytosis. For example, the tryptase mMCP-7 interacts with proteoglycan through histidine and diffuses away from the complex after exocytosis. Conversely, mMCP-6 binds to proteoglycan through arginine or lysine, and the positive charge of these residues prevents its diffusion from the complex and results in its retention in the tissue (179). Furthermore, the chymase mMCP-1, which is induced in the intraepithelial mast cells arising in the jejunum during helminthic infection (228), diffuses from the chondroitin sulfate E proteoglycan that predominates in these mast cells. In human mast cells, chymase and CPA (which are expressed in the same subset of mast cells) are complexed with a proteoglycan subspecies (likely containing heparin) that is different from the subspecies complexed with tryptase (likely chondroitin sulfate E) (229). The targeted disruption of the *N*-acetyl/*N*-sulfotransferase-2 (NDST-2) gene, an enzyme required for heparin biosynthesis, revealed that heparin proteoglycans are required for mast cells to express immunoreactive mMCP-4, mMCP-5, and CPA (230,231), even though the mast cells of these mice contained steady-state levels of mRNA for these proteases that were comparable to those found in the mast cells of normal congenic control mice. The expression of immunoreactive tryptases mMCP-6 and mMCP-7 were unaffected in these NDST-2 knock-out mice. It thus appears that heparin proteoglycan synthesis is absolutely required for the normal expression of chymases and CPA but not tryptases.

Arachidonic Acid Metabolism

Both rodent and human mast cells rapidly synthesize the eicosanoid inflammatory mediators, LTC_4, LTB_4, and PGD_2 from endogenous membrane arachidonic acid stores when they are stimulated by FceRI (232,233) or by c-*kit* with recombinant soluble SCF (145). In response to either stimulus, arachidonic acid is released from cell membrane phospholipids by the action of a calcium-dependent cytosolic phospholipase A_2 ($cPLA_2$) (234) and is converted sequentially to 5-hydroperoxyeicosatetraenoic acid (5-HPETE) and then to LTA_4 by the actions of 5-lipoxygenase (5-LO). 5-LO is reversibly translocated from the cytosol to the perinuclear envelope (235), and it requires the cooperation of an integral membrane protein, 5-lipoxygenase–activating protein (FLAP) (236), for its metabolic function. LTA_4 is then converted by an LTA_4 hydrolase to LTB_4 (237), or it is conjugated to reduced glutathione by LTC_4 synthase (LTC_4S) (238), an integral membrane protein with homology to FLAP, to form LTC_4, the parent compound of the cysteinyl leukotrienes. Both LTB_4 (239) and LTC_4 (240) are exported to the extracellular space by distinct, energy-dependent steps. LTB_4 is a potent chemotactic mediator for neutrophils (241), through a 7-transmembrane–spanning receptor (242). LTC_4 is sequentially converted extracellularly to the receptor-active metabolites, LTD_4 and LTE_4 (243). These mediators, acting through another 7-transmembrane receptor, Cys-LT-1 (244), are potent bronchoconstrictors in humans (245,246) and mediators of vascular permeability (247); they also induce mucus secretion by isolated airways *in vitro* (248), and they recruit eosinophils to the airway wall when experimentally instilled into human subjects *in vivo* (249). PGD_2 is generated by the conversion of arachidonic acid through the sequential actions of prostaglandin endoperoxide synthase-1 (PGHS-1) or PGHS-2, and the hematopoietic form of PGD_2 synthase (250). PGD_2, like the cysteinyl leukotrienes, is a bronchoconstrictor (251), and its active metabolite, 9a,11b-PGF_2, is a potent constrictor of coronary arteries (252). Thus, the lipid mediators of mast cells are likely involved in several aspects of allergen-induced tissue dysfunction, including acute airflow obstruction, alterations in vascular caliber and tone, and leukocyte recruitment.

As with the profile of mast cell granule constituents, mast cell subpopulations differ in their patterns of arachidonic acid metabolism. Rat peritoneal mast cells, a prototypical constitutive mast cell population, respond to IgE-dependent activation with preferred generation of PGD_2, whereas mast cells from the rat intestinal mucosa generate LTC_4 in preference to PGD_2 (233,253). Human mast cells from different tissue sites also display heterogeneity of arachidonic metabolism. Mast cells from human intestine generated a wide range of PGD_2 (1 to 55 ng, mean = 21.3 ng) and cysteinyl leukotrienes (0.2 to 14.2 ng, mean = 4.4 ng) per 10^6 mast cells, when they were stimulated *in vitro* with anti-IgE (103). Human lung tissue mast cells generated levels of LTC_4 and PGD_2 comparable to their intestinal counterparts (254,255). In contrast, human uterine mast cells generated larger quantities of both PGD_2 (89 ng/10^6 cells) and LTC_4 (45 ng/10^6 cells) (256), whereas human skin mast cells generated PGD_2 and almost no LTC_4 (257). Thus, both rodent and human mast cells exhibit several patterns of arachidonic acid metabolism based on their tissue locations. The pattern of intertissue heterogeneity of arachidonic acid metabolism exhibited by human mast cell subsets does not parallel the heterogeneity of their corresponding protease composition, a finding indicating that these features are regulated differently.
