81 THE IMMUNOCOMPROMISED HOST

Catherine J. Wu, M.D., and Jerome Ritz, M.D.

Normal immune competence relies on the coordinated activity of a variety of hematopoietic cells [granulocytes, monocyte/macrophages, specialized antigen-presenting cells, natural killer (NK) cells, T cells, and B cells] and hematopoietic cell-derived factors (complement, cytokines, and antibodies). Both innate and adaptive (Chapter 1) immune mechanisms are essential for generating a robust and effective response to microbial or viral challenge.

The clinical spectrum of disease in patients with deficiencies in single or multiple components of this complex system demonstrates the importance of each of these components in maintaining immune competence. Some immune deficiency states arise as a result of *primary* (congenital) defects (Chapter 28). These include immunodeficiencies affecting T cells, such as DiGeorge syndrome, whose etiology lies in defective thymic development, or B cells, such as combined variable immunodeficiency, in which antibody production is impaired. Other primary immunodeficiency states, such as Chediak-Higashi disease, affect predominantly neutrophils, in which neutrophil chemotaxis and granule function are defective. Although primary immune deficiencies are rare, they have provided important information about the role of specific components of the immune response as well as interactions between different elements of the immune system.

Acquired immune deficiencies are more commonly encountered, either as a result of systemic illness or secondary to therapy for other illness. The sequelae of infection by human immunodeficiency virus (HIV), in which $CD4^+$ T cells are progressively depleted, is an illustrative example of a systemic illness that results in acquired immune deficiency. Other systemic illnesses that result in immune compromise include collagen-vascular disease (Felty syndrome, systemic lupus erythematosus), hematologic malignancy [multiple myeloma, chronic lymphocytic leukemia (CLL)], aplastic anemia, and nutritional deficiency.

Modern therapies for serious systemic illnesses can cause significant immune impairment. Immunocompromise due to neutropenia after chemotherapy is a common problem in oncologic clinical practice, and increases the risk of life-threatening infection. Bone marrow transplantation (BMT) results in a prolonged period of immune deficiency as the transplanted immune system reconstitutes from hematopoietic progenitor cells. Immunosuppressive agents (e.g., cyclosporine, tacrolimus, and corticosteroids) are used extensively after bone marrow and organ transplantation as well as in the treatment of rheumatologic and oncologic disease, and significantly compromise normal immune function. Systemic illnesses often affect multiple components of the immune system, and reflect the coordinated nature of the immune response against pathogens. Nonetheless, several acquired immune-deficient states can affect predominantly one arm of the immune response, and this can serve to highlight the importance of these particular functions in host defense. Regardless of whether immune compromise is due to primary or acquired deficiency, improved understanding of which immune components are impaired can help identify the possible pathogens to which the immunocompromised host is susceptible, and direct therapy. In the following sections, components of the immune response are considered individually, and the acquired deficiency states associated with each, and possible treatments are described.

ACQUIRED COMPROMISE OF NEUTROPHIL FUNCTION

Manifestations

Clinically, acquired neutropenia as a result of therapy is among the most commonly seen complications after treatment with cytotoxic agents for oncologic and rheumatologic disease. Granulocytopenia is a serious complication because (a) it predisposes the patient to infections caused by a wide array of pathogens, and (b) it can be associated with rapid progression, often in the absence of classic signs and symptoms of infection. Thus when neutropenia is severe, infections rapidly become life threatening, and require prompt diagnosis and treatment. In patients with cancer, the correlation between number of circulating granulocytes after the administration of cytotoxic therapy and risk of infection has been well established. In 1966 Bodey et al. (1) described the course of 63 patients with acute leukemia (age range, 1 to 77 years) and demonstrated that the incidence of proven infection and the absolute number of circulating granulocytes were clearly related. Risk of infection increased progressively with both duration and magnitude of granulocytopenia <1,000 cells/μL. At 100 cells/μL, the incidence of infection increased dramatically. Nevertheless, severe infections occurred more frequently during relapse than during remission, suggesting that other factors also played a role in predisposing to infection (1). Other investigators have demonstrated that patients on the verge of recovery are at considerably lower risk of bacteremia than are those who have recently received cytotoxic therapy and are expected to be neutropenic for an extended period (2). Although these early studies were performed in patients with cancer, these findings have also been found to apply to other neutropenic patients.

Bacterial infections represent the main source of infection in patients with acquired neutropenia. The spectrum of infectious agents has evolved over the past three decades, and reflects changes in clinical practice (3). In the 1950s and 1960s, when cytotoxic treatments were first being developed, gram-positive infections were most commonly encountered. In the 1970s, gram-negative organisms emerged as the most common pathogens in neutropenic patients. Since the 1980s and 1990s, gram-positive bacteria are again commonly encountered (4). Despite these general trends, there is significant institutional variation in the prevalence of particular pathogens, and therapeutic interventions must be adapted to reflect these variations (5). With prolonged neutropenia, invasive fungal infections also occur with increased frequency (6). Viral infection and parasitic infection, in the setting of isolated granulocytopenia, are less common.

Etiology

CHEMOTHERAPY AND RADIATION THERAPY

Cancer treatment with most cytotoxic therapies and radiation therapy commonly results in transient suppression of bone marrow hematopoiesis. This results in a decrease in the number of hematopoietic cells circulating in the periphery, including granulocytes, which typically lasts for a few days up to 1 week or longer. In some cases, the degree of neutropenia is mild, with no clinical sequelae; in others, it may be quite profound, thus markedly increasing the risk of life-threatening infection. The depth and duration of treatment-related neutropenia is related to the dose and the specific cytotoxic agents used, as well to the intrinsic bone marrow reserve of the patient. Thus neutropenia generally becomes more severe, and recovery is delayed after repeated cycles of chemotherapy deplete the hematopoietic reserve of the bone marrow.

Although quantitative deficiency in neutrophils after chemotherapy is clearly an important cause of the susceptibility to infection, *in vitro* studies also have demonstrated that the drugs used to deliver cytotoxic treatment can directly impair phagocytic function. Various investigators have demonstrated that cytotoxic agents can inhibit specific granulocyte functions, including hexose monophosphate shunt activity, superoxide production, phagocytosis, chemotaxis, and microbicidal activity. Implicated agents include methotrexate, 6-mercaptopurine, vincristine, vinblastine, anthracyclines, cyclophosphamide, carmustine, and platinum compounds (7,8,9,10,11,12 and 13). Many cytotoxic regimens also include glucocorticoids, which are known to have many effects on immune effector cells. The major effect of glucocorticoids on granulocyte function is a decrease in chemotactic activity. This inhibits accumulation of granulocytes at the site of infection and decreases the localized inflammatory response (14). This may contribute to the clinical observation that many of the signs and symptoms of infections are “masked” in patients taking glucocorticoids. Steroids also have important effects on circulating monocytes, including monocytopenia and functional defects in monocyte chemotaxis, phagocytosis, and killing of bacteria and fungi (15).

BONE MARROW APLASIA

Aplastic anemia (AA) is a disease of primary bone marrow failure. The initial presentation of these patients is typically related to severe or recurrent infection, with subsequent discovery of neutropenia and marrow aplasia (16). Infection also is the leading cause of death in this patient population. A retrospective evaluation of 150 patients with AA, admitted to the Clinical Hematology Branch of the National Institutes of Health (NIH) between 1978 and 1989, revealed that 36 (62%) of 58 deaths were attributable to infection (17). Sixty-seven percent of these were bacterial infections; 23% fungal, 7% viral, and 3% were parasitic infections. AA patients vary with respect to the degree of neutropenia, and this study demonstrated that the single most important factor for developing severe and fatal infections is the degree of neutropenia and monocytopenia. Marrow aplasia also is a manifestation of paroxysmal nocturnal hemoglobinuria (PNH), and these patients similarly can have neutropenic fever (18).

Pure white-cell aplasia (PWCA) is a rare syndrome characterized by severe pyogenic infections and neutropenia. PWCA is generally caused by autoantibodies directed against myeloid progenitor cells, and approximately 70% of cases are associated with thymoma. In some cases, PWCA may occur several years after removal of thymoma. Bone marrow examination shows almost complete absence of myeloid precursors, with normal erythroid precursors and megakaryocytes. Marrow inhibitory activity is seen in both immunoglobulin G (IgG) and IgM fractions of patients' sera and disappears as the marrow recovers. PWCA has been reported in association with ibuprofen therapy, in which *in vitro* serum inhibitory activity required both drug and complement, and the clinical syndrome resolved once ibuprofen was discontinued. Cyclophosphamide, steroids, cyclosporine, and intravenous immunoglobulin (IVIG) have provided effective treatment of PWCA in some patients (19).

MALIGNANT DISEASE OF THE MARROW

In acute myeloid leukemia (AML), myeloid cells are arrested in an early stage of differentiation and cannot develop into mature neutrophils. In addition, several studies have documented significant functional defects in mature granulocytes from patients with AML (20,21). Abnormalities in granulocyte myeloperoxidase activity have been correlated with subsequent development of infection (22). Patients with acute lymphocytic leukemia (ALL) have been reported to display similar functional defects (23). At the time of diagnosis, nearly two thirds of children with ALL have fever, and the majority are neutropenic due to bone marrow replacement with malignant cells (24).

IDIOSYNCRATIC DRUG REACTIONS

Drug reactions that cause leukopenia range from mild to profound, and are characterized by the reduction or disappearance of neutrophilic granulocytes from the peripheral blood. Patients with drug-induced agranulocytosis are at high risk of life-threatening infections, and studies report a mortality rate of 6% to 30% (25). Agranulocytosis is associated with the use of various categories of drugs summarized in Table 81.1. The incidence of drug-induced agranulocytosis is estimated to be approximately 2.6 to 10 cases/million drug exposures/year, although it is difficult to know the precise incidence because these cases are often not reported (26).

Class of Medication	Examples of Specific Drugs	References
Antithyroid agents	Propylthiouracil Methimazole	(27,28)
Phenothiazines	Chlorpromazine Prochlorperazine Promazine Mepazine Thioridazine	(29–31)
Sulfonamides	Trimethoprim-sulfamethoxazole Sulfasalazine	(32–37)
Antibiotics	Cephalosporins Aztreonam Aminoglycosides	(38,39)
Antiarrhythmic agents	Procainamide Quinidine Hydralazine Captopril	(40–43)
Anticonvulsant drugs	Phenytoin Carbamazepine	(44,45)
Antiinflammatory agents	Phenylbutazone Oxyphenbutazone Indomethacin Colchicine Gold salts Penicillamine	(46–49)
H_2-receptor antagonists	Cimetidine	(50)

TABLE 81.1. Medications Associated with Idiosyncratic Agranulocytosis

Drug-induced agranulocytosis can result from at least two different mechanisms. Most instances result from drug-induced antibodies that, in the presence of the drug, react with granulocytes, their bone marrow precursors, or both (51,52 and 53). The abrupt onset of granulocytopenia, usually beginning 1 to 3 weeks after the first dose of the drug, is a characteristic feature of this mechanism. The development of drug-induced antibodies is frequently associated with severe systemic symptoms such as chills, fever, extreme malaise, skin rash, and severe sore throat. After recovery, there is a prompt recurrence of these abnormalities if the patient is reexposed to the drug. If a bone marrow biopsy is obtained early in the course, a marked depletion of mature granulocytes and granulocyte precursors but adequate numbers of erythroid precursors and megakaryocytes is seen. If performed after recovery has begun, the bone marrow biopsy reveals large numbers of promyelocytes and early myelocytes with prominent azurophilic granules that may resemble the marrow of a granulocytic leukemia. In the presence of drug, antibodies in the serum may react with mature granulocytes in agglutination or other test systems and may inhibit growth of granulocyte colonies *in vitro* (54,55 and 56).

Some drugs, such as phenothiazines, produce agranulocytosis by a different mechanism, which involves suppression of differentiation of committed progenitor cells of all three marrow lineages (41,57,58). However, because of the short intravascular residence time of granulocytes, the disorder often is seen as agranulocytosis with only mild anemia and thrombocytopenia. The typical clinical setting in which this is seen is a psychiatric patient in whom an insidious onset of leukopenia develops 2 to 15 weeks after beginning a new medication. Alternatively, agranulocytosis is discovered because of a routine blood count in an asymptomatic patient or because of a blood count prompted by evidence of infection. Recurrence slowly develops over days with reexposure to the offending drug or when a different phenothiazine is administered. Bone marrow biopsy reveals a markedly hypocellular bone marrow resembling that of aplastic anemia. There is no evidence of drug-induced serum antibodies. Recently it was suggested that the reactive metabolites of drugs implicated in agranulocytosis may interact with specific components of the extracellular matrix and interfere with the normal regulation of granulopoiesis. This results in decreased production of granulocytes because normal myeloid maturation is dependent on certain components of the stromal microenvironments [intercellular adhesion molecule (ICAM)-1, vascular cell adhesion molecule (VCAM)-1, CD11b/CD18, heparin sulfate proteoglycans, fibronectin, hemonectin] (59).

In addition to the drugs associated with agranulocytosis, many commonly used medications have documented effects on phagocyte function. These agents include nonsteroidal antiinflammatory drugs (NSAIDs) (60,61), opiates and narcotic analogs (62), ethanol (63), benzodiazepines (64), methylxanthines (65), b-adrenergic blocking agents (66), phenytoin (67), inhaled and intravenous anesthetics (68), gold compounds (69), nicotine (70), allopurinol, cyclosporine (71), heparin (72), calcium-channel blocking agents (73), and antibiotics (74).

VIRAL INFECTIONS

Neutropenia after viral infection is seen more commonly in children than in adults, especially after infection by measles, chickenpox, rubella, influenza, infectious hepatitis, yellow fever, sand fly fever, HIV, Colorado tick fever, or dengue fever. The mechanisms for neutropenia in these patients have not been well defined but may result from nonspecific suppression of marrow hematopoiesis by cytokines secreted in response to the viral infection. In addition, rickettsial disease, miliary tuberculosis (TB), malaria, kala-azar, and relapsing fever have been associated with neutropenia. In contrast to that after viral infection, neutropenia after bacterial infection is unusual but can occur after salmonella infection, tularemia, and brucellosis. In this setting, neutropenia often indicates exhaustion of bone marrow reserves as well as margination and localization of neutrophils to sites of bacterial infection.

RHEUMATOLOGIC DISEASES

Felty syndrome is a complication of rheumatoid arthritis, and is characterized by the following manifestations: (a) severe, long-standing arthritis; (b) splenomegaly; (c) severe neutropenia; (d) serologic abnormalities, including elevated gamma globulins, high titer of rheumatoid factor, antinuclear antibodies (ANAs), and evidence of mixed cryoglobulins (cold precipitable immune complexes); and (e) normocellular or hypercellular bone marrow with increased numbers of early myeloid forms. The neutropenia of Felty syndrome is not entirely understood. Several mechanisms have been implicated including impaired granulopoiesis, increased destruction of granulocytes secondary to immune complexes or antineutrophil antibodies, and excessive margination (75). Whereas the appearance of the bone marrow usually suggests increased granulocyte production, granulopoiesis may be depressed in some individuals. In some patients, the bone marrow has been found to contain T lymphocytes that suppress normal marrow granulocyte colony growth *in vitro* (76). In other patients, increased amounts of immunoglobulin bound to granulocytes have been demonstrated as well as increased amounts of immunoglobulin in serum that can bind to granulocytes of other individuals. In these patients, accelerated

clearance of immunoglobulin-coated neutrophils and suppression of granulopoiesis by serum immunoglobulins appear to contribute to the neutropenia (77,78 and 79).

Patients with systemic lupus erythematosus (SLE) have increased risk of infection, often due to alterations in both the number and the function of granulocytes (80). This risk increases with use of corticosteroids and other immunosuppressive agents and in the presence of impaired renal function. Approximately 47% of these patients are leukopenic, due to neutropenia (81). Neutropenia may occur because of immune destruction, marrow suppression, hypersplenism, or drugs. SLE serum has been shown to increase neutrophil aggregation, and this may contribute to the neutropenia (79,82). The evidence for bone marrow suppression by SLE sera comes from the examination of effects of SLE sera on bone marrow colonies growth *in vitro*: 18 (34%) of 42 SLE sera retarded bone marrow colony growth, whereas no effect was seen with 40 control sera (83). Conversely, 12 (40%) of 30 sera from patients with other inflammatory diseases also retarded growth. It has been demonstrated that there is a normal chemotactic response of neutrophils from patients with SLE, but the generation of chemotactic factors was decreased in ten (43%) of 23 patients (84). Serum from 22 (73%) of 30 SLE patients interfered with phagocytosis and lysosomal release in normal neutrophils (85,86).

NUTRITIONAL DEFICIENCY

Neutropenia can be seen in association with anemia of nutritional deficiency of vitamin B_{12}, folate, and copper (87). These nutritional deficiency states are characterized by ineffective myelopoiesis and megaloblastic changes in the bone marrow.

Diagnostic Evaluation of Granulocytopenia

Neutropenia can be generated by decreased production of granulocytes, a shift of granulocytes from the circulating to the marginating pool, peripheral destruction, or a combination of these factors. In general practice, granulocytopenia is usually defined as an absolute neutrophil count (ANC) <500 and is calculated as follows (88):

$$\text{ANC} = \text{WBC} \times (\%\text{bands} + \%\text{mature neutrophils}) \times 0.01 \quad (1)$$

In a patient newly discovered to have neutropenia, a careful history should be elicited to determine the approximate onset of neutropenia (5). In particular, recent exposure to cytotoxic therapy, or drugs that are associated with neutropenia or agranulocytosis, should be determined. On physical examination, the presence of splenomegaly is helpful and might suggest that increased destruction of granulocytes contributes to neutropenia. Additional examination of peripheral blood can determine if other hematopoietic lineages are affected. In many cases, it will be necessary to examine the bone marrow to determine whether there is any evidence of failure to generate myeloid precursors, or whether there is an arrest in myeloid maturation, or marrow infiltration with leukemic cells. One mechanism by which neutropenia is generated is the development of antibodies to neutrophil antigens such as NA1, NA2, ND1, ND2, and NB1, as well as antigens shared by erythrocytes and to human leukocyte antigens (HLAs) (51). These antibodies, usually of IgG and IgM type, can be detected by a variety of assays, such as leukoagglutination, opsonization, immunochemical assays, direct antibody binding, and complement activation (54,89). Detection of antineutrophil antibodies (ANAs) is helpful in establishing the diagnosis of immune neutropenia, although a negative assay does not exclude the diagnosis. Although not commonly used, detection of increased serum lysozyme or lactoferrin reflects increased destruction of neutrophils.

If fever appears in a granulocytopenic patient, successful management depends on early intervention. Once fever develops, aggressive diagnostic efforts should be undertaken to identify specific causes of febrile illness, with the goal of identifying potential sources of infection to optimize therapy. Special attention should be directed at intravascular-access devices, wounds, and the perirectal area. Standard assessments include cultures of urine, blood, sputum, stool, and cerebrospinal fluid (if mental status changes or signs of meningismus are present). A chest radiograph should be obtained to determine whether there is any evidence of pneumonia. If an intravascular-access device is present, blood cultures from each lumen of the device should be obtained. Even with a comprehensive evaluation, a definite infectious cause is found in only 30% to 50% of cases. In a prospective study evaluating >1,000 consecutive episodes of febrile neutropenia, no features were found that reliably distinguished bacteremic patients from those with unexplained fever (24).

Various *in vitro* studies have been developed to examine neutrophil function (e.g., respiratory burst, phagocytosis), and are described in detail in Chapter 20. Outside of the setting of research or diagnosis of congenital defects, these tests are not used in general clinical practice.

Treatment of Granulocytopenia

EMPIRIC ANTIBIOTICS

Because bacteremias in severely neutropenic patients are often rapidly fatal, empiric antimicrobial therapy should be promptly instituted in patients with ANC >500/µL, even if no clinical signs of infection are detected other than fever (90). Moreover, empiric antibiotics are often continued until neutropenia has resolved, even if specific pathogens are not identified. Increased awareness of the necessity of timeliness of intervention has resulted in improved outcomes. Over the past decade, more intensive chemotherapeutic protocols have been developed, with consequent increased degree of immunosuppression and prolonged use of antibiotics. These developments have resulted in the increased incidence of invasive fungal infections, as well as the emergence of antibiotic-resistant bacteria (3,91).

The choice of empiric antibiotics is designed to maximize activity against organisms that are commonly encountered or particularly virulent or both. Because gram-negative bacteria have been the most frequently isolated pathogens in neutropenic patients, and these tend to be quite virulent, broad-spectrum antibiotics that provide effective therapy against these organisms are an essential component of any empiric regimen. Other required features of empiric antibiotic regimens include the ability to achieve high serum bactericidal levels that provide increased effectiveness in the absence of neutrophils and an acceptable toxicity profile. To prevent the emergence of resistance, the use of a combination of agents has been recommended. Early experience using an aminoglycoside and expanded-spectrum penicillin such as carbenicillin demonstrated a synergistic effect against *Pseudomonas aeruginosa* and resulted in improved clinical outcome (92). Such combination regimens are still widely used, but the development of more effective cephalosporins has led to further evaluation of the need for combination regimens (90). A meta-analysis of 12 randomized controlled trials comparing ceftazidime as single-agent therapy with combination therapy for treatment of febrile neutropenia did not demonstrate any advantage of combination therapy over monotherapy (93). As newer antibiotics are continuously being developed, the role of these agents for empiric therapy of severely neutropenic patients should be evaluated in prospective randomized trials. In addition to efficacy, important factors that influence the widespread use of these new agents in this setting include toxicity profile, emergence of resistance, ease of administration, and cost.

Empiric treatment of gram-positive bacteria in severely neutropenic patients also is important. Nevertheless, vancomycin is generally not indicated as part of the initial regimen. In a randomized study of a vancomycin-containing versus a non–vancomycin-containing regimen, the incidence of secondary gram-positive infections was reduced in the vancomycin-containing group. However, no differences in morbidity were attributed to gram-positive infections between the two groups, and all gram-positive infections in the non–vancomycin-treated group were successfully treated by the addition of vancomycin after the organism was identified (94). Similarly, a large retrospective analysis showed no excess morbidity when the use of vancomycin was delayed by waiting for either a clear microbiologic or clinical indication (95,96). The reduced empiric use of vancomycin in this setting limits the emergence of vancomycin-resistant bacteria and also reduces the toxicity associated with this agent.

Patients with severe neutropenia and persistent fever also are at risk for development of invasive fungal infection (97). Two prospective randomized trials demonstrated the efficacy of empirical amphotericin B in persistently febrile neutropenic patients (98,99). In both studies, patients who received amphotericin B after a course of antibiotics had superior outcome to patients who were treated with antibacterial agents alone. Deaths in a significant number of patients who did not receive amphotericin B were due to fungal infections. Other randomized trials have demonstrated similar efficacy of intravenous amphotericin B and oral ketoconazole (100,101). However, use of ketoconazole was complicated by difficulty in tolerating oral medication and erratic absorption in this patient population (102). New liposomal formulations of amphotericin B have been developed with similar efficacy and with decreased toxicity (103).

To determine the source of bacterial infection in neutropenic patients and whether identification of colonizing bacteria might help in the initial antibiotic management of neutropenic patients, nose, throat, urine, and stool cultures were obtained serially in 652 febrile patients. In those patients that developed sepsis and a specific causative pathogen was isolated, 62% were colonized with the infecting organism (104). These findings demonstrate that serious infections in patients with severe neutropenia are most often caused by organisms that have colonized the individual before the development of neutropenia. However, surveillance cultures at a single body site were not predictive of subsequent infection, and several pathogens were often isolated in addition to the organism responsible for infection. Moreover, the costs of performing routine surveillance cultures are enormous (105,106). Thus routine surveillance cultures are not recommended in general practice.

Traditionally, patients with febrile neutropenia remain hospitalized with antibiotic therapy until fever and all signs of active infection have resolved and neutropenia has resolved. The possibility that certain favorable subgroups of patients may be effectively treated with antimicrobial regimens as outpatients (107,108 and 109) is being currently explored.

The management of fever in patients with AA is a particular clinical challenge because the appropriate duration of the empiric antibiotic regimen has not been defined. In contrast to cancer patients in whom febrile neutropenia develops after cytotoxic therapy, neutropenia in AA is not self-limited, and the neutropenia may last for months or years. Patients with ANC <100 are at highest risk, and the high incidence and grave outcome of fungal infection merit special consideration. In most patients,

antibiotic therapy is continued for only 10 to 14 days, followed by careful observation. This recommendation is based on a series of randomized studies in which patients with fever and neutropenia were assigned to either discontinue antibiotics on day 7, or day 14, or until resolution of granulocytopenia. In a large percentage of afebrile patients who stopped antibiotics on day 7, recurrent fever developed, and in an alarmingly high percentage of persistently febrile patients whose antibiotics were discontinued, hypotensive episodes developed. In contrast, patients who stopped antibiotics on day 14 often responded to reinstitution of their initial regimen if fevers recurred (110).

MYELOID COLONY-STIMULATING FACTORS

Granulocyte colony-stimulating factor (G-CSF) is a lineage-specific growth factor that increases circulating neutrophils by stimulating release from storage pools and by shortening the maturation time in bone marrow. Granulocyte-macrophage (GM)-CSF has broader hematopoietic effects due to the stimulation of a less committed progenitor cell population and other cells such as mature monocytes and dendritic cells. Functionally, neutrophil respiratory burst; adherence, phagocytosis, and bacterial killing are normal if not enhanced *in vivo* after treatment with either agent.

Before the advent of CSFs such as G-CSF and GM-CSF, the treatment of patients with neutropenia was limited to the administration of antibiotics and to the occasional use of granulocyte infusions. In three major randomized trials in adults receiving moderately myelosuppressive chemotherapy, CSFs were shown to enhance recovery of granulocytes and to reduce the incidence of febrile neutropenia by approximately 50% (111,112 and 113). The value of CSFs has not been established in less myelosuppressive regimens (114,115), and their use is not currently recommended with many chemotherapy regimens (114). Exceptions are those patients who have had a history of recurrent febrile neutropenia during earlier cycles of chemotherapy and conditions that markedly increase the risk of systemic infection (e.g., ongoing active infection or open wound). There is evidence that CSF administration can decrease the probability of febrile neutropenia in subsequent cycles of chemotherapy after documented occurrence in earlier cycles. CSFs also can be used to prevent prolonged neutropenia causing excessive dose reduction or delay in chemotherapy administration (111,116,117).

Because most myeloid leukemia cells express receptors for CSFs, there has been concern whether these agents could induce leukemic transformation when used after chemotherapy in patients with myeloid malignancies or myelodysplasia. As a result, several studies have examined the outcome of postchemotherapy CSF administration in patients with AML. In one trial conducted in older patients (55 to 70 years) with AML, patients randomized to receive GM-CSF were found to have a modest but significant reduction in duration of severe neutropenia and incidence of severe infection (118). There was a trend toward higher complete response rates and a significant prolongation of median survival in patients receiving GM-CSF. A subsequent trial conducted in similar patients was less encouraging (119). A statistically significant but clinically inconsequential reduction in the duration of severe neutropenia was seen, but there was no significant difference in the incidence of serious infection, days of hospitalization, acute mortality, or complete response rate.

In adults, the recommended dose of G-CSF is 5 µg/kg/day, and of GM-CSF is 250 µg/m^2/day, subcutaneously or intravenously as clinically indicated (114). CSFs are generally started 24 to 72 hours after completion of chemotherapy and continued until ANC >10,000/µL after neutrophil nadir. The predominant side effect of G-CSF is medullary bone pain, and appears to occur more frequently at higher doses. In randomized trials, 15% to 39% of patients receiving 5 µg/kg/day have had this symptom (111,112 and 113,120). Less frequent side effects include exacerbation of preexisting inflammatory conditions (eczema, psoriasis, vasculitis) (121), occasional rashes, rare allergic reactions, acute febrile neutrophilic dermatosis (Sweet syndrome) (122,123), transient leukemia cutis in CML patients, and rare injection-site reactions. Laboratory abnormalities occur frequently and include elevations in lactate dehydrogenase (LDH), uric acid, and serum and leukocyte alkaline phosphatase, presumably secondary to increased myeloid cell turnover. In patients with advanced cancer, a 25% to 50% decrease in platelet counts has been reported with doses greater than 10 µg/kg/day (124).

Whereas the largest experience with CSFs has been in patients receiving cancer chemotherapy and BMT, CSFs also have been successfully used for treatment of neutropenia not associated with cancer. Prolonged administration of G-CSF and GM-CSF has been used to maintain normal neutrophil counts in patients with Felty syndrome (125) and SLE (126). Of concern, in several patients with Felty syndrome, leukocytoclastic vasculitis and flares of arthritis developed after the use of CSFs. However, this was rare if G-CSF was administered at lower doses (126,127). CSFs are now commonly used in the treatment of Felty syndrome and are preferred to previous treatments such as methotrexate, lithium, testosterone, cyclosporine, and splenectomy (128). CSFs also have been used to overcome HIV-mediated leukopenia and to circumvent the myelosuppressive effects of antiviral agents (129,130).

GRANULOCYTE TRANSFUSIONS

Granulocyte transfusions were first used more than 30 years ago. At that time granulocytes collected from patients with CML were infused into patients with severe neutropenia, and infusions of large numbers of cells often effected resolution of life-threatening infections (131). Subsequent studies suggested that clinical response and survival correlated directly with the number of granulocytes infused (132). Although effective in some settings, the routine use of granulocyte transfusions was quite problematic. Granulocytes were difficult to collect from normal donors, as the number of circulating granulocytes available for collection was relatively small. Moreover, granulocyte function deteriorated rapidly during storage, and granulocyte infusions were frequently associated with severe complications. Thus, even though several encouraging randomized clinical studies advocated the use of granulocyte transfusions in the setting of life-threatening infection and neutropenia, they largely fell out of favor as a therapeutic modality (133).

Over the past decade, there has been renewed interest in granulocyte transfusions because patients are receiving increasingly intensive myelosuppressive regimens, which are associated with prolonged periods of neutropenia. In addition, administration of G-CSF can increase circulating granulocytes more than tenfold and mobilize granulocyte progenitors (134,135). Thus large numbers of normal granulocytes can now be harvested from normal donors with relatively little toxicity.

Several controlled studies have evaluated the use of therapeutic granulocyte transfusions. As a group, these studies are limited by small numbers and heterogeneous patient populations, and clinical results varied (136,137,138,139,140,141 and 142). In general, the studies appear to support the use of granulocyte transfusions for patients with persistently severe neutropenia. Studies that showed no benefit appeared to reflect inadequate granulocyte transfusion support. To be effective, the dose of granulocytes transfused should be greater than 2 to 3 × 10^{10} PMN (not less than 1 × 10^{10}). Daily granulocyte transfusions should be continued until infections have resolved or until ANC increases above 500/µL. In addition to cell dose, the effectiveness of granulocyte transfusions is influenced by the extent of recipient alloimmunization and donor histocompatibility, likelihood of endogenous granulocyte recovery, and whether the organism is sensitive to antimicrobial agents. Toxicity to transfusions can be very severe, ranging from low-grade fevers to rigors, dyspnea, pulmonary infiltrates, and hypoxia. Some degree of toxicity can be prevented by administering granulocyte transfusions slowly, at 1 to 2 × 10^{10} cells per hour. Increased toxicity with concomitant administration of amphotericin B has been reported (143). In general, granulocyte transfusions should be considered for persistently neutropenic patients with unusually severe and progressive infections that cannot be controlled with antimicrobial agents. This includes patients with progressive bacterial infections, systemic fungal infections, congential disorders of granulocyte dysfunction, fungal infections after BMT, and newborns with bacterial infections (133). The use of prophylactic granulocyte transfusions has not been supported by prospective studies and is not recommended.

ACQUIRED COMPROMISE OF T-CELL FUNCTION

Manifestations

T-cell immunity is necessary for control of viral, protozoan, bacterial, and fungal infections. Essential to the development of mature T cells is surface expression of rearranged T-cell receptor (TCR) genes in conjunction with surface expression of CD3. Individuals are able to respond to diverse pathogens and stimuli, new and old, because of the very high degree of complexity of the TCR repertoire. Once the TCR is engaged, in the presence of costimulatory signals, a series of intracellular events leads to activation of the T cell. Peripheral T cells are subdivided into the $CD4^+$ (T helper) and $CD8^+$ [cytotoxic T lymphocytes (CTLs)] subsets that recognize and respond differently to processed peptide antigen. In normal immunocompetent adults, the total number of $CD4^+$ and $CD8^+$ T peripheral lymphocytes is remarkably stable. These T-cell subsets comprise both naive and memory cells, whose numbers are maintained by separate homeostatic regulators. The thymus normally involutes during adolescence, and the production of new $CD4^+$ and $CD8^+$ T cells decreases with increasing age. Recent thymic emigrants express CD45RA, whereas T cells in the memory compartment express CD45RO (144).

The specific pathogens encountered and the spectrum of clinical findings in patients with acquired defects of T cell–mediated immunity vary depending on the underlying disease, the degree of immunosuppression, and the presence or absence of other host defense abnormalities. Typically, patients with acquired T-cell deficiency are susceptible to infections caused by intracellular organisms, which are capable of surviving and replicating within macrophages, B cells, or other cell types. This observation attests to the importance of T-cell function for macrophage activation and subsequent microbicidal activity. Many of these agents are not pathogenic in individuals with normal T-cell function. Infections found in hosts with defective T-cell immunity typically fall into the following categories: (a) bacterial (e.g., *Mycobacteria*, *Legionella*, *Nocardia*, *Salmonella*); (b) fungal (e.g., *Clostridia neoformans*, *Histoplasma capsulatum*); (c) viral [e.g., varicella zoster virus (VZV), cytomegalovirus (CMV), Epstein-Barr virus (EBV), herpes simplex virus (HSV)]; and (d) protozoan (e.g., *Pneumocystis carinii*, *Toxoplasma gondii*, *Strongyloides*).

Etiology

CHEMOTHERAPY FOR MALIGNANT AND NONMALIGNANT DISEASES

Previous reports have examined the phenotypic immune reconstitution of patients receiving intensive chemotherapy and found that return of $CD4^+$ T-cell numbers is inversely proportional to age. Younger patients promptly recovered total $CD4^+$ T cells, including subsets of $CD45RA^+$ (naive) cells, presumably because of output of new T cells from the thymus (145). In older patients in whom the thymus is involuted, recovery of $CD4^+$ T cells was slow and numerically incomplete. Moreover, most $CD4^+$ T cells expressed the memory marker CD45RO, suggesting that they were derived from the expansion of residual peripheral T cells that survived cytotoxic chemotherapy, rather than from the production of new T cells in the thymus (146,147).

RECONSTITUTION AFTER MYELOABLATIVE THERAPY AND HEMATOPOIETIC STEM CELL TRANSPLANTATION

Myeloablative therapy followed by hematopoietic stem cell transplantation is frequently used in the treatment of patients with hematologic malignancies. Mature T and B cells present in the stem cell product (bone marrow or peripheral blood stem cells) contribute to immune function after transplant, but full and long-lasting immune reconstitution after myeloablative therapy is dependent primarily on the differentiation of new immune cells from undifferentiated hematopoietic progenitor cells. After transplantation, the T-cell compartment typically reconstitutes slowly, with the $CD4^+$ population lagging behind the $CD8^+$. This results in inversion of the normal CD4/CD8 ratio for prolonged periods after BMT (148,149 and 150). $CD8^+$ T cells reach normal numbers by 3 to 4 months after BMT, whereas $CD4^+$ numbers do not normalize until 6 to 12 months after BMT. NK cells are among the first cell populations to return. In the first month after transplant, NK cells often represent the predominant lymphoid population, especially in patients who receive marrow depleted of mature T cells. Approximately 30% of NK cells express CD8, and this likely contributes to increased CD8 numbers early after BMT (151,152). In addition to the presence of mature $CD3^+$ $CD4^+$, and $CD3^+CD8^+$ T cells, detectable populations of T cells in the peripheral circulation are normally present only during fetal life or in the adult thymus, reflecting recapitulation of lymphoid ontogeny after BMT. These include $CD3^{dim}CD4^-CD8^-$ double-negative, and $CD3^+CD4^+CD8^+$ double-positive T cells, as well as $CD1^+$ cells and increased numbers of TCRgd T cells (153,154).

Although thymic function declines with age, normal individuals are able to maintain a highly diverse TCR repertoire. Without a highly diverse T-cell repertoire, the ability of foreign antigens to escape detection increases, and the subsequent development of an effective T-cell response to external pathogens decreases. The complexity of the TCR repertoire in an individual can be measured by quantifying the use of various TCR Vb genes in peripheral T cells (155). Moreover, the diversity of the CDR3 regions generated within populations of T cells can be measured by the method of spectratyping (156,157). Recent studies from our laboratory and others have directly examined reconstitution of the T-cell repertoire after myeloablative therapy and hematopoietic stem cell transplantation by using spectratyping (158,159,160,161 and 162). In this method, polymerase chain reaction (PCR) with TCR Vb family-specific primers is used to amplify the CDR3 regions of all T cells that have rearranged TCR Vb genes. Because normal polyclonal T cells each have unique CDR3 regions, the size display of normal T cells with a diverse TCR repertoire demonstrates a series of eight to ten peaks with a gaussian distribution. As shown in Fig. 81.1A for a typical patient 3 months after allogeneic BMT, the CDR3 pattern demonstrates a large number of clonal and oligoclonal peaks as well as absent use for some of the TCR Vb families. However, by 1 year after BMT, this profile has normalized, and most of the CDR3 patterns demonstrate normal polyclonal profiles (Fig. 81.1B). In patients who have engrafted completely with donor cells and have no posttransplant complications, TCR Vb repertoire reaches normal levels of diversity by 12 to 18 months after transplant (158). This occurs more rapidly in pediatric patients, presumably because of a higher level of thymic function in these individuals (163,164). Reconstitution of normal TCR repertoire appears to be delayed in patients who have posttransplant complications such as graft-versus-host disease (GVHD) (162) and in patients who have mixed hematopoietic chimerism rather than complete donor hematopoiesis (158).

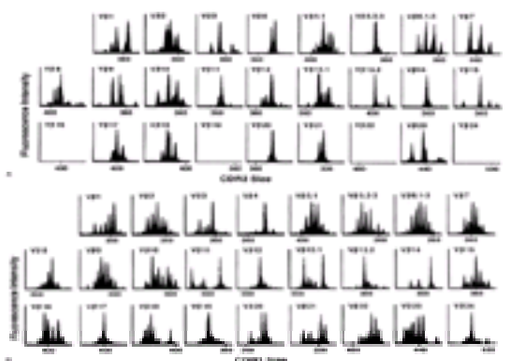

Figure 81.1. T-cell receptor Vb spectratype. CDR3 regions are amplified by reverse transcription/polymerase chain reaction (RT-PCR) from peripheral blood T cells by using 26 different Vb family primers and a single constant region primer. The PCR-amplified product is separated on a DNA sequencing gel and analyzed by using GeneScan software. **A:** CDR3 spectratype is derived from peripheral blood T cells obtained from a single patient 3 months after allogeneic stem cell transplantation. **B:** Spectratype is derived from the same patient 1 year after transplant and demonstrates marked improvement, with most patterns showing a normal polyclonal CDR3 profile.

Rearrangement of the TCRa gene during normal thymic differentiation results in the excision of a well-defined fragment containing the TCRd gene. As shown schematically in Fig. 81.2, this excised genomic DNA becomes circularized and is retained within the maturing T cell as a stable episomal fragment. This episomal fragment, which has been termed a TCR excision circle (TREC), is neither degraded nor replicated with subsequent cell division (165,166). The presence of TRECs is therefore a unique marker of a cell that has undergone TCR gene rearrangement and has been used to identify those T cells that have recently emigrated from the thymus. Quantitative PCR assays for TRECs have been developed and used to measure thymic output of new T cells (165). In normal individuals, TREC levels are high in cord blood and remain relatively high in peripheral blood T cells for the first two decades of life (167). TREC levels subsequently decline, but TRECs remain detectable in peripheral blood throughout adult life (168). This observation provides evidence for continued T-cell neogenesis in adults despite thymic involution (169). In patients who have undergone allogeneic stem cell transplantation for congenital immune deficiency, TREC levels increase rapidly after transplantation, indicating successful generation of new donor T cells (170,171). In adult patients, TREC levels remain low for at least 3 months after allogeneic BMT, and in many cases, TRECs are not detectable. As shown in Fig. 81.3, TREC levels begin to recover by 6 months after BMT and achieve normal levels by 1 year after BMT (172). This demonstrates that T-cell neogenesis from hematopoietic donor stem cells recovers in adult individuals, but the recovery period is prolonged. Adult patients usually remain susceptible to opportunistic infections for at least 1 year after BMT, and, in part, this is due to the slow reconstitution of T-cell neogenesis. This results in a markedly abnormal and deficient T-cell repertoire and inability to respond effectively to many external antigens.

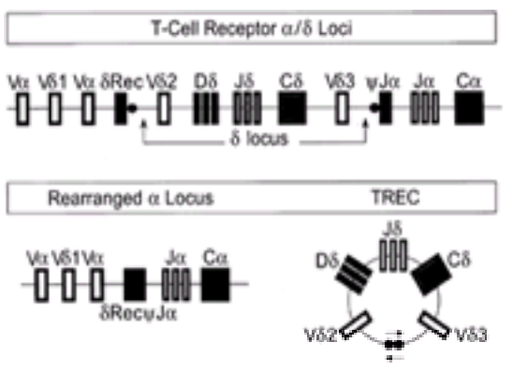

Figure 81.2. Derivation of T-cell receptor excision circles (TRECs) during rearrangement of the T-cell receptor a gene. (See Color Figure 81.2.)

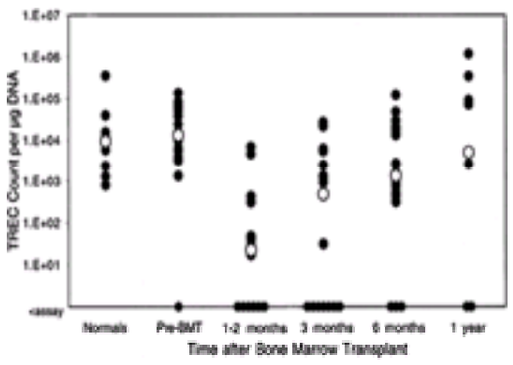

Figure 81.3. Quantitative assessment of T-cell receptor excision circles (TRECs) in peripheral blood lymphocytes during the first year after allogeneic stem cell transplantation in adult patients. The number of TREC copies/µg RNA were determined by quantitative reverse transcription/polymerase chain reaction. Patients received myeloablative conditioning followed by infusion of T cell–depleted bone marrow from human leukocyte antigen (HLA)-matched siblings. Peripheral blood samples for TREC analysis were obtained at various times after stem cell infusion and results compared with age-matched normal donors. *Solid circles* represent values for individual patient samples. *Open circles* represent median values for all samples at each time point.

After hematopoietic engraftment of donor stem cells, acute and chronic GVHD represent the most common immunologic complications of allogeneic BMT. Although a variety of host factors influence the clinical manifestations and severity of these reactions, both acute and chronic GVHD are mediated primarily by donor T cells. In the context of this potentially severe immunologic reaction, GVHD is associated with a variety of defects of T-cell function. For example, $CD4^+$ helper T-cell number and function are decreased, and the number of activated (DR expressing) $CD4^+$ and $CD8^+$ T cells is increased (173,174 and 175). In addition, patients with GVHD have a reduced capacity to produce new $CD4^+$ CD45RA T cells (176,177). Because patients with severe GVHD are always treated with immune-suppressive agents, it is difficult to determine whether the functional impairment of T cells is due primarily to GVHD or to immune suppressive therapy. Nevertheless, patients with GVHD represent a population at very high risk for opportunistic infections, and uncontrolled infections represent the most common cause of death in these individuals (178).

Because T cells are the primary mediators of GVHD, depletion of mature T cells from the donor marrow is an effective strategy for prevention of GVHD after allogeneic BMT. Several different methods have been developed for *ex vivo* depletion of T cells (179,180). These methods vary greatly in the extent to which mature $CD3^+$ cells are depleted and in the extent to which other cell populations are affected. In patients who receive T cell–depleted marrow, the incidence of GVHD is relatively low, and few patients are required to also receive immune-suppressive medications for GHVD prophylaxis. Nevertheless, reconstitution of T-cell immunity is delayed in these individuals because it is primarily dependent on the generation of new T cells from hematopoietic progenitor cells rather than from the transfer of functionally mature T cells from the donor (149,181). Mature donor T cells also play an important role in eliminating residual recipient leukemia cells after BMT. This effect has been termed “graft versus leukemia” (GVL), and patients who receive T cell–depleted donor marrow also have decreased GVL and increased risk of leukemia relapse after BMT (182,183). Recent studies have suggested that infusion of donor T cells after BMT can restore this GVL effect, but the ability of donor T-cell infusion to restore T-cell immunity against opportunistic infections has not been examined (184,185,186,187,188 and 189).

In addition to deficiencies in the number and diversity of mature T cells, previous studies have also demonstrated substantial functional abnormalities in peripheral T cells after myeloablative therapy. These functional deficiencies include impaired responsiveness to mitogens, soluble antigens, and allogeneic cells (149,190). These functional defects have been attributed to defects in various intracellular signaling pathways as well as to the impaired secretion and ability to respond to exogenous cytokines such as interleukin (IL)-2 (191,192,193 and 194). These functional cellular deficiencies have also been observed in recipients of autologous stem cells, although the extent and duration of deficiency is less pronounced than that in recipients of allogeneic stem cells (161,190,195). These functional abnormalities persist for prolonged periods but generally resolve gradually and often recover to normal levels by 12 to 18 months after transplant.

IMMUNOSUPPRESSIVE DRUGS

Because T cells are important effectors of the immune response, many therapies have been designed to suppress T-cell function in patients with immune overreactivity. Immunosuppressive drugs are commonly used in clinical practice after allogeneic bone marrow and solid organ transplantation to prevent GVHD or graft rejection, respectively. Immunosuppressive agents also are used extensively in rheumatologic and autoimmune disease, and in the treatment of various hematologic malignancies. In all of these clinical situations, the use of these drugs is associated with impaired T-cell immunity and increased susceptibility to a variety of pathogenic agents. In general, the degree of immune suppression is dependent on the duration of therapy and the specific agent that is used, as well as on the underlying disease. Moreover, although the effects of immunosuppressive agents on T-cell function are discussed in this section, these drugs often also affect other cellular systems as well, such as B cells, monocytes, and phagocytes. These other cellular effects increase the level of immune deficiency and also affect the susceptibility to opportunistic infections.

CORTICOSTEROIDS

Corticosteroids (e.g., prednisone, methylprednisolone, dexamethasone) are among the most commonly used immunosuppressive agents. At very high doses, these drugs are directly lympholytic. They also inhibit the immune system by directly blocking the activation of lymphocytes and macrophages. With corticosteroid use, early events in the induction of antigen-specific T-cell stimulation are not inhibited, but subsequent events leading to transcription and production of lymphokines are blocked (196,197 and 198). Thus corticosteroids effectively inhibit IL-2 production, with subsequent inhibition of T-cell proliferation and expansion of effector CTLs.

Corticosteroids also inhibit production of lipid mediators of inflammation by macrophages, such as leukotrienes and prostaglandins (199,200). Macrophage production of cytokines, tumor necrosis factor (TNF), IL-1 and chemokines, and nitric oxide also is inhibited (201,202 and 203). These effects on macrophages are the probable cause of the lack of fever in patients with pyogenic infections taking steroids. Other effects of corticosteroids on lymphocytes and macrophages include alteration in trafficking and availability of these cells for recruitment into sites of infection or delayed-type hypersensitivity (DTH) skin tests (204,205 and 206).

CYCLOSPORINE AND TACROLIMUS

Although dissimilar in chemical structure, both cyclosporine and FK506 (tacrolimus) block calcium-dependent events in lymphocyte signaling by forming a ternary complex with one or more specific binding proteins, and the calcium-dependent phosphatase calcineurin B (207). This results in blockade of T-cell activation, inhibition of IL-2 production and other lymphokines, and thus inhibition of T-cell proliferation and expansion of CTLs (208). There is also inhibition of T-cell interactions with B cells, and thus decreased antibody production in response to antigen stimulation (209). The prolonged use of cyclosporine and tacrolimus in solid organ and marrow transplant recipients has been associated with an increased risk of EBV lymphoproliferative disease (210,211,212 and 213).

ANTITHYMOCYTE GLOBULIN AND ANTI–T-CELL MONOCLONAL ANTIBODIES

T cell–specific antibodies such as OKT3 (anti-CD3), antithymocyte globulin (ATG), and Zenapax (daclizumab) are used extensively in solid organ transplant recipients as well as in the treatment of GVHD after allogeneic stem cell transplantation (214,215,216,217 and 218). OKT3 is a murine monoclonal antibody, whereas ATG is a polyclonal antibody prepared in sheep, horses, or rabbits immunized with human T cells or thymus. Daclizumab is a humanized IgG1 monoclonal antibody, which binds to the a chain of the IL-2 receptor (CD25) (219). Humanized monoclonal antibodies specific for other antigens expressed on T cells such as CD2 (220) and CD52 (221,222 and 223) also are undergoing evaluation as immune-suppressive agents in clinical trials. Preparations of polyclonal antibodies vary in their potency and selectivity for T cells, and their antigenic specificity is not well defined or controlled (180). Monoclonal antibodies have the advantage of having well-defined specificity, but the target antigens can be expressed on various cell types. Thus OKT3 has very specific reactivity for CD3-positive T cells, but antibodies targeting CD2 also are reactive with undifferentiated T cells in the thymus and NK cells, which express this antigen. Antibodies targeting CD52 effectively deplete T cells *in vivo* but also target many other hematopoietic cells that express this common adhesion molecule. In contrast to broadly reactive anti–T-cell antibodies, daclizumab is reactive only with activated T cells and NK cells that express high-affinity IL-2 receptors.

The immunosuppressive activities of anti–T-cell antibodies are, in large part, dependent on their ability to deplete T cells *in vivo*. These reagents generally bind to circulating T cells rapidly after intravenous administration and subsequently also bind to T cells in lymph nodes and tissues. Binding of antibody to the T-cell surface results in complement activation and deposition of complement components on the target cell membrane. To varying degrees, target cells are depleted by complement-mediated cell lysis, opsonization, and antibody-dependent cellular cytotoxicity (ADCC). Monoclonal antibodies also are capable of direct functional effects on T cells mediated by the specific target antigen. Thus OKT3 also can inhibit T-cell activation by dysregulation of the TCR/CD3 complex, which renders T cells anergic to subsequent activation by specific antigens (224). Similarly, antibodies to adhesion molecules or cytokine receptors also may exhibit functional effects through

inhibition of cell trafficking or cytokine signaling.

FLUDARABINE

Fludarabine is a newly developed nucleoside analog used in the treatment of CLL, which has been proven to provide effective therapy for this disease (225,226). Patients who receive fludarabine are known to develop low levels of CD4 T cells and are at increased risk for development of opportunistic infections (227,228). Low CD4 counts often persist for months after completion of fludarabine therapy (228). The mechanism whereby fludarabine induces prolonged immune deficiency is not entirely known, but recent studies have demonstrated that levels of cellular STAT1 protein become markedly depleted after *in vitro* exposure to fludarabine (229). T cells from patients receiving fludarabine also have low levels of STAT1. Depletion of STAT1 protein appears to be secondary to reduced expression of STAT1 mRNA, but it is not known how fludarabine induces this effect. STAT1 is an important cellular mediator of the interferon (IFN) signaling pathway, and mice deficient in STAT1 have defects in T cell–mediated immunity similar to that observed in mice deficient in IFN-g. This functional defect also is similar to that observed in patients receiving fludarabine, and this may be responsible for at least some of the impaired T-cell function in these patients. Other nucleoside analogs such as pentostatin also are associated with impaired T-cell function (230,231), but it is not known whether these other agents have similar effects on cellular STAT1.

TOTAL LYMPHOID IRRADIATION

Total lymphoid irradiation (TLI) has been used in Hodgkin disease, as well as in solid organ transplants. Its immunosuppressive effect results from its ability to reduce circulating T and B cells by 50%, with a similar reduction in lymphocyte proliferative responses *in vitro* (232,233). Circulating levels of lymphocytes are reduced during the first 6 to 12 months after treatment, and return to baseline after 2 to 3 years (233). Patients subjected to TLI are at increased risk of CMV and varicella infection (234).

OTHER CHEMOTHERAPEUTIC AGENTS

Cytotoxic agents such as azathioprine, cyclophosphamide, chlorambucil, and methotrexate inhibit the development of primary antigen-specific responses by inhibiting DNA synthesis and by blocking the proliferation of cycling cells (235).

HODGKIN DISEASE

Patients with early-stage Hodgkin disease often demonstrate impaired T-cell proliferative responses to mitogen stimulation *in vitro* (236). Patients with more extensive disease who have otherwise good performance status frequently exhibit impaired delayed hypersensitivity with negative skin tests against multiple antigens (e.g., tuberculin, coccidioidin, histoplasmin, and mumps antigen), defective signaling pathways, and abnormal ADCC (237,238,239 and 240). Patients with advanced Hodgkin disease often exhibit generalized depletion of tissue lymphocytes and typically demonstrate lymphopenia and a depressed CD4/CD8 ratio (241). Radiotherapy for Hodgkin disease also results in depletion of T-helper cells, resulting in increased incidence of herpes zoster infection during the first and second years after completion of radiotherapy (242,243). Untreated patients generally have normal antibody responses, but this can change after treatment with chemotherapy and radiation. The most common infections in this population are characterized by granuloma formation (*Mycobacterium tuberculosis*) and by persistence within macrophages and monocytes (*Listeria monocytogenes* and salmonella). There is a correlation between measured abnormalities and the predisposition to infections such as varicella-zoster or *L. monocytogenes* (244,245).

VIRAL INFECTION

HIV infection is a prototypic example of an infection that selectively targets T cells. HIV infection leads to the preferential depletion of memory $CD4^+$ $CD45RO^+$ T cells, which are more likely than naive T cells to be engaged by antigen (246,247,248 and 249). $CD8^+$ T cells undergo an initial peripheral expansion followed by gradual loss of memory $CD8^+$ cells. As viral infection progresses, the T-cell repertoires of both $CD4^+$ and $CD8^+$ T cells undergo shrinkage (250). Recent studies have shown that infection with HIV is associated with impaired generation of naive T cells in the thymus as well as memory T cells, resulting in a markedly deficient T-cell repertoire (251). This effect is reversible after the institution of effective antiviral therapy (165).

Diagnostic Evaluation of Acquired T-Cell Deficiency

The evaluation of suspected T-cell deficiency begins with the immunophenotypic analysis of peripheral blood lymphocytes by flow cytometry. Established methods to measure relative and absolute numbers of cells present in various T-cell subsets are based on phenotypic assessment using monoclonal antibodies against surface antigens specific for each subset. These include measuring the total number of $CD3^+$ cells as well as $CD3^+CD4^+$ and $CD3^+CD8^+$ T cells. Measurement of $CD4^+$CD45RO and $CD4^+$CD45RA subsets can be used to determine the number of memory versus naive T cells, respectively.

Assessment of T-cell function *in vitro* can often demonstrate deficiency even when numeric evaluation of T cells and T-cell subsets is normal or detects only minimal deviation from normal. These assays include evaluation of proliferation after TCR triggering with anti-CD3 monoclonal antibody or stimulation with mitogens [phytohemagglutinin (PHA)], soluble antigens, or allogeneic cells. T-cell secretion of IL-2, IFN-g, TNF, or other cytokines can also be measured after appropriate *in vitro* stimulation. The ability to generate a CTL response to allogeneic target cells can be measured with cytotoxicity assays after *in vitro* priming and coculture with the target cells.

More recently, several techniques have been developed to measure antigen-specific T cells accurately (252,253). Antigen-specific T cells are generally present at low frequency in peripheral blood but increase after *in vivo* exposure to antigen. Before antigen exposure *in vivo*, antigen-specific cells are found within the naive T-cell compartment. These rare cells reflect the frequency of T-cell precursors capable of responding to antigen presented by appropriate major histocompatibility complex (MHC) molecules. After antigen stimulation and selection *in vivo*, antigen-specific T cells are primarily found within the memory T-cell compartment. The ELISPOT assay quantifies the number of T cells that secrete INF-g after stimulation with a specific antigen or peptide (254,255 and 256). Individual responding T cells are identified as spots in methylcellulose plates coated with anti–IFN-g antibodies. Alternatively, responding T cells can be enumerated by flow-cytometric techniques that stain INF-g–secreting cells after *in vitro* stimulation with a defined antigen (257,258,259 and 260).

It also is possible to enumerate $CD8^+$ T cells with receptors for specific antigenic peptides (261). Because the TCR expressed by $CD8^+$ T cells only recognizes specific peptides presented by HLA class I molecules, these cells can be identified by molecular constructs consisting of soluble HLA class I molecule with specific peptide bound in the antigen-presenting cleft. These constructs are engineered as tetrameric complexes with fluorescent tags and can be used with flow-cytometric methods to quantify the number of T cells expressing peptide-specific TCR. Because TCRs recognize only HLA-bound peptide, definition of the HLA class I restricting element as well as the bound peptide is required before this method can be applied. Despite these requirements, this method is increasingly used to monitor specific $CD8^+$ T-cell responses *in vivo* (262,263,264 and 265). Although it has been technically more difficult to construct peptide/HLA class II tetramers, recent reports suggest that it will also be possible to apply similar methods to monitor specific $CD4^+$ T-cell responses (266).

Molecular techniques have been developed to measure directly the diversity of the T-cell repertoire *in vivo*. One method described previously examines T-cell repertoire by characterizing the spectrum of rearrangements of the TCR Vb genes. This technique, called CDR3 spectratyping, uses PCR to amplify the Vb gene rearrangement of the CDR3 region of the TCR (Fig. 81.1) (156,157). TCR spectratyping of T cells from normal donors demonstrates a highly diverse and polyclonal TCR repertoire with a typically gaussian distribution of CDR3 species of approximately eight sizes for each Vb region. In contrast, strong immune responses such as acute GVHD, solid organ transplant rejection, infection, and autoimmune diseases are associated with oligoclonal or monoclonal CDR3 patterns in peripheral blood as well as in the affected tissue (160,267,268,269,270,271,272,273,274,275 and 276). Patients with HIV infection have been found to normalize their T-cell repertoire after effective antiretroviral therapy (250,277). CDR3 spectratyping also has been used to characterize the T-cell response after donor lymphocyte infusion (DLI) (159,160,278). Patients with relapsed CML after allogeneic BMT were found to have markedly abnormal TCR repertoires, but T-cell repertoire complexity was restored after DLI. Moreover, the response to DLI was associated with the appearance of new clonal T-cell populations in peripheral blood. Taken together, these studies demonstrate that severe deficiencies in the T-cell repertoire can be reversible and that CDR3 analysis provides a sensitive method for characterization of the T-cell repertoire as well as for following changes in individual patients over time.

Another recently developed molecular technique is detection of TRECs (Fig. 81.2) (165,166). (See under section on thymic function.) The process of TCRa gene rearrangement, which is central to the differentiation of all T cells expressing conventional TCRab receptors, results in the generation of an episomal DNA fragment termed TREC. TRECs become stable intracellular episomes, which are neither degraded nor replicated with cellular division. TRECs are found in almost all maturing T cells within the thymus and at very high levels in cord blood T cells (167). Relatively high numbers of TRECs are found in peripheral blood T cells in the first two decades of life, and TREC levels subsequently decline with increasing age (167). Levels of TRECs within a mature T-cell population decline with ongoing cell division, and as a result, TREC levels are higher in naive T cells (168). These studies suggest that TRECs can be used as an accurate measure of thymic function and the general level of T-cell neogenesis in an individual. After effective therapy, TREC levels can increase and return to normal age-dependent levels (165,169). This

indicates that T-cell neogenesis is not a static process in adults and that the output of new T cells with diverse repertoire can improve with appropriate therapy.

Treatment of Acquired T-Cell Deficiency

PROPHYLACTIC THERAPY FOR OPPORTUNISTIC INFECTIONS

T-cell immunocompetence is required for protection against protozoan and viral infections. Prophylactic therapy is indicated in patients with documented and persistent T-cell deficiency. Patients with HIV infection and patients reconstituting after allogeneic stem cell transplantation are examples of the exclusive use of prophylactic therapy in which clear clinical benefit has been documented (279). In these patients, prophylactic therapy is directed at common causes of opportunistic infections. This most commonly includes prophylaxis for HSV and HZV with acyclovir and prophylaxis for *P. carinii* with trimethoprim/sulfamethoxazole. Alternative regimens are available for patients who are allergic to or unable to tolerate these medications. Prophylactic regimens for other viral infections such as CMV also are commonly used, especially in patients who harbor latent virus and are at high risk for development of active disease.

ADOPTIVE T-CELL IMMUNOTHERAPY

Over the past decade, the notion that T cells are critical to protection against viral infections has been validated by the demonstration that infusion of virus-specific T cells can effectively treat viral infection (280). Riddell et al. (281) administered CMV-specific $CD8^+$ T-cell clones to recipients of matched sibling stem cell grafts, and demonstrated that CMV-specific immune responses were reconstituted. In none of the treated patients did CMV disease develop. No adverse effects were observed from the adoptive transfer of these clones. Subsequently, Walter et al. (282) isolated virus-specific $CD8^+$ CTL clones from the blood of immunocompetent allogeneic stem cell donors, expanded them to large numbers *in vitro*, and transferred them into recipients early after transplant. Infused doses of 10^9 cells/m^2 were well tolerated and resulted in good restoration of CTL responses in the recipient. However, consistent with the notion that maintenance of $CD8^+$ T-cell immunity to chronic viral infections requires a concurrent $CD4^+$ T-helper response, they found that strong CTL responses persisted only in patients who also recovered $CD4^+$ CMV-specific T cells.

Other investigators have used adoptive T-cell immunotherapy to prevent and treat EBV-associated lymphoproliferative disease (EBV-LPD) (283). Bone marrow and solid organ transplant patients are at high risk for EBV-LPD, especially in the early posttransplant period when functional donor/recipient T cells are scarce. Risk factors for the development of posttransplant EBV-LPD include the use of marrow from a mismatched related or closely matched unrelated donor, T-cell depletion of donor marrow, and intensive immunosuppression (284). The incidence of EBV-LPD ranges from 5% to 25% in patients with these predisposing characteristics, and patients with EBV-LPD respond poorly to chemotherapy or IFN-a (285,286). Reduction in the degree of immunosuppression can induce regression of EBV-LPD, and this underscores the importance of immune competence for control of EBV infection.

Posttransplant EBV-LPD is a good model for evaluating the efficacy of adoptively transferred antigen-specific CTLs, because tumor cells express all the latent-cycle virus-encoded antigens, most of which are targets for virus-specific immune responses [e.g., EBV-associated nuclear antigen (EBNA) 1, 2, 3a, 3b, 3c, LMP1, 2a, and 2b] (287,288). Moreover, most normal donors are immune to EBV and carry a high frequency of EBV-specific CTL precursors (289). The use of T-cell infusions for EBV-LPD was first reported by Papadopoulos et al. (290,291), in which single infusions of donor T cells at doses of 0.35 to 1.0 × 10^6 $CD3^+$ cells/kg induced clinical remissions in five allogeneic marrow transplant recipients. The therapeutic effect was attributed to the reconstitution of EBV-specific immunity by repletion of CTL precursors present in the donor lymphocyte infusion. They observed that responses occurred within 2 weeks after infusion and that there was shrinking of lymph nodes 3 to 4 weeks after cell infusion. Using genetically marked EBV-specific CTLs, other investigators have shown that these virus-specific effectors can persist in the recipient for at least 18 months and can expand *in vivo* in response to renewed challenge with EBV-infected cells (292,293). In one series, none of 26 patients who received prophylactic CTLs from allogeneic donors developed EBV-LPD, whereas patients who did not receive donor cells had a cumulative risk of 14%. More recently, Gustafsson et al. (294) monitored quantitative levels of EBV DNA in posttransplant patients, and showed that administration of prophylactic autologous EBV-specific CTLs can prevent the development of overt disease.

Although the first line of treatment for HIV infection is combination antiretroviral therapy (see Chapter 74), several lines of evidence indicate that $CD8^+$ cells are the primary effector cells in the host defenses against HIV (295,296,297,298 and 299), and thus adoptive transfer of HIV-specific T cells can be considered. Some investigators have demonstrated the ability to expand polyclonal or HIV-specific CTL clones *in vitro*, and the safety of infusion of the expanded T cells (299,300 and 301). Nevertheless, infused $CD8^+$ T cells appear to be short-lived and result in only transient responses because of the limited survival of CTLs *in vivo*. This observed effect may be due to inadequate T-helper cell activity (302).

Donor lymphocyte infusions have been shown to be especially efficacious for treatment of some hematologic malignancies after allogeneic BMT (187,188,303). In patients with relapsed CML after allogeneic BMT, remissions can be achieved in up to 80% of patients with unfractionated or CD8-depleted donor lymphocyte infusions (184,185 and 186). T cells mediate this antileukemia effect, but it is unknown whether the donor T cells are directed against leukemia-associated antigens or against minor histocompatibility antigens (mHAg) (304). In patients in whom this has been analyzed in detail, the immune response initiated by infusion of mature donor T cells appears to be a coordinated response involving both B- and T-cell immunity to a variety of antigens (278,305,306,307,308,309 and 310). Thus both leukemia-associated antigens and mHAg may be targets of this immune response. In addition to initiating an antitumor response, an important observation in several studies has been that donor T-cell infusion also leads to consistent improvement in broad measures of T-cell function. This includes improvement in the generation of new T cells from the thymus measured by TREC assays (172) as well as improvement in the complexity of the T-cell repertoire measured by spectratyping (159,160,278). The mechanism for this reversal of T-cell immune deficiency is not known. In particular, it is not known whether this is a direct effect of donor T-cell infusion or whether the improvement in T-cell function is secondary to the elimination of leukemia cells that may have had an immune suppressive effect *in vivo*.

INTERLEUKIN-7

Although the thymus undergoes progressive involution in adults, recent studies have demonstrated that the generation of new T cells persists throughout adult life in normal individuals. Currently, this can best be measured by quantitative TREC assay, and several studies suggest that depressed levels of thymic function and T-cell neogenesis can improve with appropriate therapy. Stimulating thymic generation of new T cells may be a novel method for improving T-cell function *in vivo* and for enhancing the ability of an individual to respond to a variety of antigenic stimuli. As a result, there has been renewed interest in administration of cytokines or hormones to augment thymic function. Examples include epidermal growth factors, which can stimulate proliferation of thymic epithelium or enhance thymopoiesis before thymic involution [i.e., growth hormone (GH), insulin-like growth factor (IGF)-1]. Alternatively, cytokines such as IL-7, which play an important role in early B- and T-cell development, may also provide a mechanism for enhancing thymic function in adults (311). Several murine models of BMT have demonstrated that exogenous IL-7 can enhance thymopoiesis and accelerate immune reconstitution (312,313). In murine models, IL-7 has been shown to augment the generation of antiviral CTLs (314,315). Thus far, however, clinical trials of IL-7 have not yet been initiated.

ACQUIRED COMPROMISE OF B-CELL IMMUNITY

Manifestations

The most important functions of B cells are to generate antibodies and to act as antigen-presenting cells (APCs) that can assist in T cell–mediated immune responses. Antibody responses are essential for cure and prevention of many bacterial and viral infections, and immunodeficiencies related to B cells primarily result in inadequate production of specific antibodies. Immunoglobulins and complement each have associated opsonic, lytic, and neutralizing activities and function predominantly against bacterial infections. Thus patients with impaired B-cell function tend to have recurrent and chronic infections. In contrast to patients with T-cell deficiency, these infections are most often due to encapsulated bacteria, but other organisms such as enteroviruses and *Giardia lamblia* also can cause significant disease in these individuals.

As discussed in other chapters, T cells play an important role in the regulation of B cells and in the generation of appropriate antibody responses to many antigens. Patients with significant T-cell deficiency will therefore often also have deficiencies in humoral immunity. There are, however, several well-documented instances in which patients primarily acquire significant deficiencies of B-cell function, and T-cell function remains largely intact.

Etiology

HEMATOLOGIC MALIGNANCIES

Deficiencies in antibody production have been described in patients with CLL and plasma cell dyscrasias (multiple myeloma, Waldenström macroglobulinemia) (316,317 and 318). These deficiencies of antibody production can be clinically significant, and patients with these diseases frequently have recurrent severe bacterial infections. These infections are often due to polysaccharide-encapsulated pathogens such as *Streptococcus pneumoniae*, *Haemophilus influenzae,* or *Neisseria*

species. In patients with progressive CLL or multiple myeloma, infections are a major cause of death.

Patients with CLL have an intrinsic defect in B-cell function, which leads to unbalanced immunoglobulin chain synthesis and hypogammaglobulinemia (317). This persistent and often profound hypogammaglobulinemia was first recognized in the 1940s and 1950s (319). The likelihood of developing hypogammaglobulinemia correlates with the duration of disease and is as high as 70% by 7 years after diagnosis (320,321). This immune defect is not reversed by therapy with conventional agents, despite a concomitant hematologic response in the primary disease process (322). It is estimated that infectious complications will develop in up to 80% of patients with CLL, ranging in severity from moderate to life threatening, and infection accounts for up to 60% of deaths in these patients (317). The incidence of infection correlates with the duration and stage of the disease, as well as serum levels of immunoglobulins (particularly IgG) (323). Serious infections are most often due to encapsulated bacteria, but infections caused by staphylococci and enteric gram-negative bacilli also occur (317). The risk of infection increases with administration of corticosteroids and cytotoxic drugs. Other immune defects in this patient population include alteration in the normal ratio between T4 and T8 cells, especially with advanced disease (324).

Multiple myeloma has been associated with suppressed antibody responses by nonmalignant B cells. This defect is, at least in part, related to decreased numbers of normal B cells. In addition, immune feedback mechanisms are triggered in response to the high levels of monoclonal immunoglobulin seen in almost all patients with myeloma (318). It has been proposed that increased catabolism of immunoglobulins in these patients also contributes to decreased levels of nonmalignant immunoglobulins (318). As a result of this acquired defect in B-cell number and function, patients with multiple myeloma are at increased risk of developing serious infections. Savage et al. (325) found a biphasic pattern of infection, with infections due to *S. pneumoniae* and *H. influenzae* occurring earlier in the course of disease (first 8 months of diagnosis) or in patients responsive to therapy. In contrast, gram-negative infections occurred more frequently in patients with refractory or advanced disease.

Patients with acute leukemia have been found to have lower levels of antibody to the core glycolipid of the Enterobacteriaceae than do noncancer patients, and their antibody levels decrease after intensive cytotoxic therapy (326). Cytotoxic chemotherapy, radiotherapy, and steroids all adversely affect B-cell as well as T-cell functions, and can result in diminished opsonizing activity, inadequate agglutination and lysis of bacteria, and deficient neutralization of bacterial toxins. Cytotoxic therapy also can blunt the humoral response to vaccine administration, but adequate responses have been documented for patients in remission receiving maintenance chemotherapy. Thymomas are associated with marked aberration of the immune response, most severely affecting humoral immunity (327). These patients may have antibody-mediated autoimmune diseases, such as myasthenia gravis (328), or recurrent infections (sinopulmonary infections due to encapsulated bacteria), and may have a profound depletion of B cells and serum immunoglobulins (329,330).

ALLOGENEIC BONE MARROW TRANSPLANTATION

Myeloablative therapy followed by allogeneic BMT results in a prolonged period of B-cell as well as T-cell deficiency. $CD20^+$ B cells are often entirely absent from the peripheral blood early after stem cell transplantation, but these cells return to normal levels by 1 to 2 months after BMT (151). The proliferative response of B cells to mitogenic stimulation returns to normal by 2 months after BMT and parallels the recovery of phenotypic B cells (149). Donor-derived antibody production can be detected as early as a few months after BMT. However, BMT recipients are more typically incapable of normal antibody production to capsular polysaccharide antigens of encapsulated respiratory bacteria for prolonged periods after BMT (331,332 and 333). Analysis of variable heavy-chain (V_H) genes present in circulating B lymphocytes early after transplantation demonstrate V_H use similar to that seen in fetal B lymphocytes, consistent with recapitulation of B-lymphocyte ontogeny (334). Moreover, there appears to be a recapitulation of the transient hypogammaglobulinemia of infancy. After stem cell transplantation, IgM recovery precedes IgG and IgA recovery. IgM recovery takes 9 to 12 months; IgG recovery starts at 9 months; and IgA levels return to normal by 2 to 3 years after BMT (335). Without replacement of immune globulin, transplant recipients have reduced IgG, IgA, and IgM during the first 6 months after BMT (333).

In the absence of specific immunosuppressive treatment, acute GVHD has little effect on the tempo of lymphoid reconstitution, as measured by absolute lymphocyte count. In contrast, patients with chronic GVHD demonstrate multiple immune deficits, such as the decreased capacity to develop an antigen-specific T-cell response and to produce specific antibodies, especially to polysaccharide antigens, while having increased incidence of autoantibodies (336). These effects are exacerbated by the use of immunosuppressive agents. In patients with chronic GVHD, immunizations with recall antigens (e.g., tetanus, diphtheria toxoids) or new antigens [e.g., keyhole limpet hemocyanin (KLH)] reveal sustained defects in antibody production, including decreased primary antibody production, decreased immunoglobulin switching, and decreased secondary antibody production (336). These patients also have prolonged inability to produce antibodies to polysaccharide antigens, which are the primary antigenic determinants of the encapsulated respiratory bacteria (337). Before routine administration of prophylactic antibiotics and IVIG after stem cell transplantation, patients with chronic GVHD showed an increased incidence of infections with encapsulated respiratory bacteria (178). With the routine administration of prophylactic antibiotics and IVIG, the incidence of infectious complications has decreased in these patients (338).

Diagnostic Evaluation of Acquired B-Cell Deficiency

Quantitative assessment of immunoglobulin production can be measured by direct measurement of immunoglobulin levels. Normal immunoglobulin levels vary with age, and laboratories should provide age-adjusted normal levels. Interpretation of results may be difficult because low levels of immunoglobulin do not always correlate with patients' ability to generate specific antibody responses against new antigens. Moreover, most people with low IgG subclass levels have clinically adequate antibody responses to defined antigens.

The number of circulating B cells can be determined by immunofluorescence assays using monoclonal antibodies specific for B-cell surface antigens such as CD20 and CD19. These monoclonal antibodies are often used in conjunction with monoclonal antibodies specific for k and l light chain to determine whether B cells are polyclonal or monoclonal. Although normal peripheral blood does not contain a large population of B cells (usually <10%), flow-cytometric analysis using B cell–specific monoclonal antibodies can be very useful in determining whether the number of circulating B cells is normal in patients with suspected immune deficiency.

Functional tests of humoral immune deficiency also include the evaluation of specific antibody responses after administration of vaccine *in vivo*. Specific antibody responses to tetanus toxoid, *H. influenzae* B toxoid conjugate vaccine, pneumococcal vaccine, and hepatitis B vaccine can be measured by enzyme-linked immunosorbent assay (ELISA). Another functional test is the measurement of *in vitro* immunoglobulin production in response to B-cell mitogens such as pokeweed mitogen. This is primarily a research tool, and is not routinely used in the clinical setting.

Treatment of Acquired B-Cell Deficiency

ACTIVE IMMUNIZATION

In patients with normal T-cell function, active immunization often provides an effective method for enhancing the B-cell response to specific antigens. This is most effective in patients with relatively mild B-cell deficiency and is less effective in patients with profound B-cell abnormalities and in patients with T-cell deficiency. Nevertheless, many patients do not receive adequate vaccination. For example, it was recently estimated that the pneumococcal vaccine has been given to only 21% of those individuals in whom vaccination is indicated (339,340 and 341). This was found despite evidence that there is increasing severity and incidence of pneumococcal infection and increasing frequency of penicillin-resistant pneumococcus. The pneumococcal vaccine contains 23 of the serotypes responsible for more than 88% of the pneumococcal bacteremias in the United States. However, this vaccine provides protection in only 61% of immunocompetent individuals and is less protective in immunocompromised patients. Nevertheless, pneumococcal vaccines are recommended for patients with multiple myeloma, nephrotic syndrome, immunosuppression due to BMT, HIV, and functional or anatomic asplenia due to Hodgkin disease or to other hematologic disorders (sickle cell anemia) (279,342). Other vaccines recommended for this patient population include the influenza virus vaccine as well as the vaccine for *H. influenzae*.

Although vaccination of high-risk patient populations reduces the risk of serious infection, intrinsic defects in humoral immunity limit the ability to develop adequate protective antibody responses. For example, patients with multiple myeloma typically generate an increase in antibody titers after vaccination. However, because preimmunization titers are frequently low, postimmunization titers often fail to reach protective levels (343). In addition, postimmunization antibody levels decrease rapidly, in part because of increased catabolism of immunoglobulins. Because these patients frequently receive repeated cycles of immunosuppressive treatment, maintenance of adequate antibody levels to polysaccharide antigens remains difficult despite vaccination. Nonetheless, pneumococcal vaccine is recommended for prevention of serious pneumococcal infections in these patients, and revaccination should be considered in patients with a rapid decline in pneumococcal antibody levels.

Likewise, patients with CLL should receive polyvalent pneumococcal vaccine, although its efficacy in this populations has not been demonstrated unequivocally. These patients also display a suboptimal response to vaccination, which may be related to impaired antibody production, as well as to defects in antigen presentation (344,345). A series of investigators have examined patients with CLL who received typhoid, diphtheria, influenza, and mumps vaccines. These investigators found that antibody responses were poor, whether the patients had normal immunoglobulin levels or were hypogammaglobulinemic.

After allogeneic stem cell transplantation, several studies have assessed the ability to produce specific antibodies in response to a variety of antigens (tetanus toxoid, diphtheria toxoid, poliovirus, hepatitis virus) (346,347 and 348). These studies have shown that patients generally have increased antibody levels when either the donor

or recipient is immunized before BMT (349). Maximal antibody responses are obtained when both donor and recipient are immunized (349). If patients are not immunized after BMT, antibody production is not maintained, and clinically significant antibody levels are no longer detectable 1 year after BMT (350).

Live attenuated viral (measles, mumps, rubella, oral poliovirus, yellow fever) or bacterial [bacille Calmette-Guérin (BCG)] vaccines should not be administered to patients who are immunosuppressed as a result of leukemia, lymphoma, advanced malignancy, symptomatic HIV infection, or who are receiving therapy with alkylating agents, antimetabolites, radiation, or large doses of corticosteroids. The Centers for Disease Control (CDC) recommends that patients with leukemia who are in remission and more than 3 months after completion of therapy may be given live virus vaccines. In BMT recipients, administration of measles/mumps/rubella (MMR) vaccines is safe and efficacious for patients in remission 2 years after transplantation who do not have active GVHD (279).

PASSIVE IMMUNIZATION

Passive immunization involves the administration of preformed antibodies with the goal of replacing qualitatively or quantitatively defective immunoglobulins. Various studies have examined the use of a variety of antibody preparations, including pooled immunoglobulins, immunoglobulins collected from individuals with high titers of specific antibodies (hyperimmune sera), and monoclonal antibodies.

In patients with hypogammaglobulinemia not associated with malignancy or cytotoxic treatment, administration of pooled immunoglobulins has been effective in preventing infections due to encapsulated bacteria and in the treatment of certain enteroviral infections (351,352,353 and 354). In patients with malignancy, this benefit is not as clear (355). In patients with plasma cell dyscrasias, immunoglobulin supplementation is thought to be of little help, given the increased clearance of antibody (356). In CLL, prophylaxis with IVIG has been shown to decrease but not to eliminate respiratory infections in high-risk patients. In a randomized placebo-controlled multicenter study, the course of 81 CLL patients who were either hypogammaglobulinemic or had a history of infection was monitored (357). Those that received immunoglobulin replacement (400 mg/m^2/kg every 3 weeks) had significantly fewer bacterial infections (23 infections in 41 patients) than did those who received placebo (42 infections in 40 patients). In particular, infections caused by *S. pneumoniae* and *H. influenzae* but not gram-negative organisms were less common in the patients who received immunoglobulin. In addition, patients who received IVIG remained free of serious bacterial infections for a longer period than did control patients, but the benefit was limited to moderate or minor infections and not to a decrease in major or life-threatening infections. There was no difference in the incidence of viral or fungal infections in the two groups. Because of the high cost of therapy (358) and its limited ability to prevent serious bacterial infections, monthly IVIG should be considered only in patients with hypogammaglobulinemia who experience repeated bacterial infections. A potential limitation of prophylactic IVIG therapy is that although IgG is replaced, the most common immunoglobulin deficiencies present in CLL are often either IgM or IgA, which are not replaced by this therapy.

After allogeneic stem cell transplantation, bacterial, fungal, and viral infections (especially CMV) are a major cause of mortality and morbidity. Patients who are at highest risk for CMV disease are those individuals who are CMV seropositive before transplant or who have received marrow from a CMV-seropositive donor. In this group, the rates of CMV infection approach 70% after transplant in some studies (359). Thus IVIG has been evaluated as a source of passive immunity against CMV, bacterial and fungal infections, as well as an immunomodulator to decrease the development of acute GVHD. Numerous studies have been conducted to study the efficacy of IVIG or CMV hyperimmune globulin in preventing posttransplant complications from CMV infections, other infections, and GVHD (360,361 and 362). Nevertheless, the results of these studies have not been conclusive, because there are substantial differences in patient characteristics, the chemotherapy and radiation therapy regimens, GVHD prophylaxis regimens, supportive care procedures, and differing antibody titers of IVIG products that were used. Most studies have shown benefit in CMV-seronegative recipients undergoing BMT (362). CMV hyperimmune globulin has been shown to be effective prophylaxis against symptomatic CMV infection in seronegative recipients undergoing renal transplantation (363). In BMT patients, CMV hyperimmune sera and IVIG have been used in conjunction with ganciclovir in the prevention and treatment of CMV-associated disease (364,365). In general, combined approaches using passive immunization with specific antiviral drug therapy have shown greater efficacy in selected studies (366). Because IVIG remains a very expensive therapy, the use of IVIG should be reevaluated as newer and more effective antiviral agents become available for clinical use.

82 AGING AND THE IMMUNE SYSTEM

Marc E. Weksler, M.D., and Paul Szabo, Ph.D.

“The concept of age as a factor determining serologic response is comparatively new in immunologic thought.” Leona Baugartner, 1934 (1)

Biologic aging is the consequence of time on living organisms. In general terms, an organism changes constantly throughout life. *Development* refers to that constant change starting when biologic function increases and becomes more adaptive, and ending with *senescence*, when biologic function decreases and becomes less adaptive. Thus senescence is one part of development. During senescence, physiologic variance increases as homeostatic reserve diminishes. This process may be aptly termed *homeostenosis*.

Immune senescence is associated with a greater frequency of infectious and neoplastic diseases. Epidemiologic research suggests that infectious disease ranks eighth among the most common causes of all deaths in the United States but rises to rank fourth in persons older than 65 years. Cancer incidence is known to increase exponentially after age 30 years. Cigarette smoking offers probably the most important avoidable risk of cancer. However, aging appears to be an even greater risk factor. The extent to which immune senescence and the decline in “immune surveillance” contribute to the age-associated increase in cancer is debated. However, most agree that age-associated changes in the immune system, such as the appearance of monoclonal immunoglobulins and clonal lymphocyte expansions, usually precede the appearance of lymphoid neoplasms including chronic lymphocytic leukemia, multiple myeloma, and lymphoma.

Thymic involution is the most striking change associated with aging and has been known for more than 100 years. This gross anatomic change in the thymus gland was recognized long before its immune function was discovered. The principal function of the thymus gland is now recognized to be the production of a naive and diverse population of T lymphocytes. As the production of naive T lymphocytes decreases, cell-mediated and humoral immunity that depends on T lymphocytes declines. The production of B lymphocytes by the bone marrow in mammals also is reported to decline with age. It appears that the rate at which the bone marrow produces B-lymphocyte precursors is regulated by $CD8^+$ T lymphocytes. Thus an age-associated decline in the production of both T and B lymphocytes may be expected to occur as a result of thymic involution. It is generally believed that thymic involution is the pacesetter of immune senescence.

Because of the gradual involution of the central organs of lymphocyte development, immune senescence does not lead to the type of immune deficiency associated with congenital absence of T or B lymphocytes. This is not surprising, as the lymphocyte repertoire is well established before the onset of thymic involution. Thus immune senescence is associated with neither a decline in the number of blood lymphocytes nor the concentration of serum immunoglobulins. Interestingly, some cytokines produced by T lymphocytes increase, while other decrease with age. Interleukin (IL)-2 production by T lymphocytes decreases with age although T-lymphocyte production of other cytokines, such as IL-4 and IL-6, increases with age. This is discussed further later. Immune senescence is more precisely characterized by shifts in the number, distribution, and activity of lymphocyte subsets, antibody specificities, and cytokines with age. For this reason, immune senescence is best described as a process leading to a state of immune dysregulation.

CELL-MEDIATED IMMUNITY

Effect of Age on Thymocyte Development and T-Lymphocyte Development

The involution of the thymus begins at the time of sexual maturity and is completed by midlife, about age 50 years in humans, although a striking decrease in thymocyte size can be seen associated with illness (2). The decreasing mass of the thymus reflects a progressive decline in the number of thymocytes, leading to a decrease in overall production of T cells. Hormone release also influences the mass of the thymus (3,4). Thus, elevated thymic involution is reported to be slowed by thyroid hormone levels or depressed sex hormone levels. Factors intrinsic to the immune system that have been reported to contribute to thymic involution include decreased migration of thymocyte precursors from the bone marrow to the thymus, decreased entry of precursors into the thymus, and decreased differentiation of precursors within the thymus. Surprisingly, it is reported that the number of the thymocytes in early development is comparable in old and young individuals. It is concluded that the production of precursors and their entry into the thymus are not rate limiting. However, the number of thymocytes that have rearranged their T-cell antigen receptor (TCR) b-chain genes and that therefore are at a later stage in development declines progressively during aging. This suggests that impaired rearrangement of the TCR b-chain gene complex may underlie the age-associated decrease in thymocyte number associated with thymic involution. Consistent with this idea is the report that a mouse line, expressing rearranged a- and b-chain TCR transgenes, does not undergo thymic involution (3). However, we have found that this is not a general finding. Three other TCR transgenic mouse lines demonstrate normal thymic involution, suggesting that the expression of rearranged TCR transgenes is not sufficient, in itself, to prevent thymic involution (4). Decreased production of IL-7 also has been suggested to contribute to thymic involution. This cytokine is known to stimulate the proliferation of T-lymphocyte precursors within the thymus. Preliminary studies suggest that the repeated injections of IL-7 increase the number of T-lymphocyte precursors within the thymus of old mice (5), but whether this is the major factor that controls thymic involution is unknown.

Effect of Age on Peripheral T Lymphocytes

As discussed earlier, impaired thymocyte development during aging is associated with decreased production of T lymphocytes (6). Despite the decreasing number of T lymphocytes exported from the thymus during aging, the number of peripheral T lymphocytes does not decline. There appear to be two reasons for this: (a) long life span of T lymphocytes, and (b) their capacity for self-renewal. During early life, immune reactions to environmental antigens lead to clonal expansion of memory T cells, and a decrease in the number of naive T cells generated by the thymus. These cells represent the diverse T-cell repertoire. At all times of life, clonal expansion is followed by clonal regression. Early in life, naive lymphocytes from the thymus maintain the number and diversity of the T-lymphocyte repertoire after clonal regression. Later in life, fewer naive cells and more memory T cells are circulating. Clonal expansion and involution continues, but at a reduced rate.

As unstimulated lymphocytes are lost from the repertoire, lymphocytes undergoing clonal expansion or self-renewal take their place. Early in life, holes that develop in the T-cell repertoire as a result of clonal expansion and loss of cells are refilled by naive T cells produced by the thymus gland, However, such holes in the T-cell repertoire can be filled only as long as the thymus gland continues to export a diverse repertoire of naive T cells. Age-associated involution of the thymus results in a decreasing diversity of the peripheral T-lymphocyte repertoire. Two observations support this idea: (a) the greater age-associated depression in the primary as compared with the secondary immune response: these responses reflect the naive and memory lymphocytes, respectively; and (b) the greater restriction in the T-lymphocyte repertoire regenerated in old compared with young subjects after peripheral T-lymphocyte depletion that may be caused by radiation, chemotherapy, or human immunodeficiency virus (HIV) infection (7). The increased rate of infection and death of elderly individuals after peripheral T-cell depletion by HIV infection is attributable, at least in part, to the impaired rate and limited diversity of T-lymphocyte regeneration (8).

Extrathymic production of T lymphocytes occurs in the intestine. However, there is little evidence that extrathymic production of the g/d T lymphocytes that are produced in the intestine maintains the number or diversity of peripheral T lymphocytes during aging. The number of g/d T lymphocytes expressed as a percentage of blood T lymphocytes does not appear to vary with age, as would be expected if extrathymic production replaced thymic production of naive lymphocytes (9).

In addition to the age-associated decrease in the diversity of the T-lymphocyte repertoire, shifts in the relative number of T-lymphocyte subsets also result from the decreased production of T lymphocytes by the thymus during aging. There is a significant increase in the ratio of $CD4^+$ to $CD8^+$ T lymphocytes during aging (Table 82.1). In both subsets, the shift occurs in the ratio of naive to memory T lymphocytes, which express the CD45RA or CD45RO surface molecules, respectively (10).

	Young Donors	Aged Donor	Statistical Significance (paired *t* test)
CD4[a]	60.2 ± 2.9	73.4 ± 5.5	$p < .0001$
CD8[a]	38.7 ± 3.7	28.6 ± 1.7	$p < .0500$
CD4 + CD45RA[b]	60.3 ± 6.0	44.7 ± 7.3	$p < .0500$
CD4 + CD45RO[b]	46.4 ± 8.1	65.6 ± 8.3	$p < .0500$
CD8 + CD45RA[c]	73.0 ± 8.0	46.6 ± 4.0	$p < .0500$
CD8 + CD45RO[c]	23.2 ± 3.8	62.7 ± 7.2	$p < .0500$

Expression of cell-surface markers was measured by immunofluorescence and analyzed on a Coulter profile flow-cytometry system. Young donors were 20 to 32 years old: mean, 26 years. Aged donors were 55 to 85 years old: mean, 76 years. Six pairs of donor in each group were studied.

TABLE 82.1. $CD4^+$ and $CD8^+$ T-Cell Subsets in Peripheral Blood

The difference between memory and naive T cells requires further discussion. Early in life, the thymus exports a large number of naive T lymphocytes, and immunologic experience is limited. The percentage of naive T lymphocytes exceeds that of memory T lymphocytes. As time passes, exposure to antigens stimulates the activation of naive T lymphocytes and their transformation into memory T lymphocytes. This, combined with the age-associated decrease in the output of naive T lymphocytes from the thymus, leads to the reciprocal shifts in the percentage of naive and memory T lymphocytes. In elderly subjects, the percentage of memory T lymphocytes actually exceeds that of naive T lymphocytes (Table 82.1). Naive T lymphocytes respond poorly if at all to recall antigens. In contrast, a high percentage of memory T lymphocytes respond to specific recall antigens. Naive and memory T lymphocytes differ not only in the molecules required for their activation but also in the cytokines they produce. Naive T lymphocytes produce a T-helper (Th)1 profile of cytokines [e.g., IL-2, interferon (IFN)-g], whereas memory T lymphocytes produce a Th2 profile of cytokines (e.g., IL-4, IL-6). For this reason, the reciprocal change in the naive and memory T-lymphocyte subsets during aging not only limits the response to new antigens but also alters cytokine-dependent immune responses (11). Age-associated alterations in T-lymphocyte expression of CD28 and CD40L also compromise antibody responses to foreign antigens (12). A subset of $CD4^+CD28^-$ T cells has been defined in aging individuals that has been postulated to play a role in the poor proliferative response seen *in vitro*. An abnormality in activity of a nuclear transactivating factor has been suggested as the cause of the defect (13).

Effect of Age on Cell-Mediated Immunity *In Vivo*

The role of the thymus gland in the development of immune competence was demonstrated by neonatal thymectomy of experimental animals (14). Neonatally thymectomized animals are markedly impaired in cell-mediated and T-cell–dependent humoral immunity. If thymectomy is delayed by a month, until after the peripheral T-cell repertoire is established, defects in cell-mediated immunity develop only after a long interval and are less striking. This observation partially explains the long interval between the involution of the thymus at puberty and the appearance of impaired cell-mediated immunity during the second half of life.

The cutaneous delayed-type hypersensitivity (DTH) reaction is a classic manifestation of cell-mediated immunity and the first to be shown to decline during aging (15). Virtually all young adults express DTH to many common environmental antigens. In the elderly, DTH reactions are elicited by few antigens, and the intensity of the DTH reaction is diminished. The loss of DTH with age appears to be yet another risk factor that contributes to shortened survival (16). However, such tests of DTH might be attributable to differences in the interval between sensitization to an environmental antigen and the testing of the DTH reaction in old and young humans. To control for this difference, young and old humans were sensitized to a novel antigen, nitrochlorobenzene, and the DTH reactivity tested after the same interval in all individuals. The results of these better-controlled experiments confirmed an age-associated defect in the DTH response (15). In addition to environmental antigens, infectious agents induce DTH reactions. An age-associated decline in DTH to *Mycobacterium tuberculosis* (MTb) or varicella-zoster virus (VZV) antigens also is observed.

Infection with MTb or VZV usually induces protective immunity that reduces the number of infectious organisms but rarely eliminates organisms from the body. Viable MTb and VZV remain latent for decades in the lungs or nervous system, respectively. As immune senescence develops and the DTH reaction declines, reactivation of tuberculosis or VZV as “shingles” occurs in elderly adults. Thus cell-mediated immunity plays an important role in preventing the dissemination of these microorganisms that results in the reactivation of disease.

As discussed earlier, infection is a major problem in the elderly. Influenza is a classic example. Immune protection from influenza depends on both humoral and cell-mediated immunity to the virus. The T lymphocyte–dependent antibody response to the influenza-specific hemagglutinin (HA) is essential to prevent influenza infection. During aging, the antibody response to influenza HA after infection or vaccination declines, and the virus is cleared more slowly from the circulation (17). The increased severity of influenza in the elderly reflects the decreased generation of influenza-specific cytotoxic T lymphocytes required for the clearance of influenza-infected cells and recovery from the disease (18). Thus age-associated impairment in T-lymphocyte function contributes to the increased susceptibility to and severity of influenza in the elderly.

Effect of Age on the Proliferation of T Lymphocytes *In Vitro*

Age-associated impairment in cell-mediated immunity observed *in vivo* appears to be more complex than that which can be explained by depletion of naive cells and expansion of the memory cell populations. Studies have demonstrated multiple defects in the lymphocytes from aged subjects. It is possible to separate the effects of the “aged” environment on T-lymphocyte function from defects intrinsic to the T lymphocytes and/or antigen-presenting cells by measuring their function *in vitro*, where the effect of the aged environment is eliminated. Initially, *in vitro* studies focused on the proliferation of T lymphocytes in culture, as cell-mediated immunity depends on lymphocyte clonal expansion *in vivo* (19). In virtually all studies, an age-associated decline in the proliferation response of T lymphocytes cultured with mitogens is noted in humans and experimental animals. This proliferative defect is intrinsic to T cells, as the capacity of antigen-presenting cells does not change with age (20).

During a normal life span, T lymphocytes make proliferative responses to the large number of antigens in the environment. Cell division is accompanied by a decreasing length of telomeres, the terminal portions of chromosomes (21). The average length of telomeres on chromosomes in T lymphocytes decreases with age. In addition, at every age, the length of telomeres in memory T lymphocytes is shorter than that in naive T lymphocytes, as antigen-driven proliferation is associated with the transition of naive into memory T lymphocytes. At some point in the proliferative history of the cell, the length of the telomeres becomes too short to permit further division. The causal relationship between telomere length and proliferative capacity was demonstrated in experiments in which the gene coding for the enzyme telomerase, which maintains telomere length, was transfected into fibroblasts, cells with a finite proliferative capacity. Transfected fibroblasts maintained their telomere length and had an increased proliferative capacity compared with untransfected fibroblasts (22).

The reactivation of tuberculosis in the elderly is correlated with a decline in MTb-specific DTH *in vivo* and decreased proliferation of T lymphocytes cultured with MTb antigens. DTH reactivity is essential to contain viable MTb within granulomas formed by monocytes. The granuloma reaction is highly dependent on the production by T lymphocytes of IFN-g and the response of monocytes to this cytokine. Based on *in vitro* studies, the T-lymphocyte production of and response of monocytes to IFN-g have been reported to become impaired during aging, contributing to disease exacerbation (23). An age-associated defect in the proliferative response of T lymphocytes cultured with VZV antigens also has been demonstrated and correlated with decreasing DTH reaction to VZV. The defect in T-lymphocyte proliferation from elderly subjects cultured with VZV antigens is correlated with a low frequency of VZV-responsive T lymphocytes (24). Interestingly, the low frequency of VZV-specific T lymphocytes in elderly humans can be boosted by immunization with an attenuated VZV. Current clinical studies will determine whether immunizing elderly subjects with the live, attenuated, OKA strain of VZV will decrease the frequency of shingles and postherpetic neuralgia in elderly adults by increasing cell-mediated immunity to VZV antigens.

A large body of evidence suggests that T lymphocytes from aged individuals also have defects in signal transduction after interaction of mitogenic molecules with their receptors on the surface of the T cells. This defect contributes to their impaired proliferative response (25). Many age-associated defects in early cytoplasmic steps in T-lymphocyte activation, such as the mobilization of free intracellular calcium and phosphorylation of proteins necessary for gene activation, have been documented. Among the many genes whose activation is necessary for proliferation are protooncogenes. These genes play an important role in the entry of T cells into the cell cycle before cell division. The c-*myc* protooncogene encodes a DNA-binding protein that is essential for the transit of T lymphocytes from the G_0 to G_1 phase of the cell cycle. The steady-state level of c-*myc* mRNA is lower in phytohemagglutinin (PHA)-activated T cells from aged as compared with those from young persons (26). The expression of another protooncogene, c-*jun*, detectable within 30 minutes of T-lymphocyte activation by PHA, which encodes another DNA-binding protein, AP-1 (27), is defective in the lymphocytes of aged subjects. Because the IL-2 enhancer contains an AP-1 binding site, a decline in the expression of AP-1 may play a critical role in the age-associated decline in the secretion of IL-2 by T lymphocytes, as discussed earlier.

Similar abnormalities in the induction of cyclin-dependent kinases important in cell division and in the kinase activity of Raf-1 have been discredited (28,29). Pathways that lead to JNK activation are similarly reported to be age sensitive (30). Some suggest that a defect in Fas-mediated apoptosis is responsible for the expansion in memory T cells.

Aging also is associated not only with the decreased production of IL-2 by activated T lymphocytes, as has already been discussed, but there also is a decreased response to exogenous IL-2 in culture (31). The decreased response to IL-2 of activated T lymphocytes from old donors (32) is due to their failure to express high-affinity IL-2 receptors (IL-2R). The high affinity IL-2R is made up of a three-protein complex. The IL-2R a and b chains bind IL-2 with low or intermediate affinity, respectively. A third, IL-2R g chain does not bind IL-2 but interacts with the other two chains to form a high-affinity complex. The a and b chains of the IL-2R are expressed similarly on activated lymphocytes from old and young donors. However, only 50% of the activated T lymphocytes from elderly donors express high-affinity IL-2R, presumably because the expression or activity of the IL-2R g chain is altered during aging (32).

Not all cytokines produced by activated T lymphocytes in culture decrease with age. There is an age-associated increase in the secretion of Th2 cytokines, IL-4 and IL-6, by activated T lymphocytes in culture (11). As a generalization, it appears that aging is associated with a shift in the production by activated T cells from cytokines with a Th1 profile (signature cytokine, IL-2) seen in the first half of the life span to a Th2 profile (signature cytokine, IL-4) seen in the second half of the life span. This shift in cytokine profile also is observed *in vivo* (Table 82.2) (33). It is known that Th1 and Th2 cytokines can stimulate greater production of their own class of cytokines and inhibit the production of the other class of cytokines. Administration of IL-2 to old mice reversed the age-associated shift in cytokine expression by T lymphocytes. Thus the ratio of IL-2–expressing to IL-4–expressing T lymphocytes is increased 1.5-fold in IL-2–treated mice compared with 0.7-fold in untreated old mice (Table 82.2). A further abnormality is an increase in IL-10 production *in vitro* by lymphocytes of aging individuals after PHA stimulation (34).

Animals	IL-2 Expressing (%)	IL-4 Expressing (%
Young	6.1	5.2
Old	2.0	3.1
Old IL-2 treated	12.2	8.1

[a] Percentage of IL-2 or IL-4 expressing CD25+ T lymphocytes ex vivo. CD25+ T lymphocytes were solated by using magnetic beads and permeabilized. The percentage of permeabilized CD25+ T lymphocytes expressing intracellular cytokine was determined by flow cytometry (29).

TABLE 82.2. Percentage of IL-2 or IL-4 Expressing T Lymphocytes Activated *In Vivo*[a]

In part this shift in cytokine production reflects the age-associated shift from naive to memory T lymphocytes. Both memory and naive T lymphocytes produce IL-2, but memory T lymphocytes are the predominant producers of IL-4 and IL-6. This shift in cytokine secretion may contribute to the altered susceptibility of the elderly to certain infectious diseases and the increasing level of serum Ig. It is possible that it contributes to the increasing frequency of B lymphocytes secreting immunoglobulin (Ig), of monoclonal serum Ig, and autoantibodies, as well as the benign and malignant clonal B-lymphocyte expansions that occur during aging (35).

HUMORAL IMMUNITY

Effect of Age on the Development of B Lymphocytes

As discussed under B-cell development, pro-B cells and other cells in this lineage are produced in the bone marrow. In contrast to the thymus, which is entirely given over to cells of T lineage, B-lineage cells make up only a small proportion of bone marrow cells. The great majority of bone marrow cells are hematopoietic precursors, whose production continues throughout life. This makes it difficult to appreciate a decline or “involution” of B-lineage cells by gross or microscopic examination. However, the study of bone marrow cells by using flow cytometry and antibodies specific for the various stages of B-lymphocyte development has permitted the effect of age on bone marrow B-cell development to be determined. With these tools, we now appreciate that the number of bone marrow B-cell precursors decreases with age. This involution of the bone marrow lymphoid compartment begins after thymic involution (35).

Pre-B lymphocytes are the most numerous of the B-lineage cells in the bone marrow, and their number decreases by 60% to 90% during aging. Interestingly, the number of pro-B lymphocytes does not decrease with age; thus it appears that age-associated defects affect the transition of pro-B to pre-B lymphocytes. The generation of pre-B lymphocytes from pro-B lymphocytes depends on the expression of the pre-B receptor, made up of a three-protein complex: the Ig heavy chain, l5, and VpreB (see Chapter). When Ig rearrangement does not occur, as in RAG-deficient mice, no pre-B cells are produced (36). During aging, the rearrangement of the Ig heavy-chain genes in pro-B lymphocytes is impaired (37). Pre-B lymphocytes without the pre-B receptor are highly susceptible to apoptosis, explaining the increased percentage of apoptotic pre-B cell in the bone marrow. Despite the decreased rate of B-lymphocyte production, the number of peripheral B lymphocytes is maintained during aging in part by an age-associated increase in their life span and their capacity for self-renewal (38). However, when peripheral B lymphocytes are depleted, their regeneration is slower in old mice than in young mice (39), and diversity of the regenerated B-lymphocyte population decreases in elderly mice. The diversity of the B-cell repertoire depends on the generation of naive B lymphocytes in the bone marrow. Therefore the decreased diversity of the B-lymphocyte repertoire in old mice after their peripheral depletion suggests an impaired production of naive B lymphocytes by the bone marrow. In Fig. 82.1, it can be seen that a diverse B-cell repertoire before cyclophosphamide administration is regenerated in young but not in old mice. Furthermore, in young mice with B-cell populations of limited diversity before peripheral B-cell depletion, the B-cell population that is regenerated is more diverse than that originally present, suggesting the generation of naive cells. In contrast, in old mice, the B-cell population of limited diversity does not gain greater diversity after peripheral depletion. These findings are consistent with an age-associated decrease in the production of naive B lymphocytes by the bone marrow.

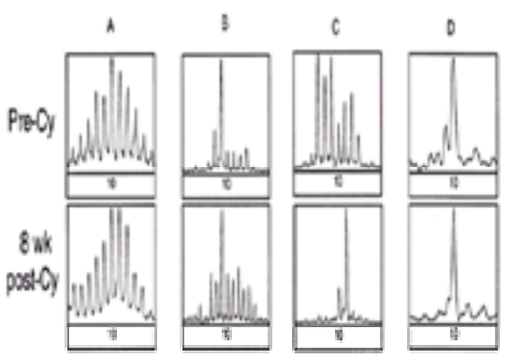

Figure 82.1. Effect of age on the diversity of the B-lymphocyte repertoire spleen cells were obtained from 2-month-old **(A, B)** and 18-month-old **(C, D)** BALB/c mice by partial splenectomy before 4 and 8 weeks after treatment with 200 mg cyclophosphamide/kg. The diversity of the B-cell repertoire with respect to immunoglobulin M CDR3 mRNA size shown before and 8 weeks after cyclophosphamide treatment.

Effect of Age on the Peripheral B-Lymphocyte Subsets

B lymphocytes are divided into two subsets based on the surface expression of the CD5 molecule. Most B lymphocytes do not express surface CD5, and in mice, are generated in the bone marrow. These “conventional” B lymphocytes are the principal source of antibody to foreign antigens. CD5-positive B lymphocytes are generated in the peritoneal cavity of mice. The repertoire of the population of $CD5^+$ B lymphocytes includes many antibody molecules that have not undergone somatic rearrangement and are in the germ-line configuration. The antibody is skewed toward the production of autoantibodies. The percentage of $CD5^+$ B lymphocytes increases during aging, reflecting the continued production of $CD5^+$ B lymphocytes in the peritoneal cavity at a time when the production of $CD5^-$ B lymphocytes in the bone marrow is decreasing (40). This shifting balance of $CD5^-$ to $CD5^+$ B lymphocytes appears to be the cellular basis for the age-associated shift in the specificity of antibodies from foreign to autologous antigens.

Old and young mice were immunized with trinitrophenylated keyhole limpet hemocyanin (TNP-KLH), an antigen that stimulates $CD5^-$ B lymphocytes, or TNP-Ficoll, an

antigen that stimulates $CD5^+$ B lymphocytes. Young mice produced comparable numbers of splenic anti-TNP plaque-forming cells (PFCs) when immunized with TNP conjugated to either carrier. In contrast, old mice produced few anti-TNP PFCs after immunization with TNP-KLH than with TNP-Ficoll. This finding suggests that aging compromises the response of $CD5^-$ but not $CD5^+$ B lymphocytes to foreign antigens. Thus, a greater antibody response to a foreign antigen in older individuals may be achieved by targeting the available $CD5^+$ B lymphocytes.

Effect of Age on Natural and Induced Antibodies to Foreign Antigens

The first report suggesting an effect of age on the immune system was published more than 70 years ago by Thomsen and Kettel (42). These investigators reported that the titer of natural antibodies in human serum to the A and B erythrocyte antigens (isoagglutinins) declines with age. Forty years later, the decline in natural antibody specific for a foreign antigen, in this case, salmonella flagellin, was confirmed (43). It is now recognized that the antibody response of elderly humans to virtually all vaccines, including encephalitis, hepatitis, influenza, and tetanus toxoid, is less than that observed in young individuals (44). In contrast, the magnitude of the antibody response to most T-independent antigens such as pneumococcal polysaccharides is maintained during aging. However, the duration of protective immunity achieved by pneumococcal vaccine is shorter in old compared with young humans (45). For this reason, humans older than 65 years should be revaccinated with pneumococcal vaccine every 5 to 8 years.

The effect of age on the antibody response to a foreign antigen was studied in greater detail in mice immunized with hapten-conjugated protein. Old mice immunized with nitrophenylated-bovine gamma globulin elicited a reduced PFC response with a preferential loss of high-affinity and IgG antibody–producing cells compared with the response of young mice (46). It is known that high-affinity antibody activates complement more efficiently than does low-affinity antibody, and it is interesting that (a) antiphosphorylcholine (PC) antibodies protect a higher percentage of mice from challenge with living pneumococci than do low-affinity anti-PC antibodies from old mice (47).

Production of high-affinity antibody has been demonstrated to occur within germinal centers (GCs). It is here that high-affinity antibodies are generated by somatic mutation, and IgG antibodies are formed after isotype switching. During the initial response to antigen, B cells with affinity for the introduced antigen migrate to GCs, where they undergo clonal expansion, somatic hypermutation, isotype switching, and subsequent selection. It is now recognized that these processes are all compromised in aging. Furthermore, aging is associated with a decrease in the number and size of GCs as a result of impaired Th-cell function (48). Transfer experiments have revealed that defects intrinsic to both B and T lymphocyte from old mice contribute to the decreased affinity maturation seen in aged animals. It is not known whether the loss of GCs during aging is the cause or the consequence of this process.

In humans, the level of all serum Ig except for IgD remains unchanged or increases with age. In mice, the level of IgM, IgG, and IgA increases with age, as does the number of splenic and bone marrow Ig-secreting B lymphocytes (49). If Ig specific for most foreign antigens decreases during aging, what are the specificities of the antibodies that maintain or increase the level of serum Ig?

In contrast to the decreasing production of most antibodies to foreign antigens, the level of autoantibodies increases with age. This age-associated shift in Ig specificities from foreign to autologous antigens was first reported 40 years ago when the level of serum anti–salmonella flagellin antibodies and autoantibodies specific for the nucleus were compared in humans of different ages (Fig. 82.2). It was observed that the titer of antibodies specific for the foreign antigen, salmonella flagellin, decreased with age, whereas the percentage of persons with antinuclear autoantibodies increased with age. Subsequent studies revealed that 60% of healthy elderly persons have autoantibodies specific for one or more of the following autoantigens: nucleoprotein, IgG, or thyroglobulin (50). With the exception of the oldest cohort studied, which had a lower level of autoantibodies than did the rest of the population older than 65 years, the percentage of individuals with autoantibodies increased with age (51). Of interest, centenarians also have lower levels of antithyroglobulin autoantibodies than do younger elderly humans. In contrast, organ-nonspecific autoantibodies increase with age, including the oldest age cohorts. These studies raise the possibility that organ-specific autoantibodies are related to chronic disease and are a factor for shortened survival.

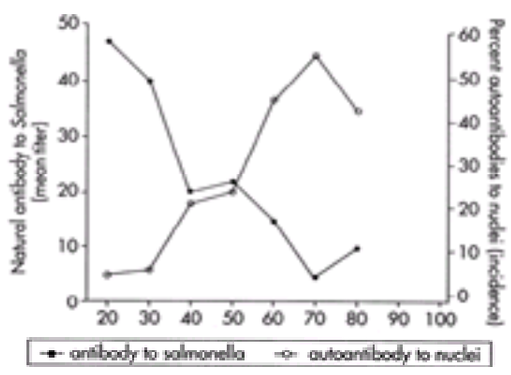

Figure 82.2. Age-associated cross-wiring of the immune system. Serum was obtained from individuals between ages 20 and 80 years. The titer of natural antibody to salmonella flagellin and the percentage of individuals with antinuclear antibody were measured. (Adapted from Rowley MJ, Buchanan H, Mackay JR. Reciprocal change with age in antibody to extrinsic and intrinsic antigens. *Lancet* 1968;2:24, with permission.)

In mice, four factors have been suggested to contribute to the age-associated increase in autoantibodies: (a) an increase in the frequency of autoantibody-producing B lymphocytes detected by limiting dilution analysis (52); (b) polyclonal activation of B lymphocytes in old mice, possibly stimulated by increased IL-4 and/or IL-6. There are 5 to 10 times as many splenic B lymphocytes secreting Ig in unimmunized old compared with young mice (41); (c) age-associated decline in intrathymic negative selection of autoreactive T cells (53); and (d) cell-transfer experiments suggest that the aged environment stimulates autoantibody production (54). Thus more autoantibodies are generated in old compared with young mice given syngeneic bone marrow cells.

The age-associated shift in antibody specificities from foreign to autologous antigens also is observed after immunization with a foreign antigen. Thus immunization of humans with tetanus toxoid stimulates a greater number of autoantibody-producing lymphocytes in the elderly compared with that in the young (55). Similarly, old mice immunized with sheep erythrocytes (SRBCs) produce fewer B lymphocytes secreting anti-SRBC antibodies but many times the number of B lymphocytes secreting antimouse RBC antibodies compared with these responses in young mice (56). The age-associated loss of the exquisite specificity of the immune response to the nominal antigen, we have termed “cross-wiring” of the immune response. Immunization of old mice with a foreign antigen activates more autoantibody-producing lymphocytes than lymphocytes producing antibodies to the nominal antigen. The cellular basis of the cross-wiring of the immune response during aging appears to be due to the decreasing ratio in the number and activity of conventional $CD5^-$ to $CD5^+$ B lymphocytes with age, as discussed earlier.

Although the serum concentration of autoantibodies increases with age, we found no change in the autoantibody repertoire. Thus comparison of the specificities of autoreactive Ig in serum from young and old mice or humans with lysates of normal tissues reveals the same pattern of binding (57). The binding profile of serum Ig to a large number of proteins from normal tissues that have been electrophoretically separated is unchanged during aging.

Despite the increased production of autoantibodies during aging, the incidence of autoimmune disease does not increase with age. Autoimmune diseases usually are seen for the first time during the middle third of the life span. Pernicious anemia and thyroiditis, which occur late in life, are exceptions to this generalization. Similarly in animals, the induction of experimental autoimmune disease is more difficult in old compared with young animals. Old animals are more resistant than young to the induction of autoimmune hemolytic anemia or arthritis by xenogeneic erythrocytes or type II collagen (58).

Among the organ-nonspecific autoantibodies that increase with age are antiidiotypic autoantibodies (59). These autoantibodies are of particular interest as they can suppress the immune response to foreign antigens by reacting with surface Ig on antigen-specific B lymphocytes and inhibiting their secretion of antibody to the foreign antigen. The antiidiotypic autoantibody response is a good example of the cross-wiring of the immune response: old mice produce greater quantities of antiidiotypic autoantibodies and lesser quantities of antibodies to foreign antigens. Thus the appearance of this class of autoantibodies not only reflects the state of immune dysregulation observed during aging but also may contribute to the immune deficiency associated with it.

Transfer studies in mice have been used to identify the cellular basis of the age-associated increase in the antiidiotypic autoantibody response (59). Long-lived splenic T lymphocytes but not bone marrow cells transplanted from old mice to young mice transferred the capacity to produce a strong antiidiotypic autoantibody. T lymphocytes from old mice stimulated antiidiotypic autoantibody production by B cells from young or old mice. Furthermore, depletion of peripheral T cells from old mice decreased the production of antiidiotypic autoantibodies and led to an increase in the production of antibodies to foreign antigen.

Studies in humans suggest a clinical impact of antiidiotypic autoantibody production (60). Elderly humans, previously immunized with tetanus toxoid, have a higher level

of serum antiidiotypic autoantibodies before boosting than do young individuals. The level of antiidiotypic autoantibodies before immunization of old and young individuals with tetanus toxoid is inversely correlated with the level of antitetanus antibodies that develops after immunization. Thus, the elderly subjects with the highest level of antiidiotypic autoantibody made the lowest antitetanus-antibody response. These results confirm the importance of age-associated antiidiotypic autoantibody in the impaired antibody response to vaccines in humans.

Clonal Lymphocyte Expansion during Aging

The immune response becomes less heterogeneous with respect to isotype, antigen-binding affinity, idiotype, and the size and sequence of the Ig heavy-chain variable region during aging (35). This is due, in part, to the decreased production of naive lymphocytes by the thymus and bone marrow and the decreased diversification of the naive B lymphocytes as a result of decreased somatic mutation and isotype switching within the GCs. As the primary sites of lymphocyte production lose their capacity to export a naive repertoire of diverse specificity, the memory lymphocyte population maintains the total number of lymphocytes by peripheral renewal and clonal expansion. The age-associated increase in the incidence of serum monoclonal Igs presumably reflects the increasing frequency of B-cell clonal expansion during aging (35). Direct evidence for age-associated clonal B- and T-lymphocyte expansion has been obtained by cloning and sequencing studies of the CDR3 portion of the mRNA for the TCR and BCR in both humans and mice.

It had been recognized for a long time that clonal lymphocyte expansion is often followed by lymphocyte malignancies. Each year, in 1% of humans with monoclonal serum Ig, multiple myeloma develops. Lymphoma and chronic lymphocytic leukemia also occur late in life after the expansion of clonal B or T lymphocytes. The links between age-associated malignancies and clonal lymphocyte expansions, which precede them, include the expression of the $CD5^+$ surface marker on nearly all expanded B-cell clones and chronic lymphocytic leukemia cells. Furthermore, 50% of chronic lymphocytic leukemic cells produce autoantibodies, as do spontaneously activated B cells in elderly humans and experimental animals. It remains to be proved by “molecular fingerprinting” that the lymphocyte malignancies are derived from the clonal lymphocyte expansions. Studies are now under way to establish whether the nucleic acid sequence of the variable region of the BCR expressed by expanded clonal lymphocytes also is expressed by the lymphocyte malignancies that occur later in life.

Enhancing Protective Immunity in the Elderly

Understanding the mechanisms underlying immune senescence leads to suggestions for ways to maximize the immune response to vaccines of the elderly. First, foreign antigens might be targeted to $CD5^+$ B lymphocytes, whose function is better maintained during aging than is that of $CD5^-$ B lymphocytes. Second, antigens may stimulate a better immune response if delivered to lymphoid compartments whose function is less compromised during aging. The production of antibodies specific for a foreign antigen by mucosal lymphocytes has been reported to be better maintained during aging than that by splenic and lymph node B cells (61). This raises the possibility that antigen presented to mucosal surfaces of the respiratory, digestive, or urinary tract may induce better protective immunity than can be achieved by intramuscular or subcutaneous immunization.

Another factor contributing to the poor response of elderly to conventional vaccines is that higher doses of antigen may be required to achieve a maximal immune response in old compared with young subjects. Live recombinant viral vaccines that express a relevant antigen may offer advantages. Viral proliferation increases the quantity of foreign antigen to the level that best stimulates each recipient, old or young. We have demonstrated the proof of this principle in mice (62). Young mice immunized with a nonproliferating viral vaccine expressing the PR-8 influenza virus hemagglutinin (HA) produced a high level of anti-HA antibodies and anti-HA cytotoxic T lymphocytes (CTLs) and had complete protection from influenza challenge. In contrast, old mice made modest immune responses that protected only 50% of them from influenza challenge. However, immunization with a live recombinant vaccinia vaccine expressing the influenza HA stimulated both old and young mice to produce high antibody and CTL responses to HA, and the mice were completely protected from influenza challenge. In summary, improved protective immunity might be achieved in older humans if antigen dose, composition, and route of antigen delivery were altered to target lymphocytes and the lymphoid compartments where activity is best maintained during aging. Finally, the use of living, attenuated or recombinant vaccines may offer distinct advantages in inducing or maintaining protective immunity in the elderly. In this regard, we await with great interest the results of ongoing studies using the attenuated VZV, now used in children to prevent chickenpox, to maintain immunity to this virus and thus decrease the reactivation of the latent virus in the elderly, leading to shingles and postherpetic neuralgia.

83 HEMATOPOIETIC STEM CELL TRANSPLANTATION

Michael B. Maris, M.D., and Rainer Storb, M.D.

Hematopoietic stem cell transplantation (HSCT) is an effective and increasingly used modality for the cure of both malignant and nonmalignant diseases. For patients with malignant disorders, much effort has been dedicated over the last 30 years in optimizing the doses of radiation and chemotherapy (referred to as conditioning) used to maximize tumor cell kill and minimize regimen related toxicity (1,2,3 and 4). For those patients with nonmalignant diseases (Table 83.1) such as severe aplastic anemia (SAA) and severe combined immunodeficiency disease (SCID), the goal has been to optimize host immunosuppression for facilitating donor engraftment (5,6,7,8,9 and 10). At the same time, voluntary marrow or infant cord blood registries have been set up to expand the pool of donors beyond immediate family members. The safety of HSCT continues to improve, as exemplified by the reduced incidence of mortality from opportunistic infections. Despite this, substantial challenges remain. In particular, regimen-related toxicity and graft-versus-host disease (GVHD) remain difficult problems for some patients. Older patients have more regimen-related toxicity and mortality due to the combined effects of high-dose chemoradiotherapy and GVHD, and therefore most transplant centers will not offer HSCT for patients older than 50 years (11). A number of groups have recently reported on a variety of nonmyeloablative HSCT programs that use attenuated doses of chemotherapy and/or radiation (12,13,14,15,16 and 17). Preliminary reports have described significant antitumor responses due to immunologically mediated allogeneic effects, otherwise known as the *graft-versus-leukemia* (GVL) effects. Nonmyeloablative HSCT is performed in some centers on an outpatient basis and permits the application of this procedure to elderly and infirm patients who otherwise would not tolerate a conventional HSCT (11).

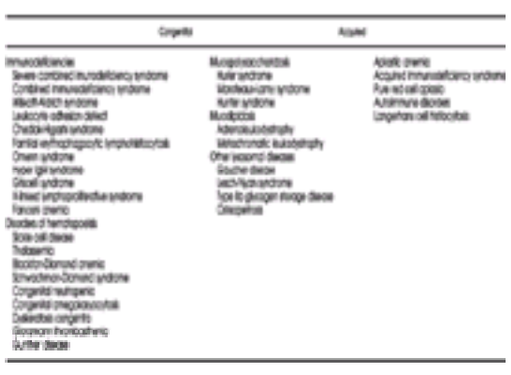

TABLE 83.1. Nonmalignant Diseases Corrected by Hematopoietic Stem Cell Transplantation

The changes occurring in the field of HSCT have been striking since the last edition of this book. As HSCT becomes more widely used and the list of medical indications grows, it will become more common to care for these patients in the general medical community. Therefore, it is prudent for general practitioners and medical subspecialists to have some familiarity with the indications and complications of HSCT. This chapter provides an overview of HSCT, including donor/recipient selection, transplantation techniques, indications, complications, and the future directions of HSCT.

SOURCE OF HEMATOPOIETIC STEM CELLS

An adequate number of stem cells for HSCT can be obtained from the bone marrow, the peripheral blood, or the umbilical cord of newborn infants. Bone marrow contains a high concentration of stem cell and has been the most common stem cell source. Stem cells circulate in the peripheral blood in low numbers, and their number can be greatly increased after exposure to chemotherapy, cytokines, and growth factors. These peripheral blood stem cells (PBSCs) are easily collected with standard apheresis techniques. The use of PBSCs is becoming more common primarily because it negates the risk of general anesthesia required for harvesting of bone marrow. The observation of large quantities of stem cells in the umbilical cord of newborn infants has led to the recent use of this product in allogeneic HSCT.

The stem cells can be transplanted in an autologous, syngeneic, or allogeneic manner. An *autologous* graft is collected from the patient in remission and transplanted at a later time. A *syngeneic* graft is from a monozygous twin who is identical at all genetic loci. *Allogeneic* grafts can be taken from nonsyngeneic siblings or alternative donors. Allogeneic donors who have been used with success include human leukocyte antigens (HLA)-identical siblings, HLA-mismatched relatives, and HLA-matched unrelated donors. Most allogeneic grafts come from genetically different siblings who are nonetheless genetically identical for the HLA coded for genes within the human major histocompatibility complex (MHC). An alternative donor refers to a family member who is genetically HLA identical at one haplotype and phenotypically identical at the other or mismatched for one or more HLA alleles. Acceptable sibling and family donors are found approximately 35% of the time. The identification of phenotypically identical *unrelated donors* is possible through large national and international registries of volunteers such as the National Marrow Donor Program (NMDP), and a donor can be found for approximately 50% to 60% of white patients. The underrepresentation of minorities has made the identification of donors difficult for ethnic groups other than whites. A Cord Blood Registry also is available for donation.

In vitro manipulation of the stem cell graft may be performed either to reduce the number of alloreactive T cells in allogeneic grafts or to reduce the risk of infusion of contaminating tumor cells in autologous grafts. Alloreactive T lymphocytes can be removed by a variety of techniques to reduce the risk of developing GVHD. These techniques are effective at preventing GVHD, but also may lead to increased risks of rejection and relapse that result in no net survival advantage. Often autologous grafts are treated *in vitro* with antibodies with or without complement or alkylating chemicals in attempts to purge the graft of tumor cells. The use of the alkylators perfosfamide and mafosfamide, which are similar to cyclophosphamide (CY) results in delayed myeloid and platelet engraftment; the efficacy of this treatment is yet to be clearly demonstrated in randomized controlled trials.

COLLECTION AND INFUSION OF HEMATOPOIETIC STEM CELLS

The three principal sources of HSCs that are commonly used include bone marrow, PBSCs, and umbilical cord blood (18). The harvesting of bone marrow is performed

while the donor is under anesthesia. Multiple punctures are made through the skin and the cortex of the iliac crest with the aspiration of less than 5 mL of marrow per puncture. This process is continued until 10 mL of marrow per kilogram of donor weight is removed. This will provide 1×10^8 to 8×10^8 nucleated cells per kilogram recipient body weight. The marrow is collected in a heparinized tissue-culture medium and is screened through wire mesh to remove tissue particles before infusion to the recipient.

The collection of PBSCs is usually performed at a local blood bank or the apheresis unit in the hospital. Filgrastim combinant human granulocyte colony-stimulating factor (rhG-CSF)] is the most commonly used agent to mobilize stem cells from the marrow into the peripheral blood. Other agents that can be used to mobilize stem cells include granulocyte-macrophage colony-stimulating factor (GM-CSF), macrophage stimulating factor (M-CSF), interleukin 3 (IL-3), and PIXY 321 (a fusion protein of GM-CSF and IL-3). Autologous mobilization typically uses chemotherapy with or without rhG-CSF. Interestingly, growth-factor administration can contribute to the mobilization of hematopoietic and epithelioid tumor cells into the peripheral blood (19). The typical dose of filgrastim is 10 to 16 µg/kg subcutaneously over a 4- to 5-day period. PBSCs are collected by using an apheresis machine. Nine to 12 L of blood can be processed over a 3-hour period. Two apheresis collections are usually performed on consecutive days. The stem cell yield of the PBSC collection is estimated from the number cells that express the cell-surface marker CD34. The $CD34^+$ cells represent both committed and noncommitted progenitor cells.

Life-threatening complications from bone marrow or PBSC collection are rare. Among more that 10,000 marrow harvests performed at our institution, there have been no deaths, although several deaths have been reported worldwide (20). These included one due to cardiac arrest, one to ventricular tachycardia, one to aspiration pneumonitis, and one to *Klebsiella* septicemia. More commonly, donors of bone marrow harvest will experience local pain at the harvest sites that will improve over several days to several weeks (21). Most donors who receive large doses of filgrastim for stem cell mobilization will have pain of hip, spine, and long bones due to proliferation of the myeloid marrow. This pain can be quite debilitating and difficult to control even with narcotic analgesics (22,23). Although G-CSF is generally safe, the long-term effects on hematopoiesis are unknown. The possibility of adverse effects on normal volunteer donors has prompted the NMDP to limit the donation of PBSCs to patients on experimental protocols and to monitor donors periodically over several years for adverse outcomes.

PREPARATION OF THE RECIPIENT FOR TRANSPLANTATION

Role of the Major Histocompatibility Complex in Human Stem Cell Transplantation

The HLA system is an integral portion of the immune system and is the primary barrier to successful HSCT. The HLA genes encode cell-surface molecules or *antigens*, whose function is to bind to T lymphocytes, resulting in immune responses (24). These genes are located in two clusters on the p21.3 band of the short arm of chromosome 6. They encode HLA class I (-A, -B, -C) and class II (-DR, -DQ, -DP) antigens. The genes are passed to siblings as a haplotype. The HLA haplotypes segregate in a classic mendelian fashion, creating a 25% chance of shared HLA identity of the major MHC antigens between siblings with the same parents.

The clinical success of allogeneic HSCT is directly related to the disparity of the HLA between donor and host. The host alloimmune response can cause the rejection of the graft. Conversely, the uncontrolled alloimmune response of the graft can cause life-threatening GVHD. The effector mechanisms that contribute to graft rejection and GVHD are T cells in the HLA-matched and -mismatched setting, whereas natural killer (NK) cells have been implicated in causing rejection in the HLA-mismatched setting (25,26 and 27). Improvements in the understanding of the HLA system and improved donor selection at the molecular level may reduce the complications and improve the results of allogeneic HSCT.

Human Leukocyte Antigen Typing: Serologic, Mixed Culture, and Molecular Techniques

Traditional methods for identifying the major HLA antigens have used serologic typing (24). The clinical importance of HLA antigen disparity has been shown to be important in HSCT outcomes such as overall survival, leukemia free survival, (Fig. 83.1) and engraftment. Mononuclear cells of the peripheral blood are incubated with panels of alloantisera consisting of anti-HLA antibodies. Lysis of cells is measured in a complement-mediated microcytotoxicity assay. A single epitope (private specificity) or multiple epitopes (public specificities) uniquely characterize the serologically defined HLA molecules. A cross-reactive group (*CREG*) refers to HLA antigens of the same subclass (e.g., HLA-A1), recognized by similar serology. Some CREG antigens are molecularly very similar and may differ by only a single amino acid substitution. The HLA-D antigens have traditionally been defined by cellular mixed-culture toxicity assay.

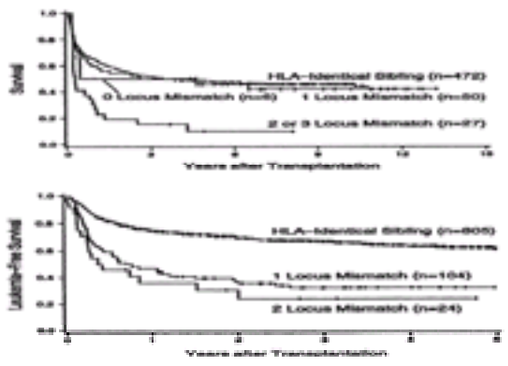

Figure 83.1. Effect of donor and recipient human leukocyte antigen (HLA) disparity on survival after marrow transplantation. Probability of survival in patients with chronic myeloid leukemia in the chronic phase, acute myeloid leukemia in first remission, or acute lymphoblastic leukemia in first or second remission, according to the degree of donor and recipient HLA disparity. Results from a single-center study. B: Probability of survival in patients with chronic myeloid leukemia in the chronic phase, acute myeloid leukemia in first remission, or acute lymphoblastic leukemia in first remission. Results from a study of the International Bone Marrow Transplant Registry. (A: reproduced from Anasetti C, Beatty PG, Storb R, et al. Effect of HLA compatibility on engraftment of bone marrow transplants in patients with leukemia or lymphoma. *Hum Immunol* 1990;29:47–91, with permission. B: Reproduced from Szydlo R, Goldman JM, Klein JP, et al. Results of allogeneic bone marrow transplants for leukemia using donors other than HLA-identical siblings. *J Clin Oncol* 1997;15:1767–1777, with permission.)

More recently several groups have advanced to molecular typing of the genes that encode HLA antigens of the MHC (28,29,30,31 and 32). Studies have determined that serologically defined specificities are broad and may contain multiple alleles. These molecular techniques use polymerase chain reaction technology. The different techniques include sequence-specific primers (SSPs), sequence-specific oligonucleotide probe hybridization (SSOP), or direct sequencing. Most groups at this time perform at least molecular typing at HLA-DRB1 for all patients.

Significance of Human Leukocyte Antigen Disparity in Clinical Outcomes

Most alternative-donor and unrelated-donor HSCTs have been performed with serologic matching at the HLA-A, -B, and -DR. HLA differences even at the allelic level can effect HSCT outcomes as was conclusively shown in one patient with graft rejection (25) in whom a single amino acid difference in HLA B44 led to graft rejection of a donor marrow that was serologically identical to that of the recipient. In a series of retrospective studies, Petersdorf et al. (28,29,30,31 and 32) evaluated HLA disparity at the molecular level with clinical outcome in patients who have undergone HSCT for hematologic malignancies (28,29,30,31 and 32). In a study evaluating class I allele disparity in 21 patients who rejected an unrelated donor allograft, 71% were found to have allele mismatch at HLA-C alone or in combination with a one-allele HLA-A or -B mismatch (28). These combinations were identified in only 33% of controls. Multiple allele disparity at HLA-A and -B also was associated with graft failure. In a multivariable analysis, HLA-C mismatch was identified as an independent risk factor for graft rejection (28).

The importance of the class II system antigens HLA-DRB1 and -DRQ as being independent risk factors for the development of GVHD for recipients of unrelated-donor HSCT was identified in two retrospective studies (29,30). The first study evaluated DRB1 disparity in 364 patients that received grafts from HLA-A, -B, and -DR serologically matched unrelated-donor graft for hematologic malignancies. Disparities were identified by SSOP evaluation at the DRB1 alleles in 59 pairs. In multivariable analysis, patients with a one-allele DRB1 disparity were found to have increased risks of both GVHD and transplant-related mortality. The second study evaluated 449 recipients of HLA-A, -B, and -DR serologically matched unrelated-donor grafts for hematologic malignancies. Most of the donor/recipient pairs (75%) were matched at DRB1 and DQB1. The relative risks of grades III and IV GVHD were 0.42 for patients matched at both alleles, 0.55 for single-locus DRB1 mismatches, 0.61 for single-locus DRQ mismatches, and 0.71 for combined DRB1 and DQB1 mismatches. A similarly designed Japanese retrospective study found quite different results; class I HLA mismatching was highly correlated with GVHD and death, whereas no association with GVHD or mortality was demonstrated with class II mismatching. These differences are as yet unexplained, but the frequencies of the allele distribution between patients in the two studies are quite different (Petersdorf, personal communication). Nevertheless, both studies strongly suggest the biologic relevance of HLA class I and II alleles and the importance of allele-level

typing on outcome of HSCT.

Design of Conditioning Regimens

CONVENTIONAL CONDITIONING REGIMENS

The design and use of preparative regimens or *conditioning* must take into account the patient's underlying disease. In patients with nonmalignant diseases, the conditioning regimen's role is to provide host immunosuppression; in those transplanted for malignant diseases, the conditioning regimen serves the dual purpose of immunosuppression and the eradication of cancer. The underlying disease process has influenced the choice of the chemotherapy and/or radiation therapy used. Obviously, in nonmalignant disorders, no advantage exists to escalating the doses of chemotherapy and/or radiation therapy to those that are maximally tolerated. In some severe disorders of immune function, such as SCID or leukocyte functional antigen-1 (LFA-1) deficiency, the underlying dysfunction of host immunity may be so severe that the use of conditioning for host immunosuppression may not be required or may be relatively mild to obtain sustained engraftment (33). However, in other nonmalignant diseases of hematopoiesis (for example, AA or thalassemia), host immunosuppression is required to prevent graft rejection. Finally, in patients with hematologic malignancy, despite the intensity of the conditioning regimens, relapse of the underlying malignancy remains a problem (33).

Preparative regimens for SAA commonly use CY. A regimen developed in Seattle used CY at 50 mg per day on 4 consecutive days followed by stem cell infusion 36 hours after the last dose. Unfortunately, a high rate of graft rejection occurred in those patients previously transfused with unirradiated blood and, therefore, allosensitized to non-HLA antigens. Efforts to intensify the conditioning regimen to reduce the risk of graft rejection have included the addition of 3 to 10 gray (Gy) of total body irradiation (TBI) with or without lung shielding, thoracoabdominal irradiation (TAI), and total lymphoid irradiation (TLI) (33). Other chemotherapeutic agents also have been added to CY alone or CY and irradiation. The addition of viable buffy-coat infusions to the marrow grafts improved engraftment, but resulted in increased chronic GVHD (33). The successful use of antithymocyte globulin (ATG) with CY to improve host immunosuppression for second transplant after rejection of an initial allograft has resulted in ATG being incorporated in most current front-line SAA regimens (33).

In patients with genetically determined nonmalignant disorders (e.g., Wiskott-Aldrich, thalassemia major) who have normal or greater than normal bone marrow cellularity, CY (120 to 200 mg/kg) and busulfan (BU; 0.5 to 4.0 mg/kg/day for 4 days, taken orally) or dimethylbusulfan (DMBU; mg/kg intravenously) have been successfully used (34,35 and 36). Another approach has been to combine procarbazine and ATG with TBI to prepare patients with Wiskott-Aldrich syndrome (37).

Until recently, it was widely believed that patients with hematologic malignancies could be cured only with large doses of radiation and chemotherapy. Early studies in animal models demonstrated the feasibility of marrow grafting from one animal to another after the administration of myeloablative doses of TBI. Most early conditioning regimens included TBI because of the extensive preclinical experience using that modality. In principle, TBI is an effective technique for killing malignant cells; it penetrates into privileged sites such as the central nervous system (CNS) not accessible to chemotherapy because of the blood–brain barrier. Initial attempts using a single dose of TBI at 10 Gy as a single modality resulted in one of six patients with relapsed acute lymphoblastic leukemia (ALL) entering a durable remission. Thomas in 1977 (38) published a series of 100 patients demonstrating success with 10 Gy of single-dose TBI combined with CY. Because of the high incidence of interstitial pneumonia (IP) noted with single-dose TBI, investigations into fractionated schedules of TBI demonstrated efficacy with reduced incidence of IP (39).

Other groups evaluated the efficacy of chemotherapy-only regimens. Fatal cardiac toxicity was reported with very-high-dose CY (60 mg/kg/day for 4 days). Even with lower doses of CY, all patients who survived conditioning relapsed. BU (16 mg/kg) in combination with CY (200 mg/kg) was introduced by the Johns Hopkins group (40). The Ohio State transplant group and others have demonstrated the efficacy of the BuCy2 regimen, consisting of BU (16 mg/kg) with reduced-dose CY (60 mg/kg/day for 2 days) (41,42). Because of the variable metabolism and the association of therapeutic serum BU levels with prevention of leukemia relapse, some groups are now targeting BU doses to maintain therapeutic serum levels (43). Over the last decade, several groups have effectively combined etoposide with BU/CY or CY/TBI for patients with advanced hematologic malignancies to reduce the relapse rate (44,45 and 46).

NONMYELOABLATIVE CONDITIONING REGIMENS

The toxicities of conventional HSCT combined with the significant risk of relapse led many investigators to explore the use of less intensive conditioning regimens to reduce regimen-related toxicities and to rely primarily on the immunologically mediated graft-versus-tumor effect. The nonmyeloablative approaches taken by different groups can be divided into (a) reduced intensity of conventional cytotoxic regimens, and (b) pre- and posttransplantation immunosuppression to control both host and donor immune reactions, thereby preventing both rejection and controlling GVHD (17). In both approaches, the establishment of mixed or full donor chimerism provides a platform for further adoptive immunotherapy using donor lymphocyte infusions (DLIs) to eradicate residual malignant cells. Examples of investigators who used attenuated doses of conventional HSCT programs include the transplant teams of Boston, Houston, Bethesda, Geneva, and Jerusalem groups (12,13,14,15,16 and 17). The Seattle group has used a different approach based on preclinical studies in a random-bred dog model. The combination of mycophenolate mofetil and cyclosporine (CSP) was compared with other immunosuppressive medications at sublethal doses of radiation to determine if mixed hematopoietic chimerism could be obtained (47). With this combination of drugs, mixed-chimerism was obtained by using a nonmyeloablative dose of only 200 cGy of TBI, but all dogs rejected with CSP alone, and four of six dogs rejected with the combination of CSP and methotrexate (MTX) (47). With this model, the combination of mycophenolate mofetil and CSP was shown to be an effective synergistic postgrafting immunosuppressive at preventing GVHD and enhancing engraftment (47,48). The initial nonmyeloablative regimen used in Seattle for patients with HLA-matched sibling donors used pretransplant immunosuppression of 200 cGy delivered as a single fraction at 7 to 8 cGy per minute, and postgrafting immunosuppression with CSP, 6.25 mg/kg twice daily orally from day –3 to day 35, and mycophenolate mofetil, 15 mg/kg twice daily orally from day 0 to day 27 (49,50). PBSCs from HLA-identical sibling donors were infused on day 0. Donor/host chimerism in peripheral blood T cells was evaluated on days 28 and 56 by using either microsatellite markers or, for sex-mismatched donor/recipient pairs, fluorescence *in situ* hybridization of X and Y chromosomes. Recently, fludarabine, 30 mg/m^2, given on 3 consecutive days before transplant, has proven effective in reducing the small risk of rejection seen in the first 45 patients and improving the degree of donor chimerism after transplant (11).

SUPPORTIVE CARE AND OPPORTUNISTIC INFECTIONS DURING THE EARLY POSTGRAFTING PERIOD

The patient undergoing a conventional HSCT first has pancytopenia and then profound impairment of immune function due to transplant conditioning and underlying disease at the same time that primary host defenses, such as mucocutaneous integrity, are breached because of conditioning toxicity. Patients will maintain some residual immune function for approximately 2 to 7 weeks after transplant. After a conventional HSCT, the patient typically will be neutropenic for 7 to 24 days, with earlier engraftment being seen in recipients of PBSCs (Fig. 83.2) (51,52,53 and 54). After initial engraftment, severe immunologic impairment will last at least 4 months, and serious bacterial, fungal, and viral infections often occur (36,55,56,57 and 58). Immunologic impairment may persist for 6 to 12 months, and can last for years in those patients who have chronic GVHD. In general, for those patients undergoing an autologous HSCT or recipients of autologous or allogeneic PBSCs, the degree of immunologic impairment is not so profound, and immunologic recovery occurs more quickly (53,59,60).

Bacterial infections are the most common pathogens in the early granulocytopenic period. Approximately 5% of HSCT recipients may die of bacterial infections during this period. Most centers will use prophylactic broad-spectrum antibiotics at the onset of neutropenia. Fevers develop in almost all HSCT patients, but only in approximately 50% of cases will pathogens (usually bacterial) be isolated. Growth factors are not commonly used in allogeneic HSCT because they have not been demonstrated to improve outcome despite accelerated granulocytic recovery of ~6 days (61,62). High-dose intravenous immunoglobulin (IVIG) appeared to be effective in reducing the incidence of infectious complications in two randomized controlled trials but is not commonly used because of prohibitive cost (63). Laminar airflow rooms, to prevent exposure to bacterial and fungal pathogens, are no longer commonly used because of the expense, and improved efficacy could not be clearly demonstrated compared with that in rooms with filtered air (64). Not surprisingly, thorough hand washing is probably the most effective strategy to prevent nosocomial infections in HSCT patients (65). The earlier recovery of granulocytes and enhanced immune reconstitution associated with the use of PBSCs results in less regimen-related toxicity during the early posttransplant period (53,59,66).

Fungal infections continue to be a significant problem in HSCT. In approximately 10% to 20% of patients, an invasive fungal infection may develop, usually with an *Aspergillus* sp. (67). The mortality rate approaches 75% in HSCT patients with *Aspergillus* pneumonitis and is 100% for multiple organ or brain involvement (68). In the persistently febrile HSCT patient, aggressive evaluation and empiric treatment with antifungal antibiotics such as amphotericin B is warranted (67). New lysosomal preparations of amphotericin and new antifungal antibiotics show promise in being more effective and less toxic than standard amphotericin. The use of prophylactic fluconazole during the first 4 to 8 weeks after transplantation has been very effective at preventing systemic candidiasis and improving survival (67).

Viral infections are among the most important infections during the first 3 to 4 months after HSCT (55,69). Acyclovir is effective at preventing both the reactivation of the varicella-zoster virus and the herpes simplex virus 1 (the cause of the common cold sore). The reactivation or primary infection of cytomegalovirus (CMV) is the most important post-HSCT infection. Prior CMV infection and evidence of viral latency is demonstrated in 75% of individuals by detection of specific antibodies to CMV (55,70,71). The patient is typically asymptomatic during the early reactivation of CMV. Before the use of effective antiviral medications, the incidence of CMV pneumonitis was 15%, with a case fatality rate of 50% to 85% (55). Patients who are CMV seronegative before transplant and who receive a CMV-negative graft can be protected from primary CMV infection by the transfusion of CMV-seronegative blood products or blood products rendered leukocyte poor by filtration (72). Ganciclovir (dihydroxyethylethoxymethoguanine) combined with CMV immunoglobulin has demonstrated efficacy for established infections (73). High-dose ganciclovir results in reduction but not complete elimination of CMV infections and pneumonia in seropositive patients (74). Two randomized placebo-controlled studies have shown that ganciclovir can prevent fatal CMV pneumonias (73,75). Prophylaxis with ganciclovir in CMV-seropositive patients is effective while receiving therapy;

however, there appears to be an increased incidence of late CMV disease, possibly caused by delayed reconstitution of HLA-restricted cytotoxic T lymphocytes (CTLs) to CMV antigens (76). The major complication of ganciclovir therapy has been marrow suppression. Because of these concerns, a strategy used for CMV-seropositive patients after HSCT is to monitor for evidence of reactivation by searching for inclusion bodies in peripheral blood mononuclear cells (PBMCs) (76). Ganciclovir is then used at "induction doses" for 1 week, and the dose is decreased by 50% thereafter. In this way, only patients with CMV reactivation at risk for progression are exposed to ganciclovir, with the associated risk of neutropenia and delayed CMV-restricted CTL reconstitution. These strategies have greatly reduced the risk of mortality due to CMV. Other strategies being developed include the *ex vivo* expansion of donor-derived, CMV-specific cytotoxic T cells to be used when there is evidence of CMV reactivation or infection (77).

Other potential opportunistic infections such as *Toxoplasma gondii* and *Pneumocystis carinii* pneumonia are rarely clinical problems now in HSCT because of the effective use of antibiotic prophylaxis with trimethoprim or trimethoprim/sulfamethoxazole.

The toxicities due to conventional conditioning regimens, the complications of HSCT, and the severe immunologic impairment that follows necessitate the performance of HSCT in highly specialized facilities with experienced physicians, nurses, and support staff. Special attention should be directed at symptoms that suggest infections, primarily because of the rapidity in which certain infectious complications can become life threatening. In those patients with chronic GVHD, daily antibiotic prophylaxis with penicillin should be given to reduce the incidence of infections with encapsulated organisms. This has been shown to improve patient survival (78). The supportive care for HSCT patients has improved over the last 30 years and probably is a contributing factor in the better results seen with time.

GRAFT FAILURE

In the setting of a conventional allogeneic HSCT, graft failure is a significant complication due to the associated high case mortality rate (79,80 and 81). Graft failure usually occurs either as the persistence of the conditioning regimen–induced pancytopenia with no evidence of donor-derived cell recovery or the decrease in the donor-derived cell counts after initial recovery, resulting in aplasia. The incidence of graft failure is low from an HLA-identical sibling (<5%), but the risk increases proportional to the degree of HLA disparity. For example, the rate of graft failure increases from 7% to 10% for phenotypically HLA-identical pairs to 15% to 25% for two and three HLA loci–mismatched pairs. There also is a significant risk of graft failure after T-cell depletion of the graft, even though a recent study suggested that T-cell depletion of the host could abrogate this problem (82). Donor T cells are presumably needed to destroy host effector cells capable of rejecting the graft.

There are two types of graft failure: early (<1 month) and late (>1 month). The mechanisms that underlie these types of graft failure depend on (a) the intensity of the conditioning regimen, (b) the degree of HLA mismatch, (c) the T-cell content if the graft; and (d) the nature of the postgrafting immunosuppression. A much higher incidence of graft failure occurs in those patients with AA who received previous transfusions of red cells and platelets (83,84 and 85). This pretransplant sensitization to alloantigens (allosensitization) is mediated through memory T lymphocytes and is clearly involved in graft rejection (85). T lymphocytes are clearly associated with rejection, and NK cells have been implicated as mediators of rejection in allogeneic HSCT (25,26 and 27).

In humans the incidence of graft rejection can be decreased by intensifying the conditioning regimen, but this usually results in an unacceptable increase in transplant-related mortality (86). Recently, groups have explored using the relatively T cell–specific purine analog, fludarabine, in conditioning regimens and have demonstrated significant immunosuppression with a minimal degree of toxicity (11,12,87). Another promising method is targeting antibodies to cell-surface molecules of the host necessary for cell adhesion or effector functions to improve immunosuppression (anti–LFA-1, anti-CD44) (88). Selective depletion of T cells to decrease the risk of GVHD, but permit engraftment and GVL, are being explored. Finally, improved postgrafting immunosuppression with new combinations of drugs, such as mycophenolate mofetil and CSP, also may function to suppress host effector cells to facilitate engraftment (47,89).

GRAFT-VERSUS-HOST DISEASE

Incidence and Pathophysiology

Theoretically, acute GVHD can be expected to occur in all cases except for syngeneic and autologous transplants. This result would be anticipated because of highly polymorphic minor histocompatibility antigen differences even between HLA-identical siblings (90,91 and 92). T lymphocytes of the donor graft recognize antigens of the host as foreign, become sensitized, proliferate, and attack host tissue, thereby producing the clinical symptoms of GVHD (91,93). However, syndromes that appear clinically identical to GVHD have occurred in recipients of syngeneic and autologous transplants (94,95). This finding illustrates that the pathophysiology of GVHD is complicated and may also be related to autologous T-cell reactivity in the course of reestablishment of the immune system.

GVHD was first described in lethally irradiated mice that were then infused with allogeneic marrow cells. These animals developed *secondary disease,* a syndrome of diarrhea, skin changes, and liver abnormalities later defined as GVHD. In 1966, Billingham (96) described the three requirements for GVHD to occur: (a) the inclusion of immunologically reactive cells in the graft, (b) the expression of tissue antigens in the host not present in the donor, and (c) the inability of the host to reject the graft immunologically (96). Subsequently, the immune-reactive cells were identified as T cells, and the tissue antigens expressed by the host cells were identified as major and minor HLA antigens. The pathophysiology of GVHD has been reviewed (90,91,93,97,98 and 99). The initial step in GVHD is believed to be an afferent phase in which resting mature T cells respond to antigens presented by host dendritic antigen-presenting cells (100). A second signal from IL-1 leads to the activation of T cells and expression of the IL-2 receptor on their surface. Autocrine IL-2 secretion results in T-cell clonal proliferation. The efferent phase may include cytokine dysregulation, which could contribute to further tissue and target-cell damage (97). Animal studies suggest that tissue damage is mediated by secondary effector cells that include cytotoxic T cells, macrophages, and dendritic cells (91). Some investigators are evaluating the role of cytokine production in initiating, perpetuating, and amplifying T-cell allogeneic reactivity (97).

Acute GVHD occurs in approximately 10% to 80% of allogeneic transplant recipients. The incidence and severity depends on the degree of HLA disparity between donor and host, the gender of donor and host, depletion of T cells, the pretransplant conditioning regimen (TBI vs. no TBI), and the posttransplant GVHD prophylaxis regimen (99). The primary targets of GVHD include the skin, gut, liver, and hematopoietic system (101,102,103,104 and 105). The clinical manifestations include a dermatitis that can range from a macular papular rash to severe desquamation with bullae formation. Gastrointestinal mucosal involvement can result in large volumes of stool that sometimes can be bloody. Symptoms include anorexia, nausea, vomiting, crampy abdominal pain, and diarrhea. Liver involvement rarely results in a right upper abdominal pain and tenderness. Laboratory results can demonstrate hyperbilirubinemia, elevated transaminases, and elevated alkaline phosphatase. Profound deficiencies of immune function result directly from the adverse effects of GVHD compounded by the immune-suppressive therapy used to control GVHD (99).

The diagnosis of GVHD is made clinically and usually confirmed pathologically by evidence of apoptotic bodies at the tips of the rete ridges in the skin and the base of the crypts of the gut epithelium (106). Grading systems of GVHD rely on clinical parameters that are readily measurable and correlate well with patient prognosis (Fig. 83.3) (101). Whereas lower grades of GVHD are correlated with low morbidity and mortality, higher grades are highly predictive of mortality (101,107,108).

Prophylaxis for and Treatment of Acute GVHD

Before the discovery of CSP, initial strategies to control GVHD centered on the use of the antimetabolite, MTX, and chemotherapy after allogeneic transplants (105,109). MTX schedules were continued weekly up to 3 months. An unacceptably high incidence of acute GVHD resulted from omitting immunosuppressive drugs in patients given unmodified allogeneic marrow (110). MTX and CSP were shown in controlled prospective trials to be equivalent at reducing the severity of GVHD (111,112). Results of these randomized studies have been corroborated by retrospective analyses performed by the marrow transplant registries (113,114). Although a large randomized trial failed to show differences (112), a smaller trial suggested a higher leukemic relapse recurrence rate in patients treated with CSP (115), similar to findings made in a retrospective analyses of registry data (116,117).

When CSP is combined with a short course of intermittent MTX (given over the course of 11 days), prevention of acute GVHD was significantly improved compared with treatment with either drug alone (118,119). Survival advantages have been clearly realized in patients given transplants for SAA (120), myelodysplastic syndrome (121), and chronic myeloid leukemia (119). In patients given transplants for acute leukemia in first remission, the survival advantage from prevention from GVHD was offset by a higher leukemic relapse rate (122), but a retrospective review by the IBMTR demonstrated a decreased relapse rate. The MTX and CSP combination, which reduces the incidence of acute GVHD in HLA-identical siblings to 30% to 40% in North American patients, is reported to be even more effective in patients of Japanese origin. Morishima et al. (123) reported only 5% incidence of acute GVHD and attributed this result to a lesser degree of genetic diversity among Japanese patients. At this time, the combination of methotrexate with CSP for acute GVHD prophylaxis is used in ~75% of the transplant centers worldwide. Recent prospective multiinstitutional trials of CSP and MTX compared with tacrolimus and MTX demonstrated decreased acute GVHD in the tacrolimus arm in recipients of both HLA-matched sibling and matched unrelated-donor HSCT, but no survival advantage in either patient group (124,125 and 126). In a randomized study, the use of prophylactic corticosteroids combined with CSP was found to be no better than CSP in preventing acute GVHD and possibly in contributing to more chronic GVHD (127). The City of Hope team in a randomized trial compared CSP and MTX with CSP and prednisone. The incidence of acute GVHD was less in the CSP/prednisone arm, 47% to 28%, respectively (128). A randomized trial of CSP and short-course MTX compared with CSP and prednisone showed less acute GVHD (9% to 23%) in the former arm (129). A randomized trial of an anti–IL-2–receptor antibody did not demonstrate efficacy (130). Some newer immunosuppressive drugs that show promise in acute GVHD prophylaxis and treatment include mycophenolate mofetil combined with CSP, fusion proteins or antibodies to the T-cell receptor costimulatory molecule CD28, and others (48,131,132).

Depleting the HSC graft of T lymphocytes by immunologic or mechanical means is another way to reduce the risk of acute GVHD (133,134,135 and 136). Various techniques have produced reductions in the number of T lymphocytes infused by 1 to 3 logs. With the removal of T cells, most of the differentiated lymphocytes that cause GVHD are presumed eliminated, and the immune system is expected to return to an early prenatal state (137). It is presumed that newly formed allogeneic T cells become tolerant to the host and recognize the host as self. Nearly all clinical studies have shown a significant reduction in acute GVHD when T-cell depletion is used (133, 135 and 136). However, the reduction of GVHD in these studies is almost always accompanied by substantial increases in the risk of graft rejection and leukemic relapse (134,135). The net effect usually is no discernible improvement in overall survival (134). Attempts to overcome graft rejection and relapse by selectively depleting only $CD8^+$ lymphocytes produced equivocal results (138). Similarly, the use of an anti–LFA-1 monoclonal antibody to prevent rejection of T cell–depleted grafts has not been convincingly successful (139,140). Favorable results of T-cell depletion have been reported by Roy et al. (141) and Soiffer et al. (142), who depleted T cells with anti-CD6 monoclonal antibody and rabbit complement; by Schattenberg et al. (143), who used the elutriation technique; by Young et al. (144), who used a two-step soybean lectin agglutination and sheep red blood cell rosette procedure; and Hale et al. (82), who used a rat monoclonal IgM antibody CAMPATH-1G to deplete the graft and host T cells. Reports from the first group indicate a degree of mixed chimerism of donor and host cells after marrow grafting that has resulted in a stable equilibrium without a higher risk of relapse (145).

To date, T lymphocyte depletion of HSCT has not produced an improved event-free survival because of the high risk of graft rejection and leukemic relapse. However, the impressive decrease in acute GVHD suggests that T-cell depletion may yet prove to be promising, provided that graft rejection and relapse risks can be reduced. Improvements in conditioning regimens, newer immunosuppressive medications, targeted antibody therapy, and possibly genetic manipulation of donor T cells may facilitate achieving this goal.

Treatment

The mainstays for treatment for acute GVHD are corticosteroids, ATG, and CSP. Prednisone is usually initiated at doses of 1 to 2 mg/kg/day. The response rate in limited single-organ acute GVHD is approximately 50% to 60%, but decreases to 30% in patients with severe multisystem acute GVHD. In one randomized study, the addition of corticosteroids after transplant on day 15 did not decrease the incidence of acute GVHD or change outcome (124,146,147). In a recent study, early treatment with very large doses of methylprednisolone (10 mg/kg/day) was found to be no more efficacious than standard-dose methylprednisolone (148). For those patients for whom front-line therapy fails, the therapeutic options and success at achieving control of GVHD are limited. Approximately 25% to 40% of patients can be salvaged with ATG (149,150). Monoclonal antibodies to block cytokines responsible for T-cell proliferation have demonstrated promise in a recent trial (151). Oral psoralen to enhance the effect of ultraviolet light (PUVA therapy) is effective in some patients at controlling steroid-resistant acute GVHD of the skin and may improve survival (152,153).

CHRONIC GRAFT-VERSUS-HOST DISEASE

Chronic GVHD occurs in 25% to 50% of recipients of allogeneic HSCTs at 3 to 18 months after transplantation (reviews in 104; 93,154,155). The clinical manifestations resemble collagen vascular disease, including skin lesions, keratoconjunctivitis, buccal mucositis, esophageal and vaginal strictures, intestinal involvement, chronic liver disease, generalized wasting, pancytopenia, immunologic dysfunction, and obstructive bronchiolitis. Risk factors for the development of chronic GVHD include HLA disparity, patient age, and previous acute GVHD. If chronic GVHD is left untreated, most patients become disabled or die of infection. Prednisone given alone or combined with CSP is the most effective therapy for chronic GVHD (156). With therapy, approximately 50% of patients survive with Karnofsky performance scores of 100%, and another 25% with scores of 80% to 90%. In half of the patients, therapy can be discontinued after 9 to 12 months. Newer agents that have shown responses in small groups of patients with chronic GVHD include thalidomide (157,158 and 159), tacrolimus (160,161), and mycophenolate mofetil (131,162,163). Nevertheless, the management of patients with chronic GVHD remains unsatisfactory.

GRAFT-VERSUS-TUMOR

One reason for the success of allogeneic transplantation for malignancy is the alloimmune responses mediated against the host tumor cells. Early animal studies by Barnes et al. (164,165) demonstrated the eradication of leukemia from mice receiving allogeneic marrow compared with those given syngeneic marrow after myeloablative irradiation. Mathé et al. (166) coined the term “adoptive immunotherapy” to describe the antitumor response of allogeneic cells. In 1973, Bortin et al. (167) described the GVL effect (167). Weiden et al. (168,169), in a series of retrospective studies later confirmed by the International Bone Marrow Transplant Registry (IBMTR), described the decreased incidence of leukemia relapse in recipients of allogeneic transplants in whom GVHD developed, presumed to be due to a GVL effect. Supporting this observation of a GVL effect in allogeneic HSCT is the observed increase in incidence of relapse after T-lymphocyte depletion of the donor graft (134,135). Kolb et al. (170) provided direct evidence of GVL by using DLIs to achieve complete remissions of leukemia in allogeneic transplant recipients in whom relapse of chronic myelogenous leukemia developed. Finally, success has been demonstrated in attenuated transplant regimens (see end of chapter) that rely primarily on an allogeneic effect of the graft on the tumor (12,171,172 and 173). Antitumor responses from either GVHD or response to DLI has been demonstrated for Hodgkin disease, non-Hodgkin lymphoma, multiple myeloma, chronic myelogenous leukemia, acute myelogenous leukemia, acute lymphocytic leukemia, and renal cell

carcinoma (172,174,175,176,177 and 178).

Clinical studies to augment the GVL effect by manipulating postgrafting immunosuppression (or withholding it completely) have been largely unsuccessful (110,179). These studies demonstrated increased transplant mortality due to the detrimental effect of worsened GVHD and no change in the incidence of leukemia relapse. The use of DLI (add back) after T lymphocyte–depleted HSCT to decrease the risk of relapse is being prospectively studied. Studies that use cytokines, such as IL-2, to augment a GVL response are currently in progress.

INCIDENCE AND ORIGIN OF RECURRENT MALIGNANT DISEASE

The recurrence of malignant disease remains a major cause of failure of HSCT (105,180,181,182,183,184 and 185). In more than 95% of cases, the original malignant cell population reappears, as shown by blood genetic markers. Such reappearance demonstrates the inability of current pretransplant-conditioning regimens to eradicate all clonogenic cells in every patient. Donor-type cells have been implicated as the cause of recurrent leukemia in fewer than 5% of cases. The escape from immune surveillance probably plays a major role in relapse after allogeneic HSCT (186), which may be correlated to a low absolute lymphocyte count after HSCT and slow lymphocyte recovery (187). The treatment of relapsed disease is difficult and the options limited (see previous section). Another complication is the development of Epstein-Barr virus lymphoproliferative disorder (EBV-LPD), which occurs in 12% to 25% of patients after T cell–depleted HSCT (188). The EBV-LPD arises from poor T-cell immune surveillance that allows the uncontrolled reactivation of EBV in previously infected B lymphocytes of donor origin. EBV-LPD/lymphoma has had a high case mortality rate. Therapies have included generation of cytotoxic lymphocytes before transplant, unmodified DLI, and a recent study demonstrated a response with rituximab, a monoclonal antibody to CD20 (189,190).

HEMATOPOIETIC AND IMMUNOLOGIC RECOVERIES

Hematopoiesis after conventional HSCT is stable, as exemplified by patients with stable hematopoiesis who are more than 20 years after transplant. Nevertheless, certain functional impairments may remain for prolonged periods, including poor granulocyte chemotaxis, reduced clonogenic precursors in the marrow, and diminished immunologic function (57,191). Clonal dominance suggestive of reconstitution of hematopoiesis from a small number of pluripotent hematopoietic stem cells has been reported in several experimental situations and in two patients (192). However, studies by our group using methylation site polymorphisms on the inactivated X chromosome in more than 20 allogeneic recipients of female marrow grafts, monitored for more than 20 years after transplant, failed to show evidence of clonal dominance and are consistent with polyclonal reconstitution (193,194). Mixed hematopoietic chimerism seen after some T cell–depleted HSCTs may restrict T-cell–repertoire diversity through interactions of host and donor cells (195).

After transplant, the HSCT recipient's immune system consists of three components, each of which can provide some protection from infection (57). First, traces of the host immune system may be operative, as documented by transient production of host-type isohemagglutinin titers in ABO-incompatible recipients for as long as 12 months. Second, immune cells from the donor are transplanted along with the stem cells and convey “instant” immune function to the recipient. Transfer to the recipient of donor immunity to a number of recall and neoantigens has been documented in 85% of patients without GVHD and in 45% of patients with chronic GVHD. Finally, the most important component is regeneration of the immune system originating from the grafted stem cells. All recipients, regardless of the kind of transplant, have within 30 days a return of normal monocyte/macrophage function, cytotoxic effector cell–mediating natural killing, antibody-dependent killing, and lectin-dependent killing (191). Beyond 4 to 5 months, most patients without GVHD show a return to normal of most other immunologic parameters. Nevertheless, even among healthy, long-term survivors, a few fail to produce the appropriate humoral antibodies, and 30% to 40% of these patients show persistent *in vitro* B-cell defects and decreased T-cell activity, which are even more pronounced in patients who have chronic GVHD (63).

The differences in the recovery of the immune function between children and adults implicate the importance of the thymus in T-cell immunologic reconstitution (137,191). Attempts to accelerate immune recovery by administering cytokines, grafting thymic tissue or thymic epithelial monolayers, and injection of thymosin fraction V or thymopoietin, however, have been unsuccessful (196,197 and 198).

LATE EFFECTS

Growth and Development

Regimens that incorporate TBI carry a greater risk of causing endocrine dysfunction compared with chemotherapy-based regimens, especially in children (199,200 and 201). These abnormalities include hypothyroidism, growth hormone deficiency, delayed puberty, and primary ovarian failure. Hypothyroidism that requires hormone replacement occurs in 5% to 25% of children treated with TBI. Growth hormone deficiency also is common, occurring in more than 50% of patients treated with TBI. Many children have an abnormal growth velocity that is typically multifactorial and includes factors related to irradiation and chemotherapy, including lesions of cartilage, bone, and the epiphyseal growth plate; hypothyroidism; gonadal damage; and delayed or precocious puberty (202). Children with abnormal growth velocity and growth-hormone deficiency have not demonstrated a consistent response to growth-hormone replacement therapy (202). After TBI, many prepubertal females will have delayed onset of menses or primary ovarian failure. High-dose cyclophosphamide (Cytoxan) has been implicated in causing amenorrhea in women older than 40 years (203). However, there is a disproportionately higher incidence of children born to women that have received a chemotherapy rather than a TBI regimen. Other problems that can afflict survivors after allogeneic HSCT include chronic obstructive pulmonary disease (204), hepatic problems (205), depression, and chronic pain (206), but overall the health and performance are typically very good, and most patients are able to be employed (206,207).

CLINICAL RESULTS

Aplastic Anemia

Pancytopenia and a hypocellular marrow characterize severe aplastic anemia (SAA). SAA can result as an idiosyncratic effect from drug exposure and has occurred in association with hepatitis, drug abuse, and pregnancy, but in the majority of the cases, no inciting etiologic factor is identified. The response of patients to immunosuppressive therapy, high-dose CY, and failed allogeneic HSCT suggests an immunologically mediated mechanism directed at the hematopoietic stem cells (208). Other factors such as defective marrow stem cells and impaired or defective marrow environment also may play a role in some individuals. Cellular mechanisms that suppress hematopoiesis are likely important in some patients with SAA, as demonstrated by the increased levels of cytokines interferon (IFN)-g and tumor necrosis factor that inhibit both hematopoietic progenitor cells and stem cells (209). However, no correlation of increased IFN-g level or suppressing activity could be detected in an earlier study of SAA patients (210). The etiologic role of CD4 cells was suggested by the overrepresentation of HLA-DR2 in white patients with SAA (208), but this was not confirmed in a much larger group of Seattle patients (R. Storb, unpublished data). In its severe form, AA has a mortality of 80% to 90% despite supportive care; most patients die within 6 months of diagnosis. During the early 1970s, the observation that acquired AA could be corrected by the infusion of syngeneic marrow led to the treatment of this disease by allogeneic marrow transplantation from HLA-identical sibling donors (192,211). HSCT is considered front-line therapy in those patients with an HLA-identical donor. For those patients without an HLA-identical donor, a trial of immunosuppression with a combination of ATG, methylprednisolone, and CSP is usually successful in achieving recovery of autologous hematopoiesis in 30% to 65% of patients (84,212). Unfortunately, the risk of relapse is significant, and mortality for nonresponders is high (84). The use of an unrelated HSC donor may be necessary for any of the surviving 50% to 60% of patients who have not responded or relapsed after immunosuppressive therapy and do not have an HLA-identical sibling or alternative donor (213,214 and 215).

By the mid-1970s, three major problems were identified that limited the success of allogeneic HLA-identical marrow transplantation: graft rejection, acute GVHD, and chronic GVHD. The incidence and severity of these complications have diminished since then.

GRAFT REJECTION

HSCT recipients are treated before transplant with intensive immunosuppressive therapy to prevent graft rejection. In most regimens, CY is given either alone or in combination with TBI, TLI, TAI, or ATG. It has been demonstrated in animal models that previous blood transfusions will increase the risk of rejection despite otherwise adequate immune suppression, presumably because of sensitization of the host to minor histocompatibility antigens present on donor cells (83,84 and 85). During the early 1970s, graft rejection was the major cause of failure of marrow transplants after CY, with rejection rates ranging from 30% to 70%, and survival on the order of 40% to 45% (216,217). Avoiding transfusions, the standard use of irradiated and/or leukocyte-reduced transfusions and the introduction of the CY/ATG regimen have reduced the risk of graft rejection over time and have improved survival (Fig. 83.5, Fig. 83.6, and Fig. 83.7). Predictive factors for rejection among multiply transfused patients given CY were a low marrow cell dose (<3 × 10^8 marrow cells/kg body weight) and positive *in vitro* tests for cell-mediated immunity of recipient against donor cells, consistent with the concept of transfusion-induced sensitization (85).

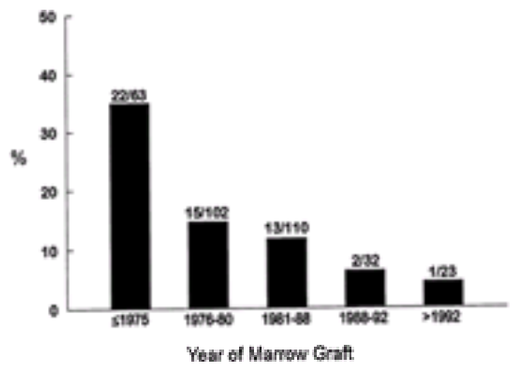

Figure 83.5. The incidence of graft rejection versus year of transplantation for patients in Seattle receiving marrow from human leukocyte antigen (HLA)-identical siblings. All patients were conditioned with cyclophosphamide-containing regimens. The numbers above the bars indicate the number of rejections per number of patients who received transplants. The data are current as of May 1997. (Reproduced from Wagner JL, Storb R. Allogeneic transplantation for aplastic anemia. In: Thomas ED, Blume KG, Forman SJ, eds. *Hematopoietic cell transplantation.* 2nd ed. Boston: Blackwell Science, 1999:791–806, with permission.)

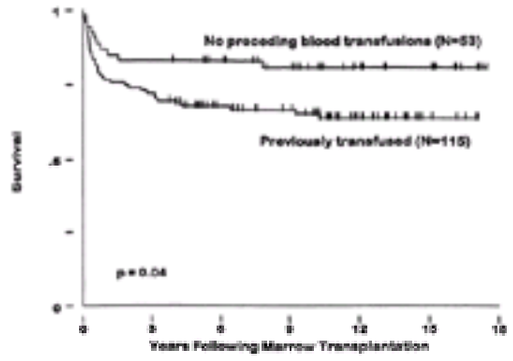

Figure 83.6. The effect of transfusion status on actuarial survival*. Tick marks* denote censoring times of surviving patients. The data are current as of January 1996. The *p* values were calculated by using the log-rank test and are two sided. (Reproduced from Doney K, Leisenring W, Storb R, Appelbaum FR, for the Seattle Bone Marrow Transplant Team. Primary treatment of acquired aplastic anemia: outcomes with bone marrow transplantation and immunosuppressive therapy. *Ann Intern Med* 1997;126:107–115.)

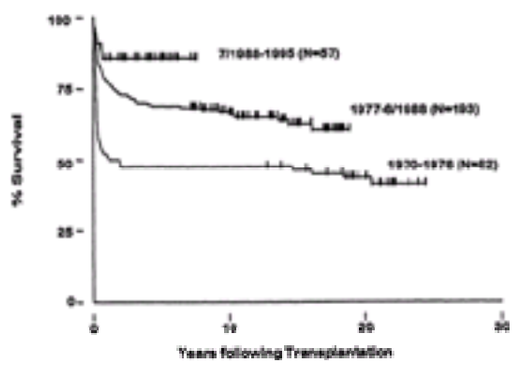

Figure 83.7. Overall survival rates by transplant year for marrow grafts from human leukocyte antigen–identical family members after cyclophosphamide conditioning. The combination of methotrexate and cyclosporine was used for graft-versus-host disease prophylaxis in some patients since 1981 and in all patients since 1985. Most patients who received transplants since July 1988 were conditioned with cyclophosphamide and antithymocyte globulin without supplemental buffy-coat cell infusions. *Tick marks* indicate surviving patients as of April 1996. (Reproduced from Wagner JL, Storb R. Allogeneic transplantation for aplastic anemia. In: Thomas ED, Blume KG, Forman SJ, eds. *Hematopoietic cell transplantation*. 2nd ed. Boston: Blackwell Science, 1999:791–806.)

Two forms of graft rejection may occur. Primary rejection occurs when there is no sign of hematologic function of the graft. Late rejection after initial recovery of hematopoiesis may be seen weeks to months after the transplant. The outlook was poor for patients with primary graft rejection, although more recent data showed that patients can be rescued with second transplants (218,219). Conditioning regimens for second transplants include those that use CY combined with TBI or, alternatively, a combination of CY and antithymocyte globulin (218). The latter regimen resulted in the successful second transplant in 15 to 19 patients and nine survivors in one of our studies (220).

A number of strategies were attempted to decrease the risk of graft rejection. The results of these trials are presented in Table 83.2. A comparative trial between 1976 and the mid-1980s evaluated the use of buffy-coat infusions after transplantation in multiply transfused SAA patients (85,221). The buffy-coat cells were given to improve the number of stem cells given and to provide lymphoid cells believed to be important in enhancing engraftment. A decrease in graft rejection was seen, but at the price of an increased incidence of *de novo* chronic GVHD (Fig. 83.8), a complication that did require prolonged immunosuppressive therapy (222). The survival of patients given buffy-coat infusions was improved compared with that of those patients not given infusions, a finding not confirmed in a retrospective analysis by the IBMTR (223). CY was combined with limited TBI or limited field irradiation by other transplant teams to increase the intensity of pretransplant immune suppression (224,225 and 226). This technique also decreased the risk of graft rejection, although the intensity of the limited-field radiation needed was high, on the order of 600 to 750 cGy, to be effective. The use of irradiation, especially limited-field irradiation, has been associated with a significant risk of solid tumors of epithelial origin compared with that in regimens using only CY (207,227).

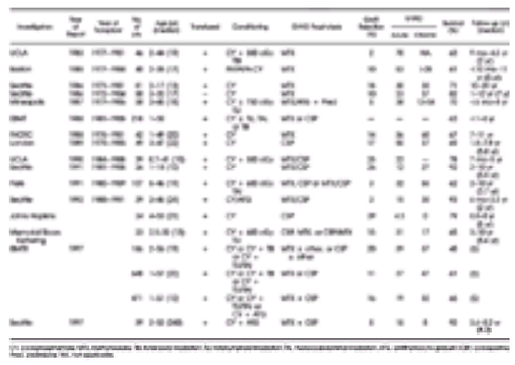

TABLE 83.2. Results of HLA-Identical Marrow Grafts for Aplastic Anemia

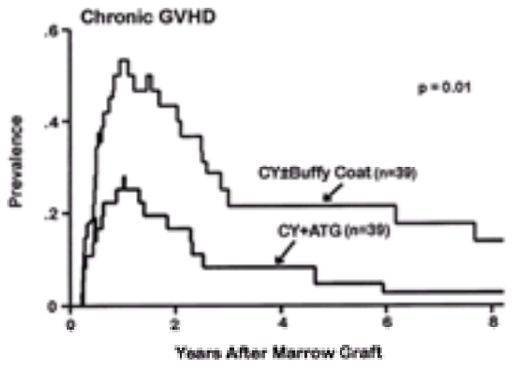

Figure 83.8. The prevalence of chronic graft-versus-host disease (GVHD) among patients with severe aplastic anemia conditioned with cyclophosphamide and given either antithymocyte globulin (ATG) or buffy-coat infusion. There was a statistically significant lower incidence of chronic GVHD among patients who were conditioned with cyclophosphamide (CY) and ATG compared with those who received CY for conditioning with or without buffy-coat infusions. The *p* values were calculated by using the log-rank test. The data are current as of January 1997. (Adapted from Storb R, Leisenring W, Anasetti C, et al. Long-term follow-up of allogeneic marrow transplants in patients with aplastic anemia conditioned by cyclophosphamide combined with antithymocyte globulin [Letter]. *Blood* 1997; 89:3890–3891, with permission.

Over the last 30 years, the incidence of graft rejection has decreased significantly (Fig. 83.5) (145,218,228). The year of transplant has emerged as an independent significant factor affecting rejection over time significantly (Fig. 83.7) (218,228). The reason for this is multifactorial and includes changes in conditioning regimens, improved GVHD prophylaxis, and better supportive care. At our institution we have found a marked decrease in rejection to less than 5% and improved survival greater than 90% when ATG is combined with CY. Furthermore, the 10-year survival for second transplants has increased from 5% to 83%, which on multivariate analysis was found to be due to GVHD prophylaxis with MTX/CSP (Fig.83.9) (218). The importance of GVHD prophylaxis with CSP was identified by the IBMTR in a retrospective analysis to be the most significant factor for improved survival in patients transplanted throughout the world (228).

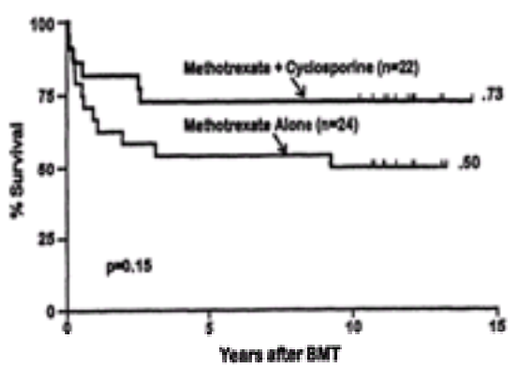

Figure 83.9. Survival of severe aplastic anemia patients given grafts from human leukocyte antigen (HLA)-identical siblings after conditioning with cyclophosphamide. Shown are the results of a randomized prospective trial comparing methotrexate (MTX) alone versus MTX and cyclosporine for graft-versus-host disease prophylaxis. *Tick marks* indicate survival as of April 1996. *BMT*, bone marrow transplantation.

SURVIVAL

The survival of patients treated more recently has improved markedly over the last 30 years (Fig. 83.7). As described earlier, improvement is due to the reduction in the incidence of graft rejection and acute GVHD. Results at our institution with patients who received CY conditioning and MTX as GVHD prophylaxis show an overall survival of 67% for multiply transfused patients at 7 to 11 years, 82% for untransfused patients observed for 1 to 12 years, and 71% for pediatric patients observed for 10 to 20 years. Pediatric patients given CY followed by MTX and CSP as GVHD prophylaxis have survivals on the order of 92%, with observation time ranging from 2 to 10 years. The survival for both pediatric and adult patients given CY/ATG before and MTX/CSP after transplant is at 93%, with an observation time of 14 years (218,229). Figure 83.7 demonstrates the improved survival over time in our patients. A recent retrospective analysis from our institution compared the outcomes of recipients of HSCT from genotypically or phenotypically identical donors with those patients treated with immunosuppressive therapy and demonstrated significant improvement of survival in all patients younger than 40 years given an HLA-identical BMT (84).

The transplant team at UCLA (230) used CY and 300 cGy of TBI, an approach that virtually eliminated the problem of rejection, but led to significant increase in acute GVHD (Table 83.2). Survival at 9 months to 4.5 years was 63%. An attempt by this group to use CY and 300 cGy of TLI followed by CSP/MTX resulted in a rejection rate of 23%, acute GVHD in 22%, and survival in 78% at 7 months to 5 years. This group concluded that 300 cGy of TLI was not sufficient to suppress rejection. The Minneapolis group (224,231) used CY combined with 750 cGy of total lymphoid irradiation along with a combination of MTX, ATG, and prednisone for GVHD prevention. Rejection was virtually eliminated; the rate of acute GVHD was 38%; and survival at 6 months to 8 years was 70%. The Boston team (232) reported rejection of 10% and survival of 61% at 10 months to 11 years, using a combination of procarbazine, ATG, and CY. The Hammersmith Hospital group (233) used CY followed by CSP after grafting. In 1989, they reported rejection of 17%, acute GVHD at 50%, and survival at 69%; observation ranged from 1.8 to 7.8 years (233). The group in Paris (234) used CY and 600 cGy thoracoabdominal irradiation followed by MTX, CSP, or a combination of the two. In 1991, they reported rejection of 3%, acute GVHD of 32%, and chronic GVHD of 62% in patients monitored from 1 to 10 years. The Johns Hopkins team (235) used CY followed by CSP and found a rejection rate of 31%, acute GVHD of 4.5%, and survival of 79% at 8.5 years. The use of alternative-donor and unrelated-donor SCT for SAA has been much less successful, with reported survival of only 30% (236). The most significant problem in alternative and unrelated HSCT is GVHD. Margolis et al. (237) reported significantly improved survival of 55% for those patients that received a T cell–depleted unrelated allograft for SAA.

A review by the European Bone Marrow Transplant (EBMT) group in 1988 (238) combined the results in patients receiving CY with or without limited-field irradiation or TBI, and given postgrafting immunosuppression with either CSP or MTX, showed an overall survival of 63% over 1 to 6 years. The rejection rate with CY conditioning regimens alone was high, but the incidence decreased when CY was combined with some form of irradiation. The incidence of acute GVHD was 40% with a variety of postgrafting immunosuppression regimens; chronic GVHD was 45%; and survival was 63% at more than 7 years after transplant. Generally CSP-treated patients did better than MTX-treated patients. Another more recent retrospective review from the IBMTR (228) demonstrated improved patient survival from 48% in years 1976 to 1980 to 66% in years 1988 to 1992. This improved survival was due to decreased early mortality from GVHD and interstitial pneumonia, and interestingly, the risk of graft failure was not found to be different. CSP was again identified as a significant factor that improved survival (228). In a study at our institution that evaluated the long-term outcomes of SAA patients that survived longer than 2 years after a BMT, it was found that a majority of patients had a return to normal function (207). However, those patients in whom chronic GVHD developed were at a much higher risk for complications that included dermatologic in 14%, cataracts in 12%, lung disease in 24%, bone and joint in 18%, solid tumor in 12%, and depression in 19% (207). The risk of solid tumors after allogeneic transplants for SAA was confirmed in a combined study of our group with the Paris group, who found that irradiation and immunosuppression with azathioprine for chronic GVHD conferred an increased risk of 5.4 and 8.3, respectively, for developing a solid-tumor malignancy (227).

In conclusion, the survival of HSCT patients with SAA has improved dramatically for patients with an HLA-identical donor and is considered the treatment of choice at this time (239). For those patients without an HLA-identical donor, a trial of immunosuppression is recommended, and if not successful, an alternative donor or unrelated HSCT should be considered. The improved survival seen over the last 30 years is directly related to better transplant conditioning, posttransplant immunosuppression, and supportive care, which have reduced the incidence of rejection, acute and chronic GVHD, and transplant complications (84,218,228,240). These improvements have resulted in long-term disease-free survivals (DFSs) of more than 90% for patients with an HLA-identical donor (218,229). Chronic GVHD continues to be a problem that directly affects the rate of posttransplant morbidity and mortality (207). The complications after transplant including secondary malignancies must be better characterized (207,227). The higher probability of secondary tumors makes radiation-based regimens inadvisable in HLA- identical HSCT recipients (207). Improvements must be made in the use of alternative and unrelated HSCT programs to decrease the complications that affect survival. Finally, nonmyeloablative approaches may be helpful in reducing the transplant-related toxicity of HSCT for SAA, but strategies will most likely be developed to overcome the rejection risk from prior allosensitization.

Nonmalignant Disorders of Hematopoiesis

Table 83.1 lists the genetic diseases that are successfully treated with HSCT. Since the first report in 1968, HSCT has been the treatment of choice for SCID, a rare fatal syndrome due to a variety of genetic abnormalities that results in the abnormal function of lymphocytes. Disease-free long-term survival after allogeneic HSCT is greater than 55% (241,242 and 243). Failures are due to poor immunologic status after grafting and involve infections, primarily interstitial pneumonia. The longest survivor is more than 32 years after his transplant. The EBMT retrospectively analyzed 214 HLA-nonidentical T cell–depleted transplants for SCID. An improved DFS was noted for SCID variants with absence of functional T and B cells (B-SCID) compared with variants deficient in T cells but with present B cells (DFS of 35% vs. 60%, respectively). The median follow-up was less than 5 years. Other factors associated with poor survival included lung infection before HSCT, and the use of monoclonal antibodies for T-cell depletion. Patients with B-SCID had increased incidence of death due to early infection, slower rate of engraftment, increased incidence of GVHD, and slower T- and B-cell reconstitution. Patients who received a BU and CY conditioning regimen appeared to have improved outcomes, although this was not statistically significant compared with other regimens (243). The Duke University group (244) used *in vitro* T-cell depletion with soybean lectin and sheep erythrocyte rosetting as GVHD prophylaxis for 89 infants with SCID, using no pretransplant conditioning and no postgrafting immunosuppression except in two of the three cord blood recipients (244). There was a significant degree of HLA nonidentity with 77 patients given HLA-haploidentical parental marrow, 12 patients given HLA-identical marrow from a related donor, and three patients given unrelated placental cord blood. The overall survival was 81% at a follow-up between 3 months and 16.5 years, specifically, of 78% for haploidentical transplant recipients survived compared with 100% for HLA-matched sibling transplant recipients. The incidence of acute GVHD was very low. There was a return of normal T-cell function in all but four of 72 surviving patients, but the B-cell compartment was mostly composed of recipient cells with abnormal production of antibodies, requiring the use of IVIG replacement therapy in 45 patients (244). Filipovich et al. (245) reported the results of eight infants with SCID given non–T-cell–depleted marrow transplants from phenotypically HLA-matched donors using various GVHD prophylaxis regimens (245). Engraftment was found to be 100%, with survival of 75% at 1 to 3 years. Preexisting opportunistic infections were the cause of death in the two patients who died during the study (245).

Wiskott-Aldrich syndrome is an X-linked primary immunodeficiency characterized by a clinical triad consisting of thrombocytopenia with small platelets, eczema, and immunodeficiency, usually reflected by recurrent otitis media. Most reports on transplants are from single institutions that have used a variety of different regimens. TBI has been used to create “marrow space” for the new marrow to grow. The Boston group has used ATG and procarbazine for additional immunosuppression. Because of concerns about the late effects of irradiation, many groups use chemotherapy-based regimens containing CY and either BU or DMBU (246,247), with survival for recipients of HLA-identical sibling grafts of greater than 85%. Ozsahin et al. (248) performed transplants using CY/BU conditioning in ten patients with HLA-identical grafts, and 16 patients with HLA partially matched, related T-cell–depleted grafts. Survival was 80% for HLA genotypically identical recipients and 60% for HLA partially matched related-donor recipients. Unfortunately, seven patients died of viral infectious complications, primarily EBV-LPD (248). Successful transplants using HLA-matched and -mismatched unrelated donors were demonstrated with GVHD prophylaxis consisting of CSP/prednisone or CSP/ATG or anti-CD 5 ricin A chain immunotoxin without T-cell depletion (245). In this study, engraftment was found to be 100% with 83% survival at 1 to 3 years (245). The Sloan Kettering Memorial group (249) performed BMT for 17 patients with Wiskott-Aldrich syndrome using BU/CY for HLA-identical sibling marrow recipients and BU/CY and TBI for those patients given HLA-disparate grafts from their parent. Ten of the 11 patients with HLA-identical or phenotypically HLA-matched parent grafts survive. However, only one of the six patients with HLA-disparate parental grafts survives, with others dying of transplant-related causes.

Fanconi anemia is a genetic disorder associated with diverse congenital abnormalities, chromosomal fragility, progressive bone marrow failure, and an increased risk of leukemia and other cancers. A unique feature of Fanconi anemia is the impaired DNA repair mechanisms that make patients susceptible to developing malignancies and unusually sensitive to conventional HSCT chemotherapy-conditioning programs (242). Fanconi anemia patients, therefore, have an increased incidence of regimen-related morbidity and mortality and, after transplant, are very sensitive to secondary malignancies (207,227). Older reports have achieved long-term DFS of approximately 60% (242,250). More recent studies using attenuated conditioning doses of CY with or without irradiation using GVHD prophylaxis with CSP and either MTX or prednisone have reported improved survivals between 89% and 100% (251,252 and 253). The IBMTR (254) reviewed the results of HLA-matched (n = 151) and alternative or URD (n = 48) HSCT using a variety of attenuated conditioning regimens for Fanconi anemia patients. The 2-year probability of survival was 66% for recipients of HLA-matched sibling and 29% for alternative or unrelated donor transplants, respectively. Factors associated with improved survival of patients in this study included: younger age; higher platelet count before transplant; the use of ATG with conditioning; a lower-dose CY with limited field irradiation (instead of TBI); HLA-matched sibling transplant instead of alternative or unrelated transplant; and CSP for GVHD prophylaxis (254). Unfortunately, even less toxic strategies are still required to decrease the significant early mortality associated with alternative and unrelated HSCT for patients with Fanconi anemia (254,255). A multiinstitutional clinical study evaluating the role of the nonmyeloablative unrelated HSCT approach for Fanconi anemia patients is currently under way.

Other diseases of marrow failure (pure red cell aplasia, Blackfan-Diamond Langerhans cell histiocytosis, lymphohistiocytosis) (256,257,258,259,260,261 and 262), hemoglobinopathies (b-thalassemia, sickle cell disease) (263,264), enzyme deficiencies that result in toxic build-up of metabolic substances (Gaucher disease, mucopolysaccharidosis, Hurler syndrome) (265,266), and other disorders (267,268) have been cured with HSCT.

In thalassemia major, DFS has ranged between 53% and 87% (269,270 and 271). Good results also have been obtained after HSCT for sickle cell disease with event-free survival of 93%, overall survival of 93%, and rejection or recurrence of disease of 14% (263). The use of HSCT is somewhat controversial because of the risk of treatment-related mortality. For that reason, only high-risk patients with HLA-identical siblings are usually selected for HSCT (263). Unfortunately, complications stemming from iron overload will increase the risk of death associated with this procedure (264). With both diseases, prevention through genetic counseling should be given high priority. Gene therapy to correct the defects that cause thalassemia and sickle cell disease are possible in principle; however, the efficiency of transfection vectors and fidelity of transduction of stem cells must be vastly improved before this becomes a therapeutic option (272).

Autoimmune Disease

Multiple sclerosis, systemic lupus erythematosus, and scleroderma are immune-mediated diseases that typically afflict young, otherwise healthy individuals and can on occasion have rapid and debilitating courses (8). The usual treatments for these disorders include immunosuppressive medications including corticosteroids, and on occasion, pulsed CY. There have been case reports of patients achieving durable remissions of autoimmune disorders after HSCT for concurrent hematopoietic malignancies (273,274). HSCT has been demonstrated to cure animals afflicted with several experimentally derived autoimmune disorders (275,276). Recently, several groups have developed HSCT programs targeting severe autoimmune diseases with poor prognostic features (9,10). The rationale for this approach is that ablation of the immune system with high-dose chemotherapy will arrest the underlying autoimmune process by removal of effector lymphocytes. The reconstitution of the immune system would ideally occur without the production of pathologic effector cells. The mechanisms by which the autoimmune process could be arrested or cured include the following: (a) deletion of autoimmune effector lymphocytes; (b) recapitulation of lymphocyte ontogeny without the antigenic signal that triggered the autoimmune process; (c) change of the ratio of suppresser and effector cells, resulting in suppression or tolerance; or (d) the complete replacement of host cells by allogeneic cells, resulting in a new lymphocyte repertoire (9). An obvious concern is that the use of autologous stem cells will result in reinfusion of contaminating effector cells mediating the autoimmune process. $CD34^+$ selected stem cells are being used in some centers to reduce the risk of contamination with immune effector cells. Most conditioning regimens use CY and ATG with or without G-CSF (10,277). Preliminary results from our institution and the Northwestern Hospital transplant group indicate improvement or stabilization of disease in the majority of patients treated (10,277,278).

Malignant Disorders

In 1975 Thomas et al. (105) presented results on the recipients of allogeneic HLA-identical sibling transplants for patients with refractory leukemia. Approximately 10% to 15% of these patients were found to be long-term survivors. Improved outcomes were subsequently demonstrated in acute leukemia patients who were in first or second complete remission compared with conventional chemotherapy. This led to the use of HSCT in a variety of other malignant disorders. Depending on the stage of malignancy when HSCT is carried out, recurrent disease may account for 20% to 75% of treatment failures. For allogeneic HSCT, significant acute GVHD is diagnosed in 30% to 75% of patients, depending on the level of genetic disparity (Fig. 83.4) (79,279,280). Acute GVHD has a case fatality rate of 5% to 50% and thus may account for 10% to 25% of treatment failures. Conditioning regimen–related toxicity and infections during the early pancytopenic period may result in 5% to 20% of deaths. The incidence of interstitial pneumonia has decreased in recent years because of improved prophylaxis and treatment of CMV reactivation. Failure of the marrow graft usually only occurs in the setting of T-cell depletion. Myelodysplasia and secondary acute myeloid leukemia (AML) is an increasingly recognized problem in autologous HSCT, especially after “purging” of the graft with chemotherapy (281,282 and 283).

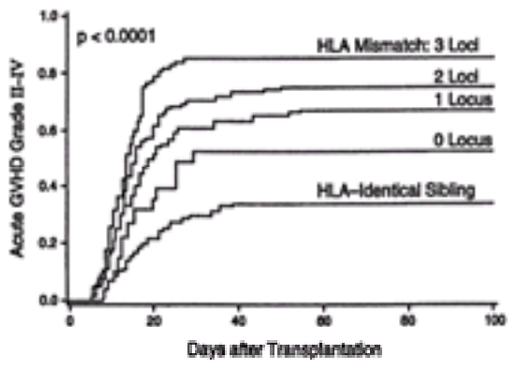

Figure 83.4. Effect of donor and recipient human leukocyte antigen (HLA) disparity on acute graft-versus-host disease (GVHD). Probability of grade II to IV acute GVDH according to the degree of mismatching for HLA-A, -B, and -D/DRB1 in patients who received transplants from a haploidentical relative or an HLA genotypically identical sibling. All patients received unmodified marrow and methotrexate plus cyclosporine for GVHD prophylaxis. (Reproduced from Anasetti C. Hematopoietic cell transplantation from HLA partially matched related donors. In: Thomas ED, Blume KG, Forman SJ, eds. *Hematopoietic cell transplantation.* 2nd ed. Boston: Blackwell Science, 1999:904–914, with permission.)

The exposure of tumor cells to chemotherapy results in the development of resistant clones by a variety of mechanisms. The use of very high doses of chemotherapy followed by HSCT is a way to overcome marrow toxicity and, ideally, to overwhelm any tumor-resistance mechanism. Unfortunately, even with the extremely high doses of chemotherapy used in HSCT, a significant proportion of patients will not be cured (4,284,285 and 286). The problem of relapse is much less for recipients of allogeneic recipients of HSCT because of the GVL effect. There are clearly cures with the use of autologous transplantation, but again, the relapse rate is high. Most recent strategies have focused on decreasing the risk of GVHD in allogeneic HSCT and reducing the risk of relapse in autologous HSCT, but the absolute success of any one technique such as T-cell depletion or tumor cell purging has not been conclusively demonstrated (148,287,288).

ACUTE MYELOID LEUKEMIA

Acute myeloid leukemia (AML) is a disease that results in a loss of control of proliferation of early myeloid cells in the bone marrow and an arrest in myeloid development with associated marrow-production defects usually manifested by granulocytopenia, thrombocytopenia, and anemia. The standard of care over the last 15 to 20 years has been to offer allogeneic HSCT to patients with a HLA-identical sibling donors, and it has been demonstrated to cure 50% to 78% of patients (2,3 and 4,289,290). Approximately 3,500 allogeneic SCTs are carried out each year for AML (291). Of the HSCTs performed from HLA-identical sibling donors, 60% are performed as consolidation in first complete response (CR), 10% for patients who never achieve a CR, 10% to 15% in second CR, and less than 5% for more advanced disease (291). Interestingly, although the majority of patients with AML are older, the median age of transplantation is 30 years, and fewer than 5% of patients receiving HSCT are older than 50 years because of the poorer outcomes in this group (11).

The most common conditioning programs for HLA-identical sibling SCT for AML in first CR use CY/TBI or BU/CY (3,292,293 and 294). A retrospective analysis by the French Bone Marrow Transplant Group (293,294) comparing CY/TBI with BU/CY showed improved DFS, decreased relapse, and reduced transplant mortality for the CY/TBI group. However, an excess of transplant-related mortality in the BU/CY group was seen, related primarily to GVHD. These results were not confirmed in a retrospective multivariate analysis by the EGBMT (294), which showed equivalent transplant-related mortality of approximately 23%, relapse rate of approximately 26%, and DFS of approximately 54%. However, a report from the Nordic transplant group (292,295), recently updated, confirmed the increase in transplant-related mortality in patients who receive BU conditioning that was related to increased incidence of GVHD, as well as of hepatic and pulmonary complications. Attempts to improve tumor eradication by intensifying pretransplant chemotherapy or irradiation in the transplant conditioning regimen have resulted in a reduced incidence of relapse at the expense of worsened regimen-related toxicity and mortality, negating any benefit in improved survival (Fig. 83.10 and Fig. 83.11 (3,296,297 and 298). The addition of etoposide to HSCT conditioning regimens appears to be well tolerated, and there appears to be improved DFS in small nonrandomized studies (299,300). GVHD prophylaxis with CSP/MTX used in later AML HSCT studies probably accounts for some of the recently observed improved DFS (301). In contrast, a retrospective analysis by Carlens found that CSP/MTX prophylaxis was associated with worsened outcome because of increased relapse of leukemia, presumed to be due to less acute GVHD (286). A recently published randomized trial compared different doses of intravenous CSP during the peritransplant period in pediatric patients with acute leukemia and showed that an increased dose of CSP resulted in decreased acute GVHD and statistically increased leukemia relapse compared with a lower dose (302). In a large retrospective analysis, Frassoni (285) reported improved DFS due to lower incidence of transplant-related mortality over time for patients receiving HSCT for AML that could not be correlated to any one factor, but was hypothesized to be due to overall better supportive care (285). Factors shown to affect adversely the outcome of HLA-identical HSCT for AML include (a) female donor and male recipient pair, (b) intermediate and high-risk disease, (c) disease beyond first CR, (d) lower number of stem cells infused, (e) poor-prognosis cytogenetics, (f) older age of patient, and (g) increased time from diagnosis to SCT (286,303).

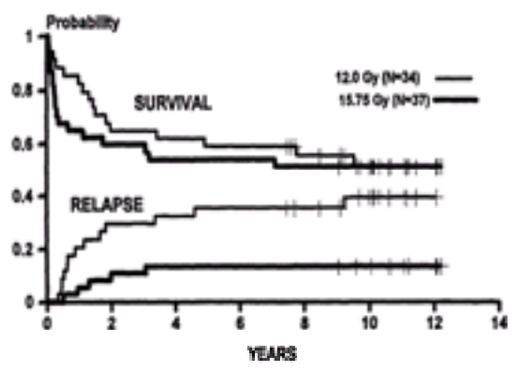

Figure 83.10. Kaplan-Meier estimates of survival and cumulative incidence of relapse for patients conditioned for human leukocyte antigen (HLA)-identical marrow transplantation by 120 mg/kg cyclophosphamide and 12.0 Gy or 15.75 Gy of fractionated total-body irradiation. Results are updated to February 1998. (Reproduced from Clift RA, Buckner CD, Appelbaum FR, et al. Long-term follow-up of a randomized trial of two irradiation regimens for patients receiving allogeneic marrow transplants during first remission of acute myeloid leukemia [Letter]. *Blood* 1998;92:1455–1456, with permission.)

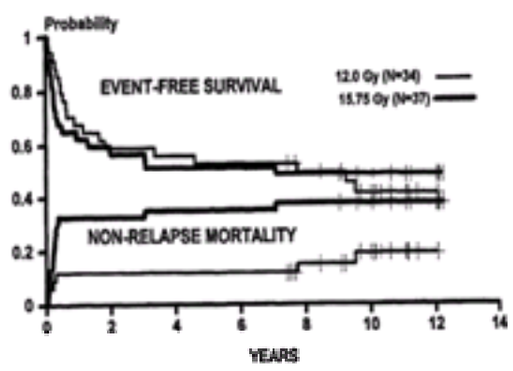

Figure 83.11. Kaplan-Meier estimates of surviving event-free (relapse and death were identified as events) and of dying of causes other than relapse for patients conditioned for human leukocyte antigen–identical marrow transplantation by 120 mg/kg cyclophosphamide and 12.0 Gy or 15.75 Gy of fractionated total-body irradiation. Results are updated to February 1998. (Reproduced from Clift RA, Buckner CD, Appelbaum FR, et al. Long-term follow-up of a randomized trial of two irradiation regimens for patients receiving allogeneic marrow transplants during first remission of acute myeloid leukemia [Letter]. *Blood* 1998;92:1455–1456, with permission.)

Over the last 15 years, autologous HSCT has become an important therapy for the treatment of AML. Single institutional studies demonstrated a DFS of 45% to 55%, but most of this survival advantage could be ascribed to selection bias. A major concern of autologous HSCT, especially in diseases like AML, is the infusion of tumor cells along with HSCs. Many groups have attempted to "purge" the marrow *ex vivo* with chemotherapy (e.g., mafosfamide, perfosfamide) to reduce the risk of tumor contamination (304). The European Cooperative Group for BMT presented a retrospective study that demonstrated significantly decreased relapse and improved leukemia-free survival for recipients of mafosfamide-purged autologous HSCT (305). Other groups have not demonstrated that these strategies have improved outcome primarily due to delayed granulocytic and megakaryocytic engraftment in treated patients (300,306). Another concern about autologous HSCT, especially in those patients who have received *ex vivo* purging, is the increasingly well-recognized high incidence of myelodysplasia and secondary AML due to infusion of HSCs previously exposed to chemotherapeutic agents (307,308). The role for purging must be addressed in randomized trials.

The superiority of allogeneic HSCT compared with conventional chemotherapy has been shown in retrospective studies (309) and some older prospective randomized studies (289), but not others (310). Autologous HSCT has been shown to be better than chemotherapy in some studies (298,300) and equivalent in others (306,311). Most large comparative studies use "genetic" randomization of patients with HLA-identical donors to the allogeneic HSCT arm of the trial and then randomize those patients without an allogeneic donor to the autologous HSCT or chemotherapy arms. These studies have been difficult to perform, primarily because of the attrition of patients from their assigned treatment arms (297,312). Nevertheless, the studies performed to date have demonstrated either superiority of the allogeneic arm, especially in high-risk individuals (285,313), or rough equivalency in regard to survival and DFS compared with autologous HSCT or chemotherapy (Fig. 83.12) (297,312).

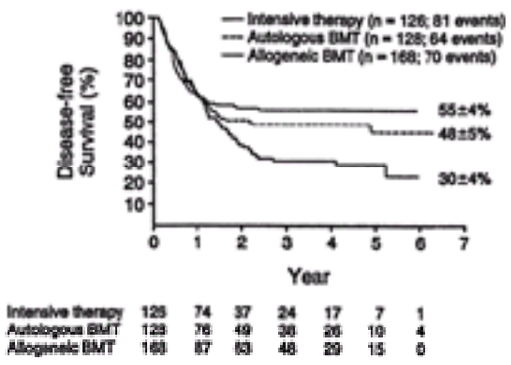

Figure 83.12. Kaplan-Meier estimates of disease-free survival for patients assigned to allogeneic bone marrow transplantation (BMT; *dotted line, n* = 168), autologous BMT (*dashed line, n* = 128), or intensive consolidation chemotherapy (*solid line, n* = 126). Percentages represent estimated disease-free survival rates ± standard error of the mean. The number of patients at risk is shown below each time point. (Reproduced from Zittoun RA, Mandelli F, Willemze R, et al. Autologous or allogeneic bone marrow transplantation compared with intensive chemotherapy in acute myelogenous leukemia: European Organization for Research and Treatment of Cancer (EORTC) and the Gruppo Italiano Malattie Ematologiche Maligne dell'Adulto (GIMEMA) Leukemia Cooperative Groups. *N Engl J Med* 1995;332:217–223, with permission.)

In those patients with AML who have refractory or advanced disease beyond first CR, the probability of obtaining another CR with chemotherapy is low. During early first relapse, it was found to be advantageous to proceed directly to HSCT rather than to attempt reinduction chemotherapy for a second CR (Fig. 83.13) (314). For patients with advanced disease, a variety of agents such as etoposide, melphalan, and cytarabine have been used in addition to CY/TBI to intensify the conditioning regimen (44,315,316 and 317). For these patients, there is a 30% chance of long-term survival after autologous or allogeneic HSCT (287). The use of PBSCs has been shown to reduce the transplant-related mortality in advanced-stage hematologic malignancies by improving the rate of engraftment and hematopoietic reconstitution (53,54,59,66,318). This effect may be due to an increased number of SCs and committed progenitors transplanted (319).

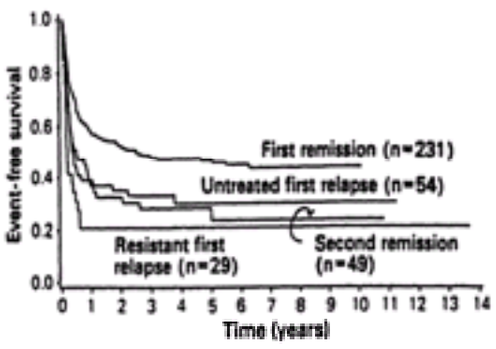

Figure 83.13. Effect of remission status at transplantation on disease-free survival after allogeneic bone marrow transplantation for patients with acute myelogenous leukemia. The treatment of acute non-lymphoblastic leukemia by allogeneic marrow transplantation. *Bone Marrow Transplant* 1987;2:243–258, with permission.)

As induction and consolidation regimens for AML have improved, there has been concern about exposing "cured" patients to otherwise unneeded toxicities of HSCT. It is obviously not possible to predict which patients will relapse after chemotherapy, but certain clinical and laboratory findings have been identified as prognostic indicators of relapse. A low-risk younger patient has a 30% to 40% chance of relapsing after achieving a CR, and the probability of entering a second CR is less than that for a achieving a first CR; this probability decreases with age. Some investigators, therefore, have recommended HLA-identical HSCT or autologous HSCT for patients in first CR who have poor prognostic factors or for those beyond first CR (288,320), but others have argued for allogeneic HSCT as "consolidation" therapy (304,321). For those patients without an HLA-identical sibling donor who relapse after first CR or with poor prognostic features, an alternative or unrelated HSCT should be considered (322).

ACUTE LYMPHOBLASTIC LEUKEMIA

Acute lymphoblastic leukemia (ALL) is characterized by arrest of growth and uncontrolled accumulation of lymphoblasts. The probability of obtaining a complete remission by using combination chemotherapy in adults is 70% to 85% and 95% in children. Most, but not all, children who enter a CR will eventually be cured with further chemotherapy (185). Adults and infants, on the other hand, have an incidence of relapse of 40% to 60% and have a much lower probability of cure, attributable to the higher incidence of high-risk features in adults (323). Poor prognostic features used to decide between HSCT and chemotherapy include older age, high white blood cell count at diagnosis, a mediastinal mass, and certain morphologic and cytogenetic features.

The majority of phase II studies evaluating allogeneic HSCT for ALL in adults have demonstrated a leukemia-free survival of 21% to 64%, with a relapse probability of between 10% and 50% (324,325 and 326). A retrospective analysis by the IBMTR that compared allogeneic HSCT results with the results of chemotherapy from two German cooperative groups did not demonstrate an advantage to transplantation (327,328). A prospective trial comparing allo-HSCT with chemotherapy appeared to confirm this finding, because no difference was found in DFS (45% vs. 31%; $p = .1$) (329). However, in a subset analysis of high-risk ALL patients, a statistical difference was found in favor of allogeneic HSCT for high-risk patients in first CR. Two studies evaluated HSCT compared with chemotherapy for children beyond first remission, one a prospective study by Torres et al. (330) in patients in first relapse and the other a retrospective study by the IBMTR (331). Both studies showed significant benefit of allogeneic HSCT in terms of DFS and relapse. Another retrospective review by the IBMTR evaluating CY/TBI versus BU/CY as pretransplant conditioning demonstrated highly significant improved survival and decreased treatment failure (leukemia relapse) in those patients that received CY/TBI (332).

A subtype of ALL that contains the karyotypic abnormality termed the Philadelphia chromosome (Ph^+) carries a particularly poor prognosis and is rarely cured with chemotherapy (333). A retrospective analysis by the IBMTR of allogeneic SCT for Ph^+ ALL in first CR has shown a 2-year DFS of 38% (334). The City of Hope and Stanford groups reported better results with 3-year relapse-free survivals of 50% to 68% and probability of relapse of 12% (326). A report from our group indicated that acceptable results for unrelated HSCT for Ph^+ ALL can be obtained with a DFS at 2 years of approximately 49% (335). However, delays in initiating an unrelated donor

search for high-risk ALL continues to be a problem (336).

Autologous HSCT remains an option for patients without HLA-matched siblings. In comparative trials, superior DFS results have been found for HLA-matched sibling HSCT compared with autologous HSCT (326), but equivalent results were found in a smaller older study (337). Weisdorf et al. (338) compared unrelated HSCT and autologous HSCT for ALL and found DFS results that were equivalent for patients younger than 18 years, but improved DFS rates were found for recipients of unrelated HSCT in disease beyond first CR (338). In the future, molecular markers of minimal residual disease detected by polymerase chain reaction technology may become a useful tool in predicting the relapse of “good-risk” ALL patients and determining which patients should proceed immediately to HSCT.

CHRONIC MYELOGENOUS LEUKEMIA

The median survival of patients with CML is 45 months after diagnosis, but occasional patients have survived up to 20 years (339). No patient has been cured of CML by conventional means, and retrospective evaluations have not demonstrated survival advantages in using chemotherapy (340,341). IFN therapy has been demonstrated to produce a hematologic disease response in the majority of patients treated (340,341). A modest increase in survival advantage of 20 months, however, has been demonstrated only when interferon is combined with chemotherapy (342,343). The cost and side effects of IFN therapy are substantial (340,341). A recent report from Druker et al. (344,345) reported excellent disease responses by using a tyrosine kinase inhibitor in a group of patients with CML in chronic phase and blast crisis for whom IFN therapy had failed. No significant side effects were reported. Although these initial results are unprecedented and quite encouraging, the durability of the disease responses is yet to be determined.

Allogeneic HSCT is the only known cure for CML currently available (86,86,346,347,348 and 349). However, transplant-related complications may shorten the lives of some patients, and there is controversy over the up-front mortality of allogeneic HSCT and the improbability of cure with interferon with or without chemotherapy (341,343). In addition, there is evidence that exposure of CML chronic-phase patients to BU and interferon, and delaying HSCT beyond 2 years will negatively affect the probability of success of allogeneic HSCT (343,350,351 and 352). In experienced transplant centers, patients with CML chronic phase less than 1 year from diagnosis have 1-year and 5-year probabilities of survival after HLA-identical sibling HSCT of 90% and 81%, respectively (Fig. 83.14) (350). For recipients of HLA-identical sibling HSCT, the estimated survivals and event-free survivals were equivalent after conditioning with CY and TBI as compared to BU and CY, but there was significantly more regimen-related toxicity in the CY/TBI arm (Fig. 83.14) (346). The expected survivals after progression to accelerated and blast crisis are clearly worse and reported to be at 28% to 40% and 15%, respectively (Fig. 83.15) (348,349). The primary problem is leukemic relapse, which approaches 50% to 75% in advanced-stage CML patients (Fig. 83.16) (348,349). Support for unrelated HSCT comes from a retrospective analysis from the Hammersmith Hospital, which demonstrated a 2-year survival of 73% and a 2-year leukemia-free survival of 73% (353). At our institution, DFSs at 5 years of 74% for patients younger than 50 years have been observed (354).

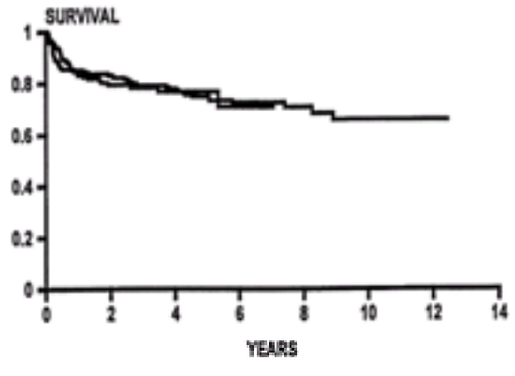

Figure 83.14. Kaplan-Meier probabilities of survival of 336 patients transplanted for chronic myeloid leukemia in chronic phase (CP). Patients were categorized by transplant regimen. Patients in the group with the shorter period of follow-up were treated with the busulfan + cyclophosphamide (CY) regimen, and the other group received the cyclophosphamide (CY) + total body irradiation regimen. The lines are not labeled because there is clearly no significant difference between the statistics they represent. (Reproduced from Clift RA, Buckner CD, Thomas ED, et al. The treatment of acute non-lymphoblastic leukemia by allogeneic marrow transplantation. *Bone Marrow Transplant* 1987;2:243–258, with permission.)

MYELODYSPLASTIC SYNDROME

The myelodysplastic syndromes (MDSs) are clonal hematopoietic disorders characterized by ineffective hematopoiesis, progressive cytopenias, and, in some affected individuals, a predisposition to developing leukemia (355,356 and 357). There is no satisfactory conventional therapy for MDSs (341,355). Cytotoxic therapy has resulted in CR in some people, but these remissions have been short. HSCT has been the only curative treatment for this heterogeneous disease (121,358,359). Best results with HSCT have been in MDS patients without excess blasts, in which event-free survivals have ranged from 41% to 56% (121,358,359). Chemotherapy-based

conditioning regimens appear to be effective for MDSs (359,360). Risk factors that adversely affect the outcome of HLA-matched sibling HSCT include older patient age, a higher percentage of marrow blasts, and previous cytoreductive chemotherapy (361). Autologous HSCT is an option for some patients without an HLA-identical sibling donor, but is imperfect because of difficulty mobilizing stem cells in some patients and the high risk of relapse after transplant (362). The use of unrelated HSCT is an option for patients without an HLA-identical donor (363). In general, therapy for treatment-related MDS and secondary AML arising from exposure to alkylating agents and radiation before autologous SCT is problematic (307,308,364). This therapy-related MDS is rarely cured with chemotherapy and is more difficult to treat with HSCT, primarily because of the higher incidence of regimen-related toxicity and relapse (365,366).

B-CELL MALIGNANCIES AND HODGKIN DISEASE

The treatment of advanced stage B-cell malignancies, chronic lymphocytic leukemia (CLL), non-Hodgkin lymphoma (NHL), and Hodgkin disease by allogeneic or autologous HSCT has met with limited success, but generally with superior results to those with salvage chemotherapy (367,368,369,370,371,372,373,374,375,376 and 377). Typically most patients with these diseases are older, have received a significant amount of chemotherapy before HSCT is considered, and, therefore, have poor bone marrow reserve (371,378,379 and 380). These factors are believed to contribute to the significant regimen-related toxicities and poor survival that occur after allogeneic HSCT. Most retrospective series and the few prospective studies have shown generally worse survival after allogeneic HSCT compared with autologous HSCT (372,373,379,380,381,382 and 383). Recent small, single-institution trials have demonstrated better results with allo-HSCT, with DFS at 2 years approaching 70% (384,385 and 386). However, autologous HSCT remains the initial therapy of choice in advanced stage, B-cell malignancies. The significant risk of relapse combined with the risk of developing therapy-related myelodysplasia and secondary AML after autologous HSCT for B-cell malignancies reflects the imperfection of this therapy (307,364,385,387).

MULTIPLE MYELOMA

Multiple myeloma (MM) is a malignancy of plasma cells that usually results in the accumulation of paraproteins, and is characterized clinically by lytic bony lesions, renal failure, anemia, and hypercalcemia (388). MM is considered incurable with conventional therapy, and median survival is typically 3 years (388). The use of allogeneic HSCT is limited in the therapy of MM primarily because of the older age of patients and the high degree of transplant-related mortality of approximately 40% to 45% (389,390,391 and 392). However, prolonged DFS, a much lower relapse rate, and molecular CRs in those patients who survive an allo-HSCT compared with recipients of autologous-HSCT suggest that a graft-versus-myeloma effect exists (390,391,392 and 393). Autologous HSCT is associated with much less transplant-related mortality than is allo-HSCT and has shown relatively equivalent DFS in younger patients (392,394,395). Autologous HSCT has been demonstrated to have better CR rates and improved event-free survival and survival compared with chemotherapy alone (396). Recently Barlogie et al. (397) showed encouraging results with an aggressive program using early-after-diagnosis tandem autologous HSCT to improve the probability of achieving a CR, followed by IFN as immunotherapy (397). The early use of autologous HSCT in the disease course of MM may be beneficial because of lessened exposure of the hematopoietic stem cells to alkylator chemotherapy that would improve the ability to mobilize stem cells and possibly reduce the risk of developing therapy-related myelodysplasia (1,307,389). In both autologous and allogeneic HSCT studies, factors that predict poor response and poor survival include elevated b_2-microglobulin, karyotypic abnormalities, prolonged exposure to chemotherapy, and in most studies, chemotherapy-unresponsive disease (390,394,397,398). Obviously, less toxic conditioning regimens are needed for allogeneic HSCT, and more effective methods are required for autologous HSCT to improve the survival of MM patients.

OTHER HEMATOLOGIC DISEASES

Allogeneic HSCT has been successful in more rare myeloproliferative and stem cell disorders such as myelofibrosis, hairy cell leukemia, and histiocytic medullary reticulosis (399,400 and 401).

SOLID TUMORS

Many centers have investigated the use of autologous HSCT for a variety of solid tumors (402,403,404,405 and 406). The use of autologous HSCT for breast cancer increased dramatically after the publication of encouraging phase II studies in the early 1990s. More recently, early analysis of all of the randomized controlled trials did not demonstrate survival benefits for women with high-risk or grossly metastatic breast cancer (407,408), except for one study that, unfortunately, was found to be falsified (409). Whether autologous HSCT is useful in certain subsets of patients with breast cancer, such as high-risk stage III, chemotherapy-responsive stage IV, or in solid tumors in general, are valid questions that must be addressed under the auspices of well-designed randomized controlled trials.

TARGETED THERAPY

Monoclonal antibodies directed at cell-surface antigens of malignant cells provide an ideal way of directing therapy to the appropriate cells. Antibodies directed at specific antigens have been found to be efficacious in providing tumor responses in CLL and breast cancer, although the mechanism(s) of action remains uncertain. However, not all directed antibodies provide disease responses. Recently, humanized monoclonal antibodies conjugated to cytotoxic antibiotics or radioactive isotopes have been used to treat non-Hodgkin lymphoma and AML (410,411 and 412). These techniques also have been used in conjunction with autologous and allogeneic HSCT (413,414).

Coupling radioactive isotypes to bone-seeking substances such as holmium ethylenediaminetetramethylene phosphonic acid (^{166}Ho-EDTMP) provides another approach of localizing therapy to the bone marrow and reducing systemic toxicities. This approach has obvious utility in patients with MM or leukemia. Canine studies have shown that ^{166}Ho-EDTMP was distributed to bone, and after 24 hours, the concentration of isotope is 200-fold that in any other organ (415). Marrow suppression was achieved with this technique because the marrow is never farther from the bone than 200 to 400 µm and the -emitting isotope has a range of several millimeters. Increasing doses of the path length of the ^{166}Ho-EDTMP led to increasingly prolonged and severe myelosuppression, but complete myeloablation was not achieved. It was reasoned that repopulation of marrow was achieved by circulatory hematopoietic stem cells sequestered in the spleen. This hypothesis was supported by the complete marrow aplasia that occurred when splenectomy was performed before the administration of ^{166}Ho-EDTMP.

ALLOGENEIC STEM CELL TRANSPLANTATION FROM ALTERNATIVE DONORS AND HAPLOIDENTICAL FAMILY MEMBERS

Genotypically HLA-identical sibling HSCT donors can be found only in less than one third of all patients. Extended searches of patients' families will identify a phenotypically identical or one HLA antigen–mismatched family member at frequency of 10% to 11%. Results of 281 HLA-haploidentical transplants compared with 967 concurrent genotypically HLA-identical marrow grafts were analyzed by Anasetti et al. (79), who found significant increase in graft failure in the recipients of haploidentical grafts (79). Graft failure was seen in 2% of genotypically HLA-identical siblings, 7% of phenotypically HLA-identical recipients, 9% of one-HLA-locus–mismatched recipients, and 21% of two-HLA-locus–mismatched recipients (180). The risk of acute GVHD is 2.16 times higher with a haploidentical HSCT than with HLA-identical HSCT. However, the HLA-nonidentical recipients have a reduced risk of leukemic relapse, presumably because of a greater graft-versus-leukemia effect. As a result, survival of HLA-haploidentical recipients who differ at only one locus on the nonshared haplotype is identical to that of HLA-identical siblings (Fig. 83.1). Because of the sharply increased transplant-related mortality, survival for two- and three-HLA-loci–mismatched patients is significantly worse. Similar results have been reported by the IBMTR (416).

ALLOGENEIC HUMAN STEM CELL TRANSPLANTATION FROM UNRELATED DONORS

The incidences of acute and chronic GVHD are much higher in recipients of unmodified unrelated HSCT compared with recipients of HLA-identical sibling grafts (182). Similar to the HLA-nonidentical family member setting, this adverse effect is somewhat offset by a lower relapse rate. Survival is similar for CML patients younger than 50 years receiving fully phenotypically HLA-matched grafts compared with HLA genotypically identical HSCT at our institution (354). In those patients given an unrelated HSCT for leukemia, event-free survival is similar to that with HLA-identical siblings, probably because of the greater graft-versus-leukemia effect (182). In contrast, in patients with CML in chronic phase, survival of those given an unrelated HSCT is expected to be 45% to 50% for all patients compared with 70% to 75% among similarly treated patients given HLA-identical sibling grafts (279,354,417). This survival difference is due to the higher incidence of transplant-related complications generally attributable to GVHD. It is clear that improved GVHD prevention and management remains the major hurdle in providing safe alternative and unrelated HSCT. Allele-level typing may result in better matching of unrelated donors, which may result in less GVHD and a smaller pool of “ideally” matched donors (30,31,418). However, a major focus in the future will be to determine permissive HLA mismatches that will provide donors for most if not all patients (181,280,418,419).

Nonmyeloablative Human Stem Cell Transplantation

Almost simultaneously over the last 6 years, there has been interest in the development of nonmyeloablative transplant regimens by several groups (12,13,47,87,173,420). The rationale by which these regimens operate is that engraftment, usually mixed hematopoietic chimerism or simply mixed chimerism, can be obtained from reduced doses of radiation or chemotherapy used to condition patients. This state of mixed chimerism has been seen in some cases after standard allogeneic transplant (421,422 and 423), but is more common after the depletion of T lymphocytes in the graft or with less intensive transplant-conditioning regimens (87,173,422,424). Most nonmyeloablative HSCT programs attempt to use postgrafting DLI to convert mixed chimeras to full donor chimeras and as immunologic therapy to eradicate the underlying malignancy or hematopoietic defect. It has recently been shown in the dog model that long-term stable mixed chimerism is due to

mutual host/donor tolerance, which could be disturbed only by DLIs from donors sensitized to minor host histocompatibility antigens induced by repeated skin grafting from the host (425).

Most nonmyeloablative HSCT programs only attenuate current standard conditioning regimens and, therefore, must still be carried out in the hospital setting. The regimen currently used in Seattle is performed in the outpatient setting. The conditioning regimen uses three doses of fludarabine (30 mg/m^2/day for 3 days) followed by a single dose of 200 cGy of TBI on the day of HSCT. Postgrafting immunosuppression with mycophenolate mofetil and CSP, initially demonstrated to be synergistic in the dog model (47), provided control of host-versus-graft and GVH reactions (420). Of 29 patients who were too old or medically infirm for a conventional HSCT given a nonmyeloablative HSCT at our center, all had mixed donor/host chimerism at day 28, with a higher degree of chimerism seen in patients with significant previous exposure to chemotherapy (11). Mixed donor/host chimerism appeared to be less stable in these older patients treated thus far compared with that seen in the young dog, and most patients went on to full donor engraftment or, in fewer than 16%, to rejecting the allografts (50,426). The rejection of a graft after a nonmyeloablative transplant was nonfatal and accompanied by autologous hematopoietic recovery in all cases (426). Since the addition of fludarabine as part of the pretransplant immunosuppression, no patient has rejected his or her grafts and, in general, higher degrees of donor chimerism have been observed (11). GVHD of grade II to III has occurred in more than 50% of patients with engraftment, and this correlates to a higher degree of donor chimerism (426). Antitumor responses and complete remissions after nonmyeloablative HSCT have been observed in patients with CML, CLL, multiple myeloma, and Hodgkin disease, among others, mediated by the allogeneic effect on the tumor cells (50,427). DLI has been used infrequently in this initial cohort. DLI does not appear to prevent rejection, but when administered for persistent or progressive disease, tumor responses and complete remissions have been observed (427).

CONCLUSIONS

In the last 30 years, the efficacy of HSCT at curing a variety of diseases has been established. Allogeneic HSCT from an HLA-matched sibling is the treatment of choice for SAA, SCID, CML, MDS, a number of fatal genetic diseases, and high-risk or advanced-stage AML and ALL. Autologous HSCT is efficacious for a variety of hematologic malignancies, and its role is being defined for solid tumors and autoimmune diseases. The role of allogeneic HSCT for malignant diseases other than CML, MDS, and high-risk or advanced-stage AML and ALL is less clearly defined and should be investigated through well-designed, randomized controlled trials. The major limitations of allogeneic HSCT, in particular donor procurement, toxicities related to high-dose chemotherapy, and GVHD, continue to be significant problems that limit the application of this procedure to a generally younger subset of afflicted patients. The development of less toxic nonmyeloablative conditioning programs that rely on the *allogeneic effect* rather than high-dose therapy to eradicate cancer cells, coupled with improved HLA typing, larger donor registries, and better supportive care provide optimism that allogeneic HSCT will become a safer and more widely applied curative modality for a variety of malignant and nonmalignant diseases.

84 TISSUE AND SOLID ORGAN ALLOGRAFT REJECTION

Kim C. Lu, M.D., Andrés Jaramillo, Ph.D., and Thalachallour Mohanakumar, Ph.D.

Human organ transplantation, a combined achievement of medicine, pharmacology, and immunology, provides life-saving organs to patients with end-stage organ failure who have exhausted all other therapeutic options. The complexity of the transplant process arises from the immune response to the transplanted organ (rejection), when this organ is derived from another genetically nonidentical individual of the same species (*allograft*). Allograft rejection is a unique immunologic disease because the onset (*transplant procedure*) and many of the target antigens (*donor antigens*) can be easily identified. Despite these opportunities, the most basic aspects of the disease still are not well understood: the nature of the immunogenic peptides (epitopes), the identity of the effector immune mechanisms, and the factors responsible for recipient differences in the immune response to allografts. Therefore, although important advances have been made in the prevention, diagnosis, and treatment protocols, allograft rejection still occurs frequently, is incompletely controlled by current treatment protocols, and represents a major treatment cost.

In the United States, the United Network of Organ Sharing (UNOS) develops policies to allocate cadaveric organs fairly among the different transplant centers. UNOS also tabulates data on the results of transplantation (1). The most frequently transplanted organs include kidney, liver, pancreas, heart, and lung. Table 84.1 lists the rejection rates of different solid organ allografts, assuming immunosuppression with cyclosporine/FK506, azathioprine, and prednisone. One-year graft failure rates were between 10.6% (for kidney allografts) and 36.2% (for intestine allografts), and the 5-year rates were less promising, between 31.5% (for heart allografts) and 62.6% (for intestine allografts). Kidney transplants, particularly the living-related ones, have the lowest rates of graft failure (about 6%) (1).

Type of Organ	1-Year Graft Failure (%)	5-Year Graft Failure (%)
Kidney (cadaveric)	10.6 ± 0.3	35.3 ± 0.2
Kidney (living-related)	5.5 ± 0.3	21.6 ± 0.3
Liver	18.6 ± 0.5	33.9 ± 0.3
Pancreas	23.8 ± 2.4	58.4 ± 2.4
Intestine	36.2 ± 7.5	62.6 ± 6.2
Heart	14.9 ± 0.6	31.5 ± 0.4
Lung	23.7 ± 1.1	58 ± 0.8
Heart-lung	41.8 ± 5.3	59.5 ± 2.5

Data derived from the 2000 Annual Report by UNOS.

TABLE 84.1. One- and Five-Year Graft Failure Rates of Solid-Organ Allografts

Five-year graft failure rates of living-related kidney allografts are given in Table 84.2 (1). Of note, a six-antigen mismatch from a living related donor does as well as a perfect match from a cadaveric donor (2). Transplant surgeons have pointed to cold ischemia time to explain this phenomena. After all, living-related donation is scheduled electively. The organ is often harvested from an adjacent room. With minimal ischemia time (less than 1 hour), the kidney may face less reperfusion injury (3,4). No satisfactory hypothesis has been offered to explain why a six–human leukocyte antigen (HLA) mismatch from a living donor is not as vigorously rejected.

No. of HLA Mismatches	Cadaveric Allografts Graft Failure Rate (%)	Living-Related Allografts Graft Failure Rate (%)
0	28.4 ± 0.8	13 ± 0.6
1	31.3 ± 1.2	21.5 ± 1.1
2	33.5 ± 0.7	23.3 ± 0.7
3	34.9 ± 0.5	24.4 ± 0.6
4	36.5 ± 0.5	21.6 ± 1.4
5	38.3 ± 0.6	25 ± 1.6
6	40.7 ± 1.1	29.2 ± 2.7

HLA, human leukocyte antigen.Data derived from the 2000 Annual Report by United Network of Organ Sharing (UNOS).

TABLE 84.2. Influence of HLA Matching on 5-Year Graft Failure of Cadaveric Versus Living-Related Kidney Allografts

Still, as described subsequently, HLA matching is the standard for allocating cadaveric kidney allografts. A harvested kidney may be preserved up to 48 hours, until HLA matching can be done. Furthermore, recipients can be sustained with dialysis until they can receive the graft (3). For practical reasons, prospective HLA matching is not done for heart or lung allografts. First, the organs are difficult to preserve. Thus, there is not enough time to define the HLA antigens before transplantation. Thus, organs are allocated based on the UNOS waiting list without consideration of HLA matching (4). While waiting for a graft, heart recipients can receive artificial mechanical hearts or left-ventricular assist devices. A lung recipient could, on a short-term basis, exist on extracorporeal membrane oxygenation, or ECMO (3). Matching for HLA between donor and recipients is not routinely done for liver allografts. Whereas livers can be preserved for a short time, for various reasons, recipients do not mount a strong immune response. Even livers with a different ABO blood type can be accepted, assuming standard immunosuppression (4).

LABORATORY METHODS IN CLINICAL TRANSPLANTATION

Identification of HLA Phenotypes

The HLA class I antigens (A, B, and C) are expressed on all nucleated cells and are recognized by $CD8^+$ T cells. On the other hand, the HLA class II antigens (DR, DQ, and DP) have a selective tissue distribution, are expressed by antigen presenting cells (APCs), and are recognized by $CD4^+$ T cells. Also, such HLA class II antigens can be expressed by a variety of nonimmune cell types upon stimulation with interferon (IFN)-g. Every individual inherits six HLA antigens (three class I, three class II) from each parent. All such antigens are codominantly expressed. The entire set of HLA-A, B, C, DR, DQ, and DP antigens located on chromosome 6 is called a

haplotype. Because HLA differences lead to rejection, transplant physicians attempt to match donor and recipient HLA antigens. For practical reasons, only HLA-A, B, and DR are considered before transplantation (5). Hence, every individual has six alleles to type and match. As indicated in Table 84.2, better-matched grafts have better survival.

It is necessary to determine the HLA antigen composition in prospective donor–recipient pairs before kidney transplantation. Two methods have been used in clinical transplantation to determine a person's HLA phenotype: (a) Traditional tissue typing is based on a complement-dependent cytotoxicity (CDC) test, in which patient lymphocytes are incubated with specific anti-HLA antisera and complement. A positive reaction is indicated by lysis of the lymphocytes. The HLA type then is determined based on the lysis of cells by specific antisera. The alloantisera used in the CDC assays are limited in quantity and are often not specific for a single HLA allele. Production of anti-HLA monoclonal antibodies has encountered many difficulties, including reactivity to framework HLA antigenic determinants present in all alleles. In addition, the CDC assays require millions of viable lymphocytes, which are often difficult to obtain from children and from any patients with corticosteroid therapy, leukemia, or end-stage renal disease. In addition, in cadaveric donors, HLA class II typing is often difficult using peripheral blood lymphocytes and is usually done using lymphocytes isolated from spleen or lymph nodes (6). This may make organ retrieval more time-consuming, leading to a longer cold ischemia time. (b) One of the important technical improvements in the field of tissue typing has been the development of molecular methods for typing the alleles of HLA class I and II genes (6). With new molecular techniques based on the nucleotide sequence of the HLA alleles, such alleles can be typed more accurately using fewer cells. Therefore, a serologically defined HLA type may be divided further into several subtypes at the DNA level. To differentiate between allelic differences, sequence-specific DNA primers (SSPs) are used. If the SSPs can anneal to a fully complementary strand, the corresponding allelic fragment can be amplified by means of the polymerase chain reaction (PCR) technique and directly visualized on an agarose gel. In the case where no complementary strand exists, no amplification occurs (6). Another approach to DNA typing is hybridization of PCR-amplified, biotin-labeled genomic DNA with sequence-specific oligonucleotide probes (SSOP) prebound to a nylon membrane. These SSOPs also bind only to a fully complementary sequence in the amplified DNA. The SSOP-bound allelic DNA then can be visualized by the addition of an avidin–peroxidase conjugate that binds to the biotin-DNA complex. The addition of the appropriate substrate causes the complex of the biotinylated-DNA and SSOP to turn blue in the nylon membrane (6). Although molecular techniques are superior to standard CDC methods, several continuing problems are encountered by the new molecular techniques of HLA typing. As new HLA alleles are discovered and defined, increasing numbers of SSPs and SSOPs are required for more accurate typing. Routine clinical SSP and SSOP testing usually lacks the ability to detect new alleles, unless unexpected cross-reaction patterns are observed. Nevertheless, these molecular approaches have dramatically improved histocompatibility testing for clinical transplantation and also have improved histocompatibility laboratory operating accuracy and efficiency. Previous studies have shown that 12% of kidney allografts are lost during the first year posttransplant because of acute rejection, despite complete HLA matching by conventional methods (7). This observation indicates the presence of undetected HLA mismatches in these recipient–donor pairs that play an important role in allograft rejection. With the use of new emerging techniques such as sequence-based tissue typing, it should be possible to detect a true HLA match from a list of potential related or unrelated donors in both solid organ as well as bone marrow transplantation. The result should be better graft survival, less graft-versus-host disease (GVHD), and reduced immunosuppression following transplantation.

Detection of Prior Sensitization to HLA Antigens

Even more important than the determination of the HLA phenotypes of both donor and recipient are the evaluation and identification of the anti-HLA antibodies in the serum of recipients before transplantation. A major risk factor for graft survival is host presensitization by means of prior transplants, pregnancies, or blood transfusions. Transplanted allografts into a presensitized host with circulating complement-binding antibodies can be lost within minutes to hours because of hyperacute rejection (8,9 and 10). Noncomplement-binding antibodies acting in parallel with a secondary cell-mediated immune response also can induce accelerated rejection within 72 to 96 hours posttransplantation (11). Prior sensitization to HLA antigens in prospective recipients is detected by cross-match techniques in which donor target cells, usually lymphocytes, are incubated with recipient serum in the presence of rabbit complement. Next, eosin dye is added to the serum-treated donor cells; dead targets fail to exclude the eosin dye and stain darkly, whereas viable targets exclude the eosin dye and appear as unstained refractile cells. Several modifications of this technique have improved the sensitivity of this visual method: (a) the addition of antihuman serum amplifies the detection of small but clinically relevant levels of antidonor immunoglobulin G (IgG) that otherwise would remain undetected. (b) Low levels of antibodies bound to donor cells can also be detected by means of the fluorescence-activated cell sorter (FACS), which measures the binding of a second labeled antihuman IgG antibody (6).

NATURE OF THE TARGET ALLOANTIGENS

Major Histocompatibility Antigens

The most important of the antigens expressed by the allograft are the HLAs encoded within the major histocompatibility complex (MHC) on chromosome 6. In normal immune responses, T cells recognize foreign antigens when presented as peptides in association with self-MHC molecules. Details of MHC gene structure and function are given in Chapter 3. In the transplant response, the precise molecular nature of the recognition of the foreign MHC alloantigen is less clear. Most likely, nonself-MHC alloantigens can be directly recognized, with or without peptide (12). Despite these fundamental differences, the cascade of events that occur during the process of allograft rejection appears to be essentially the same as that which occurs against foreign antigens such as bacteria or viruses. These processes lead to the recognition and destruction of the invader, in this case the allograft.

Based on basic immunology research and the transplant experience, better HLA matches correlate with better graft survival and less rejection. Table 84.2 lists the 5-year survival rates for kidney allografts. For the cadaveric organs, the six-HLA match has a 28.4% graft failure rate. The worst match, that is, six mismatches, has a much higher graft failure rate of 40.7% (1). These rates fit with the theory that MHC determines histocompatibility. The more HLAs that are matched, the more histocompatible the graft is. Yet, HLAs are not the only antigens important to histocompatibility. Again, even “perfect” kidney allografts with six HLA matches have at least a 28.4% rejection rate at 5 years (1). In addition, several studies have reported that 10% to 20% of kidney allografts are lost as a result of acute rejection, regardless of a complete HLA match and negative T- and B-cell cross-matches (7). As described above, allograft rejection is mediated largely by the recipient T cells against the highly polymorphic MHC molecules expressed on the donor cells. Other non-MHC antigens exist, however, that are fully capable of triggering graft rejection.

Minor Histocompatibility Antigens

As mentioned, an allograft transplanted between a donor and recipient matched at the MHC genes has a higher acceptance rate; however, allograft rejection still can occur. Such rejection has been caused by the disparities in polymorphic gene products called minor *histocompatibility antigens* (MiHAs) (13,14,15 and 16). It is estimated that the murine genome may contain up to 720 MiHA genes. In humans, this number is estimated to be even larger. Most of these loci are located on autosomal chromosomes, but a few also map to mitochondrial DNA and the Y chromosome (17). Because of the great number of MiHA genes, only identical twins can share all their transplantation antigens, both MHCs and MiHAs. Siblings, even if they are MHC identical, generally match for only about half the total number of MiHAs. The importance of MiHAs in transplantation is manifested by several clinical findings. First, in MHC-matched solid organ transplantations, the disparities in MiHAs often lead to graft rejection (18,19). The second involvement of MiHAs is related to the graft-versus-host disease in MHC-matched bone marrow transplantations (18,19). Third, MiHAs are also involved in the graft-versus-leukemia effect in bone marrow transplantation. The graft-versus-leukemia effect can lead to the eradication of residual host leukemic cells by the engrafted bone marrow transplant (20). The MiHAs also can cause the insidious clinical complications of chronic rejection of MHC-matched solid tissue and organ grafts.

The immune responses to single MiHAs are much less potent than responses to allogeneic MHC molecules because the frequency of responding T cells to a given MiHA is significantly lower. Indeed, MiHA-specific T cells need to be primed *in vivo* before they can be detected *in vitro* in a mixed lymphocyte reaction. The response to MiHAs is similar to the response to viral infection. All cells in the graft express the MiHA, and so the entire graft is destroyed in such responses, just as the analogous responses to tissue-specific peptides can destroy an entire tissue in autoimmunity.

Both $CD4^+$ and $CD8^+$ T-cell cooperation is required for MiHA-mediated graft rejection. Both cells recognize their specific MiHAs in a MHC-restricted manner. This cooperation was implicit from early studies on responses to H-Y antigens in which permissive and nonpermissive MHC class I and class II alleles could be identified that affected $CD8^+$ cytotoxic T-cell generation and skin graft rejection (17,21). The mouse strains expressing permissive alleles allow the generation of both $CD4^+$ T cells and $CD8^+$ cytotoxic T-effector cells; thus, the H-Y antigen can elicit a functional immune response. Whereas the mouse strains expressing nonpermissive alleles have the precursors for the $CD8^+$ cytotoxic T-effector cells, no *in vivo* responses to H-Y are generated because of the lack of appropriate $CD4^+$ T-helper function.

The major features that distinguish MiHAs from other transplantation antigens are that MiHAs are recognized by T cells but not by antibodies and that MiHAs are recognized in a MHC-restricted manner. It is now clear that MiHAs are peptides derived from polymorphic proteins that are presented by MHC molecules on the allograft (22,23). The fact that the MiHAs are peptides recognized in association with MHC molecules explains many of the features of these antigens that were known but poorly understood for a long time. First, it is difficult, if not impossible, to detect humoral responses to MiHAs, probably because most MiHAs come from intracellular proteins; thus, even if an antibody response were to occur, it could not be detected at the cell surface. Second, MiHAs do not stimulate a primary *in vitro* cell-mediated response, whereas MHC antigens evoke a powerful primary response in both mixed lymphocyte reaction and cell-mediated lympholysis assays. This is in agreement with the general difficulty in detecting *in vitro* T-cell responses to peptides of nominal protein antigens unless they have been primed *in vivo*. Third, recognition of MiHAs is MHC-restricted; that is, secondary responses require that the MiHAs be presented in association with the same MHC molecules as during the primary exposure.

These MiHA-specific T-cell clones have been used for the identification of the sequence of these peptides. Because MiHAs are recognized by T cells in the context of

MHC antigens, an obvious approach was to isolate the peptide antigens from their respective MHC molecules. After isolation of the peptides by means of high-pressure liquid chromatography and mass spectroscopy, it has been possible to identify the chemical nature of several human MiHAs presented by HLA-A2.1 and HLA-B7 molecules (11,24,25 and 26). The clinical potential of MiHAs remains to be assessed. Some areas are worth mentioning, however. GVHD is one of the most feared complications of allogeneic bone marrow transplantation (20). In HLA-identical bone marrow transplantation, disparities in MiHAs between the donor and the recipient, with the MiHA being presented by the recipient cells, can induce GVHD (19). In bone marrow recipients with severe GVHD, cytotoxic T cells specific for recipient MiHAs can be isolated from peripheral blood leukocytes (14). A retrospective study showed an association between mismatched MiHAs and the occurrence of GVHD in recipients of bone marrow from HLA-identical donors (18). The high immunogenicity of some of the MiHAs together with the recently identified amino acid composition of the peptides is the foundation for attempts at immunomodulation of GVHD. MiHA peptide analogs may function as MHC or T-cell receptor antagonists that might block the harmful T cells reactive to host MiHAs after HLA-identical bone marrow transplantation. The role of MiHAs in solid organ transplantation is still not well understood, but some recent studies indicated that MiHAs may play a role in renal allograft rejection. Cytotoxic T-lymphocytes restricted to self-MHC and reactive to MiHA can be isolated during the rejection of transplants between HLA identical donor–recipient combinations (27,28).

Tissue-Specific Antigens

A primary target in the immunopathogenesis of renal allograft rejection is the endothelium of vessels within the graft. In fact, immunopathologic studies of hyperacute, acute, and chronic rejection of kidney allografts show evidence of vascular endothelial cell damage (29). This finding suggests that vascular endothelium may be the sensitizing immunogen in a transplanted kidney because it expresses high levels of ABO, HLA, and endothelium-specific, non-HLA antigens (30,31). In fact, Moraes and Stastny (32) showed that 96% of patients who experienced acute kidney allograft rejection also developed antibodies to vascular endothelial cells and 53% showed no cytotoxicity to donor T and B cells. These results were confirmed by Cerilli et al. (33), who also found that 96% of kidney allograft recipients who rejected their transplanted organs had antibodies that reacted with vascular endothelial cells; up to 50% of these patients had no reactivity to T and B cells. These reports indicate that the antibodies detected in these patients were directed against an antigenic system that is independent of HLA and ABO antigenic systems and that is expressed on vascular endothelial cells but not on lymphocytes. In fact, a non-HLA antigenic system expressed on human vascular endothelial cells was first reported by Moraes and Stastny (32) and was shown to be of importance in the rejection process of kidney allografts (34). These studies showed that 60% of cadaveric renal allograft recipients who experienced graft rejection within 7 weeks posttransplantation had antivascular endothelial cell antibodies compared with only 2% of patients with no rejection episodes within this period of time. Moreover, in related studies, our laboratory demonstrated non-HLA complement-fixing antibodies against kidney epithelial cells in up to 78% of rejected renal allografts eluates (35,36). These eluates also reacted with monocytes but not with matched T or B cells (36). These observations strongly suggest that the presence of specific complement-binding antidonor vascular endothelial cell antibodies is highly detrimental to kidney allograft survival and that such antibodies can develop in the absence of anti-HLA antibodies.

In addition to antibodies, T cells also recognize tissue-specific antigens. Manca et al. (37) first reported that lymphocytes from a rejected human kidney allograft, expanded *in vitro*, lyse donor kidney fibroblasts but not donor leukocytes. Given the current understanding of allorecognition (Fig. 84.1), kidney fibroblasts process an intracytoplasmic, kidney-specific protein, present the peptide on class I MHC, and are recognized by $CD8^+$ T cells. Previous studies from our laboratory showed that such tissue-specific peptides, recognized by tissue-specific clones derived *in vitro*, can be isolated and identified (38). Yard et al. (39,40) also isolated kidney-specific T-cell clones from graft infiltrating lymphocytes. These tissue-specific T cells from a single cloning experiment constitute 50% of the total number of clones isolated and were all $CD8^+$ cytotoxic T cells. The high number of tissue-specific clones is consistent with the cytolytic activity of the parent graft-infiltrating T-cell line. This line recognized donor kidney epithelial cells but not donor lymphocytes. Poindexter et al. (41) also reported that more than 10% of the T-cell clones isolated from rejecting biopsies were cytotoxic only to kidney epithelial cell lines but not to HLA-matched lymphoid cells. This finding suggests a role for these cytotoxic T cells in allograft rejection. These results strengthen the hypothesis that tissue-specific $CD8^+$ cytotoxic T cells are a significant component of graft-infiltrating T-cell populations and may play an important role in allograft rejection. The same group also identified a kidney-specific nanomer peptide that is recognized by cytotoxic T-cell clones in an HLA-A3 restricted manner (38). This suggests that tissue-specific peptides may behave similar to minor histocompatibility antigens.

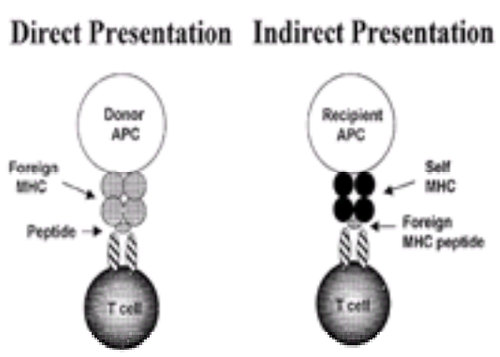

Figure 84.1. Mechanism of allorecognition. Direct allorecognition involves recognition of foreign major histocompatibility complex (MHC) class I molecules with a variety of peptides present in the antigen presentation groove. Indirect allorecognition involves recognition of peptides derived from foreign MHC molecules and presented by self-MHC class II molecules.

MECHANISMS OF ALLORECOGNITION

Various hypotheses have been proposed to explain allograft rejection. In 1955, Billingham et al. (42,43) reported that isografts (organs transplanted between members of the same inbred mouse strain) were not rejected; however, allografts were rapidly rejected in 8 to 10 days. They also noted that if a recipient receives a second skin allograft from the same donor, the second allograft is rejected more rapidly. If the second skin allograft is from a different donor strain, this rejection is not accelerated. Hence, these results were suggestive of specific immunologic recognition and memory in the rejection process. The cellular basis was then elucidated when adoptively transferred lymphocytes transferred the ability to reject the allograft. When an organ from one individual is transplanted into another nonidentical individual of the same species, several cellular and molecular immunologic processes are activated, which, if left untreated, result in rejection of the allograft. This allogeneic immune response consists of a variety of mechanisms directed against the nonself-foreign antigens expressed by the graft. Two models of alloantigen recognition have been proposed (Fig. 84.1) (8,12,17,44). In direct alloantigen recognition, the recipient's T cells recognize foreign MHC molecules directly, without processing by self-APCs (17,44). Recognition is probably due to the inherent natural affinity of the T-cell receptor for MHC molecules. This process is explained in the context of negative and positive selection in the thymus, where T cells are educated to distinguish self from nonself. T cells with too high an affinity for self-MHC molecules plus self-peptides are deleted (*negative selection*), whereas T cells with low affinity for self-MHC molecules plus self-peptides are selected for maturation and exit the thymus for the peripheral immune organs (*positive selection*). This process ensures the deletion of high-affinity autoreactive T cells and the presence in the periphery of low-affinity autoreactive but nonpathogenic T cells with the potential to recognize self-MHC molecules plus foreign peptides with high affinity. Because developing T cells with a high affinity for nonself-MHC molecules would not have been eliminated in the thymus, they should be present in the periphery. These T cells recognize foreign MHC molecules expressed by parenchymal cells of the allograft (Fig. 84.1). For more details on T-cell development, see Chapter 5.

In indirect alloantigen recognition, soluble foreign MHC molecules, possibly shed by apoptotic or necrotic parenchymal cells in the allograft, are phagocytosed and processed by self-APCs infiltrating the allograft during the rejection process. Subsequently, peptides derived from these foreign MHC molecules are recognized by $CD4^+$ T cells as epitopes presented by self-MHC class II molecules expressed on self-APCs (Fig.84.1) (8,12). This mechanism is the same as that involved in the recognition of natural foreign peptides. Several studies showed that indirect allorecognition occurs and is relevant to the process of allograft rejection (45,46 and 47). In addition, a growing body of evidence indicates that during rejection, this pathway of alloantigen recognition by $CD4^+$ T cells has a level of importance comparable to the direct pathway by $CD8^+$ cytotoxic T cells. Further, $CD4^+$T cells may be more important in chronic rejection.

APOPTOSIS IN ALLOGRAFT REJECTION

Several studies demonstrated that programmed cell death, or *apoptosis*, occurs during both acute and chronic solid organ allograft rejection (48,49). The role of apoptosis has been examined in rejection of cardiac, hepatic, and renal allografts. Studies in both animal models and humans detected apoptosis both in allograft parenchymal cells as well as in the inflammatory cell infiltrate. Lagueris et al. (50) showed that apoptosis also occurs in human cardiac allografts. In this study, the incidence of apoptosis in myocytes, capillary endothelial cells, and connective tissue cells was associated with the histologic grade of acute rejection. Two studies have provided evidence for apoptosis in chronic rejection of murine cardiac allografts (48,49). In a heterotopic murine cardiac transplant model, Bergese et al. (48) and White et al. (49) demonstrated a significant incidence of apoptosis in the periarterial cellular infiltrates associated with sclerotic changes consistent with chronic rejection. These two studies, however, did not distinguish between apoptosis in parenchymal cells and graft-infiltrating inflammatory cells.

Krams and Martinez (51) used the terminal deoxyribonucleotidyl transferase-mediated dUTP nick-end labeling (TUNEL)-based *in situ* assay to determine the presence

of apoptosis in a rat model of orthotopic liver allograft rejection. Their studies indicated that an increased incidence of TUNEL-positive cells is observed during the first 7 days posttransplantation of liver allografts but not in syngeneic liver grafts. This increased incidence of apoptosis was associated with indicators of rejection, such as liver enzyme elevation and positive histopathology. Afford et al. (52) examined the role of apoptosis in human liver allograft rejection using the *in situ* TUNEL assay. Their studies demonstrated that hepatocyte apoptosis was common in areas of perivenular hepatocyte dropout. Apoptosis also was observed in the inflammatory mononuclear cell infiltrate in acutely rejecting allografts.

In a rat model of renal transplantation, Wang et al. (26) showed that the expression of Fas-ligand (FasL) was increased in allografts undergoing acute rejection but not in normal kidneys. In contrast, Fas expression was constitutively expressed in allografts as well as in normal kidneys. In biopsies of human kidney allografts, apoptotic cells were detected during rejection episodes (53). There is some controversy about the appearance of such cells during acute versus chronic rejection. Although apoptosis of kidney epithelial cells was preferentially observed during acute rejection in some studies, it was primarily observed during chronic kidney allograft rejection in other studies (54). Apoptosis also has been associated with acute lung allograft rejection, both in humans and in animal models (55). In addition, apoptosis-inducing Fas–FasL interactions have been shown during the development of chronic rejection in a rat lung allograft transplant model (56).

Taken together, evidence is emerging that apoptosis occurs during allograft rejection episodes. Because apoptotic cells are rapidly cleared *in vivo* by infiltrating macrophages (57), the demonstration of apoptotic cells *in situ* by TUNEL-based assays at any given time point actually might underestimate the extent of apoptosis during allograft rejection. See Chapter 12 for a more extensive discussion of apoptosis.

T-HELPER CELL TYPES 1 AND 2 CYTOKINES IN ALLOGRAFT REJECTION

Two functionally different $CD4^+$T helper (Th) cell subsets, characterized by divergent profiles of cytokine production, were identified originally by analysis of murine, and later of human, Th-cell clones (58,59). Interleukin (IL)-2, IFN-g, and tumor necrosis factor (TNF)-b are produced by murine Th1 cells, whereas the murine Th2 cells produce IL-4, IL-5, IL-6, IL-9, IL-10, and IL-13. Although human Th1 and Th2 cells also produce distinct profiles of cytokines, the synthesis of IL-2, IL-6, IL-10, and IL-13 is less restricted to a single subset compared with the murine Th cell system (60). Th1 and Th2 cells also were demonstrated *in vivo,* and their presence may correlate with ongoing cell-mediated and humoral immune responses, respectively (61). Th1 cells induce activation of delayed-type hypersensitivity (DTH) reactions as well as cytotoxic and inflammatory immune responses that eliminate intracellular pathogens, whereas Th2 cells induce B-cell responses that eliminate extracellular pathogens.

A large body of evidence suggests that activation of Th1 responses is strongly associated with the allograft rejection process (62). Both IL-2 and IFN-g are readily detected in several types of organ allografts undergoing rejection (63,64 and 65). In addition, the expression of these Th1 cytokines during allograft rejection is associated with the appearance of proinflammatory mediators. Furthermore, adoptively transferred $CD4^+$T cells were sufficient to induce rejection of both MHC class I or II mismatched skin allografts in T cell-deficient mice (66). *In situ* cytokine analysis from such skin allografts demonstrated the upregulation of Th1 cytokines (IL-2 and IFN-g) but not Th2 cytokines (IL-4). In contrast, mice rejecting orthotopic liver allografts showed *in situ* upregulation of Th1 (IL-2 and IFN-g) as well as Th2 (IL-4 and IL-6) cytokine mRNA (67). In addition, both Th1 (IFN-g) and Th2 (IL-4) cytokines have been elevated during acute lung allograft rejection (68). Therefore, multiple cytokine profiles seem to be expressed *in situ* during the acute rejection process. Therefore, it is likely that Th1 effector cells synergize with Th2 effector cells during the process of allograft rejection. In this regard, both IL-4 and IL-10 have been identified as cytotoxic $CD8^+$ cell growth and differentiation factors (69,70). Taken together, these data suggest that acute allograft rejection is mediated by a mixture of Th1 and Th2 cells or by Th0 cells capable of expressing a mixture of Th1/Th2 cytokines.

Although Th2 cells directly activate B-cell proliferation and differentiation into antibody-secreting cells, which are important in chronic allograft rejection, recent studies suggest that Th2 cytokines may be involved in the *in situ* expression of genes with “protective” functions (71). These include molecules such as antiapoptotic proteins (bcl-2 and bcl-xL), proteins protective against oxidative stress (HO), as well as proteins that block the activation of the NFkB gene. Therefore, Th2 cytokines may protect organ allografts from failure associated with chronic allograft rejection.

Therefore, in view of conflicting observations, the relevance of Th1 and Th2 cells to the complex process of allograft rejection continues to be debated. Although Th2 cells often are associated with long-term graft survival, it has not been proven that they indeed mediate organ allograft tolerance. The redundant and pleiotropic nature of different cytokines *in vivo* imply that the Th1/Th2 paradigm may not be sufficient to understand the complex immune mechanisms underlying the allograft rejection process. Indeed, Th1/Th2 paradigm may not be applicable to allograft rejection because the recipient microenvironment, the type of organ allograft, and the therapeutic strategy applied all may influence the intragraft cytokine profile produced during the rejection process. See Chapter 10 and Chapter 11 for a more extensive discussion of Th1 and Th2 cells, respectively.

TYPES OF ALLOGRAFT REJECTION

There are four main types of allograft rejection: hyperacute, accelerated, acute, and chronic. The first two types of rejection represent memory responses, where antibodies were already in circulation or immediately activated on transplantation. The last two types of rejection represent primary immune responses, that is, cell-mediated immune responses (5,72,73).

As mentioned, hyperacute rejection occurs within minutes to 48 hours. Complement-fixing antibodies bind to the vascular endothelium and active complement. Such complement activation may induce thrombosis by attracting polymorphonuclear leukocytes and platelets and activating the coagulation cascade (8,9 and 10). Initially, this type of rejection was the first obstacle to successful transplantation. This condition is not treatable and demands emergency removal of the kidney allograft. Histopathologic examination can differentiate the immunologic etiology of the condition, in contrast to thrombosis from a surgical technical error (74). Antibodies reactive to incompatible blood ABO antigens or donor HLA antigens can cause hyperacute rejection. Therefore, all allografts typically are matched for the blood group antigens. Furthermore, as mentioned, a cross-match is performed before transplantation to rule out prior sensitization to donor HLA antigens. As a result of blood group matching and the cross-match test, hyperacute rejection is rarely seen in clinical renal allograft transplantation (74). The liver is an interesting exception to the preceding discussion. At least in the short term, livers have been successfully transplanted despite a blood group mismatch (3,4), possibly attributable to better immunosuppression, the decreased relative immunogenicity of the liver, or the capacity of the liver to regenerate.

Accelerated rejection occurs within 3 to 5 days posttransplantation and can be due to the binding of both complement-fixing and noncomplement-fixing antibodies. These act through antibody-dependent cellular cytotoxicity (ADCC) and natural killer (NK) cells or monocytes to produce vascular disruption. Because of the involvement of the cellular immune response, antilymphocyte reagents have some efficacy. Frequently, this condition cannot be permanently reversed, and it recurs with more severe rejection episodes until allograft removal becomes the only therapeutic alternative (3,4).

The next barrier to successful transplantation is acute rejection, which occurs between 6 and 90 days posttransplantation, but it also may occur later, during the posttransplant period, as result of treatment noncompliance (3,4). This condition is characterized histologically by cellular infiltrates with $CD8^+$ cytotoxic T cells and an inflammatory response produced by *in situ* cytokine production by $CD4^+$ Th1 cells activated through the indirect pathway of antigen presentation by self-APCs (5,12,72,73). See Table 84.3 for a comparison of acute rejection in different organs. Many animal models, later correlated with human histology, point to the importance of the $CD8^+$ cytotoxic T cell. Although a perivascular lymphocyte infiltrate characteristic of DTH reactions is frequently present, the characteristic acute rejection lesion is thought to be mediated by a direct interaction of lymphocytes with parenchymal cells. Once activated, these cells damage both the vascular endothelium and the graft parenchyma. Allograft dysfunction and failure would inevitably ensue without more immunosuppression. Of note, NK cells also may play a role. These large lymphocytes come from a similar precursor as T cells; however, NK cells do not express T-cell receptors. NK cells kill cells that do not express self-MHC class I molecules. Therefore, because the allograft does not express recipient MHC molecules, the recipient's NK cells will attack the graft. See Chapter 19 for a more extensive discussion of NK cells.

Transplant	Acute Rejection	Chronic Rejection
Kidney	Lymphocytosis, tubulitis	Fibrosis of interstitium, concentric arteriosclerosis
Liver	Portal triad lymphocytosis, inflammation of bile ducts and subendothelium	>50% bile duct loss, foamy cell obstruction of blood vessels
Heart	Lymphocytosis, myocyte necrosis	Concentric arteriosclerosis
Lung	Lymphocytes and plasma cells around blood vessels	Fibrosis narrowing airways, concentric arteriosclerosis

TABLE 84.3. Pathology of Acute and Chronic Rejection

Antibodies do not play an important role in the first episode of acute rejection. Subsequent severe episodes of acute rejection, however, frequently include an antibody-mediated immune response that induces endovasculitis with binding of lymphoid cells on swollen, ischemic endothelial cells (74). For the development of these antibodies, the $CD4^+$ T-cell response must develop first. Acute cellular rejection may therefore have both cellular and humoral components.

Chronic rejection usually appears after 60 to 90 days posttransplantation and induces the typical obliterative disease (3,4). Clinically, patients have a slow but progressive course of allograft deterioration over a period of several months to years. This condition is not responsive to available immunosuppressive strategies. Risk factors for kidney allograft rejection include several acute rejection episodes within the first 90 days posttransplantation and the presence of medium to high levels of anti-HLA antibodies (3,4). Despite the common characteristic of fibrosis, the pathology of chronic rejection differs slightly between the different organ allografts. In the kidney and heart, pathologists note increasing arteriosclerosis in glomeruli and coronary arteries, respectively. In the lung, the fibrosis centers on the airways (4), which suggests an important role of the lung epithelium as an immunologic target during the chronic rejection of the lung allograft.

The etiology and pathogenesis of acute rejection are well understood, but chronic rejection is still being elucidated. Several hypotheses have been proposed. The fibrosis in chronic rejection may be due to healing after acute rejection. After all, a strong predictor of chronic rejection is a prior episode of acute rejection; however, chronic rejection can occur in the absence of acute rejection. Other theories include ischemic injury and a chronic DTH (5). In lung transplantation, the development of antidonor HLA antibodies precedes the onset of chronic lung allograft rejection (75). Furthermore, such antibodies have the ability to activate the proliferation of both vascular endothelial cells and lung epithelial cells (70,76). Presumably, such antidonor HLA antibodies may induce the diffuse arteriosclerosis noted in chronically rejected glomeruli and coronary arteries. The mechanism of antibody induction of graft fibrosis remains unclear, however.

Recent studies of chronic rejection championed the importance of indirect alloantigen recognition by $CD4^+$ T cells. In heart, lung, and kidney transplantation, several groups noted recipient $CD4^+$ T cells indirectly recognizing mismatched donor MHC peptides presented by recipient APCs (45,46 and 47). Perhaps cytokine secretion leads to the characteristic graft fibrosis seen on histology. This points to a primary role of $CD4^+$ T cells in this process.

CLINICAL SIGNS OF ALLOGRAFT REJECTION

Kidney Allograft Rejection

Kidney allografts do better than any other solid organ allografts. As indicated in Table 84.1, 1- and 5-year rejection rates for cadaveric allografts are 10.6% and 35.3%, respectively (1). Once procured, the kidney allograft is flushed with University of Wisconsin solution and can be preserved up to 48 hours (3,4). This allows time for HLA matching. As indicated in Table 84.2, a six-HLA antigen match has a 1-year rejection rate of 28.4% compared with 40.7% in completely unmatched grafts (1). Interestingly, a completely unmatched graft from a living unrelated donor does as well as a six-HLA antigen match from a cadaveric donor (1,2).

On the operating table, within minutes of transplantation, hyperacute rejection can occur (3). Preexisting antibodies, typically against ABO blood group incompatibilities, react with donor endothelium and initiate thrombosis and ischemia (9,10,77). Without blood flow, the graft does not become pink, and no urine follows. Grossly, kidney becomes soft, cyanotic, and edematous (30). On pathology, one can detect peritubular infiltrates of polymorphonuclear leukocytes, thrombosis of arteries and glomerular capillaries, and necrosis in the cortex and tubules. Immunoglobulin and complement can be localized to the glomerular capillaries (74,78). Such immunohistochemistry suggest that this phenomenon is mediated by the aforementioned preexisting antibodies. Because of ABO matching and crossmatch test, such rejection is rare (74).

After transplantation, the recipients are closely monitored. Within days to weeks, complaints of fever, pain over the graft, and decreased urine output suggest acute rejection. Transplant physicians may look for fever and graft tenderness; however, physical findings may be subtle (3,4). Of note, similar findings 90 days after transplantation may suggest chronic rejection. Workup includes a serum creatinine measurement. An elevated serum creatinine level documents impaired glomerular infiltration. A nuclear medicine study documents impaired vascular flow to the kidney. The definitive study is a percutaneous biopsy (3,4).

Within days to months after transplantation, acute rejection can occur. Grossly, the kidney may be swollen and edematous (74). There may be focal cortical and medullary hemorrhages. On pathology, interstitial edema with cellular infiltrates of small and large lymphocytes, plasma cells, macrophages, and monocytes may be seen (74). Such cellular infiltrates may be either diffuse throughout the cortex or focal within the periglomerular, peritubular, and perivascular spaces (79). With increasing severity, parenchymal necrosis and interstitial hemorrhage may be seen (Fig. 84.2A). On the other hand, acute rejection may show primarily vascular components. The arteries and arterioles may show subendothelial mononuclear infiltrates or arteritis (74,80). With increasing severity, one may even see fibrinoid thrombus and necrosis. Of note, a severe vascular rejection responds poorly to immunosuppression (30).

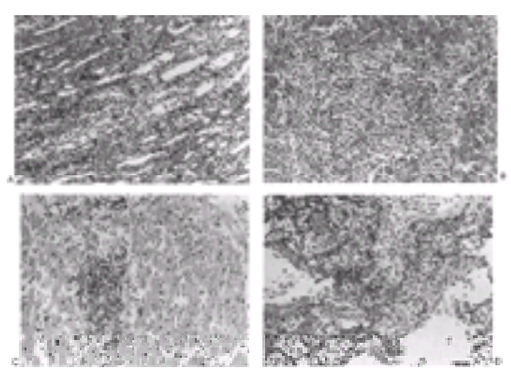

Figure 84.2. Histopathology of acute allograft rejection. A: Kidney: interstitial lymphocytic infiltrate with tubulitis. B: Liver: lymphocytic infiltrate and obliteration of structures in the portal triad. C: Heart: myocytic degeneration with interstitial lymphocytic infiltrate and edema. D: Lung: perivascular lymphocytic infiltrate. (From Kahan BD, Clark JH. Transplantation of solid organs. In: Frank MM, Austen KF, Claman HN, et al., eds. *Samter's immunologic diseases*, 5th ed. New York: Little, Brown and Company, 1995:1502, with permission.)

Sixty to 90 days after transplantation, patients may show subtle signs of chronic rejection. They may have a gradually worsening renal function, with increasing blood pressure, proteinuria, and serum creatinine. Gross pathology can show either normal size or shrunken kidneys, and the cortex may be pale (74). On histology, one primarily notes changes in the arterial circulation. Concentric, subintimal proliferation of myofibroblasts occurs in both small and large arteries. Such proliferation narrows and even occludes the arteries (78). Other common findings include atrophy of tubules, thickening of the basement membranes of tubules, fibrosis in the interstitium, and collapse of the glomeruli. These changes may be attributable to an ischemic injury (30,78,74). Fibrosis, rather than cellular infiltrates, dominates the picture of chronic rejection(Fig. 84.3A).

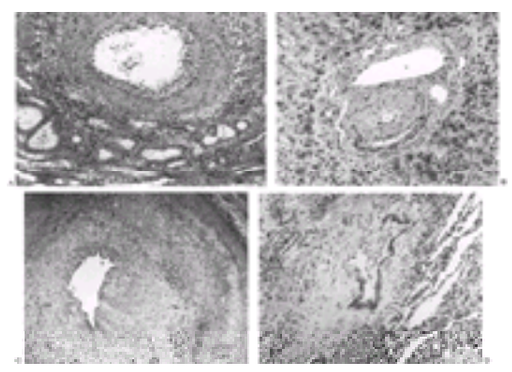

Figure 84.3. Histopathology of chronic allograft rejection. A: Kidney: luminal narrowing resulting from intimal proliferation and foamy macrophages. B: Liver: bile duct degeneration and portal triad fibrosis. C: Heart: coronary artery atherosclerosis with intimal proliferation and concentric narrowing. D: Lung: fibrosis and eccentric scarring of the bronchiole. (From Kahan BD, Clark JH. Transplantation of solid organs. In: Frank MM, Austen KF, Claman HN, et al., eds. *Samter's immunologic*

diseases, 5th ed. New York: Little, Brown and Company, 1995:1503, with permission.)

Liver Allograft Rejection

The liver is unique among the solid organs. Despite ABO blood group incompatibilities, the liver can be successfully transplanted, at least in the short term (3,4). Furthermore, for all liver transplants, the 5-year graft failure rate compares favorably with kidney allografts, the most successful transplants available (1). Why are livers so well tolerated? Some point to the many phagocytic Kupffer cells and donor leukocytes within the allograft. They suggest that chimerism, a “mixing” of donor and recipient leukocytes, can lead to tolerance. Still, many other hypotheses exist, such as the shedding of donor HLA antigen, regeneration potential, and others (4,51).

The liver is special for two other reasons. First, living-related donation may be less of an ethical challenge. After all, one only needs 25% of one's liver to live. Furthermore, the remaining liver can regenerate to the original size. Second, because the liver has two lobes, cadaveric livers have been successfully “split” between two recipients (3,4).

Currently, as a result of ABO blood group matching, hyperacute rejection in liver transplants is rare but has been documented. Some liver allografts fail within hours to days, despite no evidence of antibody induced thrombosis. Such failure, probably not immune mediated, has been termed *primary nonfunction.* Although no single risk factor has been proven in clinical studies, investigators have proposed donor hypotension, donor hepatic steatosis, and preservation injury (4).

Within days to weeks of transplantation, acute rejection can occur. Patients complain of fever, increased ascites, and pain over the graft. On further evaluation, physicians may notice both graft tenderness and a decreased amount of bile output. Initial laboratory tests may note elevated transaminases, bilirubin, and white count (3). As in kidney allografts, biopsy is the gold standard. The pathologist focuses on the portal triads and central veins. Three findings are particularly important. First, there may be a moderate to severe cellular infiltrate of lymphocytes and eosinophils, particularly in the portal triads. Still, a few plasma cells and eosinophils may be found. Second, the inflammatory cells also fill the bile ducts, often with damage to the biliary epithelium. Finally, the portal and central veins show cellular infiltrates beneath the subendothelium (4,81). The presence of all three findings differentiates acute rejection from other processes (Fig. 84.2B). For example, the biliary damage looks similar in primary biliary cirrhosis and chronic GVHD (82).

Sixty days after transplantation, chronic rejection may occur. Overall, one sees signs of portal triad atrophy and fibrosis. Diagnosis of chronic rejection require examination of at least 20 portal triads. Typically, more than 50% of the bile ducts are lost. Some have called this the *vanishing bile duct syndrome* (4). In addition, beneath the intima, foam cells (cholesterol-filled macrophages) and fibroblasts may proliferate and occlude the medium-sized arteries, perhaps adding an ischemic component to the vascular injury (81) (Fig. 84.3B).

Heart Allograft Rejection

Patients with congenital abnormalities, ischemic cardiomyopathy, and other causes of severe heart failure are candidates for heart transplants. As in other transplants, there are far more potential recipients than donors. While waiting, patients can be palliated with mechanical devices, including left ventricular assist devices and the Jarvik totally artificial heart. Patients are so sick and the hearts are so difficult to preserve that HLA matching does not play a significant role; however, the cross match test is performed to rule out prior sensitization to donor HLA antigens (3,4).

After transplantation, signs of heart failure, i.e. worsening shortness of breath, may prompt an evaluation. On lung exam, there may be diffuse crackles. The patient may also have significant jugular venous distension (3). Most rejections, however, can be detected before symptoms develop.

Patients undergo an aggressive surveillance biopsy regimen. Under fluoroscopic guidance, a catheter is threaded through the internal jugular vein into the right ventricle, and a biopsy is obtained from the right ventricular wall. If left ventricular failure is suspected, the femoral artery can be accessed so that a left ventricular biopsy can be obtained (3).

The International Society of Heart and Lung Transplantation standardized a scale for grading (0–4) acute rejection in endocardial biopsies. Grade 0 consists of normal myocardium. Mild inflammation may show a focal lymphocytic infiltrate around blood vessels or in the interstitium, without any evidence of necrosis. With increasing severity, the lymphocytic infiltrate becomes more diffuse with increasing myocyte injury and necrosis. The most severe acute rejection, grade 4, shows a more polymorphous infiltrate, with edema, hemorrhage, vasculitis, and myocyte necrosis (83,84) (Fig. 84.2C).

Chronic rejection presents as accelerated atherosclerosis in the intramuscular coronary arteries. Such rejection is the leading cause of death and graft loss after 1 year (4). Because the donor heart is denervated, the patient does not complain of chest pain. Thus, such patients routinely undergo annual cardiac catheterizations. Unfortunately, this modality is insensitive. Thus, these patients are also monitored by endocardial biopsy (4). On pathology, the subendocardial coronary arteries exhibit concentric subintimal proliferation of myofibroblasts and lipid-filled macrophages, medial sclerosis, interruption of the internal elastic lamina, and thickening of the intimal ground substance. As a result, the subendocardial and intramuscular arteries are severely narrowed (84) (Fig. 84.3C). Epicardial coronary arteries may also be involved. Unlike in nontransplanted patients with coronary artery disease, the transplanted, chronically rejected epicardial arteries are rarely calcified and contain more cells. Given the diffuse nature of the disease, the concentric lesions, and the high incidence in all age groups, such atherosclerosis is probably immune-mediated. Unfortunately, retransplantation is the only option for such patients (4).

Lung Allograft Rejection

In children with cystic fibrosis or pulmonary hypertension, bilateral lung transplantation is a viable option, particularly from living donors. In adults, emphysema is the most common indication. With a 1-year graft failure rate of 23.7%, lung transplantation provides good short-term palliation. With a 5-year graft failure rate of 58%, lung transplantation as a long-term solution suffers from chronic rejection (1).

During acute rejection, recipients may complain of fever, cough, increasing shortness of breath, and decreasing exercise tolerance. Usually, the complaints may be nonspecific. The transplant physician may begin with two noninvasive tests: chest radiograph and pulmonary function tests, both of which are nonspecific. The best test is bronchoscopy because the pulmonologist or surgeon can view the anastomosis and bronchial epithelium directly. Furthermore, transbronchial biopsy or bronchoalveolar lavage can then be done (3,4). As for heart transplantation, pathologic grading has been standardized by the International Society of Heart and Lung Transplantation (83).

Like the other solid organ allografts, ABO blood group matching has made hyperacute rejection a rare entity. Some groups propose that prior pregnancies, blood transfusion, or transplants induce the antibodies against donor MHC molecules. Thus, within minutes to hours of transplantation, the graft may fail. The patient's new lungs become less compliant, and hypoxemia results. On pathology, diffuse thrombosis, inflammation, and necrosis can be seen in the microcirculation (4). To prevent such rejection, most of the lung transplant centers perform assays to detect prior sensitization to HLA antigens. If such sensitization is found, a prospective cross match is performed to select the donors.

Between 4 days to 3 weeks, acute rejection can occur. As mentioned, patients complain of fever, shortness of breath, and decreasing exercise tolerance (3,4). Pathology either from bronchoscopy with biopsy or even from open biopsy is the gold standard for diagnosis. On pathology, one sees many lymphocytes, plasma cells, eosinophils, and neutrophils in the walls of the veins, venules, arterioles, and even medium-sized arteries. There may even be inflammation of the endothelium. Similar changes are seen in the airways, from the bronchi to the respiratory bronchioles. With increasing severity, greater infiltrates, a higher number of involved blood vessels or airways, and even necrosis may be seen. Phagocytic cells, fibrinous exudates, and blood may spill over into the alveoli (4) (Fig. 84.2D). The International Society of Heart and Lung Transplantation standardized a scale (A0–A4) to grade such rejection. Grade A0 shows no such changes. Grades A1 through A4 show minimal, mild, moderate, and severe inflammation, respectively (83).

Chronic rejection deserves special mention. This poorly understood process, bronchiolitis obliterans, involves increasing fibrosis in the airways. With increasing fibrosis, the airways narrow, and the patient has difficulty exhaling. This problem can be documented objectively by the pulmonary function test, the forced expiratory volume in 1 second (FEV_1). With worsening airway obstruction, the FEV_1 diminishes (3). This diagnosis can be verified with biopsy. Because the lesions may be scattered, bronchoscopy with transbronchial biopsy might miss the lesions. On pathology, in early stages, the bronchiolar epithelium and walls become infiltrated with lymphocytes, plasma cells, and histiocytes, followed by concentric, submucosal edema and proliferation of capillaries and fibroblasts. Over time, the infiltrates resolve, and the remaining fibrosis concentrically constricts the bronchiole, resulting in the clinical airway obstruction (Fig. 84.3D). Because of the inability to clear secretions, a pneumonia may result and exacerbate the clinical picture. Similar changes occur within the pulmonary vasculature. The concentric subintimal proliferation of fibroblasts in large elastic and small muscular inflammation results in accelerated pulmonary atherosclerosis. The arteriosclerotic plaques may show foamy histiocytes, cholesterol clefts, and myofibroblasts. Unfortunately, once diagnosed, either by clinical symptoms or by pathology, bronchiolitis obliterans is an irreversible, progressive disease

that responds poorly to aggressive immunosuppression (4). Thus, early prognostic indicators would be helpful.

Although incompletely understood, details of the pathogenesis are emerging. In adult lung transplant recipients, antibodies to mismatched donor HLA molecules precede the onset of bronchiolitis obliterans by about 20 months (75). It has been shown that antidonor HLA antibodies can induce calcium influx and new tyrosine phosphorylation on binding to lung epithelial cells (70,76). Such changes activate the epithelial cells and lead to cytokine secretion. Such cytokines could activate underlying smooth muscle cells and fibroblasts to create the characteristic fibrosis of chronic rejection. A significantly increased precursor frequency of T cells reactive to peptides derived from mismatched donor class I HLA and presented on recipient MHC also has been seen in lung transplant recipients with bronchiolitis obliterans syndrome (BOS) (46). This suggests a role for $CD4^+$ T cells and indirect antigen presentation of donor HLA peptides in the pathogenesis of BOS. Further studies to elucidate the pathogenesis of bronchiolitis obliterans may improve the treatment and prognosis of lung transplants.

IMMUNOSUPPRESSIVE TREATMENT OF ALLOGRAFT REJECTION

As evident from the preceding discussion, many modalities are now available to prevent rejection. By matching ABO blood type and avoiding a positive cross match, recipients are unlikely to have preexisting antibodies that will induce hyperacute rejection. To prevent acute rejection, patients are immunosuppressed. They may be induced, before transplantation, with anti-T-cell antibodies. Afterward, they receive azathioprine/mycophenolate mofetil, cyclosporine/FK506, and corticosteroids. New drugs are continually being developed. For example, sirolimus (85) and intravenous immunoglobulin (86) are showing promise. Details of the mechanism of action for various immunosuppressive drugs, either currently available or being developed, are discussed in Section X: Therapeutic Immunology.

If a patient has acute rejection, he or she is admitted for high-dose steroids and antithymocyte antibodies such as OKT3. For kidney patients, supportive therapy such as dialysis may be needed. Then the patient's maintenance immunosuppression may be changed from cyclosporine and azathioprine to FK506 and mycophenolate mofetil (3).

Chronic rejection is much more difficult to treat. Current immunosuppressive therapy has little effect. Some recipients have lost so much graft function that they may need to be undergo transplantation again.

FUTURE DIRECTIONS

Giving blood transfusions before transplantation decreases the incidence of rejection (3). A natural extension of blood transfusion, that is, bone marrow transplantation, also induces tolerance to donor stem alloantigens. This observation led to studies in which donor bone marrow is administrated before solid organ transplantation to make the recipient tolerant to subsequent allografts (87). Results from these studies are too preliminary at present to advocate this as a general approach to induce organ-specific tolerance.

In oral tolerance models, several studies observed that the oral administration of a given antigen induces a specific Th2 immune response to that antigen. Therefore, when rechallenged with the same antigen given intraperitoneally, orally treated animals do not develop a proinflammatory immune response to the antigens (88). It is likely that these studies may provide a means to induce specific tolerance to an alloantigen. Currently, however, how to use such modalities to induce organ-specific tolerance is not clear.

It is generally accepted that T cells need two signals to become activated. T cells must see antigen (signal 1) and a costimulatory molecule (signal 2). Various studies documented the importance of B7.1, B7.2, and CD40 in eliciting allograft immunity (89,90). Based on these studies, several groups developed methods to block such costimulation resulting in graft-specific unresponsiveness. For example, recent studies with monoclonal antibody specific for CD40 ligand resulted in prolonged allograft survival of kidney (91) and pancreatic islet allografts (92). It needs to be seen whether prolonged acceptance of the graft with this immunosuppressive reagent can cause specific allograft tolerance.

As progress in our understanding of the basic cellular and molecular mechanisms of allograft rejection is made, there is new hope for the development of better immunosuppressive treatment protocols and, eventually, the attainment of organ-specific tolerance. Several techniques for the generation of allospecific immune tolerance in experimental models already have been successful. It is still not possible, however, to accomplish routine clinical organ transplantation without the use of nonspecific immunosuppression. The ultimate goal of transplantation research is to induce organ-specific tolerance to obviate the iatrogenic diseases caused by allograft rejection and the adverse secondary effects of immunosuppressive agents.

85 IMMUNOLOGY OF XENOTRANSPLANTATION

Jeffrey L. Platt, M.D.

The transplantation of organs, tissues, or cells between individuals of different species is referred to as *xenotransplantation*. In recent years, xenotransplantation has been of increasing interest because the use of animals as organ and tissue donors as a source of transplants could overcome the severe and worsening shortage of human organs available for transplantation. This shortage restricts the application of organ transplantation to 5% to 15% of the patients who might benefit in the United States (1), and it is now widely acknowledged to be the major limitation of transplantation. Another reason for interest in xenotransplantation is that the use of animal organs or tissues in lieu of human organs or tissues might, in some cases, avoid the susceptibility to viral infection. Avoiding viral infection was the rationale for several baboon-to-human liver transplants (2) and for the transplantation of baboon bone marrow in a human patient with acquired immunodeficiency syndrome (AIDS). Another reason for interest in xenotransplantation is that, through genetic engineering of the xenotransplant source, the xenograft might provide a vehicle for the delivery of a gene or a diverse set of genes, the expression of which might be difficult to gain enduringly through other means (3). For example, transgenic techniques might be used to express antiviral genes in stem cells.

TISSUE SOURCE AND DONOR FACTORS

The type of organ or tissue transplanted and the phylogenetic distance between the donor and the recipient has profound importance for the immune response to xenotransplantation (Fig. 85.1). The type of organ or tissue grafted determines the nature of the blood supply and, thus, the nature of the contact between the transplant and the immune system of the host (Fig. 85.2), and it determines the relative contribution of donor and host “growth” factors to the survival and function of the graft. The phylogenetic distance determines biologic and immunologic compatibility.

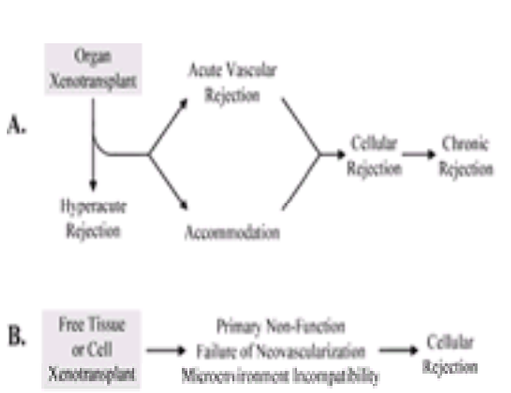

Figure 85.1. The immunologic response to xenotransplantation. The immune response to xenotransplantation can be classified according to whether the graft consists of isolated cells or free tissues, such as islets of Langerhans or of a primarily vascularized organ, such as the kidney or heart. A: Vascularized organ grafts are subject to hyperacute and acute vascular rejection caused by the action of antidonor antibodies on donor endothelium. If hyperacute or acute vascular rejection are averted, the graft may undergo accommodation, a condition in which the graft appears to resist injury despite the return of antidonor antibodies to the circulation and the presence of an intact complement system. A vascularized organ graft also may be subject to cellular rejection and chronic rejection more or less like the corresponding types of rejection observed in allografts. B: Free-tissue grafts are subject to failure caused by primary nonfunction, failure of neovascularization or failure of the microenvironment to support the survival, and function of the foreign tissue. If the free tissue or isolated cells engraft, they are then subject to cellular or humoral rejection. (Reprinted and adapted from *Nature* 1998;392 (Suppl):11–17, Hamilton Magazines, Ltd. with permission.)

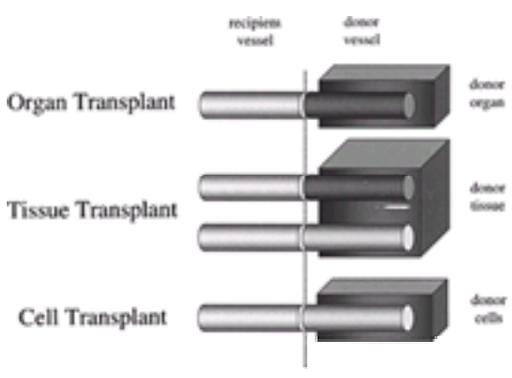

Figure 85.2. Antigen presentation in a free tissue graft: implications for the immunogenicity of xenografts. Free-tissue xenografts are generally vascularized by spontaneous anastomosis of donor and recipient blood vessels and by neovascularization. Spontaneous anastomosis (organ and tissue transplant) allows the presentation of foreign antigen by foreign major histocompatibility complex (MHC) as modeled in the upper left of Figure 85.3. Neovascularization (tissue and cell transplant) results in presentation of foreign antigen by recipient MHC as in the upper right of Figure 85.3. If neovascularization or spontaneous anastomosis were to be impaired, the mechanism of antigen presentation might differ from the mechanism that would predominate in a free tissue allograft.

Xenografts consisting of isolated cells, such as hepatocytes, derive their vascular supply entirely by the ingrowth of blood vessels of the recipient (4) (Table 85.1). Free tissue grafts, such as pancreatic islets or skin, derive their vascular supply in part from the host and in part from the spontaneous anastomosis of donor and recipient blood vessels. The blood vessels of the recipient in cell and tissue grafts pose a barrier between the graft and the immune system of the recipient. This barrier may be sufficient to allow survival of xenografts with no more immunosuppression than allografts (5). In principle, blood vessels of recipient origin might take up and present antigen of the donor. Antigen presented in this way to T-lymphocytes is said to be presented through the “indirect” pathway (6) (Fig. 85.3). The type of rejection typically

seen in cell and tissue xenografts is cellular rejection.

TABLE 85.1. Classification of Xenografts

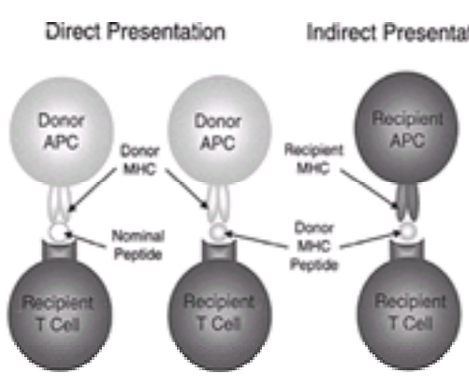

Figure 85.3. Antigen presentation in xenotransplantation. Antigen may be presented by the direct or indirect pathways. When direct antigen presentation occurs, the T cells of the recipient recognize undenatured MHC antigen of the donor expressed by donor antigen-presenting cells (APCs) or other donor cells. The peptide associated with MHC is of donor origin and either dictates specificity or may be nominal with regard to specificity of recognition. For indirect antigen presentation, the T cells of the recipient recognizes donor peptide expressed in association with MHC of the recipient.

In contrast to cellular xenografts, organ xenografts provide their own blood vessels. The interaction of the immune system of the recipient with donor blood vessels gives rise to distinct types of vascular or humoral rejection (Fig. 85.1). Organ xenografts are also subject to cellular rejection. The donor blood vessels of organ xenografts may present antigen to T-lymphocytes through the “direct” pathway (Fig. 85.3). The nature of the blood supply and the microenvironment also determine the biologic viability of the graft (Table 85.1). Cell and tissue grafts may depend on growth factors of recipient origin. If these growth factors are not compatible with the xenogeneic cells, the graft may fail. An important example of such incompatibility is found in the transplantation of xenogeneic bone marrow (7). In contrast, organ xenografts generally provide the factors needed for survival of the xenogeneic cells in the graft.

Genetic differences between the donor and the recipient are another important factor in xenotransplantation (Table 85.2). Phylogenetic distance between the donor and the recipient, of course, determines the number of antigens that might serve as a target of the immune response; however, certain genetically controlled traits have a disproportionate impact on the outcome of a xenograft. For example, the expression of a functional a1,3-galactosyltransferase gene in lower mammals leads to the synthesis of Gala1-3Gal as the terminus of some oligosaccharide chains. This saccharide is recognized by naturally occurring antibodies made by all immunocompetent humans and animals that do not express that sugar (8). This antigen–antibody system constitutes a severe immunologic barrier to xenotransplantation; yet the distribution of that glycosyltransferase in phylogeny is not a function of genetic distance (Table 85.3). Another trait that is presumably under genetic control involves the expression of cell surface molecules that promote activation of the alternative complement pathway of other species, independent of anti-body binding (Table 85.4). For example, the cells of the guinea pig allow unrestrained activation of the rat alternative pathway of complement, and, as a result, organs of guinea pigs transplanted into rats are subject to rapid and vigorous rejection (9,10). Fortunately, the alternative pathway of the human complement system is not activated primarily on porcine cell surfaces (11,12 and 13), and, thus, pigs may serve as a useful source of cells and organs for xenotransplantation into humans. Other genetic differences that may contribute to the outcome of xenografts include the species-specific functioning of cell-associated complement regulatory proteins, such as decay accelerating factor (DAF), CD59 (14), and the potential species-specific functioning of the thrombomodulin vis-a-vis thrombin and protein C (15).

TABLE 85.4. Activation of Complement on Xenogeneic Cells Via the Alternative Pathway[a]

SELECTION OF A DONOR SPECIES

Immunologic and genetic factors such as those previously described would argue for the selection of species for xenograft sources that are genetically similar to xenograft recipients. For humans, such donors might include the chimpanzee and the baboon. For several reasons, however, pigs rather than nonhuman primates are currently viewed as the most promising sources of xenografts. First, pigs are available in large numbers and in appropriate sizes; in contrast, nonhuman primates are relatively scarce and generally are much smaller than adult human men. Second, the use of pigs does not raise such severe concerns regarding zoonosis as the use of a species more closely related to humans. Third, there is the possibility of genetically engineering pigs using technologies that, for practical reasons, could not be applied to nonhuman primates.

One major hurdle to using the pig as a source of organs for clinical transplantation is that the organs of the pig are subject to severe and irreversible rejection reactions that occur when porcine organs are transplanted into primates (16). Until recently, these rejection reactions seemed to pose an insurmountable hurdle to clinical application of xenotransplantation. Studies during the past few years, however, revealed much about the molecular basis of xenotransplant rejection, particularly humoral rejection, and thus have encouraged the view that these reactions might be addressed by novel and specific therapies.

This chapter summarizes some of the recent progress regarding the humoral immune reactions that pose a hurdle to transplanting porcine organs into humans. The reader is referred to recent reviews for more detailed consideration of this subject (16,17,18 and 19).

BIOLOGIC RESPONSES TO XENOTRANSPLANTATION

Figure 85.1 shows a model for the biological responses to xenotransplantation. These responses, which manifest predominantly as rejection reactions, are also seen in allotransplants, albeit with less severity and frequency. The sections that follow summarize the manifestations of rejection of organ xenografts and the immune mechanisms that underlie these manifestations. A later section of the chapter is devoted to cell and tissue xenografts that are susceptible mainly to cellular rejection.

Whole-organ xenografts are subject to various types of rejection (Fig. 85.1). For the most part, these types of rejection are manifested as vascular disease arising in response to the interaction of the immune system of the recipient with donor blood vessels. Figuring predominantly in these types of rejection is intravascular coagulation caused by the conversion of blood vessels from anticoagulant to procoagulant and ischemia caused by the constriction or occlusion of blood vessels in the graft.

Free-tissue xenografts are not subject to hyperacute rejection but generally undergo rejection over a period of days, a tempo often more rapid than that observed for free tissue allografts. Rejecting free tissue xenografts may be infiltrated by host T cells and macrophages (20,21 and 22). Free tissue and cellular xenotransplants also may fail because of “primary nonfunction” (23), which may result from immune or nonimmune factors. The extent to which free-tissue xenografts are subject to humoral rejection following vascularization has not been established; however, studies involving the transfer of immune serum demonstrate that antidonor antibodies can mediate rejection of free-tissue grafts and, thus, suggest that humoral responses could be an important determinant of graft outcome (24,25 and 26).

Recent work in our laboratory and the laboratories of others elucidated much about the molecular mechanisms underlying xenograft rejection. These new insights are the subjects of this review. This review discusses those aspects of cellular and chronic rejection that might differ from the corresponding types of rejection seen in allografts.

HYPERACUTE REJECTION

Organs transplanted between certain species are subject to hyperacute xenograft rejection (27,28) (Table 85.2, Fig. 85.4). Combinations of donor and recipient species in which hyperacute rejection regularly occurs in unmodified recipients are called *discordant*; combinations of donor and recipient species in which hyperacute rejection rarely occurs are called *concordant* (29). In most, but not all, cases, susceptibility to hyperacute rejection and, thus, discordance is found to be a function of phylogenetic distance between donor and recipient (Table 85.2). Hyperacute xenograft rejection is characterized histologically by interstitial hemorrhage, edema, platelet thrombi, and severe injury to endothelial cells (16,30,31,32,33 and 34). In some cases, prominent infiltration of neutrophils is observed. Evidence of injury to graft endothelial cells—the presumed target of the hyperacute rejection reaction—includes swelling, vesiculation, alteration in cellular junctions, detachment, and, in some cases, lysis.

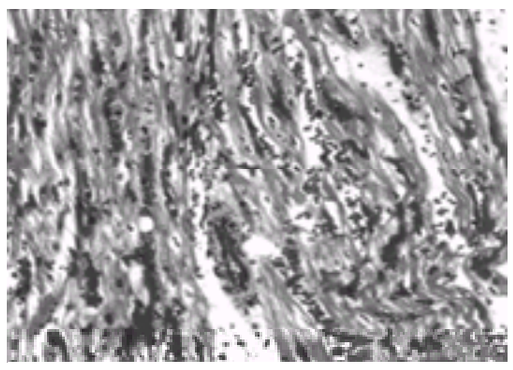

Figure 85.4. The histology of hyperacute rejection. Porcine cardiac tissue 30 minutes after heterotopic transplantation into a baboon. Hyperacute rejection is characterized by interstitial hemorrhage, edema, and thrombosis.

The pathogenesis of hyperacute rejection depends absolutely on the activation of complement, which, as discussed later in the text, may occur as a result of (a) the binding to the graft of complement-fixing xenoreactive antibodies, (b) the direct activation of complement via the alternative complement pathway on the foreign cell surfaces, and/or (c) the failure of complement regulation in the foreign organ (35). Regardless of how complement is activated, most evidence suggests that endothelial cells are the primary target of complement in this type of rejection (12,14). In addition to the structural damage to endothelium, the immunopathology of hyperacute rejection invariably reveals complement components and often immunoglobulin of the recipient along endothelial surfaces of graft blood vessels (10,12,30,32,36,37). The earliest structural change is the aggregation of platelets in small blood vessels (38). Platelet aggregation may be caused by various factors, including the interaction of platelets with matrix exposed by the action of complement on endothelium and the direct effects of complement on platelets (39). Our concept of the pathophysiology of hyperacute rejection is that it involves the loss of barrier and anticoagulant functions of endothelial cells (18). The loss of these functions allows the escape of vascular contents from small blood vessels and the attachment and aggregation of platelets leading to formation of platelet thrombi. The sections that follow discuss the components of the immune system that contribute to the development of hyperacute rejection and the mechanism through which these components might bring about hyperacute rejection.

Xenoreactive Natural Antibodies

Xenoreactive natural antibodies are thought to initiate hyperacute rejection of organs from lower mammals transplanted into humans and nonhuman primates. Xenoreactive natural antibodies are among the naturally occurring antibodies that are synthesized without a known history of sensitization (40,41). Some natural antibodies are “polyreactive” because they bind to multiple target antigens; other natural antibodies recognize blood groups (40,42,43) and bind to the surface of xenogeneic cells (44). Xenoreactive antibodies appear to be related to some anti–blood group antibodies, appear to be distinct from polyreactive antibodies (8,45), and have been implicated in the pathogenesis of xenograft rejection, particularly hyperacute xenograft rejection (27,46).

The concept that natural antibodies initiate xenograft rejection has dominated the field of xenotransplantation for 30 years (27,47). Perper and Najarian suggested that a given individual is particularly likely to have cytotoxic natural antibodies specific for the cells of disparate species and these antibodies initiate hyperacute xenograft rejection (27). Several observations point to the importance of natural antibodies in the immunopathogenesis of hyperacute xenograft rejection. First, naturally occurring antibodies directed against donor cells can be found in the serum of all mammalian species combinations (40,41). Second, xenoreactive antibodies are rapidly deposited in xenografted organs (12,28). Third, depletion of xenoreactive antibodies prevents hyperacute rejection of a subsequently engrafted organ (12,27,30). Fourth, hyperacute rejection does not occur in some species combinations in which the newborn lacks circulating xenoreactive antibodies (48). Fifth, hyperacute rejection can be induced by the administration of xenoreactive antibodies to a xenograft recipient (36).

A major advance in the field of xenotransplantation came with determination of the specificity of xenoreactive natural antibodies. Although it might be expected that the repertoire of xenoreactive natural antibodies serum would be broad, human xenoreactive antibodies predominantly recognize one epitope, Gala1-3Gal (49,50,51 and 52). Gala1-3Gal was studied extensively by Galili and colleagues (53,54), who showed that the sugar is expressed on the cells of New World monkeys and lower mammals but not on the cells of humans, apes, or baboons (Table 85.3) (51). Humans, apes, and baboons, which do not express the sugar, have specific natural antibodies for it (55). Most individuals have 5 to 40 µg of immunoglobulin M (IgM) per milliliter of plasma directed against Gala1-3Gal (56). The amount of IgG specific for Gala1-3Gal varies from 0 to 20 µg per milliliter of plasma (45). Parker and colleagues showed that the functional properties and concentration in serum of xenoreactive natural antibodies specific for Gala1-3Gal are similar to those of antibodies against blood group A and B antigens and, on this basis, proposed that the xenoreactive natural antibodies and the anti–blood group A and B antibodies may be members of a common family of natural antibodies (8,45,56).

Evidence that Gala1-3Gal might be important in xenotransplantation was first suggested by Good et al., who found that the binding of antibodies in human serum to porcine cells could be blocked by purified Gala1-3Gal but not by unrelated structures (49). Neethling et al. (52) found that antibodies directed against Gala1-3Gal can be eluted from porcine organs perfused by human plasma. Sandrin et al. demonstrated that transfection of COS cells with the murine a1,3-galactosyltransferase gene, which catalyzes the addition of aGal residues to Galb1-4GlcNAc-R to yield Gala1-3Galb1-4GlcNAc-R, induces binding of human natural antibodies to the transfected cells (50). Collins et al. demonstrated that enzymatic removal of a-galactose residues from porcine cells abrogates binding of xenoreactive antibodies to the treated cells (51). Collins et al. also showed that expression of Gala1-3Gal provides a sufficient basis for the development of hyperacute xenograft rejection when the heart of a New World monkey is transplanted into a baboon, which has antibodies specific for Gala1-3Gal (57). Sachs and Sablinski (58) and Kozlowski et al. (59) showed that depletion of Gala1-3Gal from the blood of baboons prevents the hyperacute rejection of porcine organ xenografts (58,59).

Of natural anti-Gala1-3Gal antibodies, it is IgM rather than IgG that appears to be of greatest significance in initiating the rejection of porcine organs by primate recipients. Although both human natural IgM and IgG anti-Gala1-3Gal bind to porcine cells (44), it is the binding of IgM and not of IgG that predominately initiates complement activation (13,56,60). In fact, xenoreactive natural IgG may consist largely of IgG2, which inhibits complement activation by blocking the binding of IgM (61). Consistent with this concept is the observation that administration of human IgG to a xenograft recipient does not promote the rejection of a xenograft; in fact, by diverting reactive complement proteins away from the graft endothelium, it may prevent hyperacute rejection (62). Kearns-Jonker et al. showed that antibodies may be restricted to the IGHV 3-11 and IGHV 3-74 germline progenitors in humans exposed to bioartificial livers containing porcine hepatocytes (63).

Although the epitope recognized by xenoreactive antibodies is a simple sugar, the conditions that allow these antibodies to bind to that epitope are complex. Parker et al. (56), Platt and Holzknecht (64), Cotterell and colleagues (65) showed that expression of the Gala1-3Gal epitope by itself may not be sufficient to result in significant binding of complement fixing xenoreactive antibodies. Rather, natural antibodies seem to bind preferentially to certain glycoproteins bearing that epitope. This finding emerged from analysis of the mechanisms determining the avidity of natural IgM antibodies for the Gala1-3Gal on cell surfaces (56,64). One important factor in antibody binding appears to be the clustering of epitopes, which allows multivalent interactions between antibody molecules and the cell surface. Multivalent interactions are necessary because the dissociation constant (K_d) for monomeric interactions is as low as 10^{-4} *M*, whereas the effective avidity for intact IgM is characterized by a K_d of approximately 10^{-10} *M*. The optimal clustering of epitopes is not random, however, because the binding of xenoreactive antibodies to purified proteins containing similar numbers of Gala1-3Gal substitutions varies by more than approximately 1,000-fold (64).

Further evidence that the manner in which Gala1-3Gal is expressed rather than the total number of epitopes dictates the extent of antibody binding emerged from studies on variations in antigen expression by the population of potential donors (66). Analysis of the level of binding of xenoreactive antibodies to cells from populations of pigs suggests that there is a range of antigen expression of up to tenfold (66,67). The variation appears to have a genetic basis, although it is not a simple Mendelian trait. The implications of this observation were tested by Cotterell et al. (65), who found that porcine organs with low levels of antigen expression absorb significantly fewer xenoreactive natural antibodies during perfusion with baboon blood than organs with a high level of antigen expression. Cotterell et al. also found that although binding of human IgM to porcine cells varies over a range of nearly tenfold, that range is independent of the total expression of Gala1-3Gal (65), suggesting that the way in which sugar is expressed, rather than its absolute level of expression, determines antibody binding.

The core structures bearing the Gala1-3Gal modifications recognized by xenoreactive natural antibodies include proteins of the integrin family and von Willebrand factor (64,68). The attachment of antibodies to endothelial cell integrins could disrupt endothelial integrity by hindering the ability of the integrins to contribute to cell–cell interactions (69). Antibody binding to endothelial cell integrins also may deliver signals to the cells (70,71), potentially contributing to endothelial cell activation, which, as discussed in a later section of this chapter, is thought to be important in acute vascular xenograft rejection. The binding of antibodies to endothelial cell–associated von Willebrand factor potentially might alter the interactions between endothelial cells and platelets (72,73 and 74).

Based on current understanding of the specificity of xenoreactive antibodies, it is possible to devise specific strategies for depletion of xenoreactive antibodies from the circulation of xenograft recipients. Affinity columns have been used previously for depleting isohemagglutinins, allowing transplantation of organs across ABO barriers (75), and it is reasonable to think this approach also could be used for depleting xenoreactive antibodies. One hope is that temporary depletion of xenoreactive antibodies would allow the development of accommodation for xenografts as it does for allografts. Another way to prevent graft injury initiated by xenoreactive natural antibodies is to inhibit their binding using soluble ligands. This approach has been used to prevent rejection of ABO-incompatible kidney transplants (76,77). Unfortunately, because the binding of xenoreactive antibodies to cell surfaces is extremely avid, high concentrations of a monomeric inhibitor would be needed. Nevertheless, such approaches are being developed (78,79).

Yet another approach to preventing the interaction of xenoreactive antibodies with a xenograft is to seek out or develop pigs that have low levels of antigen expression. With the identification and cloning of the gene for the glycosyltransferase responsible for the synthesis of Gala1-3Gal (80,81), the possibility of genetically engineering donor animals with decreased expression has been proposed. The recent cloning of pigs by nuclear transfer (82) and the demonstration that these approaches might allow gene targeting (83) raise the possibility that a1,3galactosyltransferase might be “knocked out.” An alternative strategy proposed by Sandrin et al. (84) and by Sharma et al. (85) involves the introduction of another glycosyltransferase, a1,2-fucosyltransferase, which would compete with a1,3-galactosyltransferase for adding the terminal saccharide onto oligosaccharide chains. Transgenic mice and pigs expressing the H transferase have been made and found to have decreased expression of Gala1-3Gal (Fig. 85.5). Yet another strategy might involve the expression of agalactosidase in transgenic animals (86).

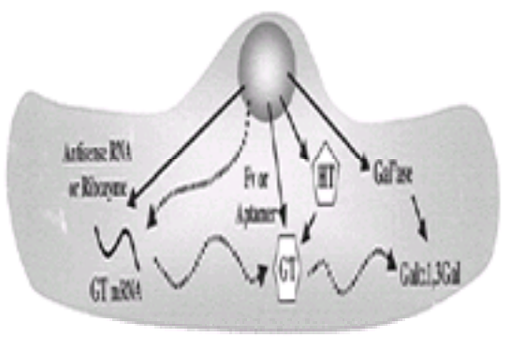

Figure 85.5. Possible ways in which Gala1,3Gal expression could be decreased by genetic engineering. Synthesis of Gala1,3Gal is catalyzed by a1,3-galactosyltransferase (GT), whose biosynthetic pathway is shown by the dashed line. Four approaches to minimizing the synthesis of the Gala1,3Gal epitope are shown here. First, the expression of antisense RNA or a ribozyme might disrupt the structure or function of the GT mRNA. Second, the introduction of a gene whose

product, such as an appropriate Fv (an antibody-like molecule), inhibits GT function. Third, overexpression of another glycosyl transferase, such as H transferase (HT), which adds terminal fucose residues, might compete for the subterminal residues that GT recognizes. Fourth, expression of a glycosidase, such as a-galactosidase, might lead to the cleavage of antigenic saccharide chains. (Reprinted and adapted from *Nature* 1998;392 (Suppl):11–17, Macmillan Magazines, Ltd. with permission.)

As another approach to obtaining donors with low levels of antigen, there is the possibility of exploiting the natural variation in antigen expression, as previously mentioned. Geller et al. (66) and Cotterell et al. (65) found that expression of lower levels of antigen by some pigs has a genetic basis. Perfusion of organs from low antigen-expressing animals with the blood of baboons leads to the deposition of little IgM and C4, in contrast to similar experiments in which organs from normal pigs are perfused.

Complement

The activation of complement is an essential step in the development of hyperacute rejection. The importance of complement in xenograft rejection is suggested by three observations. First, upon perfusion of a discordant xenograft with blood of the recipient, serum complement levels decrease precipitously because of consumption of complement in the graft (32,87). Second, complement accumulates rapidly in rejecting xenografts (12). Third, the survival of a discordant xenograft is always prolonged if complement is inhibited (88,89), if the recipient is depleted of complement by agents such as cobra venom factor (90,91), or if the graft is placed in a recipient that is congenitally deficient in complement component C6 (92,93). The role of complement in xenotransplantation was recently reviewed (16,19,94,95).

Given the importance of complement as a mediator of xenograft rejection, a critical question is how the complement system of the recipient becomes activated in the xenograft. One mechanism that may lead to complement activation is activation by the binding of complement-fixing xenoreactive antibodies to the graft. Such a mechanism of graft injury originally was proposed by Gewurz et al., who showed that, following repercussion of a xenogeneic organ graft, both xenoreactive antibodies and complement are depleted from the recipient's serum (87). Perper and Najarian suggested that a relationship exists between the phylogenetic distance between the donor and recipient of a xenograft and the importance of cytotoxic antidonor antibodies (27). Although the importance of xenoreactive antibodies in the activation of complement in xenografts has been questioned (29,96), several lines of evidence support the importance of this mechanism in clinically relevant pig-to-primate xenograft models. First, immunopathologic analysis of rejecting xenografts demonstrates diffuse deposition of the classical complement component C4 colocalized with IgM but only focal deposition of alternative pathway components factors P and B (12). Second, depletion of IgM or C2, but not factor B, from a human serum prevents activation of complement when that serum is applied to porcine endothelial cells (11,13,56,60,64,68), suggesting that complement activation requires antibody binding and an intact classical complement pathway. Third, activation of complement on porcine cells during exposure to a human serum is inhibited by C1 inhibitor (97). Fourth, depletion of xenoreactive antibodies under conditions in which the complement system remains intact prevents hyperacute rejection of pig-to-primate xenograft (12). Fifth, pig hearts transplanted into newborn baboons, which have only low levels of xenoreactive antibodies, do not undergo hyperacute rejection (48).

On the other hand, in some experimental models, hyperacute rejection can occur in the apparent absence of antidonor antibodies (98), suggesting that components of natural immunity other than xenoreactive natural antibodies may mediate immune recognition (Table 85.3). The possibility that complement activation in a xenograft might arise independent of xenoreactive antibodies was envisioned by Calne (29). Such mechanisms might include activation of the alternative pathway or foreign cell surfaces and attachment to cells or proteins other than natural antibodies capable of activating complement. In fact, the alternative complement pathway is activated on xenogeneic cell surfaces in many combinations of donor and recipient transplant models (99). Miyagawa et al. showed that activation of the alternative pathway in a guinea pig-to-rat xenograft model could trigger hyperacute rejection (9). Activation of the alternative complement pathway probably also initiates the rejection of porcine organs transplanted into dogs, a point of historic interest, as much of the early work in xenotransplantation involved analysis of pig-to-dog renal xenografts (27,28). Evidence indicating the alternative complement pathway in these models includes (a) that the recipient of a xenograft that is rejected hyperacutely can be shown to have low or undetectable levels of antidonor antibodies (9,96); (b) that further depletion of those antibodies does not prevent hyperacute rejection (10); and (c) that the alternative, but not classical, pathway activity in the recipient's plasma decreases after the graft is reperfused (100). Hyperacute rejection initiated by activation of the alternative complement pathway is particularly fulminant, perhaps because the formation of C3 convertase complexes proceeds rapidly and diffusely and does not depend on the kinetics of antibody–antigen interaction. The possibility also remains that activation of the alternative complement pathway by xenoreactive antibodies will be found to be important in some experimental models.

Complement Regulation

Xenografts may be especially susceptible to complement-mediated injury because of the regulation of complement activation. Under physiologic conditions, the activation of complement on autologous cells is controlled in part by cell-associated glycoproteins such as DAF (CD55) and membrane cofactor protein (MCP, CD46), which inhibit complement activation at the C3 convertase step, and CD59, which prevents formation of the membrane attack complex (101). These proteins may have a limited ability to control activation of heterologous complement (102), and as a result a xenograft might be especially susceptible to complement-mediated injury (9,14,103). The potential impact of a defect in complement regulation on endothelial cells surfaces is suggested by the work of Matsuo et al., who found that inhibition of decay accelerating factor by blocking antibodies in a rat model causes development of prominent vascular changes (104). It is possible that the species specificity of complement regulatory proteins is conditional on the system in which specificity is tested. For example, Miyagawa et al. found that the function of complement regulation depends on other components of the cell surface of the target cell (105). This point is not uncontroversial because recent studies by Van den Berg and Morgan suggested that CD59, and perhaps other complement regulatory proteins, can function normally between species (106). In any case, work from my laboratory showed that hearts from transgenic pigs expressing even low levels of human DAF and human CD59 transplanted into baboons, in many cases, resisted the development of hyperacute rejection (107,108). This finding suggested that control of complement is an important element of the definition of discordance and, thus, the immune barrier to xenotransplantation (19).

In addition to the control of complement by cell membrane–associated proteins, there is the potential role of immunoglobulin as a regulator of complement. Basta et al. showed that immunoglobulin can serve as an alternative acceptor for C3 and C4 (109), diverting the activated components away from target cell surfaces. Magee et al. recently tested this concept in a xenograft model (89). Administration of gamma globulin, which contains xenoreactive IgG, to primate recipients of porcine cardiac xenografts, prevented the development of hyperacute rejection in most cases. The immunopathology of the xenografts in the treated recipients revealed host immunoglobulins and C1q along endothelial surfaces, but little or no evidence of other complement components was found.

Components of Complement Involved in the Pathogenesis of Hyperacute Rejection

Another important issue is which components of complement actually mediate tissue injury in rejecting xenografts (110). Two lines of evidence suggest that the occurrence of hyperacute rejection depends on the assembly of terminal complement complexes. First, hyperacute xenograft rejection does not occur in recipients inherently deficient of C6 (92,93,111). Second, inhibition of complement using anti-C5 antibodies prevents some features of hyperacute rejection (112). Although terminal complement complexes are necessary for the development of hyperacute rejection, the formation of the membrane attack complex may not be essential. We recently found that organs from transgenic pigs expressing human CD59 significantly resist assembly of the membrane attack complex and some aspects of tissue injury; however, the development of hyperacute rejection is not averted (113). How terminal complement components might cause hyperacute rejection without assembly of the membrane attack complex may be explained by the ability of C5b67 complexes to disrupt the integrity of endothelial monolayers (114), as discussed later. On the other hand, the formation of terminal complexes, including the membrane attack complex, may not be sufficient to cause hyperacute rejection because hyperacute rejection is not seen in many ABO blood group incompatible allografts, even though the membrane attack complex can be shown to be present (115).

If assembly of terminal complexes is absolutely necessary for the development of hyperacute rejection to occur, that does not exclude the likelihood that other active components of complement may influence the well-being and function of an organ during the hours following transplantation. For example, formation of C3bi on graft endothelium provides a ligand for neutrophils bearing complement receptors (116) and other cells that might amplify the impact of ischemia reperfusion. Formation of C5a may contribute to this process by activating phagocytic cells. It also may mediate the release of heparan sulfate from endothelial cells (117), a process that may deprive endothelial cells of a number of physiologic functions (11), as discussed later.

Natural Killer Cells

Some recent studies suggested the possibility that natural killer (NK) cells might accumulate in and specifically damage a vascularized xenograft. One or more of several mechanisms might underlie the recognition of a xenograft by NK cells. First, the accumulation of NK cells in the graft and activation of those cells might be enhanced by xenoreactive antibodies deposited in the graft (118). Second, host NK cells that ordinarily are controlled by receptors specific for major histocompatibility complex (MHC) class I molecules may fail to recognize the disparate MHC class I molecules expressed in a xenograft (119). Although NK cells have not been detected in large numbers in grafts undergoing hyperacute xenograft rejection (10, 91,120), these cells have been seen in acute vascular rejection (121), and it would seem reasonable to think they may play a role in the evolution of this lesion.

Pathogenesis of Hyperacute Rejection

Hyperacute rejection is perhaps best understood as a condition in which the critical functions of endothelial cells are lost (18). It is as though the blood vessels had, in a sense, lost endothelium. The loss of barrier functions allows the rapid formation of interstitial hemorrhage; the interaction between platelets and the extravascular compartment promotes thrombosis. Loss of the protective property of endothelium allows injury by oxidants, complement, and perhaps other inflammatory agents. The sections that follow consider how the activation of complement in a xenogeneic organ graft might lead to the dramatic picture of hyperacute rejection. For more detailed consideration of this subject, the reader is referred to a recent review (122).

Complement-mediated Cytotoxicity

One mechanism that might account for loss of endothelial function would involve complement-mediated lysis of endothelial cells. Lysis or loss of endothelial cells would allow the egress of blood cells and fluid from blood vessels and would expose the underlying matrix that contains components capable of initiating platelet aggregation and thrombosis. Endothelial destruction occasionally is seen in emerging hyperacute rejection lesions, particularly in the more aggressive models such as guinea pig-to-rat. Under optimal conditions, however, endothelial cell death is not a major finding early in the course of hyperacute rejection in pig-to-primate xenografts (12,16,34). Thus, complement-mediated changes probably involve noncytotoxic processes.

Release of Heparan Sulfate

One noncytotoxic event that may contribute to the pathogenesis of hyperacute rejection is the loss of heparan sulfate from endothelium. Heparan sulfate is an acidic polysaccharide that is involved in many of the physiologic functions of blood vessels. Heparan sulfate contributes to the endothelial barrier function, which excludes blood cells and plasma proteins, and enhanced anticoagulation and protection against complement and oxidants (123,124). Thus, changes in the metabolism of heparan sulfate might account for some of the events associated with xenograft rejection (11). Consistent with this possibility, exposure of endothelial cells to human serum was found to cause the release of up to 50% of endothelial cell–associated heparan sulfate within 30 to 60 minutes (11). Release of heparan sulfate from endothelial cells depended on the binding of xenoreactive antibodies to the cells and the generation of C5a (117) and involves activation of endothelial cell–associated proteases (125). Stevens et al. showed that the same process occurs *in vivo*; about 50% of biosynthetically labeled heparan sulfate is lost within 5 minutes of the reperfusion of vascularized xenografts, and manipulations that inhibit loss of heparan sulfate also prolong the survival of xenografts (126). Other inflammatory events may cause the release of heparan sulfate from endothelial cells, perhaps accounting for other inflammatory or immune-mediated changes in blood vessels. For example, Key et al. showed that elastase released from stimulated neutrophils causes the release of endothelial cell heparan sulfate (127), and Magee et al. showed that this process may be amplified in the presence of oxidants (128).

Complement-mediated Changes in Endothelial Cell Shape and the Formation of Intercellular Gaps

Another noncytotoxic mechanism that might bring about the loss of endothelial cell function is a change in endothelial cell shape with corresponding disruption of cell–cell attachments. Saadi et al. showed that activation of complement on endothelial cells causes a dramatic change in endothelial cell shape, leading to the formation of intercellular “gaps” (114). The formation of gaps could be mediated by C5b67 (or C5b6), although the membrane attack complex accelerates the process. The formation of gaps was associated with increased production of second-messenger metabolites. For example, like other changes in the barrier function and morphology of endothelial cells, complement-mediated alteration in cell shape is associated with changes in the level of cAMP (129,130). Adding dibutyryl-cyclic adenosine monophosphate (cAMP), forskolin, an activator of adenylate cyclase, or methylisobutyl xanthine, an inhibitor of cyclic nucleotide phosphodiesterase, to the medium bathing endothelial cells prevents gap formation in response to antibody binding and complement activation. Consistent with the potential importance of this mechanism, the ultrastructure of endothelial cells in xenograft tissues obtained 5 minutes after reperfusion with recipient blood reveals the interposition of platelets between adjacent endothelial cells (Fig. 85.6).

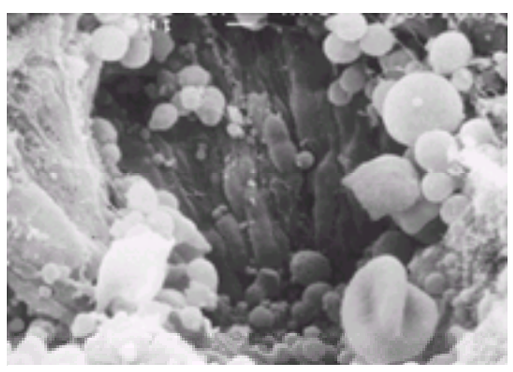

Figure 85.6. Platelet attachment during hyperacute rejection. Electron microscopy reveals platelet attachment to the endothelial lining of a porcine blood vessel undergoing hyperacute rejection after reperfusion with baboon blood.

Other Complement-mediated Changes

Activation of complement on endothelial cell surfaces causes a variety of other changes that may contribute to the manifestations of hyperacute or other types of xenograft rejection. For example, formation of the membrane attack complex on endothelial cell surfaces triggers the secretion of von Willebrand factor (131,132), which might trigger platelet aggregation and the formation and release of cell membrane vesicles, which might promote coagulation. In addition to recruiting platelets, the secretion of von Willebrand factor may contribute to the overall humoral reaction in xenografts because it can serve as a target of complement-fixing human natural antibodies (64). The membrane attack complex also changes the alteration to the surface properties of endothelial cells so as to promote assembly of prothrombinase complexes (133). Stimulation of endothelial cells and platelets also causes expression of P-selectin, which can serve as a ligand for neutrophils and platelets (134,135). These events and perhaps the generation of small amounts of thrombin may account for the observation that platelet aggregation is the earliest morphologic change observed in hyperacute rejection. In addition to causing the formation of thrombi and obstruction to blood flow, the aggregation and activation of platelets may have a direct impact on the functions of endothelial cells (38).

Tissue damage in hyperacute xenograft rejection may be amplified by reperfusion injury. Reperfusion injury is thought to involve local activation complement and to lead to endothelial cell dysfunction through various mechanisms, including the generation of toxic oxygen species, such as superoxide anion and the release of proteolytic enzymes. These mechanisms alter endothelial cell structure and function, potentially rendering the xenograft more susceptible to injury by natural antibody and complement. Consistent with this idea, we demonstrated that oxidant stress increases the susceptibility of porcine endothelial cells to the noncytotoxic effects of human natural antibody and complement (128) and that providing the second messenger, cAMP, which inhibits some manifestations of preservation injury (136), also mitigates some of the effects of natural antibody and complement on endothelium (137). These studies provide preliminary evidence supporting the idea that reperfusion injury, even at a level too low to yield dysfunction of an isograft or allograft, may contribute to tissue injury in a xenograft.

ACUTE VASCULAR REJECTION

If hyperacute rejection is prevented, a discordant xenograft is subject to another type of rejection, which we have called *acute vascular xenograft rejection* (10). Acute vascular rejection is the primary type of rejection seen in concordant xenografts and in some allografts (138,139 and 140). It is characterized pathologically by endothelial injury and swelling, ischemia, and diffuse thrombosis. An infiltrate consisting of mononuclear leukocytes and neutrophils is often observed. Acute vascular rejection is sometimes called *delayed xenograft rejection*; however, the latter term may be misleading because it suggests incorrectly that this type of rejection is a delayed type of hyperacute rejection.

That acute vascular rejection is not, indeed, a delayed form of hyperacute rejection is suggested by several lines of evidence. First, acute vascular rejection typically occurs when the complement system of a xenograft recipient is inhibited, a condition that always prevents the occurrence of hyperacute rejection (10,16). Second, acute vascular rejection occurs in complement-deficient animals, which are unable to mount an hyperacute rejection response (93). Third, treatments such as the administration of antileukocyte antibodies, which suppress acute vascular rejection by inhibiting inflammatory cells, have no impact on hyperacute rejection (141). On the other hand, administration of gamma globulin, which diverts complement away from the graft but increases antibody binding to the graft (89), prevents hyperacute rejection but not acute rejection and may even make the latter worse. Fourth, the most dramatic pathologic manifestations of acute vascular rejection, especially endothelial swelling, focal ischemic injury, and diffuse fibrin thrombi are not typically seen in hyperacute rejection (10,18).

Role of Xenoreactive Antibodies in the Pathogenesis of Acute Vascular Rejection

Several lines of evidence suggest that acute vascular xenograft rejection is caused by the continuing interaction of xenoreactive antibodies with the graft (19). First, during the days following the extracorporeal circulation of blood of patients with fulminant hepatic failure through porcine livers, the levels of antiswine antibodies in the blood of the patients increase, and this increase is observed at a time that corresponds to the period during which a xenograft is subject to acute vascular rejection (62). Second, the removal of antibodies from the circulation of xenograft recipients or inhibition of antibody synthesis by treatment with cytotoxic agents delays or averts acute vascular rejection (58,(142,143,144 and 145). Third, a type of rejection similar or identical to acute vascular rejection of xenografts is observed in allografts (146,147) and xenografts (148,149) in association with *de novo* appearance of antidonor antibodies. Fourth, acute vascular rejection of allografts and xenografts can be induced by the infusion of antidonor antibodies (36).

Role of Complement

At present, it is uncertain whether complement contributes to the pathogenesis of acute vascular xenograft rejection and how complement might do so. Clearly, the development of tissue lesions characteristic of acute vascular rejection is easily envisioned as a reflection of acute complement-mediated changes in endothelial cell structure and function, as previously discussed. Such a role for complement in acute vascular rejection is difficult to reconcile with the fact that acute vascular xenograft rejection typically is observed in xenograft recipients that had been depleted of complement (10). This difficulty may be resolved by three considerations: (a) even the most potent inhibitors of complement are incompletely effective; (b) under conditions of inflammation, endothelial cells synthesize complement components; and (c) some endothelial changes, such as the alteration in heparan sulfate metabolism, can be induced by low levels of complement. For instance, less than 1% of the complement activity in normal serum is sufficient to mediate the release of heparan sulfate from porcine endothelial cells (11,125), and less than 10% of normal complement activity is sufficient to stimulate procoagulant and proinflammatory changes in endothelial cells (150). If complement contributes to the pathogenesis of acute vascular rejection, the membrane attack complex may not be essential. Acute vascular rejection develops in transplant recipients deficient in C6 (92,93).

Endothelial Cell Activation

Based on the histopathology of acute vascular rejection, which includes infiltration of the organ by neutrophils, the thickening of endothelial cells, and pronounced thrombotic changes (10), the author proposed that the pathogenesis of acute vascular xenograft rejection might involve the activation of endothelial cells and thus the acquisition of new endothelial functions (18). This idea was supported by the observation that endothelial cells in grafts undergoing acute vascular rejection display phenotypic changes characteristic of activation (121). One new function presumably acquired by endothelium in acute vascular rejection is the ability to promote coagulation. Unlike quiescent endothelium, which prevents coagulation by serving as a barrier between tissue factor activity in the underlying matrix and plasma coagulation proteins, the endothelium in rejecting xenografts allows coagulation proteins to come in contact with tissue factor in the underlying matrix. In addition, the formation of the membrane attack complex on endothelial cell surfaces stimulates the formation of IL1a, which in turn stimulates the *de novo* synthesis of tissue factor (150) and proinflammtory products (18). Other changes, such as loss of thrombomodulin, increased expression of E selectin (151), chemokines (152), prostaglandins (153), synthesis of plasminogen activator inhibitor type 1, and changes as previously discussed, such as the alteration of cell surface promoting the formation of prothrombinase complexes, also may contribute to the procoagulant posture. In addition, the production of small amounts of thrombin, platelet activating factor, or thomboxane A2 may stimulate platelets in the vicinity of the endothelium.

Role of Platelets

Whereas the thrombi in acute vascular rejection consist mainly of fibrin, the fibrin is invariably admixed with platelets. Bustos and Platt tested the idea that platelets activated by small amounts of thrombin might activate endothelial cells (38). Indeed, human platelets so activated were found to express interleukin-1 (IL-1)-a on the surface, which together with secreted cytokines, could contribute to activation of endothelium. The relative importance of platelets and complement in triggering endothelial cell activation, and thus acute vascular rejection, remains uncertain.

Role of Inflammatory Cells

Blakely et al. (121) suggested that monocytes, which are known to express tissue factor, a co-factor for the formation of prothrombinase complexes, might cause the fibrin deposition and thus the tissue manifestations of acute vascular rejection. This view was supported by the observation that acute vascular rejection in rodents is associated with the influx of macrophages expressing tissue factor. On the other hand, the lesions early in the course of acute vascular rejection do not reveal significant numbers of macrophages (89,154), and the earliest expression of tissue factor is on graft endothelium (155). Nor is the onset or the pathology of acute vascular rejection more than modestly inhibited by the administration of agents that inhibit the interaction of inflammatory cells with xenogeneic endothelium (141), in contrast to the results achieved by antibody depletion, which significantly prolongs the survival of the transplants (154). Nor, conversely, do allotransplants with cellular rejection, which often have large numbers of invading macrophages, necessarily exhibit lesions typical of acute vascular rejection (156). Thus, although a role for macrophages cannot be excluded at this juncture, it seems more likely that these cells are a marker for tissue injury rather than the cause in acute vascular rejection of xenotransplants.

Yet another mechanism that might contribute to the pathogenesis of acute vascular rejection is the action of lymphocytes or NK cells on graft endothelium. The potential involvement of NK cells has been of special interest because the cells might be expected to be activated in xenograft recipients through stimulation carbohydrate and Fc receptors and failure of stimulation of MHC class I receptors (118,157). Consistent with this concept, human NK cells exert cytotoxic and noncytotoxic effects, such as induction of procoagulant activity on porcine endothelial cells *in vitro* (158,159). Although NK cells and other lymphocytes have been found in some rodent xenografts (160), this finding is not always observed (10) because they are not major components of pig-to-primate xenografts (89,154). Therefore, whereas lymphoid cells may well contribute to tissue injury in acute vascular rejection, they may not be essential for the manifestation of tissue lesions.

Accommodation

When antidonor antibodies are depleted from a xenograft recipient, acute vascular xenograft rejection may not occur, even after the antibodies return to the circulation. This condition, in which the graft seems to resist acute vascular rejection despite presence in the circulation of all inciting factors, is called *accommodation* (14). We first observed accommodation in ABO-incompatible kidney allografts (76,161) and postulated that a similar phenomenon might occur in vascularized xenografts (12,14,162). Accommodation also may be observed in graft recipients with circulating antidonor human leukocyte antigen (HLA) antibodies (163,164).

We have postulated that accommodation may arise through one or more of three mechanisms (12,14). First, there is the possibility that the antidonor antibodies may change in their functional properties or specificity or both. Supporting this possibility were studies in ABO-incompatible allografts in which antidonor antibodies were detected in the circulation but were generally not observed in biopsies of the transplanted organ (76,161). Another potential change in the antidonor antibodies is toward predominance of IgG2, which activates complement poorly and might compete with complement fixing antibodies for binding to target cells (61). Second, there might occur a change in the antigen. This concept is supported by the finding that carbohydrate synthesis in the kidney changes following transplantation (165). Third, accommodation might involve a change in the endothelium so that the graft becomes inured to antibody binding and complement activation. The possibility that an allograft or xenograft might acquire resistance to tissue injury and rejection is supported by recent studies showing that accommodation in a rodent model is associated with expression of “protective” genes by endothelial cells (166,167) and by observations that, with continued stimulation of endothelial cells by antibodies or complement, the sensitivity of those cells to injury decreases (168,169 and 170). As an example of one potential scenario, continued stimulation of endothelial cells with endotoxin or with IL-1 causes the cells to develop resistance to restimulation (171). Not only may the sensitivity to restimulation decrease, but the sensitivity to injury also may decrease. For example, stimulation of endothelial cells may cause an increased synthesis of DAF (172), which inhibits complement activation at the level of C3 convertase.

Regardless of the biologic basis for accommodation, further understanding of how this process is induced could be extremely useful, if not critical, to the clinical application to xenotransplantation. Not only does the occurrence of accommodation eliminate the need for continuing depletion of antidonor antibodies from a graft recipient, it also provides clues to manipulations of the donor or recipient that might prevent more chronic forms of graft rejection. The study of accommodation also could yield insights into how blood vessels might be manipulated to alter sensitivity to other injurious processes.

Therapeutic Approaches to Acute Vascular Rejection

Three general strategies might be envisioned for preventing acute vascular rejection. The first strategy involves the induction of accommodation. As discussed, accommodation might be induced by temporary depletion of xenoreactive antibodies. Studies in our laboratory have indicated that accommodation of pig organs transplanted into nonhuman primates can be achieved by depletion of all Ig (154) or of anti-Gala1-3Gal antibodies (59,173).

The second approach to preventing acute vascular rejection might involve induction of immunologic tolerance, lending to decreased production of antixenograft antibodies. Humoral tolerance has been achieved in a1,3galactosyltransferase knock-out mice (these mice make anti-Gala1-3Gal antibodies like humans) (174) by the

transplantation of normal murine bone marrow to yield mixed chimerism and autologous cells transduced with a1,3galactosyltransferase (175). These approaches seem capable of preventing rejection of Gala1-3Gal murine hearts expressing epitopes by a1,3galactosyltransferase knock-out mice. Whether the strategy would be effective between disparate species is still unknown because of the difficulties of transplanting bone marrow between species. It is hoped that treatment with porcine cytokines might allow the enduring engraftment of porcine bone marrow (7).

A third strategy for preventing acute vascular rejection involves decreasing expression of Gala1-3Gal in the transplant. To the extent that Gala1-3Gal is the major target of the xenoreactive antibodies that cause acute vascular rejection, as our work suggests (51), this strategy would have the theoretical advantage of limiting the immunosuppressive treatments that would have to be applied to the recipient. Various genetic strategies for decreasing the expression of Gala1-3Gal are summarized in Fig. 85.5. Of these, the expression of H transferase, which catalyzes production of H antigen, to which humans are tolerant, in lieu of Gala1-3Gal, has been applied with some success in pigs (84). Studies by Parker et al., however, suggest that, to effectively prevent acute vascular rejection, Gala1-3Gal expression would have to be decreased by greater than 95% (176). The recent cloning of pigs by transfer of nuclei from cultured somatic cells to enucleated zygotes (82) raised the possibility the a1,3galactosyltransferase could be "knocked out." It is also possible that the elimination of Gala1-3Gal might subject the recipient to increased risk of infection by porcine viruses, such as the porcine endogenous retrovirus (PERV), which otherwise would be neutralized by anti-Gala1-3Gal antibodies (177). Which of the preceding or other strategies will be most effective in preventing acute vascular rejection is uncertain. This question is a critical one because acute vascular rejection would appear to be the most difficult immune hurdle to xenotransplantation of organs.

XENOGENEIC CELLULAR IMMUNE RESPONSES

The initial type of rejection observed in cellular or free tissue xenografts is acute cellular rejection. If hyperacute and acute vascular rejection are averted, an organ xenograft would next be subject to rejection by cell-mediated immunity of the host against the donor (20,58,178). The central questions regarding cellular rejection of xenografts are the extent to which the cellular immune response to a xenograft might differ from the cellular immune response to an allograft and whether this response would be more severe and less subject to immune modulation than the corresponding allogeneic response. Preliminary answers to these questions have not been forthcoming because, until recently, it has been difficult to bring about survival of organ xenografts for more than a few days without the administration of massive doses of immunosuppressive agents. For example, the studies performed by Alexandre et al. involving the transplantation of porcine kidneys into baboons (142) provided some evidence for the importance of T cells inasmuch as decreases in graft function were reversed by administration of immunosuppressive agents. Also preliminary, but nonetheless intriguing, are studies by Leventhal and co-workers demonstrating that rejection of guinea pig-to-rat cardiac xenografts could be hastened by transfer of lymphocytes from presensitized animals (179). Unfortunately, these studies did not clarify the role of the transferred cells in rejection.

Studies of the cellular immune response to xenografts of free tissues such as the islets of Langerhans or the skin have provided some insight into the similarities and potential differences between the cellular immune responses to xenografts and allografts. Similar to allografts, islet and skin xenografts are subject to cellular rejection because they rapidly fail if the recipient is a normal mouse but survive if the recipient is a nude or a severe compromised immunodeficiency disease (SCID) mouse. In some cases, however, the failure of a free tissue xenograft occurs notably earlier than the failure of a free tissue allograft. This difference may reflect a greater susceptibility of the xenograft to "primary nonfunction." What is not yet clear is whether the early failure of the xenografts was caused by the immune response of the recipient as in primary nonfunction of allografts (23) or whether, at least to some extent, the failure was caused by incompatibility of the graft with the foreign microenvironment. As one example of the latter, there is the possibility that neovascularization of a free tissue xenograft may be impaired in comparison to neovascularization of a free tissue allograft. Such impairment could result in the xenograft being deprived of nutrition and the ready removal of waste products. Impaired neovascularization also could influence the way foreign antigens are presented in a xenograft (Fig. 85.2). On the other hand, free-tissue xenografts may survive for extended periods of time in recipients treated with immunosuppression that is not more intense than the immunosuppression used for allografts (180,181). Moreover, anti-CD4, which has limited effectiveness in allotransplantation, may be especially effective in preventing xenograft rejection (22).

Some recent *in vitro* observations have shed light on the potential differences between xenogeneic and allogeneic cellular immune responses. Proliferative responses to xenogeneic cells in mixed leukocyte cultures are often less exuberant than allogeneic responses or even undetectable (182). This decreased proliferative response to xenogeneic stimulation was thought to reflect the smaller repertoire of T cells that might recognize xenogeneic cells directly, a reflection in turn of positive selection leading to more cross-reactivity with allogeneic than with xenogeneic MHC. Indeed, the dampened *in vitro* response led to the suggestion that cellular immunity to a xenograft might be less intense than cellular immunity to an allograft (20,182). This idea was further supported by studies suggesting that recognition of xenogeneic cells occurs predominantly through the indirect pathway, the T cells of the host being specific for peptides of xenogeneic origin complexed with MHC on host antigen-presenting cells. Because indirect recognition would lead to activation of a smaller fraction of the T-cell repertoire, the response arising in this way would be less intense and less rapid than the response to allostimulation arising through the direct pathway. The dependence of the xenogeneic response on the indirect pathway also reflects defects in the ability of T cells to respond to xenogeneic antigen-presenting cells brought about by "incompatibility" of CD8 or CD4 with xenogeneic MHC leading to decreased coreceptor function (183,184) and by incompatibility of costimulatory pathways and cytokines (185). Recent studies have shown, however, that mouse and human T cells can recognize xenogeneic cells, such as porcine endothelial cells, directly and that under the proper conditions xenoimmune responses arising *in vitro* may be as vigorous as alloimmune responses (186,187,188 and 189), although there is some evidence of a limited frequency of T-cell precursors with the ability to recognize directly highly disparate MHC (184).

There are reasons to think, however, that the cellular response to a xenograft might be as strong or stronger than the cellular response to an allograft. First, virtually all foreign proteins contain amino acid sequences that differentiate one species from another. Thus, a xenotransplant, in contrast to an allotransplant, might give rise to a vast array of foreign peptides that could stimulate a strong response, even though the response is restricted to the indirect pathway. This concept is supported by the work of Murray et al. (186), which demonstrated that human T cells could respond to primary stimulation by porcine peptides, whereas primary responses to allogeneic peptides cannot be detected (190). These results suggest the existence of a much higher frequency of human T cells committed to respond to porcine peptides than to human peptides. Second, to the extent that the direct recognition contributes to immunoregulatory responses, defects in the direct pathway, such as those previously described, might lead *in vivo* to impaired immunoregulation and thus to stronger cellular immune response. Third, the humoral response to xenotransplantation, as it occurs *in vivo*, may give rise to increases in expression of cell adhesion molecules or release of proinflammatory mediators, which could in turn amplify cellular immune responses (150). As one example, heparan sulfate released from endothelial cells by antiendothelial cell antibodies and complement (11,124,125) may activate antigen-presenting cells leading to increased ability to stimulate proliferative (191,192 and 193) and cytolytic T-cell responses (194). In addition to depriving endothelium of the function of heparan sulfate, the release of that molecule may have other consequences. Wrenshall et al. found that heparan sulfate in soluble form activates antigen-presenting cells, leading to amplified proliferative (192) and cytolytic (194) T-cell responses. These changes are caused by the direct action of heparan sulfate on antigen-presenting cells, leading to stimulation of several immunomodulatory pathways (191,195).

Another aspect of the cellular immune response to xenogeneic cells that remains to be elucidated is the extent to which the response will be directed against MHC versus other proteins. There is evidence that human cellular immune responses generated against porcine cells *in vitro* can be directed against porcine MHC (189). Whether the porcine MHC would be the major target of *in vivo* responses remains to be determined. Also uncertain is whether the response will be subject to the kinds of regulation that impact on alloimmune responses.

Another question of potential import is the nature of the humoral immune response that would be elicited by a xenograft and how such a response might impact elicited cellular immunity. Already discussed is the observation that, when a xenograft recipient is treated with immunosuppressive therapy, the antibodies in the serum of the recipient following xenotransplantation still may recognize Gala1-3Gal as the predominant target (62). On the other hand, it seems likely that antibodies against other donor antigens, particularly polypeptides, are likely to arise and pose an additional hurdle, perhaps in the form of acute or chronic vascular rejection. This question is clearly an important one for future investigation.

Whether cellular immune responses to xenotransplants can be controlled by the same therapeutic approaches used to control cellular immune responses to allotransplants is a question of obvious practical import. Specific advice on this matter cannot be offered at present, except to consider the apparently increased efficacy of anti-CD4 antibodies in preventing rejection of cellular xenotransplants (vide supra). Some suggested that the cellular immune response to xenotransplants would be so intense that induction of tolerance would be necessary to prevent rejection (58). If tolerance is required to prevent cellular rejection of xenotransplants, it is uncertain which approach to induction and tolerance would be most effective. Studies in rodents have shown that bone marrow transplantation lending to mixed chimerism (196,197) and thymus transplantation in conjunction with bone marrow transplantation (198,199) might be effective.

ELICITED HUMORAL IMMUNE RESPONSES

Little is known about the barrier posed by elicited humoral immune responses to xenotransplantation. The potential contribution of such responses to acute vascular xenograft rejection was previously discussed. There is also the possibility that elicited antidonor antibodies will contribute to more indolent or chronic types of rejection (200). Although the importance of these responses for xenografts of all types might seem intuitive, there is some evidence that humoral responses will not cause the demise of free tissue or cellular grafts. Whether in the case of free tissue grafts the limited impact of humoral responses will prove to reflect lesser immunogenicity of the graft or the relative protection of the foreign tissue by recipient blood vessels remains to be determined.

OTHER HURDLES TO XENOTRANSPLANTATION

The preeminent hurdle to the transplantation of organs and tissues between the same species is the immune response directed against MHC antigens. Although

immune responses against MHC antigens undoubtedly pose a hurdle to xenotransplantation, such immune responses are far from the only hurdle. Discussed above is the substantial hurdle to xenotransplantation posed by natural immunity—natural antibodies, complement, and NK cells—and the likely contribution of elicited immune responses against antigens other than those encoded in the MHC complex.

If the intense and diverse responses to xenotransplantation were not enough, two other hurdles warrant brief comment. One other hurdle is the physiology of the graft: the possibility that a graft might fail or fail to function because of incompatibility with the recipient. At present, the question of physiology would appear to be more theoretical than a real hurdle as recent studies have shown that the heart, kidney, and lungs can function in highly disparate recipients. In the end, the greatest physiologic hurdle may prove to be impairment in graft function caused by xenoimmune responses.

One other hurdle worthy of comment is that of infection. There is a possibility of transferring infections from the graft to the xenogeneic recipient (i.e., zoonosis). The main agent of concern at present is the porcine endogenous retrovirus (PERV), which is a type C retrovirus that can infect human lymphoid cells in culture (201,202). Thus far, infection of humans has not been observed (203,204). Of more immediate concern is the possibility that immunosuppression or tolerance regimens might render the recipient relatively immunoincompetent and thus severely subject to infection. Still another concern is that viral infections of xenotransplants might not be adequately controlled by cell-mediated immune responses because viral peptides would be presented by xenogeneic MHC and, thus, relatively unrecognized by the T-cell repertoire of the recipient.

Despite all the hurdles discussed herein, there is increasing enthusiasm about the aspects for clinical xenotransplantation. In part, this enthusiasm springs from the urgent need for donor organs and a sense of willingness to consider xenotransplantation as a rational approach to that problem. In part, this enthusiasm also arises with the recent success in the genetic engineering of pigs as potential xenotransplant donor and from the long-term survival of experimental xenografts performed using organs from these pigs (144). Indeed, some of these results would seem to suggest that there are no fundamental incompatibilities that would stand in the way of enduring survival of a xenograft. Whether the enthusiasm for xenotransplantation proves to be well founded, progress in the field of transplantation provides dramatic evidence of how the approach to medical problems is changing. As molecular hurdles to xenotransplantation are discovered, those hurdles are being addressed through the rational design of drugs and the genetic engineering of donor animals. Thus, if it is not possible to predict that xenotransplantation will enter the clinical arena in a few years, it does seem certain that knowledge in this area will continue to advance rapidly and that knowledge will increasingly benefit the broader fields of immunology and clinical medicine.

86 CALCINEURIN AS A THERAPEUTIC TARGET

Anthony D. Cristillo, Ph.D., and Barbara E. Bierer, M.D.

Calcineurin, a serine/threonine phosphatase involved in multiple biologic functions, is the molecular target of both immunosuppressants cyclosporine A (CsA) and tacrolimus (originally termed FK506). The discovery of a single enzymatic target changed our understanding of drug action and our approach to drug development, but it also initiated focused study of calcineurin-dependent signaling pathways. Comparison of the biologic outcomes of CsA and tacrolimus administration, both *in vitro* and *in vivo*, allowed the attribution of action to a single, identifiable enzymatic activity; from this understanding, both the upstream regulators and downstream targets could be investigated. Furthermore, differences between the action of CsA and tacrolimus action now are understood in terms of drug metabolites or in terms of the different endogenous receptors, termed immunophilins, for these drugs. Immunophilins are a large family of widely expressed and well-conserved proteins that differ in their core hydrophobic pockets that are able to bind drug. Cyclophilins bind CsA, whereas tacrolimus (FK506)-binding proteins (FKBPs) bind tacrolimus and a structurally related, although biologically distinct, immunosuppressive agent, sirolimus (rapamycin). FKBPs, however, do not bind CsA, and cyclophilins are unable to bind either tacrolimus or sirolimus. The complexes formed by CsA binding to cyclophilins and by tacrolimus binding to FKBPs target and inhibit the serine/threonine phosphatase calcineurin. This chapter reviews the central role of calcineurin in lymphocyte and other cellular actions; in addition, the therapeutic and side-effect profiles of CsA and tacrolimus are discussed.

IDENTIFICATION OF THE IMMUNOSUPPRESSIVE DRUGS: CYCLOSPORINE, TACROLIMUS, AND SIROLIMUS

The immunosuppressant cyclosporine (also termed cyclosporine A, CsA) was first identified in 1970 by screening soil samples containing new strains of fungi for immunosuppressive properties (1,2) (Table 86.1). Isolated and later purified from the fungus *to lypocladium inflatum*, cyclosporine inhibited the proliferation of lymphocytes cultured in a mixed lymphocyte reaction, demonstrating its ability to suppress an allospecific response, a property that was later confirmed in *in vivo* studies (3,4). Its clinical utility is discussed in detail in the following section.

Property	Cyclosporine (Cs)	Tacrolimus	Sirolimus
Alternative names	CsA	FK506	Rapamycin
Mr (Da)	1203	822	914
Structure	Cyclic undecapeptide	Macrolide	Macrolide
Intracellular immunophilin receptor	Cyclophilins	FKBPs	FKBPs
Target of drug: receptor complex	Calcineurin	Calcineurin	mTOR
Function	Inhibition of cytokine and gene transcription	Inhibition of cytokine and gene transcription	Inhibition of growth-factor sign p70 S6 kinase activity, protein translation machine growth and proliferation
Major side effects			
Nephrotoxicity	++	++	-
Neurotoxicity	++	++	-
Hypertension	++	++	-
Hyperlipidemia	-	-	++
Leukopenia	-	-	+
Thrombocytopenia	-	-	+
Susceptibility to infection	++	++	+

FK BPs, tacrolimus (FKBP, FKBP-binding protein); mTOR, mammalian Target of Rapamycin; MW, molecular weight

TABLE 86.1. Immunosuppressant Agents

Tacrolimus also was identified by its ability to inhibit allospecific responses, and the compound was purified from soil samples. In 1975, its chemical structure was determined and shown to be a macrolide, most similar to a product isolated from *Streptomyces hygroscopicus*, termed *sirolimus* (originally rapamycin) (5) (Fig. 86.1). Whereas tacrolimus and sirolimus share structural similarity, their biologic action and their molecular targets differ (discussed later). On the other hand, whereas tacrolimus is not apparently structurally related to cyclosporine, a cyclic undecapeptide (Fig. 86.1), both agents share many of the same biologic characteristics, both are immunosuppressive *in vitro* and *in vivo*, and both target calcineurin.

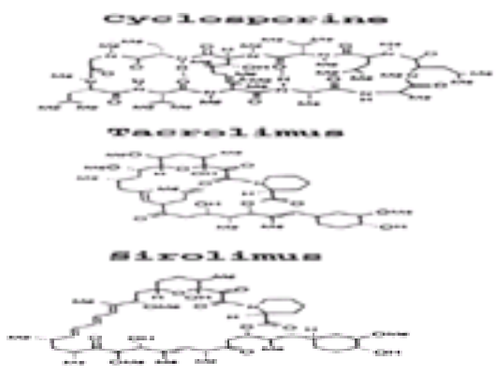

Figure 86.1. Structure of immunophilin binding agents: CsA, tacrolimus, sirolimus. Chemical structure of cyclosporine A (CsA), a cyclic undecapeptide, M_r 1,203 Da; tacrolimus (FK506, Prograf), a macrolide antibiotic, M_r 822 Da (**B**); and sirolimus (rapamycin), another macrolide antibiotic, M_r 914 Da (**C**).

Cyclosporine binds to a family of cyclophilins, whereas tacrolimus (and sirolimus) bind the family of proteins, FKBPs. The cyclophilins and FKBPs, collectively termed *immunophilins*, share the capacity to catalyze the *cis*-trans isomerization of proline-containing proteins. Within the cell, immunophilins appear to be involved in protein folding and transport (6,7 and 8). The isomerase activity of cyclophilins is inhibited by cyclosporine and that of FKBPs is inhibited by the specific ligands tacrolimus and sirolimus.[1]

Inhibition of immune function results not from inhibition of isomerase activity (9,10) but from the ability of the complexes formed by cyclosporine binding to cyclophilins and tacrolimus binding to FKBPs to bind to and inhibit the Ca^{2+}/calmodulin-dependent serine/threonine phosphatase calcineurin (11,12). Cyclosporine and tacrolimus themselves are considered prodrugs; only upon binding to their intracellular immunophilin do they acquire the ability to bind to calcineurin, leading to inhibition of calcineurin phosphatase activity.

IMMUNOPHILIN RECEPTORS FOR CYCLOSPORINE, TACROLIMUS, AND SIROLIMUS

Although the families of immunophilins differ in drug binding, they share a number of important characteristics, including species conservation and function: the ability to catalyze the cis-trans isomerization of peptidyl-prolyl bonds. Both cyclophilins and FKBPs are abundant proteins and are well represented throughout the animal and plant kingdoms, and of keen biologic interest. A complete summary of each member of the two families is beyond the scope of this chapter, but certain principles are discussed. It is important to appreciate that the effects of drug binding to these different immunophilins, leading to inhibition of endogenous immunophilin function, may be responsible for the side-effect profile or toxicities of drug administration. Only with significant understanding of the biologic properties of these immunophilins, and of their cell-type specific expression and function, will their contribution to drug effects be appreciated.

Cyclophilins

The cyclophilins all share a cyclosporine-binding domain of approximately 165 amino acids, a domain that cannot bind tacrolimus or sirolimus. More than a dozen mammalian cyclophilins have now been identified. An 18-kd cyclophilin termed *cyclophilin A* (CyPA) has been shown to mediate cyclosporine inhibition (13) and to function, in the absence of drug, in protein folding (14,15 and 16). CyPB has been shown to be localized to the endoplasmic reticulum (17) and may be secreted in inflammatory states (18). CyPB interacts with a protein termed *calcium-signal modulating cyclophilin B ligand* (CAML), localized to the endoplasmic reticulum, which appears to play a role in calcium signaling and calcium storage (19). Both CyPA and CyPB bind the third hypervariable loop of the human immunodeficiency virus gp120 envelope glycoprotein (20,21). CyPC, a 23-kd protein bound to membrane attack complex (MAC)-2 binding protein, is localized to cytosolic vesicles; its function is unknown (22). In the presence of cyclosporine, the interaction of CyPC with MAC-2 binding protein is inhibited, and CyPC may be secreted (12). Localized to mitochondria, CyPD appears to regulate mitochondrial permeability in a cyclosporine-sensitive fashion (23). Cyclophilin proteins have been detected on the surface of natural killer (NK) cells (e.g., NK-TR150, (24)) and T cells (e.g., CyPB) (25), in the nucleus (e.g., CyP-60) (26), and the cytoplasm (e.g., CyP-40) (27). CyP-40 binds to heat shock protein (hsp) 90 through its carboxyterminal tetratricopeptide repeat (TPR) domain, a 34-amino-acid degenerate motif involved in protein–protein binding (28). Whereas a complex composed of CyP-40 and hsp90, among others, has been shown to be a component of the glucocorticoid receptor complex, CyP-40/hsp90 binding is not sensitive to cyclosporine treatment (29). Therefore, the endogenous role of the cyclophilins remains an active area of current study.

FK506 Binding Proteins

The spectrum of FKBP family members is as diverse as the cyclophilin family (30,31). An FKBP of 12 kd, termed *FKBP12*, is the principal cytosolic FKBP responsible for both tacrolimus and sirolimus action IQ(Fig. 86.2) (13,32). It is an abundant protein, expressed in essentially all eukaryotic cells, and it binds both tacrolimus and sirolimus with high affinity; drug binding inhibits its endogenous isomerase activity. FKBP12.6 is a related FKBP that is robustly expressed in muscle and appears to be responsible for tacrolimus action in specialized tissue. FKBP13 is localized to the endoplasmic reticulum and has been shown to bind to erythrocyte protein 4.1 (33). FKBP23 also localizes to the endoplasmic reticulum but appears to bind calcium (34). FKBP25 is localized to the nucleus, where it has been shown to bind nucleolin. FKBP51 and FKBP52 are homologous to one another; like CyP-40, FKBP52 is a component of the steroid receptor complex (35). Of note, neither CyP-40 nor FKBP52 appears required to activate hormone binding by the glucocorticoid receptor (36).

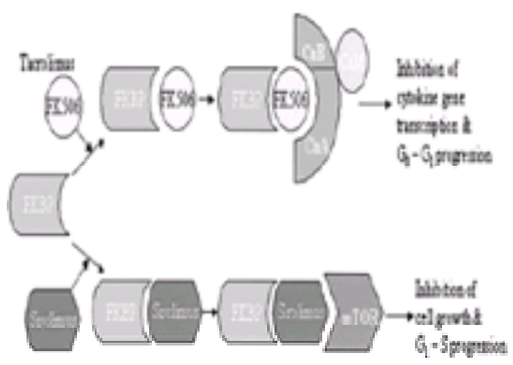

Figure 86.2. FKBP binding partners. Schematic illustration of the different binding partners of one FKBP immunophilin, FKBP12. FKBP12 binds to tacrolimus (FK506) and the complex of FKBP12 †tacrolimus, like cyclosporine †cyclophilins, binds to and inhibits the activity of the calcium/calmodulin-dependent phosphatase calcineurin, thus inhibiting cytokine gene transcription and G_0 to G_1 progression. FKBP12 binds sirolimus (rapamycin) and the complex of FKBP12/sirolimus binds to and inhibits the activity of mammalian Target of Rapamycin (mTOR), leading to inhibition of cytokine signaling, protein expression, and the G_1-S transition required for cell growth.

In the absence of tacrolimus or sirolimus, FKBP proteins, specifically FKBP12 and FKBP12.6, play important roles in ion channel function (37,38). FKBP12 binds the type 1 tumor growth factor-b (TGF-b) receptor (39) and negatively regulates internalization of the TGF-b receptor (40). FKBP12 and FKBP12.6 bind the ryanodine receptor (RyR1 in skeletal muscle and RyR2 in cardiac muscle, respectively, and both proteins bind the inositol-3-phosphate receptor (IP_3R). The IP_3R and Ryanodine receptor (RyR) channels regulate calcium-mediated signaling in diverse cell types, including muscle, heart, and immune cells. The association of FKBP12 (and of FKBP12.6) with the IP_3R and the RyR stabilizes the conformation of the receptor, modulates calcium conductance and channel gating (37,38). Furthermore, protein kinase A-dependent phosphorylation of RyR2 mediates the dissociation of RyR2 from FKBP12.6 (37) while the presence of an FKBP may provide a docking site for the phosphatase calcineurin (see below). Kinases and phosphatases, in turn, regulate receptor phosphorylation and thereby calcium channel gating (41,42). Another 12-kd FKBP, termed *inositol phosphate-binding protein* (IPBP12) is a 12-kd tacrolimus- and sirolimus-binding FKBP that binds inositol phosphates as well; it may regulate calcium flux as well (43). The importance of the FKBP/ion channel in clinical settings such as heart failure is currently being explored (42,44,45).

CALCINEURIN, A CENTRAL MOLECULAR TARGET

Because the specific molecular target of the immunosuppressant/immunophilin complexes, CsA/cyclophilin and tacrolimus/FKBP, is calcineurin (11,12), an understanding of the biologic role and function of calcineurin and of its regulation leads to an appreciation of the action of both immunosuppressant compounds. Indeed, since the discovery that calcineurin is the specific target of both CsA and tacrolimus, these agents have been used to reveal the fundamental role and importance of calcineurin in biologic systems.

Calcineurin Structure

Calcineurin is a calcium- and calmodulin-dependent serine/threonine phosphatase. A heterodimer, calcineurin, is composed of a 59- to 61-kd catalytic calcineurin A chain (CnA) and a 19-kd regulator calcineurin B (CnB) chain (Fig. 86.3); CnB is required for both proper protein folding and enzymatic activity (46). The calcineurin subunits exist in the cytoplasm of the cell as a holoenzyme. Three isoforms of the CnA subunit have been identified, and they are approximately 75% homologous to one another. Whereas CnAa and CnAb are expressed in all tissues, CnAb is expressed preferentially in cardiac tissues, and expression of the CnBg subunit is limited to the testis (47). Two isoforms of CnB have been identified: CnBa is expressed ubiquitously, and expression of CnBb is testis-specific. Furthermore, alternatively spliced forms of both CnA and CnB subunits have been identified. Little is currently known about isoform-specific expression and their biologic function. Differences in isoform-specific expression may correlate with or be important for developmental maturation or, alternatively, may help to explain tissue-specific differences in the role of calcineurin.

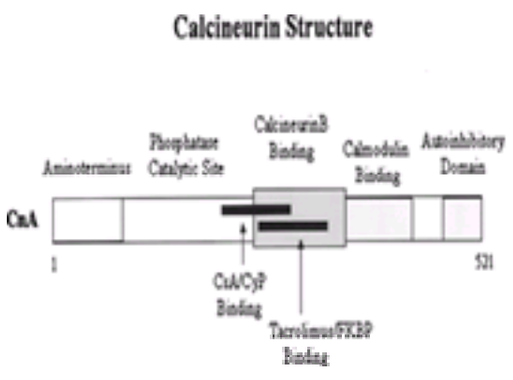

Figure 86.3. Calcineurin structure. Calcineurin is a heterodimer composed of a 61-kd catalytic subunit (CnA) and a 19-kd regulatory subunit (CnB). CnA has a phosphatase active domain, a CnB binding domain, a calmodulin-binding domain, and an autoinhibitory (AI) domain. The AI domain appears to bind at or near the phosphatase active site in the inactive form. Tacrolimus/FKBP and cyclosporine/cyclophilins bind near the CnB binding domain and prevent substrate docking.

The CnA subunit consists of the catalytically active domain, a domain for CnB binding, a domain for calmodulin binding and a carboxyterminal portion (Fig. 86.3). Both calmodulin, which associates with the carboxyterminus of CnA, and CnB independently bind calcium; calcium binding is required for enzymatic activity. The carboxyterminal domain of CnA contains a putative autoinhibitory domain as limited proteolysis or genetically engineering CnA to be deleted of the carboxyterminus has been shown to render the enzyme constitutively active (48). The carboxyterminal 97 amino acid fragment functions as an intrasteric, competitive inhibitor of calcineurin phosphatase activity (49). The solution of the structure of calcineurin, complexed with drug/immunophilin, confirmed that the carboxyterminus bound the phosphatase active site and that this catalytic site was in close proximity to, but not overlapping with, the substrate-binding site (50,51).

Calcineurin Activity

Calcineurin activity is stimulated by engagement of a number of extracellular receptors and, as predicted from its structure, regulated by calcium influx and calmodulin binding (52) and by reactive oxygen species (53). Calcineurin phosphatase activity is critical to the function of many intracellular processes and biologic functions (Fig. 86.4). These include nuclear translocation of certain transcription factors, such as nuclear factor of activated T cells (NFAT), ion channel regulation such as the gating of the RyR, protein transport, and enzymatic activity. The dependency of many of these processes on calcineurin has been revealed by the ability of cyclosporine and tacrolimus (but not sirolimus) to inhibit them.

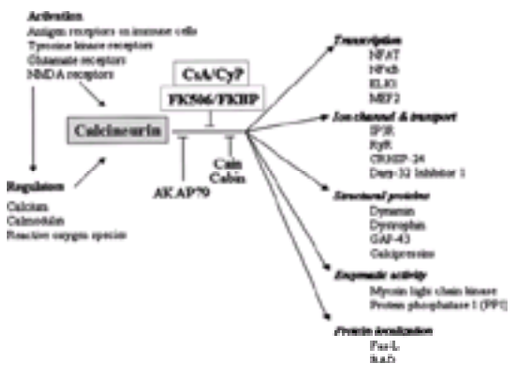

Figure 86.4. The central role of calcineurin. The calcium/calmodulin-dependent serine/threonine phosphatase calcineurin serves a number of roles, including regulation of transcriptional activity, ion channel and transport, protein interactions and localization. Calcineurin is activated by a number of receptors, as shown. Its activity is regulated by calcium, calmodulin, and reactive oxygen species, among others.

NFAT: A Target of Calcineurin

Early research focused on the role of the immunosuppressive agents in T-cell inhibition, and therefore the role of calcineurin in T-cell activation was the subject of study. Engagement of the T-cell receptor (TCR) initiates a complex series of signaling events (summarized in Fig. 86.5) that involves activation of protein kinase C (PKC) coupled with influx of extracellular calcium to the intracellular compartment. Calcium influx, together with calmodulin, leads to calcineurin activation; calcineurin-mediated dephosphorylation is required for the nuclear translocation of the transcription factor NFAT (54,55,56 and 57) as well as a number of other transcription factors (see later discussion). NFAT is a family of related transcription factors, many of which are important for transcription of the cytokine genes, including interleukin-2 (IL-2), IL-3, IL-4, tumor necrosis factor-a (TNF-a), granulocyte macrophage colony-stimulating factor (GM-CSF), interferon-g (IFNg) among others. Once in the nucleus, NFAT binds to and transactivates the DNA recognition sequence (2,58,59,60,61,62,63 and 64). Drug/immunophilin-mediated inhibition of calcineurin activity results in inhibition of nuclear translocation of NFAT and of expression of all the NFAT-dependent genes, notably the cytokine genes (64,65,66,67 and 68).

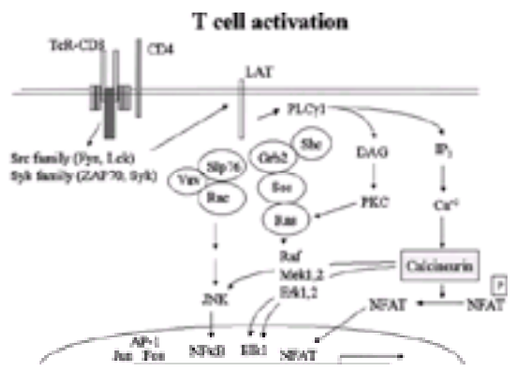

Figure 86.5. Effects of immunophilin/binding agent complex on T-cell signaling. Stimulation of T-lymphocytes via the T-cell receptor (TCR) mediates intracellular signaling events that include the activation of protein kinase C as well as an increase in intracellular calcium levels. Calcium and calmodulin are recruited to activate calcineurin, a phosphatase important for activation of a number of transcription factors. The calcium/calmodulin-dependent activation of serine/threonine phosphatase calcineurin is inhibited by both CsA/CyPA and FK506/FKBP12 complexes and *in vivo* by Cain/Cabin I.

It is important to note, however, that NFAT is not synonymous with calcineurin dependency; other mechanisms of calcineurin dependency exist. Maximal IFN-g transcription, for instance, depends on a calcineurin-dependent composite site made up of NFAT and kB elements (69). The NFAT protein is related to Rel/NFkB proteins (64,70,71) and, although different signaling pathways optimally regulate NFAT and NFkB, both proteins may bind common elements, as has been shown for the IL-4 promoter (72). This paradigm further allows for the possibility that the same element may regulate both calcineurin-dependent and calcineurin-independent transcription, depending in part on the inductive stimulus for transcription.

Transcription of a number of genes is activated by the binding of cooperating elements to composite sites on the enhancer or promoter; calcineurin dependence may relate to the sensitivity of one or more of the cooperating proteins. IL-3 and GM-CSF, for instance, are related genes that lie10 kb from one another (73) but are differentially regulated. Whereas GM-CSF is induced in T cells and in endothelial cells, cyclosporine-sensitive IL-3 transcription is induced only in T cells and NK cells. DNase-hypersensitivity of an enhancer element is eliminated after T-cell induction suggesting transcription factor binding; this site has been shown to bind Oct and NFAT elements cooperatively (74) and resembles those found in IL-2 and IL-4.

The cell type and differentiation state of the cell appear to be critically important for directing transcription and, therefore, may also be potentially crucial for calcineurin dependence. $CD4^+$ T-helper (Th) cells can be induced to differentiate to Th1-specific cells that secrete IFN-g and IL-2 and promote cell-mediated immunity or to Th2-specific cells that secrete IL-4, IL-5, and IL-10 preferentially and promote humoral immunity, immunity to intracellular parasites, and IgE secretion (for review, 75). In this context, the same transcription factor, NFAT1, is able to bind a 3' enhancer element of the IL-4 gene in activated Th2 cells but only to the IFN-g promoter in activated Th1 cells (76). Transcription of both IL-4 and IFN-g is cyclosporine sensitive, but the specific cytokine genes transcribed are controlled by access to the chromosomal site *in vivo.*

Calcineurin: NFAT Interaction

The site of NFAT interaction on calcineurin has been mapped extensively by mutagenesis and other molecular biologic techniques (for review, see 77,78). Shared among all NFAT family members is the DNA binding domain at the N-terminus; calcineurin binds to a region just aminoterminal to the DNA binding domain, a region that is not conserved in NFAT5. Furthermore, a short peptide was developed that inhibits NFAT-dependent activation of cytokine response genes but does not inhibit calcineurin phosphatase activity (78,79). This PxIxIT motif is thought to inhibit docking of NFAT to calcineurin and thus specifically inhibit this calcineurin substrate or others that rely on this binding motif (unidentified to date). If small molecules that mimic this PxIxIT-based peptide can be developed, the opportunity for selective T-cell and cytokine inhibition may be afforded. These NFAT-specific pharmacologic inhibitors may not affect other calcineurin substrates that potentially could be responsible for drug toxicity.

In addition to a specific docking site on calcineurin, NFAT contains a nuclear localization sequence that is masked, in the resting state, by serine phosphorylation on the regulatory domain (56). Neither the serine kinase responsible for NFAT phosphorylation nor the amino acids phosphorylated have been identified to date, and it remains possible that different kinases are active and responsible for the phosphorylation of different targeted residues within the NFAT family members. Calcineurin activity is required not only for NFAT nuclear translocation (56,80) but also for optimal DNA binding and transcriptional activity (81,82). Identification of calcineurin substrates coupled with molecular appreciation of the determinants of the interaction may allow for development of novel immunosuppressive agents with greater specificity and more limited toxicity.

Other Calcineurin-dependent Transcription Factors

Transcription factors other than NFAT have been identified that are regulated by calcineurin, factors often revealed by inhibition by cyclosporine or tacrolimus (83,84 and 85). Calcineurin has been shown to cooperate with PKC to activate the IkB kinase (IKK) complex. When dephosphorylated, this complex sequesters NFkB in the cytoplasm; NFkB is thus regulated by cyclosporine and tacrolimus (86,87 and 88). Furthermore, calcineurin can cooperate with another PKC isoform, PKCt, to induce activation of the MAP kinase family member Jun kinase (JNK) (89), which is responsible for c-Jun and activating transcription factor-2 (ATF-2) activation (90,91). Downstream substrates dependent on c-Jun or ATF-2 activity will therefore be inhibited by cyclosporine and tacrolimus.

Elk-1 appears to be a direct substrate for calcineurin, at least *in vitro* (92). Mitogen-activated protein (MAP) kinases induce serine phosphorylation of Elk-1, which is required for its activity. Calcineurin dephosphorylates the serine amino acid and thus represses Elk-1-dependent transcription (92) including c-Fos. Depending on the cell type, calcineurin has been shown to regulate the cyclic adenosine monophosphate (cAMP)- and calcium-responsive transcription factor cAMP-responsive element (CRE)-binding protein (CREB) (93,94,95,96,97 and 98). The molecular characteristics of this inhibition, whether direct or indirect, are yet to be explored.

Calcineurin-dependent Cytokine Effects Other than Transcription Factor Regulation

Calcineurin and JNK activity have both been shown to stabilize mRNA transcripts of a number of cytokine genes, including IL-3 and IL-2, containing *cis*-acting AUUUA-rich element in their 3' untranslated region (99,100). Cyclosporine and tacrolimus prevent this mRNA stabilization and promote degradation. Whether prevention of mRNA stabilization contributes to immunosuppressive action is not as yet clear. Other cytokines also can be affected by cyclosporine: cyclosporine increased hepatocyte growth factor expression by mechanisms that are as yet unclear.

Cyclosporine has been shown to upregulate expression of the immunosuppressive cytokine transforming growth factor-b (TGF-b) apparently through an effect on calcineurin (101,102 and 103). The effects of TGF-b expression on various immune and nonimmune cell types are complex but include induction of the cell-cycle inhibitor p21 (104), leading to inhibition of cell proliferation. Cyclosporine-dependent TGF-b promoted cancer progression and anchorage-independent growth in nude mice (105), an effect that some investigators relate to the increased incidence of secondary malignancies in patients receiving chronic immunosuppression.

Other Calcineurin Targets

Calcineurin has a role in a number of functions in addition to regulation of transcription factor localization and activity. The phosphatase has a major role in subcellular location of proteins generally, in addition to the transcription factors discussed already. A few examples will serve to illustrate the paradigm.

The proapoptotic protein Bcl 2 proapoptotic family member (BAD), a member of the Bcl-2 family, is bound by 14-3-3 proteins in the cytoplasm. Calcineurin-dependent dephosphorylation of BAD provokes the dissociation of BAD from 14-3-3, allowing binding to Bcl-X_L (106). BAD binding to Bcl-X_L prevents the latter from fulfilling its antiapoptotic function, resulting in induction of apoptosis, or cell death. It should be noted that regulation of BAD phosphorylation is not the only mechanism by which calcineurin affects the choice between survival and cell death: calcineurin activity is required for FasL (CD95L) expression and appears to be dependent on NFAT activity (107).

CLINICAL USE OF CYCLOSPORINE AND TACROLIMUS

The U.S. Food and Drug Administration has approved both cyclosporine and tacrolimus for prophylaxis and treatment of solid organ rejection, specifically in liver and kidney transplantation. In addition, these agents have been used extensively in other forms of solid organ transplantation, hematopoietic stem cell transplantation, hematopoietic stem cell disorders such as aplastic anemia, psoriasis, and a variety of autoimmune disorders such as rheumatoid arthritis and multiple sclerosis. A complete compendium of the clinical experience is beyond the scope of this chapter. Consultation with specialists familiar not only with the specific condition but, importantly, with the clinical use of these potent immunosuppressive agents should be encouraged.

It is important to appreciate that organ graft and patient survival is equivalent in controlled, randomized, multicenter treatment trials comparing tacrolimus and cyclosporine, each in combination with other agents (see, for instance, 108,109)). The utility of these earlier studies is limited by the appreciation that the optimal range for our current therapeutic blood level for tacrolimus is lower than that used in earlier efforts: the lower blood level may decrease toxicity without adversely affecting efficacy (108,109). Importantly, long-term follow-up comparing cyclosporine and tacrolimus, including late graft rejection and late toxicities (e.g., secondary malignancies, infectious complications) have not yet been reported. Cost differences will be important when the patent window expires. Finally, the importance of evaluating newer approaches to designing immunosuppressive regimens, including using cyclosporine and tacrolimus in combination with other agents, may well supersede direct comparisons of these two agents in clinical trials.

Toxicity and Side-Effect Profile of Cyclosporine and Tacrolimus

The clinical use of cyclosporine and tacrolimus is limited by extensive toxicity, particularly when used chronically. The most common side effects are nephrotoxicity, neurotoxicity, hypertension, and hyperbilirubinemia; an anticipated side effect of prolonged immunosuppression is susceptibility to infections (reviewed in 110,111 and 112). Acute nephrotoxicity with decreased glomerular filtration rate appears to be due to vasoconstriction and local ischemia. The incidence and severity of neurotoxicity, including headaches, seizures, and reversible posterior leukoencephalopathies, appear to be aggravated by coincident hypertension, hypocalcemia, and hypomagnesemia. These complications often respond to decreasing the dose of or discontinuing drug, but permanent sequelae may result. Because both cyclosporine and tacrolimus are extensively metabolized by the hepatic cytochrome P450 system, the development of hyperbilirubinemia challenges the ability of physicians to dose the medications appropriately; vigilant monitoring of blood therapeutic levels is indicated. Drug levels also should be assessed whenever medication changes are introduced, particularly those that affect the hepatic cytochrome P450 system. Therapeutic levels should be measured in the trough state (unless the patient is receiving drug by continuous infusion) and preferably performed by the same laboratory. There is a general, but not strict, correlation between levels, efficacy, and toxicity for both cyclosporine and tacrolimus; clinical judgment and experience must guide choice of agent, administration, and dosing.

Both cyclosporine and tacrolimus are lipophilic agents that are available in both oral and intravenous formulations. The diluent used for intravenous administration for both agents is a cremaphor (in olive oil) that occasionally is associated with burning of the hands and feet, a side effect often attenuated by decreasing the rate of infusion or changing to oral administration if possible. The absorption of both cyclosporine and tacrolimus is highly variable and dependent on a number of factors, including the presence of bile salts for cyclosporine. A new oral, microemulsion formulation of cyclosporine is available that is more readily absorbed and that has less variable pharmacokinetic parameters. The improved bioavailability is particularly helpful in patients with gastrointestinal difficulties or malabsorption (e.g., graft-versus-host disease, liver transplant recipients) and may translate into less erratic pharmacokinetics and decreased toxicity.

It has been difficult to segregate the side-effect profiles of cyclosporine from those of tacrolimus. The common side-effect profiles suggest that inhibition of calcineurin activity, which is common with these two drugs, may be responsible (113). Indeed, differences between different patients or patient populations may relate not to the mechanism of toxicity but rather to the specific underlying disease or organ(s) affected. It is possible but unlikely that the side effects and toxicities may be related to drug metabolites or the specific role of the immunophilin receptors. Of course, these possibilities are not mutually exclusive. A few side effects, such as hirsutism and gingival hyperplasia, have been observed only in cyclosporine-treated patients to date; these discordant toxicities are likely secondary to differences in immunophilin

expression (resulting in localized calcineurin inhibition by one but not the other agent), the biologic consequences of inhibition of specific immunophilins, or individual drug metabolites. The molecular causes of toxicity must await more careful analysis of animal models or the development of specific agents that target calcineurin substrate selectivity. It is hoped that small molecule mimetics and synthetic, bioavailable peptides or products will be developed that are specific for the biologic targets of calcineurin; these novel agents will have greater selectivity and, potentially, diminished toxicity.

CONCLUSIONS

Introduced into clinical practice only a quarter century ago, cyclosporine has forever changed the outlook for transplantation medicine. Current understanding of the intracellular receptors for cyclosporine and tacrolimus, and of the molecular target(s) of cyclosporine/cyclophilin and tacrolimus/FKBP is again modifying approaches to transplantation biology. This understanding, coupled with the development of new agents that have a different molecular mechanism and spectrum of side effects, will enlighten the design of equipotent, and less toxic, therapeutic regimens. Novel immunotherapies targeting specific, tissue-restricted proteins may limit toxicities to other organs and will further identification of such unique targets. We are approaching a molecular understanding of the biology of immunologic tolerance with the ultimate aim of inducing tolerance to allogeneic (and xenogeneic) antigens and reinstating tolerance to autoantigens in disorders of autoimmunity. At that time, targeted immunosuppressive therapy will be tailored to the molecular signaling pathway, to the affected organ system, and to the patient.

[1]It is important to consider the possibility that specific drug toxicities may be related to the effects of inhibiting immunophilin isomerase activity: If this were the case, one would predict that some toxicities of tacrolimus and sirolimus might overlap (inhibition of FKBPs), whereas that of CsA might differ.

87 T-Cell Antigen and Costimulatory Receptors as Therapeutic Targets

Maria-Luisa Alegre, Ph.D., and Jeffrey A. Bluestone, Ph.D.

OVERVIEW

The prevalence of immune-mediated diseases in America and, indeed, around the world is a significant health care problem that requires an aggressive and innovative approach toward the development of new treatment solutions. Immune-mediated diseases include a broad spectrum of autoimmune illnesses such as rheumatoid arthritis, diabetes mellitus, lupus and multiple sclerosis, solid tumors and hematologic malignancies, infectious diseases, asthma and various allergic conditions. These diseases affect tens of millions of Americans and result in annual medical and other indirect costs of more than 100 billion dollars. Furthermore, immune-mediated graft rejection impacts more than 20,000 Americans suffering from nonimmunologic diseases who receive organ transplants each year.

Historical Context

Over the past 40 years, improved results in the treatment of immune-mediated diseases have been achieved primarily through the development of increasingly potent nonspecific immunosuppressive drugs to inhibit immune responses. Immunotherapies, such as steroids, cyclosporine A (CsA) and pan-reactive monoclonal antibodies (mAbs) have met with a degree of clinical success in treating conditions such as acute immune rejection of organ transplants and severe autoimmune diseases. Such therapies, however, require life-long use that nonspecifically suppress the entire immune system, exposing patients to considerably higher risks of infection and cancer. In addition, the chronic use of these nonspecific therapies has proven to have a negative impact on long-term graft survival (1). The calcineurin inhibitors and steroids in particular are nephrotoxic and diabetogenic. For instance, in nondiabetic kidney allograft recipients, the combination of calcineurin inhibitors and prednisone are associated with the development of an insulin-dependent diabetic state in up to 25% of the patients (2). Furthermore, the use of these drugs increases financial costs and side effects (3) and is of limited usefulness in the autoimmune, allergy, and asthma settings. Finally, the calcineurin inhibitors CSA and tacrolimus appear to inhibit the development of tolerance in multiple animal models as described in Chapter 86 and subsequently herein

Immune Tolerance: The Holy Grail for Immune Therapy of Transplantation and Autoimmune Diseases

A major goal for the treatment of immune disorders is the induction of immune tolerance - selective short-term immunotherapies targeted toward eliminating only the pathogenic immune response while preserving normal, beneficial immune function. The advances in the development of tolerogenic strategies in clinical transplantation have been fueled by multiple anecdotal cases in which transplant recipients have discontinued all immunosuppression and have not rejected their transplants (4). Whereas in most cases discontinuation of immunosuppression results in either fulminate acute or chronic rejection, these successful “experiments of nature” indicate that tolerance is achievable in clinical transplantation and suggest that the establishment of allograft tolerance using intentionally designed therapies is indeed an attainable goal (5,6). Such therapies are now a real possibility because molecular techniques have begun to help unravel the fundamental processes responsible for immune regulation. In fact, unparalleled progress made over the past few years in the conceptual understanding of the mechanisms operative in the induction of tolerance and restoration of self-tolerance has led to the development of unique and selective immunomodulatory strategies.

The normal processes generally thought to regulate tolerance are based on negative selection of autoreactive T cells in the thymus (*central tolerance*) and on five peripheral mechanisms: ignorance of antigen, clonal inactivation, clonal deletion, suppression, and cytokine-dependent immune deviation (Fig. 87.1). The relative contributions of the individual processes may vary depending on the nature of the antigen and the location in which “tolerization” occurs. Recently, numerous new approaches are making their way into clinical trials based on the demonstration of long-term kidney and islet allograft survival in nonhuman primates combined with strong preclinical data in autoimmunity. These therapies include the use of anti-CD154 antibodies (6,7) and cytotoxic T-lymphocyte (CTL)A-4 (CTLA-4)Ig (8) to block T-cell costimulation, a new generation of anti-T-cell mAbs that selectively inhibit the inflammatory subset of primed autoreactive effector T cells (9,10), and a number of therapies that alter the balance of the pathogenic and nonpathogenic T-cell responses. These accomplishments signal a quantum leap in our approaches to circumvent autoimmune destruction and graft rejection and now provide realistic opportunities for major advances in immunotherapy.

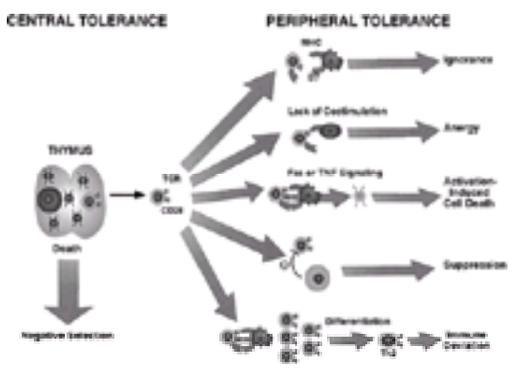

Figure 87.1. Mechanisms of T-cell tolerance. Lack of reactivity against self-antigens is thought to rely on a central mechanism of negative selection of highly self-reactive thymocytes. In addition, autoreactive peripheral T cells that may have escaped negative selection can be prevented from inducing autoimmunity by several known mechanisms: lack of attraction to the potential site of autoimmunity, killing or inactivation of reactive T cells, or induction of differentiation into cells with reduced cytotoxic potential.

Specific Immune Enhancement: a Goal for Cancer and Infectious Disease Therapies

In contrast to transplantation and autoimmune settings, infectious disease and tumor settings would benefit from specifically activating relevant T cells without stimulating bystander T cells that ultimately may give rise to lymphocyte malignancies or autoimmune disorders. Recent advances in gene therapy as well as in vaccination protocols to activate selectively tumor-specific T cells indicate that T-cell receptor (TCR) and costimulatory receptor signals are valid targets for T-cell activation as well. These approaches have combined our knowledge of the basic biologic processes that control immunization with the identification of novel or overexpressed normal proteins on infectious agents and tumor cells. Thus, the field of immune potentiation and therapeutic vaccinations provides a new means to combat these deadly diseases.

T-CELL RECEPTOR AND COSTIMULATORY MOLECULES: STRUCTURE AND FUNCTION

$CD4^+$ T cells play a major role in adaptive immune responses by recognizing specific antigens and subsequently providing help to different cell types eventually to eliminate the infectious agent or foreign antigen. A typical immune response begins when an antigen enters the body through the skin and migrates via lymphatic vessels to draining lymph nodes or penetrates through the gastrointestinal tract and migrates to the tonsils and Peyer patches. In some instances, the antigen enters the blood, where it is carried in the bloodstream to the spleen. The antigen is processed by specialized antigen-presenting cells (APCs) and presented on the cell surface in the context of major histocompatibility complex (MHC) class II molecules. The immune response is initiated when a small proportion of naive T cells, specific for a single antigenic peptide (as few as one in 10^5 or 10^6), expand in response to the antigenic peptide presented typically on macrophages or dendritic cells as APCs. The activated $CD4^+$ T cells interact with naive B cells that have soluble antigens bound by surface immunoglobulins, constituting the B-cell receptor (BCR). Signals delivered through the BCR induce changes on the surface of B cells that promote B-cell differentiation. Cell surface molecules, such as the ligands for costimulatory receptors on T cells and the antigenic peptide–MHC complexes, are upregulated on the activated B cells. This promotes the reactivation and expansion of the antigen-specific T cells. As a consequence of this activation, T cells secrete cytokines that promote B-cell proliferation, differentiation, and immunoglobulin isotype switching. Thus, the most potent immune responses combine optimal specific presentation of antigen and maximal expression of costimulatory ligands and receptors, further promoting B- and T-cell activation and differentiation into effector lymphocytes. As importantly, T-helper (Th) cells support the differentiation of cytotoxic T cells and natural killer (NK) cells.

Naive $CD4^+$ (often referred to as helper T cells, or Th cells) and $CD8^+$ T cells (also called *cytotoxic* T cells, or Tc cells) differentiate following activation into phenotypically different subsets. Th1 and Tc1 cells produce interleukin-1 (IL-2), tumor necrosis factor-a (TNF-a), interferon-g (IFN-g) but no IL-4, whereas Th2 and Tc2 cells secrete IL-4, IL-5, IL-6, IL-10, but no IFN-g. Each subset affects immune responses differently by potentiating either proinflammatory (T1 subsets) or humoral/allergic (T2 subsets) responses. For instance, Th1-type cells facilitate B-cell differentiation and immunoglobulin isotype switching toward complement-fixing immunoglobulin isotypes that promote inflammation and cytotoxicity. In contrast, the production of IL-4 and IL-5 by Th2-type cells is critical for the development of allergic and asthmatic diseases through the recruitment of histamine-producing mast cells. Therefore, T-cell differentiation plays a critical role in the pathogenesis of autoimmune and allergic diseases. Thus, therapies aimed at interfering with differentiation could prove beneficial for the induction of tolerance and for immune enhancement.

T-Cell Receptor: Structure and Function

T-Cell Receptor

The TCR is constitutively expressed on the surface of T-lymphocytes and comprises two disulfide-linked chains, termed a and b, that specifically recognize antigenic peptides bound to MHC molecules on the surface of APCs. The TCR is noncovalently associated with a complex of transmembrane small-molecular-weight polypeptides collectively called *CD3 proteins* and designated CD3g, d, e, h, and z. The intracytoplasmic domains of the CD3 molecules are longer (about 40 amino acids) than those of the a and b chains (5 amino acids) and contain phosphorylation and immunoreceptor tyrosine-based activation (ITAM) motifs for the binding of intracellular signaling molecules. On TCR engagement, these motifs become phosphorylated by intracellular kinases such as *lck* and *fyn,* inducing the recruitment of the z-associated protein (ZAP-70). These events result in activation of the phospholipase Cg1 and lead to intracellular accumulation of Ca^{2+}, an event that triggers the activation of a number of Ca^{2+}-dependent enzymes. This series of biochemical steps is followed, in turn, by the activation and nuclear translocation of transcription factors, resulting in the production of the multiple proteins expressed by activated cells. Depending on the subset of T cells as well as the stage of differentiation, these activation markers can be adhesion molecules and homing receptors necessary for trafficking, cytokines important for autocrine or paracrine functions, cytolytic enzymes that destroy cells expressing antigens recognized as foreign, and so on. Although an individual organism maintains a large diversity of TCRs, TCR molecules are in general of one species with specificity for a single ligand in each individual T cell (11).

STIMULATION BY ALTERED PEPTIDE LIGANDS

T-cell receptors recognize peptides 8 to 15 amino acids long bound to MHC class I or class II molecules. T cells can respond to variants of the same antigenic peptide by generating different effector functions, ranging from the secretion of cytokines in the absence of proliferation to altered differentiation. Recent data indicate that the different strengths of signal delivered by individual peptides can affect T-cell differentiation toward Th1 versus Th2 T cells (12,13). Under some circumstances, modifications of a peptide resulting in suboptimal interactions of the TCR with the peptide–MHC complex can lead to partial T-cell signaling, resulting in T-cell inactivation. These variant peptides, which are capable of interacting with the same TCR but lead to different phenotypic T-cell outcomes, have been termed *altered peptide ligands* (14). Biochemically, this is reflected by modified activation cascades compared with agonistic antibodies, such as partial phosphorylation of the CD3z chain, diminished Ca^{2+} flux, and reduced activation of certain kinase pathways.

Costimulatory Molecules

Ligation of the TCR, along with either the CD4 or CD8 coreceptors, by MHC molecules containing antigenic peptide is the first essential step for T-cell activation. TCR engagement is not sufficient, however, to mount a full immune response. An additional signal provided by a costimulatory receptor is also required. In fact, *in vitro* studies using human and murine T-cell clones showed that ligation of the TCR in the absence of costimulation can lead to a long-lasting state of T-cell unresponsiveness termed *clonal anergy* (15) (Fig. 87.2). On restimulation, anergic T cells are unable to secrete IL-2, the principal T-cell growth factor, even when TCR restimulation is performed in the presence of costimulatory molecules.

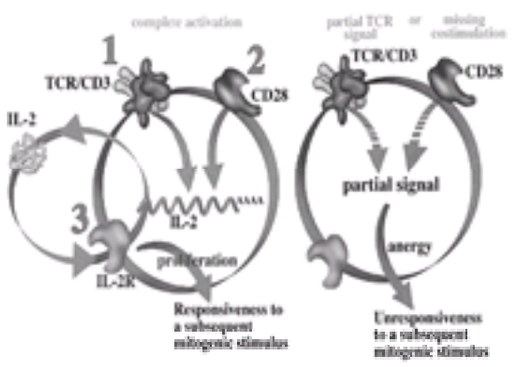

Figure 87.2. T-cell activation signals. T cells require at least two signals for complete activation. Signals delivered through the TCR (signal 1) and through a costimulatory receptor such as CD28 (signal 2) result in interleukin-2 (IL-2) production, upregulation of the IL-2R allowing IL-2 to act as an autocrine growth factor, and proliferation. In addition, T cells activated in this manner are susceptible to subsequent restimulation. In contrast, T cells receiving a partial signal through their TCR in the presence of costimulation or a complete TCR signal in the absence of costimulation become unresponsive to subsequent restimulation, a state that has been termed anergy in T-cell clones.

CD28/CTLA-4/B7 Pathway

A well-characterized costimulatory receptor on T cells is CD28 (16). CD28 is a homodimeric 44-kd glycoprotein constitutively expressed on virtually all murine T cells, all $CD4^+$ human T cells, 50% of $CD8^+$ human T cells, developing thymocytes, and plasmocytes. Signaling through CD28 in the presence of suboptimal TCR stimulation enhances T-lymphocyte proliferation as well as the production of multiple cytokines, including IL-2, TNF-a, granulocyte macrophage–colony-stimulating factor (GM-CSF), and IFN-g, as a consequence of both increased transcription and stabilization of cytokine mRNA. In addition, costimulation through the CD28 molecule also serves to improve T-cell survival, through the increased secretion of IL-2 and the upregulation of Bcl-x_L, a member of the Bcl-2 family of antiapoptotic genes. CD28 signaling appears to also favor differentiation of T cells into an IL-4-producing phenotype (17,18). T cells from mice made genetically deficient in CD28 by homologous recombination have reduced cytokine production and proliferation *in vitro* in response to various stimulators. Moreover, these mice have a significant defect in developing T-cell-dependent antibody responses. Some *in vivo* responses are well preserved in these mice, however, including the successful elimination of certain viruses and the ability to reject skin allografts (19,20) and heart allografts (21). These results suggest that either certain cells can respond in the absence of effective costimulation (specifically certain $CD8^+$ T cells) (22) or additional costimulatory molecules can compensate the lack of CD28.

CD28 has been shown to bind two ligands, B7-1 and B7-2 (also called CD80 and CD86, respectively), on APCs. CD80 is expressed on activated B cells and

monocytes as well as on dendritic cells and Langerhans cells. CD80 is upregulated on B cells on MHC class II engagement, and expression is enhanced further by the addition of exogenous IL-2 and IL-4. CD86 is 25% homologous with CD80 and is expressed on resting monocytes, dendritic cells, T cells, and activated NK cells, B cells, and other APCs. Both CD80 and CD86 are expressed on activated T cells, but the role of these molecules on T cells remains elusive. Mice deficient in B7-1, B7-2, or both have been generated. Mice lacking both B7 family members fail to form germinal centers and have immunoglobulin G1 (IgG1) and IgG2a responses, but humoral responses are more severely affected by lack of B7-2 than by lack of B7-1 (23).

Cytotoxic T-lymphocyte A4 is a 30- to 40-kd glycosylated protein that shares about 50% homology with CD28 and also binds CD80 and CD86 on APCs, although with higher affinity than CD28 (16). Unlike CD28, however, CTLA-4 is expressed on T cells only following T-cell activation and may serve to downregulate T-cell responses. Indeed, antibodies that block the binding of CTLA-4 to its ligands induce an increase in T-cell proliferation and cytokine production*in vitro*. *In vivo*, blocking mAbs increase antitumor immune responses, accelerate the onset of autoimmune diseases such as diabetes mellitus or experimental allergic encephalomyelitis, augment responses to pathogens, and accelerate cardiac allograft rejection in experimental murine models (21,24,25,26 and 27). Conversely, cross-linking of CTLA-4 reduces cytokine production and arrests T cells in the G1 phase of the cell cycle (28,29). CTLA-4-deficient mice develop a lymphoproliferative disorder and die a few weeks after birth, supporting a role of CTLA-4 in maintaining T-cell homeostasis (30,31). In addition, lack of CTLA-4 appears to promote Th2 differentiation in a CD28-dependent manner (32,33), and CTLA-4 cross-linking favors Th1 differentiation (34).

Therefore, T-cell activation depends on a subtle balance between costimulation through the constitutively expressed CD28 receptor and downregulation of the response by the inducibly expressed CTLA-4 glycoprotein. Thus, CTLA-4 may serve as a negative feedback mechanism to prevent perpetuation of T-cell activation once a productive immune response has occurred.

INDUCIBLE CO-STIMULATOR (ICOS) PROTEIN

ICOS is a novel costimulatory molecule that is expressed on T cells as a 55- to 60-kd homodimer about 20% that is homologous to CD28. Unlike CD28, ICOS is not present on naive T cells but is upregulated following T-cell activation and is retained in memory T cells. Cross-linking of ICOS results in enhanced T-cell proliferation, expression of adhesion molecules, and B-cell help. Ligation of ICOS, however, appears to augment production of IL-10 rather than IL-2. The ligand for ICOS was identified and termed *LICOS* (35). A ligand for the mouse homolog of the human ICOS also was found and termed **BB7RP-1** or *B7h*. B7RP-1 is expressed on B cells and macrophages (36). Its expression is induced by TNF-a, perhaps as a mechanism to increase antigen recognition during inflammation (37). Mice previously sensitized to the antigen oxazolone and treated with an agonist fusion molecule B7RP-1-Fc during antigen challenge display enhanced contact hyperreactivity compared with controls (36). Because of the recent discovery of the ICOS molecule, no data are yet available on the effects of ICOS blockade or cross-linking in experimental models of disease. Because of its potent effects *in vitro*, ICOS also may prove a useful target for immunomodulation *in vivo*.

Another distant member of the B7 family of molecules was discovered. B7-H1 is only 20% homologous to CD80 and CD86 and does not bind CD28, CTLA-4, or ICOS. Ligation of B7-H1 to a receptor on T cells results in increased T-cell proliferation and preferential induction of IL-10 production (38).

THE TNF/TNF RECEPTOR (TNFR) FAMILY OF COSTIMULATORY MOLECULES

The TNF/TNFR-related proteins are a growing family of molecules that include a number of costimulatory molecules, CD40L, CD30, 4-1BB, OX40, LIGHT, and TNF-related activation-induced cytokine (TRANCE). These are all expressed on activated T cells and, in some cases, have dual roles because they can enhance TCR-dependent proliferation but also trigger T-cell death under some circumstances. The ability to induce apoptosis or proliferation depends on the cell type, the stage of differentiation or activation, the transformation status, and the presence of other stimuli. Because T cells express both TNF-like and TNFR-like molecules, T-lymphocytes potentially can undergo autocrine costimulation or fratricidal programmed cell death. CD30 and CD40 lack the death domains present in the cytoplasmic tails of TNFR1 and Fas that are necessary for the latter molecules to promote apoptosis. The mechanism by which CD30 and CD40 mediate cell death is not clear but may depend in some cases on the production of TNF and subsequent signaling through the TNFR1 receptor (39).

CD40/CD40 Ligand (CD40L) Pathway

CD40, a 50-kd glycoprotein, is a member of the TNFR superfamily. It is expressed on APCs such as B cells, macrophages, and dendritic cells. CD40L (gp39, CD154), a member of the TNF superfamily, is expressed on activated T cells, mast cells, eosinophils, dendritic cells, activated platelets, and endothelial cells (40). CD40 is an important costimulatory molecule for B cells, the ligation of which promotes antibody production and proliferation. Importantly, cross-linking of CD40 also induces B7 on dendritic cells, macrophages, and B cells, therefore also increasing costimulation of T cells via CD28 binding. Recent data, however, indicate that CD40L cross-linking on human T cells can costimulate T cells directly in a CD28-independent manner and results in increased secretion of TNF-a, IFN-g, and IL-10, but not of IL-2, but also increased T cell death (41). Signaling through CD40 using agonistic antibodies has been shown to activate APCs, rendering them capable of directly costimulating $CD8^+$ cytolytic cells, bypassing the requirement for help by $CD4^+$ cells (42,43 and 44). Signals delivered through CD40 lead to activation of the transcription factor NF-kB, the accumulation of antiapoptotic molecules such as Bcl-x_L, and the production of IL-12 by dendritic cells. Mice deficient in CD40 or CD40L lack IgG, IgA, and IgE antibody responses and germinal center formation, underlining the importance of CD40L costimulation on T cells for the generation of B-cell help (45). CD40L on T cells is also necessary for priming of mice with antigen *in vivo* (46). In addition, B cells deprived of CD40 signaling appear to induce T-cell tolerance rather than priming (47). In humans, lack of CD40L on T cells results in a hyper-IgM syndrome, a human immunodeficiency associated with severely impaired humoral responses.

CD30/CD30L

CD30 was initially identified as a surface marker for neoplastic cells of Hodgkin lymphoma. Later, CD30 was found to be expressed on activated $CD4^+$ and $CD8^+$ T cells, and levels of expression were maximum if TCR stimulation was delivered in association with CD28 and IL-4 signals (48), resulting in preferential expression of CD30 on Th2-type cells (49). CD30 cross-linking induces activation of TNF receptor-associated factors (TRAF) TRAF1, TRAF2, and TRAF5 and results in activation of the transcription factor NF-kB (50). CD30 has both positive and negative roles on T-cell responses. Cross-linking of CD30 during TCR stimulation induces upregulation of IL-5, suggesting that CD30 may play a role in the pattern of cytokines produced in an immune response (49). In contrast, CD30-deficient mice display impaired negative selection (51), and CD30 overexpression enhances programmed cell death in the thymus (52), indicating that the CD30 receptor influences cell death signaling. Similarly, blockade of CD30 appears to reduce apoptosis of peripheral $CD8^+$ T cells induced by withdrawal of a TCR stimulus (53). CD30L (mCD153) is expressed on naive and activated B cells, on eosinophils, and on transiently on activated T cells. CD30L stimulates B-cell proliferation and antigen-specific antibody production in a CD40-independent manner (55).

4-1BB (CD137)/4-1BBL

4-1BB is a 39-kd glycoprotein induced on the surface of $CD4^+$ and $CD8^+$ T cells following TCR stimulation. 4-1BB is also found constitutively on monocytes, whereas 4-1BBL is expressed on activated APCs. Cross-linking of 4-1BB augments TCR-driven T-cell proliferation and cytokine secretion (56), and it increases production of IL-8 and TNF-a, but it inhibits IL-10 expression by monocytes (57). Despite being expressed on all activated T cells, 4-1BB signaling may preferentially affect $CD8^+$ T cells inasmuch as 4-1BB-deficient mice exhibit reduced antiviral $CD8^+$ T-cell responses to lymphocytic choriomeningitis virus (LCMV); $CD4^+$ T cells appear minimally affected (58). In addition, cross-linking 4-1BB *in vivo* prevents deletion of a higher proportion of $CD8^+$ than of $CD4^+$ T cells following staphylococcal enterotoxin A injection, presumably by promoting survival of $CD8^+$ T cells (59). Experiments performed using CD28-deficient mice indicate a role for 4-1BB in potentiating suboptimal CTL responses *in vivo* and *in vitro* in a CD28-independent manner (60). Finally, 4-1BB appears preferentially expressed on Tc2 rather than Tc1 cells following differentiation *in vitro*, and cross-linking antibodies on $CD8^+$ T cells result in upregulation of IL-4 by Tc2 but not IL-2 or IFN-g by Tc1 (61). Data indicate, however, that *in vivo* blockade of 4-1BB results in $CD4^+$ T-cell anergy, leading to abrogation of T-dependent humoral responses and that this event occurs in the absence of $CD8^+$ T cells (62). Like other TNFR family members, 4-1BB activates TRAF2 and results in activation of NF-kB. In addition, some costimulatory properties of 4-1BB, such as enhancement of IL-2 production by T cells, appear to be absolutely dependent on TRAF-2 activation because they do not occur in T cells from TRAF-2-deficient mice or mice transgenic for a dominant negative form of TRAF-2 (63).

Other TNF/TNFR Family Members

Other members from the TNF/TNFR family of molecules also exert costimulatory functions in T cells.

OX40 (CD134), a TNFR family member, is expressed on activated T cells, whereas OX40L is induced on B cells stimulated through CD40 and the BCR and on CD40-activated dendritic cells. T cells from OX40-L-deficient mice display reduced recall responses postantigenic priming and impaired contact hypersensitivity responses (64,65). In OX40-deficient mice, $CD8^+$ T-cell responses appear normal, whereas $CD4^+$ T cells exhibit reduced proliferation and IFN-g production, suggesting that OX40 plays a predominant role in costimulation of $CD4^+$ T cells (66). In addition, OX40 ligation on $CD4^+$ T cells may favor, directly or indirectly, upregulation of CXCR5 expression and migration of T cells into B-cell zones to support germinal center formation (67).

CD27, a member of the TNFR superfamily, is expressed on most T cells, B cells, and NK cells, whereas its ligand CD70 is expressed on activated T and B cells. *In*

vitro, anti-CD27 mAb or CD70-transfected cells can augment T-cell proliferation and cytokine production induced by PMA, anti-CD3 mAbs, or anti-CD3 plus anti-CD28 mAbs (68,69).

Expressed on activated $CD4^+$ T cells, TRANCE interacts with receptor activator of NF-kB (RANK) apparently restricted to mature dendritic cells. TRANCE shares sequence homology with CD40L and seems to share some of the functions of CD40L. In fact, blockade of TRANCE in CD40-deficient mice led to severely impaired $CD4^+$ T-cell responses to LCMV following infection *in vivo*, but it had no effect in wild-type mice, suggesting that TRANCE may be an alternative pathway bypassing CD40L for T-cell activation (70). $TRANCE^{-/-}$ mice exhibit osteopetrosis because TRANCE also plays a role in osteoclast differentiation. The absence of TRANCE also results in partial blockade in T- and B-cell development, however, underlining a crucial role of this molecule in lymphopoiesis (71).

A member of the TNF superfamily, LIGHT was recently cloned in human and mouse mononuclear cells. LIGHT appears to have a strong, CD28-independent costimulatory effect on T cells, leading to increased proliferation and secretion of IFN-g and GM-CSF. Gene transfer of LIGHT into tumor cells has resulted in rejection of an otherwise progressively growing tumor in mice, whereas blockade of LIGHT promoted reduced graft-versus-host disease (GVHD). These results suggest that LIGHT could be an important therapeutic target in clinical settings (72).

RECEPTORS ON T-CELLS FOR SOLUBLE COSTIMULATORY FACTORS

Soluble cytokines can exert costimulatory functions via receptors expressed on T cells. These cytokines can be divided into two categories based on whether they regulate expansion or differentiation of T-lymphocytes, although some may have a dual function. As stated, following activation, T cells differentiate into specific phenotypes. Most prominent, especially in the mouse, are the type-1 cells that produce IL-2, TNF-a, and IFN-g and the type 2 cells that secrete IL-4, IL-5, IL-6, IL-10, and IL-13. Cytokines can directly regulate T-cell growth and expansion. IL-2 is the prominent growth factor for type-1 cells, and IL-4 is responsible for both T-cell expansion and differentiation of the type 2 phenotype. Other cytokines act indirectly (sometimes via the APCs) to influence T-cell differentiation. For instance, IL-12 and IL-18 strongly promote type 1 differentiation. Finally, cytokines can influence other cytokines to effect differentiation. IFN-g and IL-10 can cross-regulate each other to promote Th1 and Th2 development, respectively. Therefore, cytokine administration can greatly influence the differentiation and expansion state of individual T cells bearing the same TCR, thus, potentially influencing the outcome of the immune response in the clinical setting. For the purpose of this chapter, only those cytokines/cytokine receptors that have been targeted clinically for therapeutical purposes will be discussed.

IL-2/IL-2R

Interleukin-2 is the prototype of a cytokine playing a role in cell expansion. IL-2 is produced by naive T cells following TCR stimulation as well as by T cells differentiated along the type 1 pathway. IL-2 is used in an autocrine and paracrine manner to promote T-cell proliferation, but it is also a growth factor for B cells, NK cells, monocytes, macrophages, and oligodendrocytes. It binds the IL-2 receptor (IL-2R), expressed transiently on activation of T cells, B cells, monocytes, and macrophages. The IL-2R is a complex of three polypeptide chains. The a-chain (p55, CD25) and b-chain (p75, CD122) have a low affinity for IL-2. The third subunit (g chain, p64) does not bind IL-2 but allows the formation of heterotrimeric abg complexes with high affinity for IL-2. The g-chain is also a component of IL-4R, IL-7R, IL-9R, and IL-15R and therefore is often referred to as the *common* g-chain. Mutations in the g-chain are responsible for X-linked severe combined immunodeficiency (X-SCID) because the g-chain is located on the X chromosome. X-SCID is a lethal disease characterized by reduced numbers of T cells and greatly impaired immune responses. Binding of IL-2 to its receptor induces tyrosine phosphorylation of residues within the receptor that serve as docking sites for multimolecular signaling complexes. This initiates three major pathways: the Janus kinase (Jak-STAT) pathway controlling gene transcription, the Ras-MAPK pathway leading to cell proliferation and gene transcription, and the PI3-kinase pathway involved in survival and organization of the cytoskeleton (73). In addition, IL-2 also may increase the susceptibility of cycling T cells to cell death by upregulating proapoptotic genes (74). In fact, IL-2-deficient and IL-2Ra-deficient mice develop a lymphoproliferative disease, resulting in early lethality (75,76).

IL-4/IL-4R

Interleukin-4 is involved in promoting both T-cell expansion and T-cell differentiation toward an IL-4-producing type 2 phenotype. It is produced by T cells, $NK1.1^+$ T cells, and mast cells and exerts multiple effects on T cells, B cells, monocytes, endothelial cells, fibroblasts, neuroblasts, myocytes, and others. IL-4 also induces isotype switching in B cells, leading to production of IgG1 and IgE by mouse B cells and IgG4 and IgE by human B cells. IL-4R is composed of a high-affinity a-chain (p140, CD124), which determines the biochemical nature of the induced signals and of the common g-chain, which is required for the transduction of such signals. A soluble form of the receptor is produced by alternative splicing and acts as an IL-4 antagonist. IL-4-induced growth depends on tyrosine phosphorylation events on the a-chain of the receptor. IL-4-driven differentiation depends on a region of the a-chain of the IL-4R comprising STAT6-binding sites. Indeed, IL-4 signaling activates the transcription factor STAT6, and IL-4-deficient and STAT6-deficient mice have impaired generation of type 2 responses (77,78), but STAT6-deficient T cells retain the ability to proliferate to exogenous IL-4 (79).

IL-12/IL-12R

Interleukin-12 is a heterodimeric cytokine that is composed of two chains, p35 and p40. It is produced by dendritic cells, macrophages, and B cells, and it has been shown to induce IFN-g secretion by T cells and NK cells, to enhance T-cell proliferation, and to induce differentiation into type 1 T cells. IL-12 induces direct activation of the transcription factor STAT4 (78). The receptor for IL-12 found on NK cells and activated T cells comprises a b1 and a b2 subunit, and the latter appears to play a critical role in regulating IL-12 responsiveness. Recent evidence suggests that the IL-12R may be expressed on B cells (80). Costimulation via the CD28/B7 pathway promotes IL-2 and IL-12 production by T cells and APCs, respectively, which, in turn, induce expression of IL-12Rb2. In addition, IL-12 may directly or indirectly induce B7 expression by APCs (81). Consistent with the known functions of IL-12, T cells from IL-12-deficient mice have reduced IFN-g production and defective differentiation into a type 1 pathway (82).

IFN-a

Type I interferons, IFN-a and -b, constitute a family of inducible secreted cytokines that are known to promote differentiation of human T cells toward a type 1 phenotype. This does not occur in mouse T cells, however, because IFN-g signaling indirectly activates STAT4 in human but not mouse $CD4^+$ T cells (83). IFN-g signaling in human T cells induces upregulation of IL-12 receptor, increased IL-12 responsiveness, and subsequent secretion of IFN-g. In addition, IFN-a also induces amplification of $CD8^+$ T-cell-driven responses, resulting in more potent antiviral responses (84). IFN-a is produced by lymphocytes, monocytes, and macrophages, whereas its receptor is present on most cell types. The ubiquitous expression of the receptor and the numerous effects of type I IFNs on non-T cells make it difficult to determine whether the therapeutic consequences of IFN administration to animals or humans depend on its direct effects on T-cell differentiation or on the innate immune system.

IMPORTANCE OF TCR AND COSTIMULATORY SIGNALS *IN VIVO*

It is clear that TCR and costimulatory signals are important for the generation of immune responses *in vivo*. Despite activation of a common set of enzymes and transcription factors, each costimulatory receptor appears to have unique properties in experimental settings *in vivo*. A window into the role of the respective molecules is provided by the study of immune responses in specific gene knockout mice, as discussed previously. For example, CTLA-4-deficient mice develop a lymphoproliferative disorder; mice deficient in CD28, CD40, CD40L, and B7 all lack germinal center formation; CD30-deficient mice have impaired negative selection; and so on. The role of costimulatory receptors as therapeutic targets in different models of disease has been given particular attention in recent years.

Transplantation

Strong experimental evidence indicates that TCR and costimulatory signals are essential for transplant rejection. T cells are required for acute allograft rejection to occur because animals devoid of T cells retain grafts long over the long term. In transplantation settings, interactions between receptors on T cells and their ligands are complicated by the fact that TCRs may be stimulated either directly by MHC molecules on the graft or indirectly by alloantigenic peptides presented by the MHC expressed by the host APCs (Fig. 87.3). In addition, costimulation has the potential of being delivered either by the donor or host cells and either by the same APC that presents antigen or in trans by other donor or host APCs. Although these scenarios multiply the possible combinations of events that can lead to T-cell activation, it is largely assumed that $CD4^+$ T-cells receive both the TCR and costimulatory signals from the same APCs because professional APCs of the host and donor express both MHC class II and costimulatory ligands. Effector $CD8^+$ cells, in certain cases, may receive costimulation from a different source than that expressing antigen because many target cells that express MHC class I are devoid of specific ligands for costimulatory receptors on T cells. Furthermore, different donor tissues contain different sorts of APCs and may be more or less competent at providing T-cell costimulation. As pointed out already, $CD8^+$ T cells may not always require costimulation allowing for direct activation of this subset on costimulation-deficient APCs. Thus, the use of costimulatory blockade may have different outcomes in transplanted tissues, such as skin, that have an abundant number of Langerhans cells that express high levels of costimulatory ligands versus heart allografts that contain few, if any, APCs. Therefore, each organ may elicit T-cell responses in a different manner and require different a immunotherapy for tolerance induction. The availability of B7-1- and B7-2-deficient mice as well as of B7-double knockout mice enabled investigators to address the role of donor versus host costimulation for allogeneic T-cell responses in certain models. It appears that rejection of cardiac allografts depends on costimulation by host rather than donor B7 (85), whereas lack of B7 on host cells

or host and donor cells is not sufficient to prevent rejection of skin allografts (86). This suggests that costimulation of other receptors on T cells is important for skin rejection or that skin rejection is costimulation independent. In contrast, CD28-deficient mice are competent at rejecting cardiac allografts, albeit with slower kinetics that wild-type mice (21), suggesting that CD28-mediated co-stimulatory signals are dispensable under some circumstances in this graft setting.

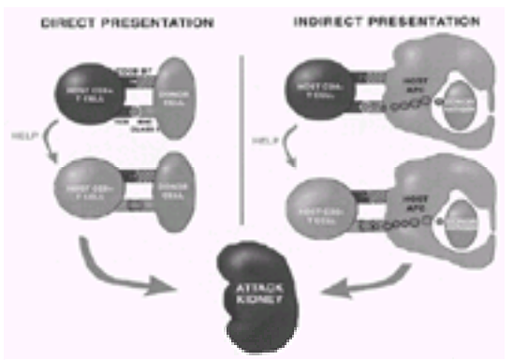

Figure 87.3. Antigen presentation in the context of allogeneic transplantation. Transplantation of allogeneic tissue introduces cells expressing foreign major histocompatibility complex (MHC) molecules to transplant hosts. Therefore, alloantigens are different from regular antigens in that they can be presented to $CD4^+$ and $CD8^+$ T cells either directly by the allogeneic MHC molecules present on graft cells or indirectly through representation of non-self peptides in the context of MHC molecules on host cells. Once activated, $CD4^+$ T cells can provide help to $CD8^+$ T cells and either subset can then directly or indirectly (via activation of other cell-types) mediate episodes of acute allograft rejection.

Autoimmune Diseases

New developments in understanding mechanisms of autoimmune diseases suggested novel immunotherapeutic approaches, such as the targeting of lymphocyte activation pathways and induction of lymphocyte anergy. New strategies are likely to affect immune regulatory pathways so that lasting tolerance rather than global immunosuppression can be achieved. Several lines of evidence implicate T cells in the pathogenesis of many autoimmune diseases. There is a striking correlation between disease progression and accumulation of $CD4^+$ T-helper cells and inflammatory cytokines in diseased tissues. Furthermore, genetic studies implicated the MHC class II complex. Multiple studies have shown that HLA-DRB*0401, *0404, *0101, and related subtypes are linked to certain autoimmune diseases, such as rheumatoid arthritis (RA) and type 1 diabetes. This association strengthened the concept that interactions between human leukocyte antigen (HLA)-DR molecules on APCs and TCRs regulate the disease process.

There is increasing evidence that costimulation plays a critical role in the development and progression of autoimmunity. A few studies showed increased expression of CD28 and CD80/CD86 in synovial fluid and tissue from patients with RA. Studies in animal models of arthritis, diabetes, multiple sclerosis (MS), and other autoimmune disorders provide strong evidence for the role of CD28 and CD40L in autoimmunity. For instance, experimental acute encephalomyelitis (EAE) is a rodent model for MS, where animals display brain infiltrates and limb paralysis following immunization with myelin-derived proteins. The CD28/B7 pathway appears to be important both for the induction and the effector phase of the disease. Mice deficient in CD28 or B7 molecules exhibit reduced disease severity than wild-type controls, and adoptive transfer of encephalitogenic T cells results in milder disease in B7-deficient than wild-type hosts (87). Similarly, MRL/lpr mice constitute a spontaneous model of lupus, in which mice develop lymphoproliferation, circulating auto-antibodies, and glomerulonephritis. The disease is also less severe in MRL/lpr mice deficient in CD28 molecules (88). Unexpectedly, deficiency in CD28 seems to accelerate and exacerbate spontaneous autoimmune diabetes in nonobese diabetic (NOD) mice (89). Why this particular autoimmune disease is accelerated whereas others are attenuated in CD28-deficient mice remains unclear but may reflect changes in the Th1/Th2 balance or development of regulatory T cells. In any case, these unexpected findings underscore the importance and complexity of the CD28/CTLA-4/B7 pathway in autoimmunity. Similar observations have been made for other costimulatory pathways. Mice transgenic for a TCR-specific for myelin basic protein (MBP) failed to develop EAE following immunization if their T cells were genetically deficient in CD40L. CD40L-deficient T cells could be induced to secrete cytokines following MBP challenge if stimulated with B7-expressing APCs, suggesting that reduced disease may result, at least in part, from the absence of CD40 signals on APCs, leading to subsequent defect in B7 upregulation (90).

A line of evidence in support of a critical role of costimulation in autoimmunity is the genetic association between certain costimulatory alleles and autoimmunity. In the NOD mouse, a diabetes susceptibility locus has been found on chromosome 1 within a region encompassing ICUS, CTLA-4 and CD28 (IDDM5), and Colucci et al. found that there is defective expression of CD28 and CTLA-4 in these mice (91). An association between polymorphisms in the CTLA-4 gene and a number of autoimmune diseases has been observed in humans (92,93,94,95 and 96). The role of CTLA-4 in controlling T-cell responsiveness makes this locus an interesting candidate gene for disease susceptibility.

Cancer and Infectious Diseases

T cells are essential for initiating or mediating tumor rejection, as most tumor cell-lines can form tumors when injected into mice that lack T cells genetically, or that have been T cell-depleted before the injection of tumor cells. In addition, chronic immunosuppression, such as that experienced by human immunodeficiency virus (HIV) patients or by patients treated long-term with immunosuppressive drugs, leads to an increased incidence of tumors, usually of viral origin. Numerous different tumor antigens have been identified that can be recognized by T cells. These antigens can be divided predominantly into three categories. The first group is composed of antigens that are not expressed in normal tissues and are therefore truly tumor specific. This is the case for the family of mitogen-activated protein (MAGE) antigens, for example, expressed in melanoma cells but not in normal cells with the exception of testis, where it is likely to be expressed exclusively in germline cells that are devoid of MHC class I and cannot present the neoantigen. The second group consists of antigens that are normally expressed in embryonic or differentiating tissues but are downregulated following maturation. An example of this is the carcinoembryonic antigen (CEA) protein produced by colon cancers. The third group comprises antigens that are expressed in normal cells but that are mutated (p53) or overexpressed (tyrosinase) in cancer cells. T cells have been shown to recognize and be activated by peptides belonging to each of these subclasses of tumor antigens. Even though T cells can react with these tumors, cancers still arise in many instances in otherwise immunocompetent patients. This may occur because of deletion or inactivation of tumor-specific T cells or because some tumor antigens do not get effectively presented to T cells. At least one example exists in mice, where the presence of an antigen expressed by tumor cells induces unresponsiveness of specific T cells, leading to cancer growth (97). Lack of costimulatory molecules on tumor cells may be a factor promoting a form of anergy of tumor-specific T cells. Indeed, costimulation appears to be important for tumor rejection. Using mouse models in which injected tumor cells can form tumors only in a subset of the animals, rejection, when it naturally occurs, depends on B7 molecules expressed by host APCs (98,99). This result confirms the importance of the CD28 pathway in normal tumor rejection.

Infectious Diseases

Antibody and CTL responses have critical roles in eliminating many pathogen infections. The important role of costimulatory signals in this setting has been increasingly realized. The absence of optimal CD28/B7, CD40L/CD40, and even 4-1BB interactions profoundly reduce generation of virus and other pathogen-specific immunity (100,101 and 102). Together, these results suggest therapeutic opportunities wherein tumor or infectious pathogen immunity might be enhanced in patients by promoting more effective T-cell costimulation in the context of immunogenic peptides. In fact, the immunologic benefit of coexpression of costimulatory molecules such as B7 or CD40 with target antigen has been exploited in a variety of vaccination protocols. In some systems, retroviruses have been used to transfect costimulatory molecules into antigen-bearing cells. In others, both the antigen and costimulatory molecules have been admixed to achieve high levels of cell surface expression. These approaches led to the increased efficacy of vaccination protocols in animal models. At present, several recombinant poxvirus, retrovirus and adenovirus vectors are currently being evaluated to induce antigen-specific immunity to a variety of infectious disease agents. This new threshold of T-cell activation has broad implications in vaccine design and development.

THERAPEUTIC APPROACHES TARGETING THE TCR

Immunotherapies that block TCR or costimulatory signals or that eliminate T cells usually result in immunosuppression and are used in settings of autoimmune diseases and transplantation where inactivation of T cells is warranted. Other treatments result in potentiation of TCR or costimulatory signals and are sought after for treatment of various cancers or infectious diseases in which activation of antigen-specific T cells is desired. Strategies that target TCR and costimulatory molecules for immunosuppression or immune enhancement are reviewed in the following.

Immunosuppressive Therapies

Antigen/MHC complex binding to the TCR/CD3 complex initiates a cascade of signaling events, beginning with the activation of several cytoplasmic protein tyrosine kinases. Recruitment of the CD4 (or CD8) coreceptor and its associated tyrosine kinase, lck, into the vicinity of the TCR complex is believed to induce phosphorylation

of CD3 proteins, ultimately leading to downstream signal progression. *In vitro* studies suggest that interruption of this signaling pathway at a number of points may lead to tolerance. Thus, mAbs directed at the TCR, altered TCR ligands, and MHC-derived peptides present novel approaches to tolerance induction that are ready to be applied clinically.

ANTI-CD3 AND ANTI-TCR MONOCLONAL ANTIBODIES

Antibodies directed at CD3 have been used since the early 1980s in human transplantation and have proven to be extremely potent immunosuppressive agents. The original mouse IgG2a antihuman CD3 mAb, OKT3, is still used to revert corticosteroid-resistant rejection episodes in the clinic, but it suffers from a high rate of "rebound" rejection when treatment is stopped (103). Several mechanisms lead to immunosuppression following anti-CD3 mAb injection. Antibody treatment induces rapid internalization of the TCR, thereby preventing subsequent recognition of antigen. In addition, administration of the mAb is rapidly followed by depletion of most T cells from the bloodstream and the peripheral lymphoid organs, such as lymph nodes and spleen. This absence of detectable T cells from the usual lymphoid regions is secondary in part to cell death following complement activation and activation-induced cell death but also to margination of T cells onto vascular endothelial walls and redistribution of T cells to nonlymphoid organs, such as the lung. Finally, anti-CD3 mAb also induces a downregulation of the function of nondepleted T cells, as defined by lack of IL-2 production and a great reduction in the production of multiple cytokines, perhaps with the exception of IL-4 and IL-10. Several problems have limited the usefulness of this mAb in transplantation and prevented the widening of its use to the treatment of autoimmune diseases. First, whereas OKT3 therapy promotes long-term graft survival, there is no evidence of clinical tolerance induction. In fact, patients often suffer from high rate of "rebound" rejection when treatment is stopped. Second, before inducing immunosuppression, anti-CD3 mAb administration results in the production of multiple cytokines, including GM-CSF, TNF-a, IL-2, IL-3, IL-4, IL-6, IL-10, IFN-g, resulting in side effects designated as first-dose reactions. Symptoms range from moderate to extremely serious and consist of high fever, headaches, nausea, vomiting, diarrhea, pulmonary edema, seizures, and coma and are due to the direct toxicity of these cytokines. Usually, only the first administration of anti-CD3 mAb induces these side effects because the TCR becomes internalized after the initial dose and is not susceptible subsequently to stimulation by the mAb. Experiments in mice using a model anti-CD3 mAb, 145-2C11, revealed that high doses of corticosteroids prevent the initial release of cytokines and reduce first-dose reactions considerably (104,105). Administration of corticosteroids prior to the injection of OKT3 is now a standard procedure in the clinic and has improved tolerance to the drug (106). Fc receptor (FcR) binding by the Fc portion of anti-CD3 mAb appears to be the cause for the initial activating properties of this agent (107). Finally, the third drawback to repeated use of the mAb is the occurrence of immunization against the mouse determinants of the antibody, which can neutralize OKT3 and prevent its immunosuppressive efficacy. Recently, genetically altered anti-CD3 mAbs were developed that are humanized to minimize the occurrence of anti-mAb antibody responses and mutated to prevent binding to FcRs (108). An analog of these humanized anti-CD3 mAbs, the chimeric antimouse CD3 mAb 2C11-IgG3, was generated by fusing the variable region of a hamster antimouse CD3 with the constant region of mouse IgG3 Fc that has intrinsic low affinity for FcRs. This new generation of anti-CD3 mAb induces selective immunomodulation in the absence of toxicity associated with conventional anti-CD3 mAb therapy (109). FcR nonbinding anti-CD3 mAbs have short-lived effects on naive T cells but deliver a partial signal in activated T cells, resulting in clonal inactivation of Th1 cells and proliferation/cytokine production by Th2 cells (110). These selective effects make these new agents particularly useful for targeting the imbalance of autoreactive Th1 cells and immunoregulatory T cells that favors certain autoimmune diseases and allograft rejection. 2C11-IgG3 also was evaluated in transplantation tolerance induction models (107,109); a short course of the mAb not only results in long-term graft survival but allows a second genetically identical graft, placed at a later date, to survive without additional therapy. Interestingly, CsA inhibits the ability of a second genetically identical graft to survive without rejection (J. Bluestone, unpublished observation), supporting the hypothesis that, although calcineurin inhibitors may have an additive immunosuppressive effect in combination with nonactivating anti-CD3 therapy, they can inhibit tolerance induction by the low FcR affinity anti-CD3 mAb. Further studies in the autoimmune disease setting have shown that short-term treatment with anti-CD3 mAb restores peripheral self-tolerance to b-cell-associated autoantigens in overtly diabetic NOD mice when applied within 7 days of the onset of diabetes (10). Moreover, unlike untreated diabetic NOD mice, these animals do not destroy syngeneic islet grafts. In an initial clinical trial, the humanized FcR nonbinding anti-CD3 mAb reversed acute renal allograft rejection in the absence of first-dose cytokine release syndrome (111). In addition, initial results from two other clinical trials are showing absence of side effects in new-onset type 1 diabetes patients (K. Herold and J. Bluestone, unpublished observations) as well as in patients with psoriatic arthritis (M. Clark and J. Bluestone, unpublished observations). Clinical efficacy of the drug in these autoimmune settings is being evaluated. Other nonmitogenic anti-CD3 mAbs also were generated. BC3 is a mouse antihuman CD3 IgG2b that has been used to treat acute GVHD in 14 patients, resulting in improvement of GVHD symptoms in most patients with minimal acute toxicity (112). Monovalent anti-CD3 mAb has been used in renal transplant patients as another means of preventing TCR cross-linking and cytokine release (113). Finally, a humanized rat antihuman CD3 in which the cytoplasmic tail was mutated to prevent glycosylation, thereby also preventing FcR binding, has shown promising results in the treatment of acute renal allograft rejection, leading to few side effects while retaining immunosuppressive properties (114).

In addition to anti-CD3 mAbs, anti-TCR mAbs have also been used in clinical trials to induce global immunosuppression in solid organ and bone marrow transplantation settings. These include T10B9, a mouse IgM, and BMA031, a mouse IgG2b (Fig. 87.4). Both these mAbs are less mitogenic than OKT3, resulting in somewhat reduced side effects, while still inducing potent lymphopenia and immunosuppression. Clinical efficacy in preventing allograft rejection was similar or slightly reduced compared with OKT3, and the incidence of immunosuppression-related infections was also comparable (115,116,117 and 118).

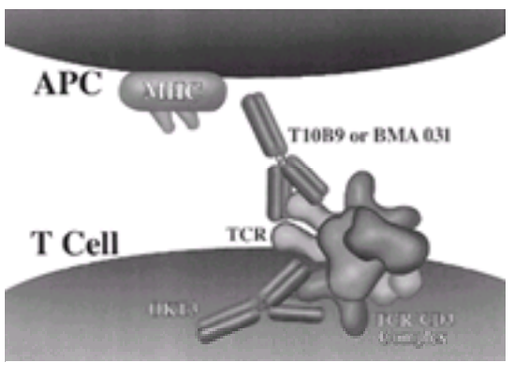

Figure 87.4. Antibodies directed to the T-cell receptor (TCR)/CD3 complex. Several monoclonal antibodies (mAbs) have been generated that recognize either the TCR or the CD3 complex of T cells. Binding of the mAbs to the TCR/CD3 complex results in TCR internalization, complement-mediated deletion of a subset of T cells, and, in some cases, inactivation of residual T cells, possibly because of the lack of simultaneous costimulation. Because all T cells constitutively express TCR and CD3 molecules, these mAbs lead to global immunosuppression.

ANTIGEN-BASED THERAPIES

Research that involves experimental therapies aimed at inducing tolerance is shifting from a global T-cell immunosuppression approach to more limited targeting of antigen-specific T cells. Therefore, attempts are being made to administer whole proteins or peptides recognized by defined TCRs in a manner that results in specific T-cell tolerance. For example, in transplantation settings, peptides derived from the donor MHC can activate T cells via the "indirect" pathway. In multiple sclerosis in humans and EAE in rodents, peptides derived from MBP and proteolipid protein can induce disease when administered in adjuvant. Different modes of administration of antigens or peptides have been used over the past years to induce tolerance rather than full activation of T cells. These include intrathymic injection of antigen or antigen-containing cells, systemic injection of soluble antigen, administration of altered peptide ligands, and oral or nasal administration of antigen. Moreover, these techniques can be combined to induce tolerance because, for example, altered peptide ligands can be administered orally. In each case, the mechanism of tolerance may be different and is described subsequently.

Intrathymic Injection of Antigen

Negative selection is a central mechanism of tolerance whereby thymocytes encountering high affinity antigen in the thymus are deleted, thus avoiding autoimmunity. Therefore, intra-thymic injection of antigen as a means of inducing deletion of antigen-specific T cells has been attempted in multiple experimental models of transplantation and autoimmune diseases. For example, intra-thymic injection of pancreatic islets in combination with depletion of $CD4^+$ T cells in mice has been shown to induce donor-specific tolerance to alloantigen by inducing clonal deletion of thymocytes directly recognizing alloantigen (119). Similarly, intrathymic injection of peptides derived from allogeneic MHC class I in combination with T-cell depletion of the recipient rats with antilymphocyte serum led to permanent acceptance of allogeneic islets. In contrast, animals treated with antilymphocyte serum, alone or in combination with intravenous injection of the peptide, did not become tolerant to the transplant (120). Tolerance following intrathymic administration of antigens appears to result both from depletion of antigen-specific thymocytes as well as from reduced IL-2 production by the remaining mature antigen-specific T cells (121). In addition, induction but not maintenance of tolerance may depend on CTLA-4 signaling because injection of anti-CTLA-4 mAb shortly after priming prevented induction of tolerance by intrathymic injection of MBP in a mouse EAE model (122). These data suggest that intrathymic injection of known antigens may have clinical applications for tolerance induction in transplantation and autoimmune settings. Thymus involutes rapidly in adulthood in humans, and whether enough tissue remains to allow for maturation of new thymocytes in the presence of the injected antigen remains a matter of debate.

Systemic Administration of Antigen

The milieu in which TCR encounters antigen appears to affect subsequent immune responses to that antigen. Thus, the route and context of antigen exposure (i.e., soluble antigen versus antigen emulsified with adjuvant, subcutaneous versus intravenous injection, or peptide fragments versus whole protein) can greatly alter the immune response. Indeed, the route of antigen administration affects the type of cells that will bind the peptide or process the antigen for presentation to T cells as well as the environment where this happens. In addition, the presence of adjuvant may induce the production of IL-12 by APCs, upregulation of costimulatory molecules or other inflammatory events, resulting in full activation rather than tolerization of T cells. As an example, skin from transgenic mice expressing galactosamine as a transgene is rejected rapidly by syngeneic recipients presensitized with galactosamine in an adjuvant solution. In contrast, recipients became tolerant to the skin transplant when galactosamine was injected intravenously in a soluble form (123). Peripheral tolerance achieved following intravenous injection of antigen depends on depletion of antigen-specific T cells and anergy because remaining T cells have reduced cytokine production on restimulation. Tolerance induced by the injection of peptides is short-lived, however, even if the emigration of new T cells is precluded by thymectomizing the tolerant mice. Reversal of tolerance probably occurs because of the limited half-life of soluble peptides, but it can be maintained with repeated peptide injections (124). Similar results have been obtained in humans. Intravenous but not subcutaneous or intrathecal injection of a synthetic immunodominant MBP peptide to patients with MS resulted in tolerance to MBP as assessed by undetectable levels of MBP autoantibodies in the serum of patients. Although a single injection of peptide reduced MBP autoantibodies for 3 months, effects lasted longer than 1 year in most patients who received two injections (125). Similarly, intravenous injection of MP4, a fusion molecule between human MBP and the extracellular domain of proteolipid protein (PLP) has been shown to prevent or ablate established EAE in mouse and primate models (126). Thus, the use of intravenous peptide administration has emerged as a potentially important therapeutic opportunity, with multiple clinical trials initiated at this time.

Administration of Altered Peptide Ligands

As stated above, ligation of a TCR by different variants of a single peptide can result in distinct T cell responses ranging from clonal anergy to Th1/Th2 skewing, to full activation. Peptides derived from human papilloma virus and from *Bacillus subtilis* contain a motif also found in a major antigenic peptide of MBP and function as altered peptide ligands on T cells specific for MBP. Recently, it has been shown that injection of these peptides prevented onset of EAE by MBP immunization in rodents and induced IL-4-producing suppressor T cells capable of preventing EAE induction (127). Similarly, altered peptide ligands can be used to tolerize encephalitogenic T-cell clones *in vivo*, thus preventing T-cell infiltration in the CNS and paralysis of the mice. This effect is dependent on IL-4 production. (128).

An example of administration of a peptide in humans that can downregulate autoimmunity is that of Copolymer 1 (Copaxone) for the treatment of MS. Copaxone is a synthetic copolymer that mimics MBP, but instead of being encephalitogenic, it causes suppression of MBP-induced EAE. Copaxone binds MHC class II HLA-DR molecules and can serve as an antagonist of the 82-100 epitope of MBP. It is thought to function as an altered peptide ligand, resulting in differentiation of MBP-reactive T cells into a less aggressive phenotype, or inducing regulatory T cells that suppress MBP-dependent inflammatory responses. In animals, Copaxone induces suppressor T cells that can transfer tolerance into naive hosts protecting against induction of EAE. Copaxone-specific T cells secrete IL-4, but no IFN-g in response to MBP, whereas they can secrete IFN-g in response to Copaxone itself. Copaxone is routinely administered subcutaneously to patients with MS with few side effects. Patients receiving Copaxone were more likely than controls to be neurologically improved and have fewer relapses (129), suggesting that altered peptide ligands may be useful in clinical settings.

Oral or Nasal Tolerance

A well-recognized approach to the induction of antigen-specific tolerance is the mucosal (oral or nasal) administration of antigens or peptides. Oral tolerance can be achieved following feeding of either low or high doses of antigen, through an effect on gut-associated lymphoid tissue such as Peyer patches. Low-dose oral tolerance appears to result from the induction of regulatory T cells that secrete antiinflammatory cytokines such as transforming growth factor-b (TGF-b), IL-4, and IL-10. High-dose oral tolerance is thought to depend on the deletion or anergy of antigen-reactive T cells.

Multiple antigens have been used successfully for the induction of oral tolerance in autoimmune diseases in small animals. The effects of these peptide/proteins in humans has had mixed results, however. The use of Copaxone for MS is an example of this therapy resulting in amelioration of a disease. Copaxone-specific T cells generated after oral administration of the polymer appear to suppress T cells reactive against MBP and also T cells responding to other myelin antigens, presumably via the secretion of inhibitory cytokines. Oral administration of Copaxone was associated with elevation of serum IL-10, TGF-a, and IL-4 as well as with the reduction of the proinflammatory cytokine TNF-a, suggesting a shift from a Th1 to a Th2-type responses in humans. Oral Copaxone-1 has been approved for the treatment of relapsing MS and has been shown to stabilize disease in 90% of patients as well as to reduce the annual rate of disease relapse. Whether the oral route of administration provides any added benefit beyond that noted due to its altered peptide ligand activity remains to be seen.

“Immunogenic” peptides and proteins have been tested orally in MS patients. These tests include oral administration of bovine myelin (130) or a combination of MBP and proteolipid protein (131). Initial phase 1 and 2 studies noted fewer relapses in treated groups compared with control groups. In addition, oral treatment with antigen promoted generation of antigen-specific TGF-b-producing T cells, suggesting a possible mechanism for suppression of inflammation of the target organs.

Type II collagen has been administered to patients with RA (132). Some efficacy was observed at the lowest dose tested, consistent with the findings in animal models that oral administration of low dose antigens induces generation of disease-suppressing regulatory T cells.

Patients with autoimmune thyroid disease have received oral animal thyroglobulin. Treatment did not produce changes humoral immunity parameters but resulted in reduced proliferation *in vitro* to certain thyroid peptides (133).

Autoimmune uveitis has been treated with oral administration of an HLA class I peptide that mimics a retinal autoantigen. Treatment resulted in reduced intraocular inflammation and unchanged or increased visual acuity (134).

Taken together, these results indicate that oral administration of antigen does have systemic effects on T cells and may be useful for the treatment of autoimmune diseases. Some larger trials, however, failed to allow definitive conclusions about the efficacy of this approach, and worsening of autoimmune diseases after mucosal administration of antigen was anecdotally reported in a animal models (135). Therefore, the use of oral administration of these immunogens awaits further examination in larger clinical trials.

ADMINISTRATION OF PEPTIDES DERIVED FROM THE TCR

The V-region hypothesis, proposed in the late 1980s, suggested that, in some instances, autoimmune diseases were mediated by a limited number of T-cell clones, each associated with a specific use of a TCR V-region. This led several investigators to hypothesize that immunization with a peptide derived from the dominant TCR might alter the pathogenicity of the T cells and ameliorate disease. This TCR peptide immunization protocol was originally developed in EAE because it was shown that T cells that recognized MBP in rats preferentially utilized Vb8.2, a specific b-chain of the TCR. Immunization of rats with synthetic peptides derived from that TCR region was effective in both preventing and, more significantly, treating EAE (136,137 and 138). Similar results were found in mice with EAE. The mechanism of action of this approach is unclear. TCR peptide immunization has been shown to activate peptide-specific T cells, stimulate production of anti-TCR mAbs, and perhaps tolerize disease-causing antigen-specific T cells. In patients with MS, vaccination with a peptide from Vb5.2 sequence, expressed on MBP-reactive T cells, reduced MBP responses and stabilized disease in the few responding patients (139). Peptide-specific Th2 cells inhibited MBP-specific Th1 cells *in vitro* via secretion of IL-10. Further clinical studies in this indication are planned.

Specific Vb subsets also are overexpressed in synovial fluid and tissues from patients with RA. A recent clinical trial evaluated immunization of RA patients with peptides derived from Vb5, Vb14, and Vb17 in incomplete Freund adjuvant (140). This therapy was well tolerated and showed a tendency toward improvement of clinical outcome; however, the true efficacy of TCR peptide immunization in these patients has yet to be determined.

Strategies for Immune Enhancement

ANTI-CD3 MAB

The activating properties of anti-CD3 mAbs have been suggested as potentially useful for tumor immunotherapy, despite the subsequent immunosuppressive effect of the mAbs. Initial animal studies showed that treatment with low doses of activating anti-CD3 mAb reduced the incidence of tumors and provided long-lasting tumor immunity in mice injected with progressive tumor cells. Tumor rejection was initially dependent on $CD4^+$ T cells and required the presence of $CD8^+$ T cells throughout the immune response, suggesting that the early cytokine release episode induced by anti-CD3 stimulation of T cells resulted in the generation of tumor-specific cytotoxic T cells.

A phase 1 clinical trial using the activating properties of a humanized anti-CD3 mAb in cancer patients has been completed. A dose of anti-CD3 mAb that results in

T-cell activation with non–life-threatening side effects and brief TCR downmodulation was identified in this trial (141). Interestingly, malignant ascites resolved in three patients following anti-CD3 administration, suggesting the potential usefulness of this molecule for the treatment of certain cancers.

ALTERED PEPTIDE LIGANDS

The use of altered peptide ligands has been proposed to enhance T-cell responses to otherwise weak antigens. The human gp100/pmel 17 differs by 3 amino acids from its mouse homolog, expressed on melanoma cells as well as in normal melanocytes. Immunization with a vaccinia virus encoding the human but not the mouse protein elicited a $CD8^+$ T-cell response and promoted rejection of an established melanoma tumor in mice (142). The human peptide appeared to have a higher affinity for MHC class I and increased the ability of T cells to secrete IFN-g.

Mice are differentially susceptible to *Leishmania* infection, depending on their strain of origin. A normally susceptible strain with T cells transgenic for a *Leishmania*-specific antigen has been shown to become resistant to subsequent infections if pretreated with peptides that differ in one amino acid from the Leishmania immunodominant peptide (143). These altered peptide ligands appear to prevent IL-4 production by T cells from these animals, an important event for generation of Th2-type cells and susceptibility to the infection.

No data are currently available on the use of altered peptide ligands for immune enhancement in patients. These high-affinity, “superagonistic,” altered peptide ligands may be an effective therapy for enhancing T-cell responses against tumor antigens and infectious agents.

ANTIGEN/APC VACCINATION

Because T cells are optimally activated by peptides and costimulatory ligands, both of which are both present on professional APCs, another approach for immune enhancement has consisted of immunizing animals or patients with APCs that express a tumor antigen. The variables in these protocols include the source of antigen (tumor cells, tumor lysate, tumor antigen, or peptides), the type of APC, and the route of administration to ensure that relevant T cells will come in contact with the antigen-expressing APCs. The first generation of vaccines was using whole cancer cells or tumor-cell lysates as a source of antigen in combination with various adjuvants, relying on APCs of the host to process and present tumor-specific antigens. These therapies resulted in occasional clinical responses and are being tested in prospective clinical trials (144).

The second generation of vaccines utilized specific APCs incubated *ex vivo* with antigen or transduced to express antigen and subsequently reinfused into patients. Among the most promising therapeutic APCs are dendritic cells because of their expression of high levels of MHC and costimulatory molecules. Dendritic cells, generated from animals or patients following incubation of blood or bone marrow cells with GM-CSF or GM-CSF and IL-4, are the optimal APC to stimulate antigen-specific T cells *in vivo*. Preclinical studies showed that animals immunized with dendritic cells previously pulsed with MHC class I-restricted peptides derived from tumor-specific antigens develop potent antitumor CTL responses and protective tumor immunity can be generated (145). Because generation of dendritic cells from patients is time consuming and cumbersome, other types of APCs have been investigated as well. Recent data indicate that leukocytes isolated from peripheral blood and immediately pulsed with antigen can be used to immunize mice against tumors if exogenous IL-12 is provided simultaneously (146). IL-12 acts as a costimulatory molecule promoting Th1 and Tc1 differentiation, a phenotype that is more effective at promoting tumor rejection. In addition, IL-12 upregulates B7 family members on host APCs, thereby optimizing T-cell activation. This provides an easy approach in humans; a clinical trial in melanoma patients using peripheral blood cells pulsed with the HLA-A2-binding peptides MAGE-3 or MART-1 is currently being completed in patients expressing an HLA-A2 allele.

Dendritic cells pulsed with a tumor antigen elicit tumor-reactive T cells in clinical trials of patients with different types of cancers. The surface immunoglobulin expressed on B-cell lymphoma has unique idiotypes that can be recognized by T cells. Forty-nine percent of patients immunized with tumor immunoglobulin protein coupled to keyhole limpet hemocyanin (KLH) and emulsified in adjuvant generated specific immune responses against the idiotypes. This correlates with a more favorable clinical outcome because patients with antiidiotypic responses were free of disease for almost 8 years compared with 1 year in patients who did not mount an immune response (147). Multiple myeloma is another B-cell malignancy in which immunotherapy directed at idiotypes may be useful. Myeloma cells do not express immunoglobulin on their surface, but they do express idiotype-derived peptides on MHC molecules. Six patients have been treated with dendritic cells pulsed with autologous idiotype and control KLH antigen. Treatment was associated with T- and B-cell responses to KLH in all patients as well as increased antiidiotype cytotoxic T cell precursor frequency in three patients (148). Numerous melanoma-specific antigens have been identified, including MAGE-1, MAGE-3, tyrosinase, gp-100, and MART-1. The MHC class I alleles that bind these peptides have been identified, allowing vaccination of patients expressing certain HLA alleles. In a pilot study, dendritic cells generated from patients were pulsed with a cocktail of gp100, MART-1, tyrosinase, MAGE-1, or MAGE-3, depending on the patient HLA haplotype, or with tumor lysate when HLA alleles were inappropriate for binding the known peptides. Cells were directly administered into uninvolved lymph nodes by ultrasound guided injection. The majority of patients displayed a DTH response to peptide-pulsed dendritic cells and had peptide-specific CTLs at the DTH site. Five patients had objective clinical responses to the treatment including 2 patients treated with dendritic cells pulsed with tumor lysate (149). This suggests that this therapy could be applied to cancers without defined tumor antigens and to patients with HLA haplotypes unsuited to bind known tumor peptides.

Finally, the role of the route of vaccine administration in vaccine efficacy has been investigated. Using radiolabeled dendritic cells, Eggert and colleagues found that intravenous administration results in accumulation of dendritic cells in the spleen, whereas subcutaneous administration leads to homing to draining lymph nodes. In a mouse model of melanoma, these investigators showed that the subcutaneous route of administration resulted in improved survival and increased CTL activity compared with intravenous injection (150).

Immunotherapy and tumor vaccination in cancer patients thus are developing rapidly and appear promising in certain settings. One must keep in mind, however, that tumors can generate multiple mechanisms of escape from the immune system, some of which would render vaccination less effective. For example, downregulation of MHC molecules would preclude MHC/peptide recognition and lysis of tumor cells by T-lymphocytes in the effector phase of the immune response. Even in this case, however, indirect presentation of tumor antigens to T cells still may allow subsequent activation of NK cells and macrophages and tumor rejection. Thus, association of immunotherapy with chemotherapy or other antitumor approaches may be warranted.

DNA VACCINATION

A novel approach to promoting immune responses against specific antigens has taken advantage of an observation first made in 1990 that intramuscular administration of “naked” DNA encoding a specific protein antigen resulted in myocyte-specific protein expression (151). Since then, numerous articles have reported the efficacy of DNA vaccines in small and large animal models of infectious diseases and cancer (152). DNA immunization elicits humoral and $CD4^+$ T-cell responses in rodents and primates, but its major advantage at the immunologic level is its capacity to induce antigen-specific MHC class I-restricted CTL responses typical of live virus vaccination, a major mechanism of protection against intracellular pathogens. The mechanisms by which these systemic responses occur following local administration of the vaccine, such as an intramuscular injection, are not fully understood but may include presentation of peptide derived from the encoded protein by the myocytes themselves, direct transfection of local APCs, or transfer of the antigen from transfected myocytes to professional APCs.

The advantage of DNA vaccination over peptide immunization is that it permits generation of entire proteins, enabling determinant selection to occur in the host without having to restrict immunization to patients bearing specific HLA alleles. A safety concern for this technique, however, is the potential for integration of the plasmid DNA into the host genome with the possibility of disrupting important genes leading to phenotypic mutations or carcinogenicity.

In humans, DNA vaccination appears to induce cellular responses. For example, all normal volunteers who were immunized with a plasmid DNA encoding a malaria protein developed specific CTLs against ten malaria peptides tested (153). These results are encouraging, but basic immunology tenets suggest that the immunization strategy would benefit from the stronger responses afforded when the immunogen is coupled with an inflammatory response. This may be achievable by the incorporation into the DNA vaccine of adjuvants, such as CpG motifs or monophosphoryl lipid A. Unmethylated CpG dinucleotides within specific DNA sequences are detected, in bacterial or viral DNA, as inflammatory signals by the vertebrate immune system and have been shown to be potent Th1-directed adjuvants in mice (154). Administration of these DNA motifs into the immunogen results in upregulation of MHC class II and costimulatory ligands on B cells, increasing both T- and B-cell responses (155). Monkeys vaccinated against hepatitis B with a CpG adjuvant developed 15 times more antihepatitis antibody titers than those who received vaccine alone (156). The ability of these motifs to promote Th1 differentiation has been taken advantage of in animal models of asthma and vaccination. Immunomodulatory DNA sequences prevents IL-5 production, eosinophil accumulation, and airway hyperresponsiveness in mice (157) and hold promises for treatment of Th2-driven allergic diseases and asthma in patients. Monophosphoryl lipid A is another bacterial adjuvant that has been shown to potentiate T- and B-cell responses to DNA vaccines in mice and may promote Th1 differentiation (158).

Finally, studies have focused on the use of DNA to deliver antigen to APCs. One strategy has been to introduce genes encoding tumor antigens directly into dendritic cells, thereby allowing the possibility of endogenous peptides being presented both by MHC class I and class II molecules. This has been achieved most successfully by using recombinant viruses to transduce APCs; traditional ways of transfecting cells, such as electroporation or chemical treatment, have failed to induce CTL responses after reinfusion of the treated APCs (145).

VIRAL VACCINATION

Another approach to generate or enhance immune responses against specific antigens consists of infecting cells with recombinant viruses that encode the protein antigen of interest. Different types of viral vectors, such as vaccinia, avipox, or adenovirus have been used, that can infect mammalian cells. Infection can be performed *in vitro* to introduce proteins of interest, such as tumor antigens, into specific cells. For example, human dendritic cells derived *in vitro* from hematopoietic progenitors, can be infected with vaccinia virus or adenovirus to express a foreign protein (159) and then can be used for vaccination of patients. Alternatively, patients can be vaccinated directly with the replication-defective virus. In a pilot clinical trial, cancer patients were vaccinated with canarypox vector and the human CEA, a tumor antigen expressed in colon cancer cells. T cells obtained from seven of eight patients after, but not before, immunization were capable of specifically lysing cell lines expressing HLA-A2 pulsed with a CEA peptide (160). Viral vaccination also allows introduction of mutant peptides derived from tumor antigens that can induce stronger CTL responses than native peptides. Valmori et al. showed increased immunogenicity following vaccination of mice with recombinant vaccinia virus containing a minigene encoding for a mutant peptide analog of melan-A, a melanoma tumor antigen (161). Thus, recombinant vaccines provide another strategy to induce the generation of strong CTL responses *in vivo* with the potential to eradicate tumors or infectious pathogens.

TARGETING COSTIMULATORY MOLECULES

As described, activation of T cells requires not only signaling through the TCR but also a second costimulatory signal that is necessary for cell-cycle progression, survival, and maximal effector function. A number of candidate costimulatory molecules have been targeted for tolerance induction because reagents that block the binding of costimulatory receptors to their ligands are more readily available than agonistic reagents. Some costimulatory molecules are soluble, such as IL-2, and many are T-cell surface receptors, such as CD28, 4-1BB, OX40, CD30, and CD40L. Each has the ability to augment the T-cell proliferative response to antigenic stimuli. It is likely that each of these molecules acts through different mechanisms, some delivering costimulatory biochemical signals to the T cell, some enhancing adhesion to APCs, and still others mediating homing to target tissues. These therapies represent some of the most promising candidates for clinical tolerance induction in transplantation and autoimmune diseases such as systemic lupus erythematosus, diabetes, psoriasis, and MS.

Strategies for Immunosuppression

TARGETING B7/CD28 INTERACTIONS

One of the most important costimulatory pathways of T-cell activation involves the interactions of the CD28 receptor with its ligands B7-1 and B7-2. Preventing ligation of CD28 molecules during TCR stimulation *in vitro* results in T-cell anergy. In contrast, T cells that are not simultaneously activated through the TCR remain unaffected by CD28/B7 blockade, as demonstrated by normal T-cell responses following washing and restimulation of T cells. Therefore, disruption of the CD28/B7 pathway *in vivo* should result in tolerance of antigen-reacting T cells without affecting T cells of other specificities not activated at the time of treatment. Several approaches have been used to disrupt the CD28/B7 interactions *in vivo*. Initially, the field exploited the finding that CTLA-4 has a significantly higher affinity for B7 ligands than CD28 by developing a soluble molecule comprising the extracellular domain of CTLA-4 fused to the hinge and Fc portion of an immunoglobulin, resulting in a reagent termed CTLA-4Ig. This reagent, as well as anti-B7 antibodies, has been used to disrupt ligation of CD28 *in vivo*.

Extensive studies in rodent transplant models suggested that inhibition of the CD28/B7 pathway is a promising strategy to promote allograft acceptance as well as to prevent or treat autoimmune diseases (16,162,163,164 and 165). In primates, the effects of B7 blockade have been modest. Treatment with a 2-week course of human CTLA-4Ig prolonged renal allograft survival in rhesus macaques, but the two animals in this study went on to reject their allograft. Similarly, CTLA-4Ig monotherapy inhibited islet allograft rejection in cynomolgus monkeys in two of five recipients (166). Interestingly, CTLA-4Ig therapy abrogated the humoral response in all the recipients. Similar inhibition of the alloantibody response was obtained in the renal allograft model (Kirk et al., and Pearson and Larsen unpublished observations). More recently, Kirk and colleagues presented data demonstrating that an antihuman B7-1 mAb can significantly prolong renal allograft survival alone or with antihuman B7-2. Thus, whereas the initial experiences in primates with agents blocking this pathway (e.g., anti-B7-1 and B7-2 mAbs and various CTLA-4Ig fusion proteins) were somewhat disappointing, new second-generation reagents and optimized protocols are being developed that will warrant testing in human trials, particularly in conjunction with other agents.

Also, CTLA-4Ig has been shown to prevent the onset of collagen-induced arthritis (CIA) in BB rats and mice and progression of diabetes in NOD mice. Lenschow et al. found that a soluble human CTLA-4Ig could prevent diabetes in NOD mice (167). The prevention of disease was due to the blockade of B7-2/CD28 interactions. Herold et al. made similar observations in diabetes induced with multiple low doses of streptozotocin (168). In murine autoimmune thyroiditis, blockade of B7-2 inhibited priming and *in vitro* activation of effector cells (169). Furthermore, the combination of anti-B7-1 and anti-B7-2 not only prevented murine CIA, but it also suppressed clinical and histologic evidence of joint inflammation. Thus, in theory, the best strategies might include CD28 blockade to suppress T-cell expansion combined with anticytokine therapy, such as anti-TNF mAbs, to inhibit Th1 effector function, promoting quiescence in the inflamed tissue and minimizing the costimulatory effects of soluble and cell-surface accessory molecules.

CD28/B7 blockade has been used in clinical trials. First, the *in vitro* principle that TCR stimulation during CD28/B7 blockade results in T-cell anergy has been applied in a pilot clinical trial involving bone marrow allograft transplantation in an attempt at reducing GVHD. GVHD is a complication arising from donor T cells recognizing recipient cells as allogeneic and foreign. Recipient peripheral blood leukocytes were collected from 12 patients before myeloablation, irradiated, and incubated *in vitro* with donor bone marrow cells mismatched for one MHC haplotype in the presence of CTLA-4Ig to induce anergy of donor T cells specific for recipient allo-MHC. Restimulation *in vitro* showed reduced responses of donor T cells against recipient but not third party cells, suggesting that donor-specific anergy had occurred. The incidence of GVHD following transfusion of these cells into patients was relatively low, suggesting the potential efficacy of this type of treatment (170). Further studies comparing incidence of GVHD prospectively when donor cells are incubated with and without CTLA-4Ig are warranted.

In addition, human CTLA-4Ig has been used *in vivo*. Forty-three patients with stable psoriasis vulgaris received four infusions of the soluble chimeric protein CTLA-4Ig (8). Forty-six percent of the patients achieved a 50% or greater sustained improvement in clinical disease activity, with greater effects observed in the highest-dosing cohorts. Improvement in these patients was associated with quantitative reduction in epidermal hyperplasia and correlated with quantitative reduction in skin-infiltrating T cells. No markedly increased rate of intralesional T-cell apoptosis was identified, suggesting that the decreased number of T cells in the lesions was probably attributable to an inhibition of T-cell proliferation, T-cell recruitment, or apoptosis of antigen-specific T cells at extralesional sites. It is important to note that, although altered antibody responses to T-cell-dependent neoantigens were observed, immunologic tolerance to these antigens was not demonstrated. This study illustrates the importance of the CD28/CTLA-4 pathway in the pathogenesis of psoriasis and suggests a potential therapeutic use for this novel immunomodulatory approach in an array of T-cell-mediated diseases. The data also emphasizes that tolerance induction, as defined by experiments *in vitro* and in small animal *in vivo*, may not reflect functional mechanisms in humans *in vivo*.

INHIBITION OF CD40/CD40L INTERACTIONS

Blockade of CD40/CD40L interactions also has been shown to affect autoimmunity. Treatment of NOD mice with anti-CD40L can prevent diabetes if administered early in life but, in some studies, did not block recurrent insulitis (171,172). Anti-CD154 antibody treatment also reduced severity of EAE both in diseased animals and in adoptive recipients of encephalitogenic T cells. This suggests that CD40/CD154 interactions may be involved in directing the CNS migration of these cells or in their effector ability to activate CNS macrophages and microglia (173).

Studies using anti-CD154 (CD40L) mAbs in experimental rodent and primate transplant models demonstrated that the interruption of CD40/CD154 interactions represents a powerful strategy to inhibit allograft rejection. In rodents, perioperative treatment with anti-CD40L promoted indefinite survival of murine cardiac allografts (174). Studies in preclinical primate models also strongly support the hypothesis that costimulation blockade will provide a powerful means to prevent rejection and promote long-term allograft acceptance. Kirk and colleagues reported that a 2-week course of anti-CD40L monotherapy markedly prolonged (>180 days) renal allograft survival in rhesus macaques (175). Anti-CD154 therapy in nonhuman primate recipients of allogeneic islets allowed for successful engraftment, long-term maintenance of function, and preservation of islet mass at levels comparable to prepancreatectomy. Several monkeys treated with anti-CD154 maintained islet and renal allograft function long after discontinuation of therapy with no evidence of rejection (176). Whereas optimal dosing, frequency of administration, and duration of therapy remain under active investigation, subsequent studies suggested that treatment for 6 months confers more durable graft protection (>1 year). Although a loss of donor-specific reactivity *in vitro* in the presence of a maintained anti–third-party responsiveness has been shown in both models, there is as yet no convincing data in rodents or primates that anti-CD154 monotherapy can induce stable donor-specific tolerance. Thus, although the precise mechanism for *in vivo* efficacy of this therapy is unclear, the achievement of nonhuman primate allografts survival for over 3 months after discontinuation of immunotherapy, in the absence of any rejection episode, indicates that deletional mechanisms, immune deviation, or long-lasting immune unresponsiveness is operating. Industry-sponsored phase 1 and 2 clinical renal transplant trials using long-term anti-CD154 maintenance therapy in calcineurin inhibitor-free protocols are now under way. The results of these trials will be extremely helpful in the design of studies using anti-CD154 in combination with other agents (e.g., anti-B7s, CTLA-4Ig, rapamycin) for tolerance induction.

COMBINED COSTIMULATORY BLOCKADE

In several murine models, simultaneous blockade of the CD28 and CD40 pathways has been shown to inhibit synergistically immune responses. For example,

simultaneous, but not independent, blockade of the CD28 and CD40 pathways markedly prolonged the survival of allogeneic skin grafts and inhibited the development of chronic vascular rejection of primarily vascularized cardiac allografts (177). This strategy greatly prolonged the survival of rat and porcine xenogeneic skin transplants in mice (164). A similar synergistic effect between these reagents has been observed in murine aortic allograft and contact dermatitis models (178,179). Furthermore, whereas anti-CD154 monotherapy is effective in the rhesus renal allograft model, there is evidence that, unlike CTLA4-Ig, this agent failed to inhibit completely the antidonor humoral response (Alan Kirk, personal communication). This finding suggests that simultaneous blockade of the CD28 and CD40 pathways may have immunologic advantages. Finally, several investigators observed that the effectiveness of costimulation blockade is significantly enhanced by coadministration of donor cells in the form of a blood transfusion, splenocytes, or bone marrow cells (7,180,181).

TARGETING OTHER TNF/TNFR FAMILY MEMBERS

Although CD28 is constitutively expressed on naive T cells and is important for initial costimulation, differentiated T cells are less dependent on CD28 and upregulate a series of other cell surface molecules on stimulation. Therefore, other costimulatory interactions may be important in regulating ongoing immune responses. Members of the TNF/TNFR family are likely to play important roles as both effector and costimulatory molecules in conditions of chronic stimulation, such as autoimmune diseases and transplantation settings. For instance, OX40 expression has been demonstrated in T cells isolated from the CNS of mice with EAE. Blocking of OX40/OX40L interactions using soluble OX40-Ig or deleting CNS-OX40$^+$ T cells with an anti-OX40-immunotoxin mAbs results in reduced severity of murine EAE (182,183). In addition, *ex vivo* stimulation of rat MBP-specific T cells with anti-CD3 and anti-OX40 mAbs resulted in T cells capable of inducing EAE following adoptive transfer, whereas stimulation with anti-CD3 mAb alone did not (184). Similarly, expression of OX40 was observed on activated T cells following bone marrow transplantation and treatment with anti-OX40 reduced lethality induced by semiallogeneic bone marrow transplantation in mice (185). Whether efficacy in either of these models results from simple deletion of OX40$^+$ T cells or blockade of the costimulatory pathway remains to be determined.

Targeting 4-1BB may be of specific interest for certain disease models because costimulation through 4-1BB seems to affect preferentially CD8$^+$ rather than CD4$^+$ T cells. Cross-linking 4-1BB *in vivo* in mice appears to accelerate skin and cardiac allograft rejection (186), pointing to 4-1BB as an important molecule to target for immunosuppression when blocking mAbs or fusion molecules become available. In addition, a splice variant resulting in a soluble form of 4-1BB has been identified in T cells, and its concentration appears to be increased in the serum of patients with rheumatoid arthritis (187), suggesting that this molecule may be an interesting target in autoimmune settings.

Finally, the list of other potential regulators of systemic and local immunology is growing continuously. Thus, it will be critical to study each, first in preclinical models, then in humans, both as monotherapy and in combination, to maximize the potential for tolerance induction.

TARGETING COSTIMULATORY CYTOKINE/CYTOKINE RECEPTOR PATHWAYS

IL-2/IL-2R

Interleukin-2R is transiently expressed on recently activated T cells and, on IL-2 ligation, promotes cell cycle progression and expansion of Ag-specific T cells. Therefore, animal and human studies in autoimmune or transplantation settings have used anti-IL-2R Abs or IL-2 fused to different immunotoxins to target specifically and to inactivate or eliminate that subset of T cells (188). Notably, a fusion IL-2-Ig molecule that was shown to bind IL-2R on T cells, fix complement, and result in T-cell deletion reduced the incidence of diabetes by 70% in a model of adoptive transfer of diabetogenic splenocytes into non diabetic male NOD mice (189). Numerous clinical trials have been performed in transplantation and autoimmune settings, initially using mouse and rat antihuman IL-2R mAbs and then humanized mAbs. Because of the low rate of rejection episodes with current global immunosuppressive agents, new therapies in transplantation require, on ethical bases, to be added to agents like cyclosporin or corticosteroids rather than replace them. Importantly, both cyclosporin and steroids inhibit T-cell activation, cytokine production, and IL-2R expression, possibly lowering the putative efficacy of an anti-IL-2R mAb. Keeping that in mind, however, anti-IL-2R mAbs seem efficacious at preventing allograft rejection despite the concurrent presence of immunosuppressive drugs, although efficacy may not be as high as with anti-T cell preparations. Interestingly, there seems to be a trend toward a reduced rate of immunosuppression-related infections, and notably of CMV infections in patients treated with anti-IL-2R mAbs, compared with patients treated with antilymphocyte serum or OKT3, suggesting more alloantigen-specific immunosuppression (190). In a study involving patients with autoimmune Th1-mediated uveitis, cyclosporin and steroids were tapered down and discontinued before administration of a humanized anti-IL-2 mAb. This treatment alone prevented intraocular inflammation and resulted in improved visual acuity in eight of ten patients, suggesting that this approach may be effective for certain autoimmune diseases as well (191). In contrast to the potent deletion of IL-2R-expressing T cells following anti-IL-2R mAb treatment in rodent models, anti-IL-2R mAbs in humans may function by preventing utilization of IL-2 by T cells or by inactivating IL-2R$^+$-T cells. Indeed, IL-2R-expressing T cells do not appear to be eliminated from the circulation (192).

Therapies that target IL-2R may be useful to complement other strategies of costimulatory blockade. Indeed, a percentage of T-lymphocytes may escape or bypass efficient blockade of CD28 or CD40 costimulatory pathways and may progress to an activated state in which IL-2R is expressed. Although high levels of activation would not be expected in the presence of costimulatory blockade, cells that escape blockade, memory cells, and preexisting autoimmune or alloreactive-specific T cells could lead to autoimmunity or allograft rejection. Targeting IL-2R could specifically affect these cells and have additive effects to those of costimulatory blockade. A subset of IL-2R-expressing T cells has been identified as suppressive T cells capable of inhibiting responses of antigen-specific T cells (193,194) and may be important in maintenance of tolerance to autoimmune diseases (195,196). Therefore, long-term effects of targeting IL-2R$^+$ T cells will have to be investigated.

Cytokine/Cytokine Receptor Pathways that Affect T-Cell Differentiation

Interleukin-4 binding to IL-4R appears important for differentiation of T cells into Th2- and Tc2-type cells. Type-2 T cells produce IL-4, IL-5, IL-6, IL-10, and IL-13 on restimulation and, in particular, provide help to eosinophils that have been implicated in the pathogenesis of allergic diseases. In addition, IL-4 also supports proliferation of mast cells and BCR-stimulated B cells and promotes immunoglobulin switch to an IgE isotype, making IL-4 a suitable target in IgE-mediated diseases. A naturally occurring soluble form of IL-4R is secreted and inhibits the biologic actions of IL-4 by preventing IL-4 from ligating IL-4R-expressing cells. A recombinant version of this molecule that contains only the extracellular portion of IL-4R and lacks the transmembrane and intracellular domains has been generated. Blockade of IL-4 signaling via intranasal administration of soluble IL-4R has been shown to reduce airway inflammation and eosinophil accumulation in a murine model of asthma (197). In addition, a clinical trial using aerosolized soluble IL-4R also shown to improve asthma scores in a phase 1 and 2 placebo-controlled trial (198).

Conversely, IL-12 in rodents and primates and IFN-a in humans promote Th1 differentiation, as discussed previously. Numerous infectious diseases appear to be regulated by the balance between type 1 and type 2 T-cell responses, such as leprosy, *Schistosoma mansoni*, and *Leishmania* infections. From the extensive study of a mouse model of *Leishmania* species, it appears that susceptible mice are more prone to generating Th2-type responses, whereas resistant strains preferentially develop Th1 responses. Furthermore, neutralization of IL-4 in susceptible strains of mice can result in Th1 differentiation and eradication of the pathogen, suggesting that, in the clinic, blockade of IL-4 may be appropriate in certain infectious diseases (199). Conversely, immunization of primates with killed *Leishmania* and human IL-12 promoted Th1 differentiation and conferred protection against parasite challenge (200).

Similarly, some autoimmune diseases are preferentially driven by Th1-type responses in both rodents and humans. These include, for example, experimental uveitis, diabetes, psoriasis, Crohn disease, rheumatoid arthritis, and EAE. In contrast, other autoimmune diseases, such as progressive systemic sclerosis and ulcerative colitis, seem to be promoted by Th2-type responses (201,202). Therefore, therapies that would modulate the Th1/Th2 balance by favoring one differentiation pathway over the other may have beneficial effects in these settings. Yet treatment with IL-4 or anti-IL-12, or IL-12 or anti-IL-4 to promote or limit Th2 differentiation, respectively, yielded controversial results in animal models, sometimes affecting the severity of the illness, but more often lacking efficacy. Thus, it is unclear at this point exactly how to translate experimental results to patients suffering from autoimmune diseases. For instance, it is likely that the events that skew differentiation of newly activated T cells may not equally affect already differentiated effector T cells. Nevertheless, an anecdotal case report of a patient treated with IL-12 as an adjuvant therapy for cancer who also suffered exacerbation of RA illustrates how manipulation of T-cell differentiation may affect autoimmune disease (203).

Strategies for Immune Enhancement

Positive costimulation of antigen-specific T cells is desirable for immunotherapies directed against cancers and infectious diseases. This has been achieved for different surface molecules in many ways, including induction of expression of costimulatory ligands on tumors via transfection, DNA vaccination, or viral transduction. In addition, when agonistic antibodies to costimulatory receptors exist, they can be used to promote tumor rejection or eradication of viral or parasitic infections.

CD28/CTLA-4/B7 PATHWAY

Activation of CD28 on tumor-specific T cells was achieved initially by transfecting tumors to express B7 molecules as a means for providing direct costimulation. Following B7 transfection, some tumors that otherwise grew progressively in mice were rejected in a T-cell-dependent manner, indicating that increasing the chance that tumor-specific T cells receive potent costimulatory signals improves clinical outcome in tumor models (204,205). One of the potential problems with this approach has been the inadvertent engagement of the downregulatory CTLA-4 molecule as a consequence of ectopic B7 expression. Thus, approaches have been developed to activate selectively the CD28 molecule on antigen-reactive T cells. In this regard, direct costimulation of T cells via injection of agonistic anti-CD28 mAb also was

shown to enhance antitumor responses in mice (206). The soluble form of the CD28 agonist is less effective than membrane-bound antibodies, however. Therefore, several groups generated membrane-bound single-chain anti-CD28 mAbs that can be expressed on tumors or locally in sites of infection (207,208). This approach led to a highly effective means of delivering CD28-specific costimulation.

Another strategy that takes advantage of costimulation is the *ex vivo* expansion of T cells as immunotherapy in cancer patients and HIV-infected persons. T cells from peripheral blood are stimulated *in vitro* using plastic beads coated with anti-CD3 and anti-CD28 mAbs (209). This protocol leads to a dramatic increase in both $CD4^+$ and $CD8^+$ T-cell numbers. The T cells are not antigen-restricted, but they include antigen-specific T cells if they are present in the peripheral blood of the patient. When this approach was used to expand T cells from HIV-infected patients, it was noted that only uninfected T cells proliferated and stimulated cells were rendered resistant to HIV-1 infection (210). In a pilot study, reinfusion of these cells into patients restored immune competence, although further evaluation of T-cell responsiveness *in vivo* needs to be performed. Similarly, clinical trials using *ex vivo* expansion and reinfusion of T cells in lymphoma-bearing patients is currently under way and will provide insight into the antitumor function of in vitro activated T cells (C. June and D. Liebowitz, personal communication).

Blockade of the negative regulator of T-cell function CTLA-4 has been used successfully in animal models to enhance T-cell function and promote tumor rejection (24) or eradication of pathogens (211). Treatment of mice with anti-CTLA-4 mAbs prevented tumor growth and conferred immunity against secondary exposure to tumor cells in mice. In some instances, the therapy induced rejection of preestablished tumors. In addition, treatment with anti-CTLA-4 mAbs in mice has been shown to increase the efficacy of vaccination with irradiated tumor cells engineered to produce GM-CSF or of chemotherapeutic regimens. These combined therapies induced rejection of tumors otherwise resistant to anti-CTLA-4 mAb monotherapy (212,213). In a mouse model in which tumor exposure induces hyporesponsiveness of TCR transgenic tumor-specific T cells, anti-CTLA-4 treatment was unsuccessful at reversing tolerance induction (214). In humans, tumors usually exist for long periods before being detected raising the possibility that tumor-specific T cells may have been rendered tolerant by mechanisms normally in place to prevent autoimmunity. If and when this is the case, anti-CTLA-4 mAb treatment may not have the potential to augment antitumor immunity. Clinical trials using anti-CTLA-4 mAbs are being designed and should yield important information.

CD40/CD40L AND OTHER TNF/TNFR PATHWAYS

Like B7, CD40 has been used as a transfected costimulatory molecule on tumor cells to increase T-cell activation. Implanted CD40-transfected tumors elicited a strong CTL response in mice, leading to eradication of the tumor and induction of long-lasting immunity that resulted in rejection following subsequent challenge with parental tumor (215). In addition, immunization with liposomes containing a tumor peptide induced CTL responses in mice that were greatly potentiated by coadministration of blocking anti-CTLA-4 and agonistic anti-CD40 mAbs, resulting in rejection of an antigen-expressing tumor (216). Interestingly, this response occurred also in MHC class II mice that lack $CD4^+$ T cells, indicating that $CD8^+$ can be directly activated in this manner. Using DNA vaccination to induce CD40L expression also increased T-cell responses. Mice treated with DNA encoding a trimeric complex of CD40L proteins did not die of metastases when challenged with a lethal dose of tumor. Similarly, coinjection of the CD40L-cDNA with *Leishmania* antigen resulted in resistance to subsequent *Leishmania* infection in mice. The increased T-cell response was blocked by anti-IL-12 and by CTLA4-Ig therapy, indicating that administration of CD40L-cDNA induced increased IFN-g production and CTL activity in an IL-12 and B7-dependent manner (217).

Triggering 4-1BB signaling also has been shown to potentiate immune responses as well. Administration of an agonistic 4-1BB-specific mAbs (218) or transfection of tumors with 4-1BBL (219) resulted in the rejection of different established tumors in mice, including otherwise poorly immunogenic tumors. Both $CD4^+$ and $CD8^+$ T-cell subsets were activated via 4-1BB in this tumor model.

Similarly, signaling through CD27 can result in immune enhancement. Mice immunized with a tumor infected with vaccinia virus encoding CD70, the ligand for CD27, were protected from tumor growth as well as from a subsequent challenge with CD70-negative tumor cells. In addition, vaccination with vaccinia virus encoding CD70 as well as the colon carcinoma tumor antigen CEA was more effective at preventing rejection of colon carcinoma than CEA immunization alone (220).

Finally, stimulation of CD30 has been used extensively as a direct tumor-targeting strategy rather than for T-cell activation inasmuch as CD30 is expressed on certain lymphomas. Bispecific mAbs containing anti-CD3 and anti-CD30 components have been used to stimulate T cells that would be in close proximity of CD30-expressing tumor cells. These therapies have proven largely successful (221,222). As the costimulatory role of CD30 molecule of T cells has been realized, however, the basis of this positive therapeutic outcome is unclear because treatment can either redirect T cells to tumor cells or costimulate tumor-specific T cells locally. The precise mechanism for induction of tumor-specific immunity remains to be analyzed in more detail.

CYTOKINE/CYTOKINE R PATHWAYS

The Th1/Th2 and Tc1/Tc2 balance also affects clinical outcome in tumor settings. It is believed that type 1 responses are desired for the rejection of tumors, possibly, in part, because IFN signaling is necessary for acquisition of a cytotoxic phenotype (223). Development of Epstein-Barr virus (EBV)-induced B-cell lymphoma is a classic complication of global immunosuppression in transplant settings. EBV infection induces Th2 differentiation because it stimulates B cells to produce IL-10, and it contains a gene, *BCRF1*, which encodes a protein with IL-10 activity in humans. Like IL-4, IL-10 promotes Th2 differentiation. Patients who develop EBV-related lymphoproliferative disorders following transplantation may therefore benefit from modulating the Th1/Th2 balance. Therefore, treatment with IL-12 or IFN-a theoretically has therapeutic potential. In fact, IFN-a not only favors Th1 differentiation in humans, but it also has direct antiviral and antineoplastic effects. Few patients with lymphoproliferative disorders have been treated with IFN-a, but a review of these cases showed that only 3 of 21 (14%) have died from the disease when treated with the cytokine. In contrast, the historical reported mortality in this type of patients ranges from 23% to 81% in the absence of IFN treatment. This result warrants further testing of this drug in this setting as well as investigation of T-cell phenotypes before and after treatment (224).

Interleukin-2 has been used as an adjuvant treatment to cancer patients as a means to expand antigen-specific T cells. Historically, IL-2 was first used *ex vivo* to expand tumor-infiltrating lymphocytes (TILs) and tumor-infiltrating NK cells (LAK cells) following biopsies or surgical excision of tumors. It was anticipated that those T cells were tumor antigen specific and that expansion and reinfusion into patients would result in eradication of remaining tumor cells. These therapies, however, have shown minimal clinical benefit over the addition of exogenous IL-2 alone. Hypotheses for the limited efficacy of this approach include the observations that reinfused T cells may not migrate to the tumor sites and that tumor cells develop mechanisms to evade immune responses, including the selective loss of the original tumor antigen against which TILs were directed. Administration of IL-2 in addition to other chemotherapy drugs, howeve, has shown beneficial effects in a number of cancer clinical trials, in particular for melanoma and renal carcinoma patients (225,226 and 227). Whether IL-2 in these cases exerts its effects by inducing tumor-specific T-cell expansion, promoting cytotoxicity of TILs, activating NK cells, or other mechanisms remains to be evaluated.

FUTURE DIRECTIONS

The past decade has seen a revolution in our understanding of the immune system and the basis for immune recognition and responsiveness. It is now well established that cellular adaptive immune responses are mediated primarily by T-lymphocytes, which have antigen-specific receptors that recognize foreign antigens. Antigen/MHC complex binding to the TCR/CD3 complex coupled with soluble and membrane-bound costimulatory signals initiates a cascade of signaling events that lead to productive immunity. In addition, the immune response is also regulated by a number of negative signaling events that control cell survival and expansion. For the first time, *in vitro* and preclinical *in vivo* studies have demonstrated that we can selectively inhibit immune responses to specific antigens without the associated toxicity of current immunosuppressive therapies. With these new insights comes the enormous promise of specific immune therapies to treat the vast array of immune disorders from autoimmunity, transplant rejection, and asthma, to infectious diseases and cancer. We will not have to “blow up the house to kill the fly anymore.” What will these new therapies look like? Most likely, they will include combination therapies that take advantage of a number of agents. On the tolerance side, these might include drugs that target the primary TCR-mediated signal either by blocking cell surface receptor interactions or inhibiting early signal transduction events. The drugs will be combined with therapies that effectively block costimulatory to prevent cell expansion and differentiation of those cells that have engaged antigen while maintaining a noninflammatory milieu by the use of antiinflammatory drugs such as anti-TNF mAbs. On the flip side, new cancer and infectious disease vaccines will be developed that promote T-cell expansion and differentiation, in addition to costimulatory agonists and agents that block the off signals that dampen immunity. Pharmaceutical and small biotech companies continue to refine the new therapeutics that will be used in combination. The National Institutes of Health (NIH) has invested in immune tolerance by creating the Immune Tolerance Network (www.immunetolerance.org), a collaborative effort that will develop new clinical strategies for the purposes of inducing, maintaining, and monitoring tolerance in humans for kidney and islet transplantation, autoimmune diseases, and allergy and asthma. A new vaccine center has been established on the NIH campus to discover new ways to promote immunity in HIV infection, emerging infections, and cancer. The future is bright as we enter the new millennium.

88 CYTOKINES AND CANCER IMMUNOTHERAPY

Glenn Dranoff, M.D.

Although the field of cancer immunology attracted considerable skepticism during the past century, it now stands firmly positioned upon a rich scientific foundation. William Coley's intriguing finding that the administration of bacterial toxins could elicit tumor regressions in some patients with advanced sarcoma continues to inspire a wealth of studies into the host/tumor relationship (1). Although the mechanisms underlying the striking antitumor effects of bacterial toxins have yet to be fully delineated, investigative efforts in this area now encompass cytokine biology, tumor antigen discovery, antigen-presenting cell function, CpG oligonucleotide chemistry, immune effector activity, and tumor angiogenesis. The clinical acumen of Coley may ultimately spawn a new generation of cancer immunotherapies based on the insights of molecular genetics, pathologic analysis, cellular technologies, and informed clinical investigation.

The scientific breadth of cancer immunology at the beginning of the new millennium is impressive. Techniques have been developed that allow the discovery of immunogenic gene products either overexpressed or selectively expressed in cancer cells. Molecularly defined cancer antigens can be incorporated into several novel immunotherapeutic strategies likely to enhance antitumor immune reactivity. Sensitive and specific methods for the quantification and characterization of specific antitumor effector cells in tumor-bearing hosts are available. Together, these technical advances provide powerful opportunities for gleaning an improved understanding of the therapeutic potential and limitations of cancer immunotherapy.

Numerous clinical trials of cancer vaccination based on these recent insights have been initiated. These early studies primarily are aimed at determining the immunogenicity, toxicity, and feasibility of the new treatment approaches. As these critical characteristics become more fully defined, a limited number of promising strategies will advance to definitive efficacy testing in the setting of minimal residual disease. The most productive selection of immunotherapies is likely to depend on a combination of clinical intuition and the demonstration of biologic activity, because it may prove difficult to elicit meaningful clinical responses in patients with advanced, multiresistant disease.

In an effort to help clarify the scientific foundation and challenges confronting the development of cancer immunotherapy, I highlight in this chapter some of the genetic and cellular advances emerging from current laboratory studies and some of the intriguing patient data emerging from early clinical investigations.

ENDOGENOUS ANTITUMOR IMMUNITY

The central problem cancer immunology must resolve is whether an antitumor host response can modulate the natural history of neoplasia. One important way to address this issue is to determine whether endogenous immune responses protect against the development of cancer. Several congenital and acquired forms of clinical immunodeficiency confer a substantial risk for particular malignancies, including Kaposi sarcoma, non-Hodgkin lymphoma, and skin cancer (2). However, these tumors are closely associated with viral infection, and their elevated incidence most likely reflects a compromise in antiviral immunity, rather than antitumor immunity *per se.*

The notion that selective defects in immunity can lead to enhanced cancer development is a more contentious issue. Whereas Paul Ehrlich (3) first formulated the concept of cancer immunosurveillance nearly 100 years ago, Lewis Thomas (4) and MacFarlane Burnet (5) subsequently elaborated on the idea and proposed that T lymphocytes play decisive roles in the process. Although Stutman (6) challenged the validity of immunosurveillance, based on the failure to find an increased incidence of spontaneous or chemically induced tumors in nude mice, the generation of immunodeficient gene-targeted mice has provided compelling support for the existence of a host defense system against carcinogenesis.

Kaplan et al. (7) presented persuasive evidence that interferon-g is involved in tumor surveillance in several murine models. These investigators showed that mice rendered interferon-g deficient (by deletion of the gene encoding the interferon-g receptor or the STAT-1 molecule) developed a greater number of tumors after exposure to 3-methylcholanthrene than did wild type litter-mate controls. Moreover, these tumors formed with a shorter latency in interferon-g–deficient mice than in control animals. To test whether interferon-g also influenced the development of spontaneous tumors, Schreiber et al. introduced a mutant p53 allele into the interferon-g–deficient background. Strikingly, doubly mutant animals developed a much broader spectrum of cancers than did mice mutant in p53 alone. Analysis of the mechanisms underlying the enhanced carcinogenesis in both of these systems revealed important roles for both the tumor cells and host innate immunity. The involvement of T lymphocytes in cancer surveillance was suggested by other experiments, which delineated an inverse association between the development of contact hypersensitivity to polycyclic hydrocarbons (a reaction dependent on CD4-and CD8-positive T lymphocytes) and the incidence of tumors induced by these agents (8).

Although these studies in murine systems strongly suggest the existence of a cancer-immunosurveillance system, the evidence for a comparable defense network in humans currently is less complete. One informative approach to unveiling such a system involves identifying characteristics of progressive cancers that may underlie escape from immune control. Analogous investigations of successful pathogens have revealed a plethora of clever strategies to undermine immune defense (9). In this context, cancer cells are highly reminiscent of both viral and parasitic agents. For example, alterations in major histocompatibility complex (MHC) molecules and other components of the antigen-presentation pathways are frequently found in progressive tumors (10) and intimate that cytotoxic T lymphocytes likely mediate some tumor destruction. In support of this idea is the finding that tumor cells generally produce soluble factors, such as transforming growth factor-b, which antagonize T-cell function (11). Moreover, tumor cells release other molecules, such as vascular endothelial growth factor, which inhibit the development and function of dendritic cells (12). Indeed, recent studies have illustrated that only immature dendritic cells reside within most breast adenocarcinomas (13).

A second method to delineate whether endogenous host immunity can play a cancer-surveillance function involves the characterization of antitumor immune responses in long-term-surviving patients. Highly provocative findings in this regard have been gleaned through the pathologic analysis of the host response to early-stage tumors. Clark et al. (14) and Clemente et al. (15) established a tight association between the generation of dense T-lymphocyte infiltrates in the vertical growth phase of primary malignant melanoma and a reduced rate of recurrent disease and tumor mortality.

An intriguing result in this work was the failure to find any survival benefit associated with lymphocytes that circumscribe, but do not infiltrate into the tumor; they are functionally equivalent to the absence of an infiltrate. Studies aimed at understanding the differences between infiltrating and circumscribing T lymphocytes are likely to reveal important new information about abortive antitumor immune responses. In this context, it is interesting to note that analogous findings have been made in studies of autoimmune diabetes, in which a periislet cell accumulation of T cells is not sufficient to mediate disease; additional events are required to trigger T-cell infiltration and destruction of the islets (16). Genome-wide mapping studies directed at elucidating checkpoints in autoimmune diabetes in mouse and human (17) may thus provide insights into the development of antitumor immunity. Mihm et al. (18) also demonstrated that these same patterns of T-lymphocyte/melanoma interaction in regional lymph node metastases similarly predict differences in recurrence and survival.

T-lymphocyte infiltrates in early-stage adenocarcinoma of the colon are associated with a favorable clinical outcome as well; their presence can be used as effectively as the standard Duke's staging system for stratifying patient risk of recurrence (19). The incidence of lymphocyte infiltrates in these patients is inversely correlated with tumor stage, underscoring the idea that progressive colon cancer may be linked to escape from host defense. In this context, those tumors in which significant CD4- and CD8-positive T-cell infiltrates are found also harbor activated macrophages expressing high levels of the B7-1 and B7-2 costimulatory molecules, suggesting effective antigen presentation and T-cell activation (20).

Although additional clinicopathologic studies remain to be performed, lymphocyte infiltrates have been variably reported with many cancers, including lymphoma, glioblastoma, and carcinomas of the stomach, breast, bladder, testes, and ovary. It will be of interest to see whether similar patterns of lymphocyte/tumor interaction will have prognostic importance in these tumors as well. If so, then cancer immunosurveillance may prove to be a general phenomenon, and a deeper understanding of these “spontaneous” host reactions may provide the foundation for crafting efficacious immunotherapy.

TUMOR ANTIGENS

Because T-lymphocyte infiltrates in early-stage tumors are associated with prolonged patient survival, an important goal of investigation is the identification of the target

antigens stimulating these responses. The discovery that T lymphocytes recognize processed peptides, derived from cellular proteins, inserted into the grooves of MHC molecules (21) revolutionized the ability to accomplish this goal. Boon et al. (22) exploited this understanding to devise the first productive approach to characterize T-cell antigens; in this strategy, tumor-specific cytolytic T-cell clones were used to probe cDNA expression libraries (derived from tumor samples) transfected into target cells expressing the relevant MHC class I molecules. The recent demonstration that vaccination with either P1A or mutated mitogen-activated protein kinase (murine cancer antigens identified with these techniques) engendered protective immunity against tumor challenge validated the power of the Boon approach (23,24). Further, early clinical trials have shown that immunization with peptides derived from the MAGE-3 and gp100 gene products (human cancer antigens identified with these methods) can evoke at least partial tumor destruction in some patients with metastatic melanoma (25,26). An alternative, highly related strategy developed by Cox et al. (27) involves the use of tumor-specific T cells to identify peptides antigens acid-eluted from MHC molecules on tumors; candidate peptides are then sequenced with reverse-phase high-performance liquid chromatography or mass spectrometry.

A different approach to tumor antigen discovery was developed by Sahin et al. (28), who used patient sera to screen tumor-derived cDNA expression libraries. The rationale underlying this strategy is that in cancer patients, coordinated humoral and cellular antitumor responses may develop; consequently, at least some of the antigens stimulating high-titer immunoglobulin (Ig)G antibodies (whose synthesis requires CD4 T cells for isotype switching) also will be targets for CD8-positive T cells (29). This hypothesis was initially validated by the finding that antibody-based expression cloning detected the tyrosinase and MAGE-1 gene products, antigens previously discovered with T cell–based methods. More important, though, was the demonstration that NY-ESO-1, a gene product first identified through serologic screening, could also be a target for MHC class I–restricted cytotoxic T lymphocytes (30).

These provocative findings illustrate the striking ability of antibody-based cloning strategies to define the repertoire of cancer antigens. In contrast to the difficulties involved in establishing tumor-specific T-cell clones, patient serum is readily available and can be applied to expression cloning without any extensive manipulations. Recently, several studies of this approach in colon carcinoma, breast carcinoma, renal cell carcinoma, and melanoma have been published (31,32,33,34 and 35). One intriguing result from this work is the identification of a limited set of gene products that stimulate antibody responses only in cancer patients; this finding suggests that serologic tests might be used effectively in cancer diagnosis.

Together, the three cancer antigen–discovery strategies have begun to clarify the rules determining immune recognition of cancer. Four classes of targets have been unveiled thus far [reviewed in (36)]. The first group, termed “cancer-testis” antigens, consists of oncofetal proteins aberrantly expressed in tumors. These gene products are broadly expressed during fetal development (their functions have not yet been elucidated), but in the adult, their expression is limited to the testis and placenta; members of this group include NY-ESO-1 and the MAGE, BAGE, and GAGE gene families. A second group of antigens is composed of mutated cellular proteins, some of which may contribute to the transformed state, such as cyclin-dependent protein kinase 4, b-catenin, and caspase 8. A third category consists of short peptides derived from intron sequences abnormally expressed in cancer cells; these include MUM-1, p15, *N*-acetylglucosaminyltransferase V, and a novel form of TRP-2.

Although the mechanisms by which these gene products can serve as cancer antigens may be readily understood, a fourth class of targets presents a conceptual challenge. This last group consists of nonmutated cellular proteins; the most thoroughly studied to date are proteins in the melanin biosynthetic pathway, including tyrosinase, gp75 (tyrosinase-related protein-1, TRP-1), TRP-2, Melan A/MART-1, and gp100/Pmel 17. These targets highlight the close connection between autoimmunity and tumor immunity (37). The variables that underlie the ability to distinguish tumor cells and normal host cells remain to be clarified. Nonetheless, some level of autoimmunity might be an acceptable toxicity in those cases in which normal tissues are not essential for survival, such as the prostate, breast, thyroid, and melanocyte.

STRATEGIES TO ENHANCE ANTITUMOR IMMUNITY

A useful hypothesis framing much current immunotherapy research is that cancer cells generally are inefficient in stimulating immune responses. This idea receives considerable support in light of recent insights into the mechanisms underlying tumor antigen presentation. Extensive studies have revealed critical roles for dendritic cells in the initiation of effective immunity (38). These rare cells function to stimulate antigen-specific T- and B-cell responses because they capture and process antigens efficiently into both MHC class I and II pathways and express a full repertoire of costimulatory molecules. Indeed, these features may explain in part why tumor cells secrete factors that inhibit the local maturation and activation of dendritic cells. Tumor cells themselves, moreover, are typically compromised in antigen presentation and lack most of the key costimulatory molecules. As a consequence, it is unlikely that T and B lymphocytes encounter tumor antigens in an optimal immunologic environment; instead, tumor-specific lymphocytes remain ignorant of a progressing mass or undergo abortive responses (39).

Based on this model of how tumor cells may evade optimal host recognition, investigators are exploring a number of approaches to improve tumor antigen presentation. One widely pursued strategy involves the direct intermingling of tumor cells and dendritic cells. The discovery of techniques to expand large numbers of dendritic cells from hematopoietic precursors by culture with granulocyte-macrophage colony-stimulating factor (GM-CSF) (40, 41) has spawned many investigations showing that dendritic cell–based vaccines substantially augment antitumor immunity in murine tumor models. Several schemes involving the *ex vivo* manipulation of dendritic cells have demonstrated activity (42,43,44 and 45), including dendritic cells pulsed with tumor antigen–derived peptides or whole tumor cell lysates and dendritic cells genetically engineered to express tumor antigens.

In addition to these strategies involving the *ex vivo* handling of dendritic cells, other approaches attempt to modify dendritic cell function *in vivo*. The cytokine flt3-ligand is a potent growth factor for dendritic cells, and its administration effectuates significant tumor destruction in multiple murine models (46,47). Immunization with plasmid DNA encoding tumor antigens can enhance augment antitumor immunity, and this involves either the transfection of dendritic cells *in vivo* or the processing by infiltrating dendritic cells of protein translated in skin or muscle (48). Recent studies have revealed that the unmethylated CpG oligonucleotides present in plasmid DNA molecules stimulate the growth and activation of dendritic cells (49). Tumor-derived heat-shock proteins, which chaperone peptide fragments, also show promise for increasing antitumor immunity, and the mechanism underlying their vaccination potential involves uptake by dendritic cells *in situ* (50).

The generation of an inflammatory focus filled with necrotic debris is a potent stimulus for dendritic cell activation (51,52). This insight provides the foundation for a number of immunization strategies that aim to elicit an inflammatory nidus at the site of tumor antigen administration. A widely studied method involves the inoculation of recombinant viral vectors expressing tumor antigens; these systems have been engineered from adenovirus, herpes simplex virus, and vaccinia and fowlpox viruses (53). It is hoped that the immune response directed against viral components will elicit a favorable mixture of cytokines, resulting in the “bystander” generation of tumor antigen–specific responses. A limitation of this strategy is that the immune response may remain directed toward viral targets, with inefficient epitope spreading to the cancer antigen.

To overcome this difficulty, several groups are evaluating a variety of adjuvants administered with tumor antigen–derived proteins or peptides. QS-21 and DETOX appear to be among the most potent of the group of saponin/microbial product complexes. These agents function as depots for sustained antigen delivery and as stimuli for cytokine production (54). Recombinant cytokines also are being administered with tumor peptides/proteins, and encouraging preliminary results have been found with GM-CSF and interleukin (IL)-12 (55,56).

The application of recombinant cytokines as vaccine adjuvants represents an extension of the pioneering studies of Forni et al. (57), who showed that the peritumoral injection of specific cytokines, particularly IL-2, could elicit tumor destruction through the local activation of neutrophils, eosinophils, macrophages, natural killer cells, and lymphocytes. This orchestrated response could in some cases generate protective immunity against wild-type tumor challenge. These striking findings stimulated a large number of investigations exploring the antitumor effects of various immunostimulatory molecules. These studies were significantly advanced with the application of gene-transfer techniques for the engineering of tumor cells, as this approach resulted in superior cytokine delivery to that which could be achieved by the injection of recombinant proteins [reviewed in (58)].

Retroviral vectors were most commonly used in these investigations because of their ability to achieve stable, high-level gene expression without the generation of replication-competent virus (59). Many immunostimulatory molecules have been evaluated for the ability to abrogate tumorigenicity; IL-12 and IL-2 are the most consistently active cytokines in this assay (60,61 and 62). The antitumor effects of these molecules remain to be fully delineated, but include the coordinated functions of CD4- and CD8-positive T lymphocytes, natural killer cells, macrophages, neutrophils, and eosinophils. The destruction of the tumor vasculature and inhibition of angiogenesis are decisive components as well (63).

An important result in this work was that the development of systemic immunity could be dissociated from the reduction in tumorigenicity of gene-modified cells (64). Although this paradox remains poorly understood, it has stimulated exploration of a second assay in which the relative abilities of different molecules to stimulate systemic immunity were compared. Because most cytokines do not inhibit tumorigenicity, this assay required the use of replication-incompetent tumor cells for vaccination. Irradiation was an appropriate tool for this purpose, for although it induces a G_2 cell-cycle arrest, it does not reduce transgene expression *in vitro* for several days.

Our own group has tested the immunization activity of more than 30 different gene products in this manner. We have found that vaccination with irradiated tumor cells engineered to secrete GM-CSF stimulates potent, specific, and long-lasting antitumor immunity in multiple murine tumor models (65). GM-CSF–based vaccinations depend on both CD4- and CD8-positive T lymphocytes and likely involve the enhanced phagocytosis and digestion of irradiated tumor cells by activated dendritic cells

and macrophages recruited to the immunization site.

EXPLORATORY CLINICAL TRIALS

The development of vaccination strategies targeting antigen-presenting cells and the identification of candidate tumor antigens have provided clinical investigators with the complex problem of evaluating the relative immunogenicity and toxicity of these new treatment approaches. Because the safety profiles of these strategies have yet to be fully defined, patients initially receiving these treatments will harbor advanced disease. It is likely that tumor cells at this stage of illness are multiresistant and markedly heterogeneous. The immune system at this point also has been compromised by the toxicity of prior cytoreductive therapies and the suppressive effects of advanced cancer. These formidable obstacles may render it difficult for immunotherapy to effectuate substantive antitumor effects in these individuals, and thus the primary goal of this phase of testing should be a preliminary assessment of immunologic activity.

The use of defined antigens for cancer vaccination presents substantial advantages in terms of feasibility and immunologic monitoring. In this context, it is encouraging that several different approaches already have revealed some degree of antitumor activity. Immunization with melanoma antigen–derived peptides alone can elicit tumor regressions; seven of 25 patients receiving a human leukocyte antigen (HLA)-A1–presented peptide encoded by the MAGE-3 gene product manifested objective tumor responses (25). Intriguingly, the presence of antigen-specific cytotoxic T lymphocytes could not be detected in the peripheral blood of these patients, suggesting that either other antitumor effector mechanisms were stimulated by vaccination or that the activated cells had been recruited to metastatic tumor deposits.

Recombinant cytokines have been added to free peptides in an effort to enhance immunogenicity. GM-CSF has been shown to stimulate antigen-specific cytotoxic T cells and delayed-type hypersensitivity reactions in patients receiving mixtures of peptides derived from Melan A, tyrosinase, and gp100; moreover, some tumor regressions have been observed as well (66). GM-CSF also appears to enhance vaccination strategies using the idiotypes present in multiple myeloma (67) and follicular lymphoma (68). This treatment approach is based on the idea that the unique immunoglobulin molecule expressed on malignant B cells can serve as a tumor-rejection antigen. A significant proportion of lymphoma patients immunized with this scheme after autologous bone marrow transplantation achieved molecular remissions, and antigen-specific CD4- and CD8-positive T-cell and antibody responses developed. High doses of IL-2 also may serve an adjuvant function, as has been suggested by recent studies of a modified peptide derived from the gp100 (26). Early trials of bone marrow–derived dendritic cells loaded with melanoma antigens or B-cell idiotypes have disclosed antitumor effects as well, although the effector mechanisms remain to be clarified (69,70 and 71).

The analysis of antigen-specific–based vaccines has been considerably advanced by the recent development of peptide epitope/MHC molecule tetramers. Tetramers are complexes of synthetic peptide epitopes and bacterially produced MHC molecules conjugated to a fluorochrome (72). Their multimeric nature overcomes the inherent low affinity and fast off-rate of T-cell receptor/MHC-peptide interactions, permitting these complexes to be used in fluorescein-activated cell sorter (FACS) analysis of bulk T-cell populations. These reagents also can be used to sort tetramer-binding cells for detailed functional studies, including antigen-induced cytokine production, proliferation, and cytotoxicity.

Although peptide and protein targets are the most widely studied targets in antigen-specific vaccine strategies, carbohydrate molecules also have elicited promising results. Furthest in development are those schemes based on the GM2 ganglioside (73); phase III trials have been initiated of vaccination with this antigen admixed with QS-21 in stage III malignant melanoma patients after lymph node dissection. Immunization with globo H also has been shown to stimulate antibody responses and modify the rate of prostate specific antigen (PSA) elevation in metastatic prostate carcinoma patients (74).

The selection of antigen loss variants may ultimately limit the overall efficacy of antigen-specific vaccines. Indeed, this already has been observed in melanoma peptide vaccine trials, where some progressive tumors were shown to lose expression of the immunizing antigen (75). The use of polyvalent vaccines may be one strategy to obviate this difficulty, and, in this context, whole tumor cells are a particularly attractive source. Allogeneic tumor cells offer many logistic advantages and could be readily adapted for large-scale clinical testing. Allogeneic melanoma cells have been used in a variety of forms, including intact cells or shed antigens with bacille Calmette-Guérin (BCG), virus-modified cell lysates, and cell lysates admixed with complex adjuvants (76,77,78 and 79). Some of these strategies have recently entered phase III testing in settings of minimal residual disease. Vaccination with allogeneic tumor cell lines engineered to express immunostimulatory molecules has been initiated as well. A pilot study of immunization with IL-2–secreting melanoma cells disclosed the generation of inflammatory reactions in metastases (80); trials of GM-CSF and B7-1–expressing allogeneic cells also have been initiated.

Although allogeneic cell vaccines are easily prepared, substantial data in murine systems suggest that tumor-specific antigens may be the most potent (81). An intriguing phase III study in support of this idea was recently reported; patients with Duke's B colorectal carcinoma showed a 61% reduction in the risk of recurrent disease after vaccination with irradiated, autologous colorectal carcinoma cells admixed with BCG as postoperative therapy (82). The administration of autologous, hapten-modified melanoma cells admixed with BCG and cyclophosphamide also has stimulated the development of inflammatory reactions in metastases (83).

Vaccination with autologous tumor cells genetically modified to express immunostimulatory molecules has recently entered clinical testing. Two small trials have examined the biologic activity of lethally irradiated, autologous melanoma cells engineered to secrete interferon-g (84,85). These studies have revealed the stimulation of antimelanoma IgG antibody responses and some minor tumor regressions. A small study of immunization using irradiated, GM-CSF–secreting autologous renal cell carcinoma cells has been published (86). Vaccination sites demonstrated an infiltrate of macrophages, dendritic cells, eosinophils, and lymphocytes. After, but not before vaccination, injections of nontransfected tumor cells elicited strong delayed-type hypersensitivity reactions consisting of lymphocytes, eosinophils, and macrophages. Similar results were found in a phase I study of vaccination with irradiated, GM-CSF–secreting autologous prostate carcinoma cells in patients with increasing PSA levels (87).

We recently reported the results of a phase I trial of 21 metastatic melanoma patients who were vaccinated with irradiated, autologous melanoma cells engineered to secrete GM-CSF (88). Although metastases resected before vaccination were minimally infiltrated with cells of the immune system in all cases, metastases resected after vaccination were densely infiltrated with T lymphocytes and plasma cells and showed extensive tumor destruction (at least 80%), fibrosis, and edema in 11 of 16 patients examined. Lymphocytes isolated from the infiltrated metastases showed marked cytotoxicity and broad cytokine production in response to autologous melanoma cells. High-titer antibodies recognizing intracellular and surface melanoma antigens could be demonstrated by Western blot and FACS analysis with postvaccination sera.

CONCLUSION

Cancer immunology has been reinvigorated by the infusion of molecular genetics, advanced cell-culture techniques, and careful clinicopathologic study. The recognition that antitumor immune responses are commonly stimulated, and that specific kinds of immune responses (those defined pathologically by brisk intratumor T-cell infiltrates) are associated with prolonged survival provides a strong intellectual foundation for the crafting of novel immunotherapies. The design of several vaccination schemes that dramatically augment tumor antigen presentation represents an important first step in this regard. Immunotherapies are likely to find their most effective application in early-stage disease, however, and thus appropriate clinical testing will take considerable time. Fortunately, the rigorous assessment of immunogenicity can now be the basis for mapping out the long-term course.

89 ANTI-TNF-a THERAPHY IN RHEUMATOID ARTHRITIS AND OTHER DISEASES

Marc Feldmann, Ph.D., F.R.C.P., and Ravinder N. Maini, F.R.C.P.

THE ROLE OF TUMOR NECROSIS FACTOR-a IN THE PHYSIOLOGY OF IMMUNITY, INFLAMMATION, AND PATHOLOGY

Basic Properties

Tumor necrosis factor-a (TNF-a) is a key mediator of inflammation, immunity, and pathology (1,2). This is now clear from the analysis of more than a decade of the properties of TNF-a *in vitro*, in animal models, from the use of anti–TNF-a biologicals in clinical trials, and lately, from observations in routine clinical practice (3,4).

TNF-a in its biologically active state is a homotrimer, which exists in two forms. Initially TNF-a is membrane bound, but subsequently the membrane form is cleaved by a surface metalloproteinase, known variously as TNF-a–converting enzyme (TACE), also known as a disintegrin and matrilysin (ADAM)17 (5) (Fig. 89.1). TNF-a is produced chiefly by monocytes/macrophages and T lymphocytes, but to a lesser extent by many other cells including mast cells, neutrophils, natural killer (NK) cells, dendritic cells, endothelial cells, and malignant cells (1,2).

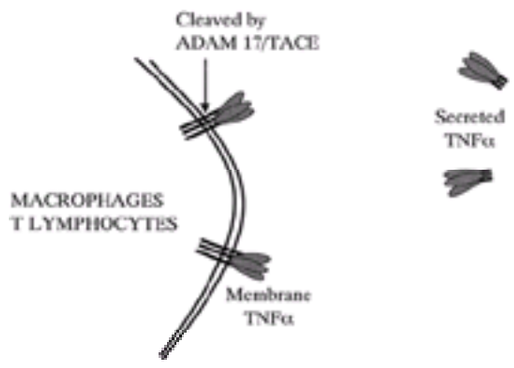

Figure 89.1. Tumor necrosis factor (TNF)-a is shown as a homotrimer on the cell surface. The soluble form of TNF-a is released by the action of TNF-a cleavage enzyme, ADAM17/TACE.

All cells of the body express TNF receptors, and thus are susceptible to its actions. There are two distinct receptors, with the p75 receptor expressed chiefly on hemopoietic cells, preferentially binding membrane TNF-a and involved in immunity, whereas the p55 receptor is ubiquitous and is involved mainly in proinflammatory and apoptotic signals (6,7). The mechanism by which the TNF receptor mediates signals is complex, but has been partly unraveled with the help of gene knockouts and other techniques.

Physiology of Tumor Necrosis Factor-a

TNF-a is one of the most rapidly released cytokines, with abundant blood levels detected within 30 minutes of lipopolysaccharide (LPS) stimulation. This is quicker than other proinflammatory cytokines such as interleukin (IL)-1 or IL-6 (8), and together with *in vitro* data, suggests that TNF-a has a special role in coordinating the response to stressful proinflammatory stimuli, such as LPS stimulation or exposure to ultraviolet light, or chronic inflammation such as rheumatoid synovitis (9). The initial source of TNF-a is probably from the cleavage of preexisting membrane TNF-a on monocytes, neutrophils, and T lymphocytes, and the release of TNF-a from mast cell granules. Subsequently, newly synthesized TNF-a by macrophages and T lymphocytes is the major source.

The actions of TNF-a on almost all cells are too numerous to describe here (for useful further details on this and other cytokine topics, the “Cytokine Reference” is useful) (10). The most important actions of TNF-a include (11)

T lymphocytes: Upregulation of CD25 (IL-2Ra chain);

B lymphocytes: Growth factor;

Macrophages: Activator, induces other proinflammatory mediators such as IL-1, granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-6, induces chemokines (e.g. IL-8, degradative enzymes);

Endothelium: Augments adhesion molecule expression [vascular cell adhesion molecule (VCAM)-1, E-selectin], induces chemokines, upregulates NOS;

Fibroblasts: Induce production of matrix metalloproteinases, prostaglandin (PG)E_2;

Chondrocytes: Induce production of matrix metalloproteinases, reduce proteoglycan synthesis;

Osteoclasts: Mediate osteolysis.

Lymphotoxin a (LT-a) is a very closely related molecule, also a homotrimer, which although sharing ~30% sequence identity, has essentially the same three-dimensional structure, and so activates the same two receptors as TNF-a. It is produced by fewer cell types, chiefly lymphocytes (T and B), and has a role in the immune system (12).

TNF receptors are clustered on the cell surface, with an association domain at their terminal region (13) (Fig. 89.2). This keeps the intracytoplastic domains apart inside the cell. Aggregation of the TNF-R is an essential step, which initiates the signaling cascade. Physiologically this is accomplished by the TNF-a (or LT-a) trimer, and the importance of aggregation is demonstrable by the agonist effects of most monoclonal antibodies to the p55 TNF-R (14). Receptor aggregation brings the intracytoplasmic domains close together, permitting the signaling process to be initiated.

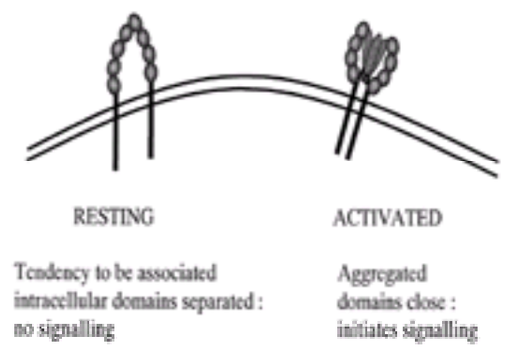

Figure 89.2. Resting and activated forms of tumor necrosis factor (TNF) receptor molecules on the cell surface. The binding of the soluble TNF-a molecule to the TNF receptors initiates signaling.

Once receptors are aggregated, a complex series of events follow and eventuate in the activation of a number of cascades. NFkB is activated, after IkB, the inhibitor of NFkB, is phosphorylated by Ik kinases and degraded by the proteosome. All three of the mitogen-activated kinase cascades, p42/44 ErK, p38 stress-activated kinase (SAPK) and p54 JUNK, are also induced. The p55 TNF-R can activate caspases involved in apoptosis very effectively, and induces apoptosis if antiapoptotic factors are not generated, as is the case in TNF-a bioassays, by blocking protein synthesis with cycloheximide or actinomycin D. Further details of TNF signaling can be found in recent reviews (14,15).

The outcome of TNF signaling is the induction of multiple genes and their products, including cytokines, chemokines, adhesion molecules and PGE_2. Some aspects of TNF signaling are still controversial, such as the role of sphingomyelinases. TNF-R signaling is summarized in Fig. 89.3.

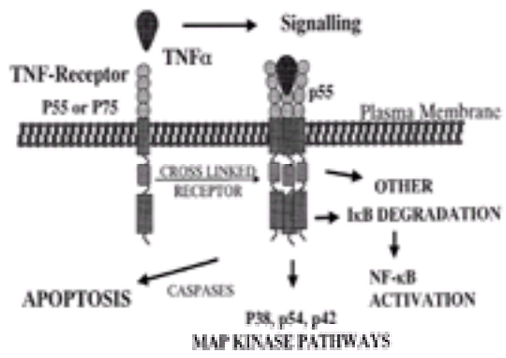

Figure 89.3. Activation of tumor necrosis (TNF) receptors, p55-TNF-R or p75-TNF-R by TNF-a induces multiple cell-signaling pathways leading to cell and gene activation.

The strongly proinflammatory actions of TNF-a are modulated by a number of mechanisms. These include the TNF-R–associated inhibitory molecules, cellular inhibitors of apoptosis (cIAPs), and the silencer of death domain (SODD). These increase the threshold of activation and are displaced when the TNF-R is cross-linked (16). A second mechanism is dependent on the shedding of the extracellular domain of the TNF-R, which leads to a reduction in receptor density, thus reducing TNF signaling efficiency. It also results in the generation in body fluids of appreciable levels of soluble TNF-Rs, which act as competitive inhibitors and reduce access of free TNF-a to the membrane receptors (17,18 and 19). Third, TNF-a synthesis, especially by macrophages, can be downregulated by a number of cytokines, including IL-4, IL-10, IL-13, IL-11, and tumor growth factor (TGF)-b.

One of the clearest ways of investigating the physiology of TNF-a is to study targeted mutations in murine models, commonly known as knock-outs (20,21). TNF-a knock-out mice have a reduced response to inflammatory stimuli such as LPS, and importantly, are unable to mount an adequate defense against intracellular parasites, such as *Listeria*, *Mycobacteria*, or fungi. However, they also are unable to control noninfectious granulomatous stimuli, including exposure to heat-killed *Corynebacterium parvum*, which result in severe liver damage, thus emphasizing the complexity of the role of TNF-a, which under certain conditions can suppress the immune response *in vitro* and *in vivo* (20,21 and 22). Lack of TNF-a is implicated in the pathogenesis of systemic lupus erythematosus in NZB/W mice (see later). Appropriate but controlled production of TNF-a is beneficial in host defense.

TNF-a–overproducing transgenic mice also have been useful in defining the pathophysiology of TNF-a. Kollias et al. (23) made a number of these, which have emphasized aspects of TNF-a pathophysiology. Some of these transgenics are created by deleting the endogenous 3' region of the TNF-a DNA, which has numerous AU-rich motifs, involved in the binding of inhibitory proteins to this important regulatory region of the TNF gene. One of these proteins is tristetraprolin (abbreviated TTP) knock-outs, which have augmented TNF-a concentrations (24).

Transgenic mice overexpressing human TNF-a develop arthritis, and some have psoriasis-type rashes and inflammatory bowel disease (21,23,25,26). The capacity of human TNF, which binds to the murine TNF-R p55 but not murine TNF-R p75 to induce arthritis, indicates that the p55 signaling pathway is essential for the development of arthritis, whereas the p75 pathway is not. Murine TNF transgenics also induce arthritis, indicating that the p75 does not have an essential “protective” role.

In most animal models of arthritis, it is clear that T cells are an important part of the pathogenesis, for example, in DBA/1 mice injected with type II collagen in complete Freund's adjuvant, or rats injected with *Mycobacteria* (adjuvant arthritis). However, this is not the case in TNF-a transgenics, which if backcrossed to lymphocyte-deficient RAG2 knock-outs, still develop arthritis, but interestingly, do not develop inflammatory bowel disease (26). Thus it appears that in the context of arthritis, the immune activity takes place upstream of TNF-a production, which can thus be viewed as a final common pathway leading to chronic inflammation.

TNF-a transgenics also have cachexia, emphasizing the role of TNF-a in the early observations of Cerami and Beutler (1), who cloned mouse TNF-a as “cachectin.”

BIOLOGIC AGENTS THAT BLOCK TUMOR NECROSIS FACTOR-a

These are diagramatically illustrated in Fig. 89.4.

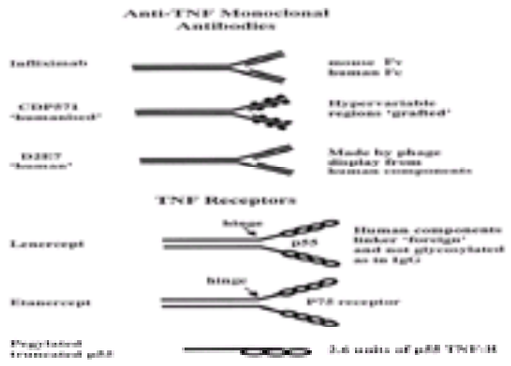

Figure 89.4. Anti–tumor necrosis factor (TNF) monoclonal antibodies and TNF receptors biologicals that have been developed for therapeutic use.

Monoclonal Antibodies

These were the first agents produced to inhibit TNF-a actions specifically. Murine monoclonals were first generated and were extensively used in sepsis trials, without success.

CHIMERIC MONOCLONAL ANTIBODY, INFLIXIMAB

Subsequently Centocor, Inc., generated a “chimeric” monoclonal by replacing three fourths of the mouse gene with human constant regions of light and heavy chains of immunoglobulin (Ig)G, but leaving the murine Fv region, producing a protein that is 75% “human,” and has the human Fc region and hence effector functions on human cells. This was used for anti TNF-a therapy for rheumatoid arthritis (RA) and Crohn disease (CD) and is now generically designated infliximab, and is sold by Centocor/J&J as Remicade® for RA and CD in the United States, and by Schering-Plough in Europe.

OTHER MONOCLONAL ANTIBODIES

Newer entrants to the field have produced other antibodies (e.g., Celltech generated a “humanized” hypervariable complementary determining region (CDR) grafted antibody CDP571, which has been used in trials. Cambridge Antibody Technology (CAT) and BASF have been using an antibody generated by phage-display technology (D2E7), which in 2000 was in phase III development.

A schematic representation of these antibodies is shown in Fig. 89.4. The logic of using humanized antibodies, to various degrees, is to reduce the immunogenicity of the “murine” determinants, and also to introduce the human Fc, which would increase circulating half-life, as well as permit the effector function of the Fc region.

Tumor Necrosis Factor Receptor Immunoglobulin G Fc Fusion Proteins

There are two TNF receptors, p55 and p75, both of which bind both TNF-a and LT-a. Thus the fusion proteins composing the Fc region of IgG linked to the hinge region, and two TNF receptors have a different specificity from the monoclonal antibodies. At present it is not known what added benefits or risks are conferred by the blocking of LT-a and TNF-a over TNF-a alone.

P75 TUMOR NECROSIS FACTOR RECEPTOR FC ETANERCEPT, ENBREL (IMMUNEX/AHP)

This dimeric TNF-R p75 human Fc molecule produced by Immunex neutralizes TNF effectively *in vitro*, and in animal models, and has been highly successful in the clinic.

p55 TUMOR NECROSIS FACTOR RECEPTOR Fc LENERCEPT

The first reported TNF-R Fc fusion protein molecule was a dimeric p55 TNF-R IgG Fc that was strongly neutralizing *in vitro*, and in animal models, but surprisingly was not very successful in clinical trials, perhaps because of immunogenicity. It has thus been abandoned by Roche.

PEGYLATED TRUNCATED p55 TUMOR NECROSIS FACTOR RECEPTOR Fc

This is a monomeric TNF-R p55 (produced by Amgen) trimmed to remove potentially immunogenic sites, and pegylated to increase its circulating half-life.

ANTI–TUMOR NECROSIS FACTOR-a THERAPY IN RHEUMATOID ARTHRITIS

Rationale

Cytokine expression studies in rheumatoid synovium and synovial fluid in the 1980s revealed a very complex pattern of cytokines, with virtually all of assayable cytokines expressed, with the exception of IL-4 (27). This led to a common belief that cytokines were not good therapeutic targets because of their “redundancy,” a term used to reflect the markedly overlapping properties of various cytokines, with, for example, TNF-a, IL-1, and GM-CSF having very similar effects. It was believed that blocking a single cytokine, from a group with overlapping properties, was unlikely to be clinically beneficial, as the remaining ones would still drive the pathologic process.

Fortunately, the redundancy of the cytokine system is much more apparent *in vitro* than it actually is *in vivo*, and this pessimistic prediction has not proven true.

The first clues that TNF-a may be a good therapeutic target came from an analysis of IL-1 regulation in mixed rheumatoid synovial cell cultures, which we had found to be a good model of the rheumatoid synovium *in vitro*. The enzymatically dissociated cells (30% T, 30% macrophages, with B cells, fibroblasts, endothelium, B lymphocytes) rapidly reaggregate into clumps containing of T cells/macrophages/dendritic cells. These cultures produce cytokines over a prolonged period (e.g., 6 to 7 days), reflecting the prolonged cytokine production found in active rheumatoid synovium. Thus high and relatively stable levels of IL-1 mRNA and protein are released by these cultures (9,28) and provide an opportunity to explore why cytokine production is perpetuated and does not switch itself off, as it does in cultures of normal tissue after stimulation with mitogens or antigens.

The tools we used to dissect the phenomenon of the problem of the prolonged expression of cytokines were antibodies, and it was found that anti–TNF-a (but not anti–LT-a) antibody markedly reduced the production of IL-1 protein, within 24 hours if measured at the mRNA level, or 2 to 3 days if measured at the protein level (Fig. 89.5) (9). This was the first clue that TNF-a has a special role in the proinflammatory cytokine network and “orchestrates” the proceedings. This concept was established by evaluating the effects of TNF or IL-1 blockade on the production of other proinflammatory cytokines, including GM-CSF, IL-6, and IL-8 (3,29). An oversimplification of our current concept of the proinflammatory cytokine network is illustrated in Fig. 89.6. It is an oversimplification to have all the signals from the immune system going via TNF and IL-1, and of course, this scheme ignores the various feedback loops and the effects of genetic polymorphisms in cytokine function. Furthermore, the longer-term influences of cell recruitment and of control of cell survival and death cannot be summarized schematically.

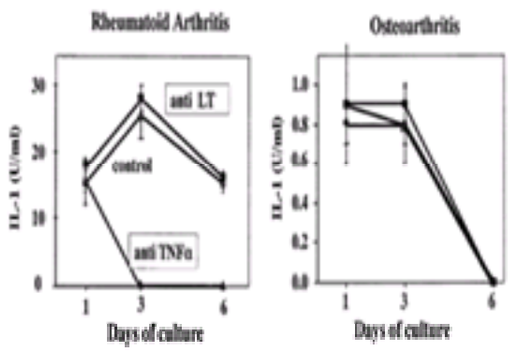

Figure 89.5. Synovial cells from patients with rheumatoid arthritis (RA) or osteoarthritis (OA) were cultured for 6 days with anti–tumor necrosis factor (TNF) or antilymphotoxin (anti-LT) monoclonal antibody. *In vitro* synthesis of interleukin-1 was inhibited by the anti-TNF monoclonal antibody in the RA but not the OA cell cultures. *Circles,* control cultures; *triangles*, with anti–TNF-a; *squares*, with anti-LT. (Reproduced from Brennan R, Chantry D, Jackson A, et al. Inhibitory effect of TNF alpha antibodies on synovial cell interleukin-1 production in rheumatoid arthritis. *Lancet* 1989;2:244–247, with permission.)

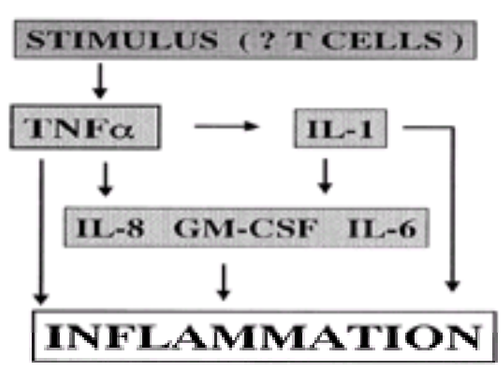

Figure 89.6. The dominance of tumor necrosis factor (TNF)-a in the cytokine cascade. TNF-a affects target cells either directly or indirectly through interleukin (IL)-1; a cascade of other cytokines is induced, each of which induces other inflammatory activities.

This analysis of the role of TNF-a in regulating other cytokines suggested that blocking TNF-a alone would be of potential therapeutic benefit. However, before that could be attempted, it was important to confirm some of the key predictions in *ex vivo* and *in vivo* situations. The presence of upregulated TNF and TNF-R expression *in vivo* was demonstrated by an *ex vivo* immunohistologic approach with fresh frozen (~1 minute) tissue, a time far too short to induce the *de novo* production of TNF *in vitro* (30).

Most important is the effect of anti–TNF-a antibody in animal models of RA. These studies have been very clear cut, with multiple groups all finding that TNF-a blockade after disease onset in animal models is effective at reducing inflammation and disease spread, as well as protecting joints from destruction (31).

Clinical Results of Anti–Tumor Necrosis Factor-a Antibody Therapy in Rheumatoid Arthritis

Overall, excellent and highly consistent results have been obtained by treating chronic active RA patients for whom all existing therapies have failed. Multiple agents that block TNF-a (+LT-a) have yielded highly significant and clinically relevant results, with the consequent approval by the Food and Drug Administration (FDA) of two of these agents (etanercept and infliximab) for clinical use in severe RA, and more on the way. The benefit and utility of these biologic agents blocking TNF-a has exceeded most people's expectations, with more than 150,000 RA patients treated by April 2001. A recent editorial reviewing anti–TNF-a therapy in RA reflects on the place and future of the therapy (32).

CLINICAL BENEFIT WITH ANTI–TNF-a INFLIXIMAB, REMICADE

This was the agent first used, and so the largest body of data exists with this drug. Phase I studies were initiated in May 1992, at the Charing Cross Hospital/Kennedy Institute of Rheumatology, on a cohort of active RA patients at the late stage of disease, for whom all prior therapy had failed. They were given a large dose of antibody, 20 mg/kg in two or four divided doses, over a 2-week period. The results were notable: many patients felt less tired and weak within hours, and diminution of pain and stiffness was marked. Swollen joints and tender joints diminished within 2 weeks, and plateaued at 6 to 8 weeks. All 20 patients improved markedly, with a duration of benefit ranging from 8 to 26 weeks before relapse (33).

This phase I trial was “open,” not blinded or placebo controlled, but the magnitude of the therapeutic benefit in patients resistant to all existing drugs made it likely to be a treatment, rather than a placebo effect. This was confirmed by assays on the serum acute-phase protein, C-reactive protein (CRP), which was reduced to the normal range within a few days. A summary of this trial is shown in Fig. 89.7.

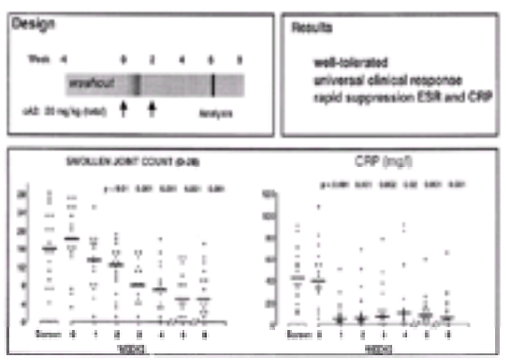

Figure 89.7. Open-label treatment with infliximab in rheumatoid arthritis (RA). Patients with active RA were infused with a total of 20 mg/kg infliximab. Mean serum C-reactive protein levels were close to the normal range, and swollen joint counts decreased significantly over the 8-week period. (Reproduced from Elliott MJ, Maini RN, Feldmann M, et al. Treatment of rheumatoid arthritis with chimeric monoclonal antibodies to tumor necrosis factor alpha. *Arthritis Rheum* 1993;36:1681–1690, with permission.)

Randomized, double-blind, placebo-controlled trials, are the currently required standard of proof that a therapy is effective. The first such trial of anti—TNF-a conducted in Europe was reported in 1994, and the results were unequivocal. The assessments used at this time were the criteria devised by Harold Paulus, a composite index comprising of numeric assessments of swollen joints, tender joints, duration of morning stiffness, and pain, as well as laboratory indices of inflammation such as erythrocyte sedimentation rate (ESR). A 20% degree of improvement at 4 weeks was the predetermined point for evaluating success. As summarized in Fig. 89.8, this 20% improvement level was reached in 8% of the placebo-infusion patients, 44% of those receiving a single infusion of 1 mg/kg, and 79% of those receiving a single infusion of 10 mg/kg. This was a very clear-cut demonstration of benefit (34). Figure 89.8 summarizes this trial.

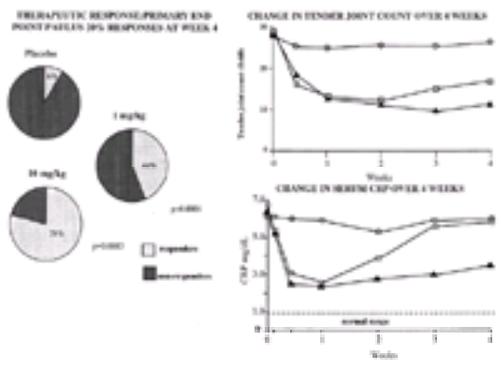

Figure 89.8. Randomized trial comparing infliximab and placebo. Patients with active rheumatoid arthritis (RA) received a single infusion of either placebo or infliximab at 1 mg/kg or 10 mg/kg body weight. At week 4, only 8% of placebo patients responded, compared with 44% and 79%, respectively, of these treated with 1 mg/kg or 10 mg/kg. Tender joint counts and serum C-reactive protein levels also decreased in the treatment groups, the effects being more pronounced in the 10-mg/kg patient group. (Reproduced from Elliott MJ, Maini RN, Feldmann M, et al. Randomised double-blind comparison of chimeric monoclonal antibody to tumour necrosis factor alpha (cA2) versus placebo in rheumatoid arthritis. *Lancet* 1994;344:1105–1110, with permission.)

The reports of these phase I and phase II trials led other companies, which had developed their TNF inhibitors for use in the then fashionable but difficult area of sepsis, to transfer their anti-TNF reagents to use in RA trials (e.g., lenercept, etanercept, CDP571).

As RA is a long-term disease, it was important to address the questions that the former short-term studies did not. For example, if TNF-a is blocked, will other pathways take over to drive the disease process? Could a chimeric antibody be used safely and effectively over the longer term? Would TNF-a blockade predispose to infections, malignancy, or autoimmunity?

The next trial lasted 6 months, and five infusions were given over this period. This demonstrated that efficacy could be maintained over this duration, with a good safety profile. As this trial incorporated infliximab with and without methotrexate (MTX), and a dose/response of infliximab (35), it helped define effective doses and demonstrated the benefit of even very low dose (7.5 mg/week) MTX as a supplement (Fig. 89.9).

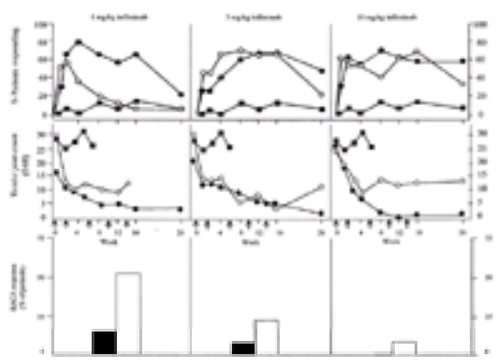

Figure 89.9. Synergy of anti–tumor necrosis factor-a and methotrexate (MTX). **Top panels:** Duration of response to therapy as defined by 20% Paulus criteria at three doses of infliximab and without MTX and placebo plus MTX. Results shown are the proportion (%) of patients responding at weeks 1, 2, 4, 8, 16, and 26. The Paulus response is achieved by 20% improvement in four of six of the following: tender-joint and swollen-joint scores, duration of morning stiffness, erythrocyte sedimentation rate, and a two-grade improvement in the patient's and observer's assessment of disease severity. **Middle panels:** Serial measurements (median values) of the tender-joint count, before (day 0), during (weeks 1–14), and after (weeks 14–26) treatment. Results are included only up to the point at which £50% of patients remained in the trial (up to week 6 for the placebo-plus-MTX group and up to week 14 for the infliximab, 1-mg/kg group). *Arrows,* the timing of infusions of infliximab at weeks 0, 2, 6, 10, and 14; *solid circles*, infliximab with MTX; *open circles*, infliximab without MTX; *squares*, placebo plus MTX. **Bottom panels**: Incidence of human antichimeric antibody (HACA) in the patient groups receiving infliximab, with (*shaded*) or without (*clear*), MTX. The rate of HACA responses is inversely proportional to the dose of infliximab. (Reproduced from Maini RN, Breedveld FC, Kalden JR, et al. Therapeutic efficacy of multiple intravenous infusions of anti-tumor necrosis factor alpha monoclonal antibody combined with low-dose weekly methotrexate in rheumatoid arthritis (see comments). *Arthritis Rheum* 1998;41:1552–1563, with permission.)

The assays for immunogenicity of infliximab revealed that there was a high frequency of anti-infliximab responses at 1 mg/kg in the absence of MTX. However, this was markedly reduced by both increasing the dose and adding MTX. These results indicate that in humans, as previously shown in experimental animals, there are mechanisms of downregulating antibody response to injected IgG, by using an immunosuppressive (MTX) or a sufficient dose of deaggregated gamma globulin. There is an extensive literature from the 1960s and 1970s that deaggregated gamma globulin (like infliximab), given intravenously, induces “high zone” tolerance, at higher doses (36). Although this appears to be the only plausible interpretation of the data, there is no proof of this mechanism, which would require challenge with aggregated IgG to prove tolerance formally. The reduction in antiidiotype antibody at higher doses is illustrated in Fig. 89.9.

A phase III study with infliximab, the ATTRACT trial, has been decoded, after 2 years of anti–TNF-a therapy given every 4 or 8 weeks. Efficacy was maintained for the 2 years. It has confirmed that antibodies can be used repeatedly in a chronic disease, with good clinical benefit (37,38). Most important, the longer-term duration of this study permitted the analysis of the effects of infliximab on joint destruction, as assessed by radiograph, using a modified Sharp score (Van der Heijde modification). The results were presented at the November 1999 American College of Rheumatology (ACR) meeting and have recently been published (38). Two key points emerged. First was that by 12 months, the progression in joint damage was arrested in more than 50% of patients, as assessed by two independent experts blinded to the treatment and sequence of the radiographs. The results were clear at all four dose regimens of infliximab used, with arrest in progression noted at all doses. When the patients were analyzed according to their clinical response, by using the 20% ACR criteria, it was observed that the patients who did not benefit at the 20% level still benefited at the radiographic level. This interesting result needs further analysis, but at face value suggests that the widely held view based on animal and *in vitro* experiments that joint destruction depends on IL-1 and not TNF-a should be reevaluated.

OTHER ANTI–TUMOR NECROSIS FACTOR-a ANTIBODIES

Much less has been published with other antibodies. Celltech reported trials with CDP571, a humanized IgG4 antibody. This was effective at 10 mg/kg but not at 1 mg/kg and so is less efficacious than infliximab (39). A second-generation anti–TNF-a is being tested by Celltech, a pegylated anti–TNF-a Fab fragment, which appears efficacious compared with placebo (40).

D2E7, a human IgG1 anti–TNF-a antibody produced by phage display by Cambridge Antibody Technology (CAT) and BASF/Knoll, is currently in phase III trials. The data reported so far indicate that it is efficacious at a wide range of doses and treatment regimens. The results as presented appear to be comparable to those reported with infliximab, although in many of the trials, D2E7 is used subcutaneously rather than intravenously. Joint protection also has been reported in an abstract. The safety profile appears to be good (41,42).

Anti–Tumor Necrosis Factor Receptor Biologicals

p75 TUMOR NECROSIS FACTOR–RECEPTOR Fc ETANERCEPT (ENBREL)

This fusion protein is administered subcutaneously, twice a week, which means that self-administration is possible. The results are comparable to those obtained with infliximab, with minor differences, possibly linked to the dose and route of administration. The recommended dose of 25 mg twice a week, s.c., was the maximum used in trials, so it is not certain yet whether it is the optimal dose.

The efficacy of etanercept was first established in a phase II trial comparing 0.25, 2, and 16 mg/m^2 over a 3-month period. There was a 61% reduction of swollen and tender joint counts at the highest doses, compared with a 25% reduction with placebo, with intermediate results at 2 mg/m^2 (43).

Phase III studies compared 10 and 25 mg, s.c., twice per week, with placebo, over a 6-month period. There was a 59% ACR 20% response at the 25-mg dose compared with 11% in the placebo-treated group (Fig. 89.10) (44).

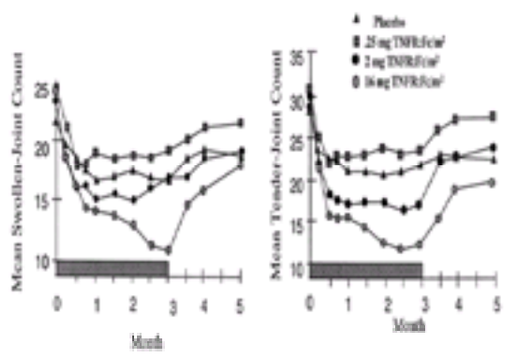

Figure 89.10. Treatment of rheumatoid arthritis with recombinant human p75 tumor necrosis factor (TNF)-R-Fc fusion protein (etanercept). Patients received subcutaneous injections of placebo or etanercept at 0.25 mg, 2 mg, or 16 mg per square meter of body-surface area, twice weekly for 3 months. Mean swollen-joint counts and tender-joint counts are shown over a 5-month period. *Shaded bar,* the treatment period; *triangles*, placebo; *squares*, 0.25 mg/m^2; *solid circles,* 2 mg/m^2; *open circles*, 16 mg/m^2. (Reproduced from Moreland LW, Baumgartner SW, Schiff MH, et al. Treatment of rheumatoid arthritis with a recombinant human tumor necrosis factor receptor (p75)-Fc fusion protein. *N Engl J Med* 1997;337:141–147, with permission.)

Like infliximab, etanercept has been used in clinical trials in conjunction with MTX. This may also augment efficacy, with a 71% ACR response rate in the combination therapy, compared with 27% with MTX plus placebo. As there was no etanercept-alone arm in this trial, it is not clear if the combination of etanercept and MTX was more effective than etanercept alone (45).

Etanercept also has been approved for juvenile RA, of the severe polyarticular type, which is not responding to other drugs. At a dose of 0.4 mg/kg (twice a week, s.c., for 90 days), 74% showed a clinical response by the predefined criteria (46).

TUMOR NECROSIS FACTOR–RECEPTOR P55 Fc (LENERCEPT)

This was the first fusion protein to be extensively tested. The results were positive, but were somewhat variable (47). The reasons for this are not fully known, but two hypotheses for the inconsistent results have been discussed. One is that there were batch-to-batch variations due to manufacturing problems. Another is that lenercept was more immunogenic than would have been predicted. Lesslauer et al. (48) reported that the extended peptide linker between the immunoglobulin Fc region and the TNF-R was the immunogenic part of the molecule, and with time, antibodies extended to the TNF-R itself (48). If the latter hypothesis is correct, then agonistic effects due to cross-linking cell-surface p55 receptors also may have contributed to variable results. It is noteworthy that Lesslauer et al. reported agonistic antibodies in a small cohort (three of seven) of patients given subcutaneous lenercept. Changes in half-life of lenercept were noted at the second injection compared with the first, which supports the concept that it was immunogenic. However, in some trials, many patients did very well, over long periods.

PEGYLATED p55 TUMOR NECROSIS FACTOR RECEPTOR

This product, developed by Amgen, has been shown to be effective in rodent and primate models, and there also is preliminary evidence in phase I/II trials in RA (49). This was a dose-ranging study, not powered for efficacy, which showed a trend to reduction in disease activity.

Biologic agents are much more costly to manufacture than are small chemical drugs, and current market costs of the anti-TNF drugs on the market are significantly higher than other anti-rheumatoid drugs. However, the multiplicity of anti–TNF-a biologicals that are being developed is likely to lead to competitive pricing in the future and make them more cost effective.

MECHANISM OF ACTION OF ANTI–TUMOR NECROSIS FACTOR-a THERAPY (INFLIXIMAB) IN RHEUMATOID ARTHRITIS

Overview

This section refers to infliximab specifically, as the only published data we have access to concerns studies with this agent. It is possible, even likely, that the pharmacodynamics of intravenous infliximab therapy at the doses achieve high serum levels and differ from those occurring with lower-dose administration by subcutaneous injections and hence lower concentrations of other anti-TNF agents. In the former, there is a rapid and virtually total TNF blockade and hence TNF clearance (“washout”), with consequent reduction in many other “downstream” cytokines. The mechanism of action of etanercept have many similarities.

Anti–Tumor Necrosis Factor-a Downregulates the Cytokine Cascade *In Vivo*

As the effect of anti–TNF-a on other downsteam cytokines was an important part of the rationale for anti–TNF-a therapy, it was of interest to evaluate whether this also was the case *in vivo*. The easiest cytokine to assay *in vitro* is IL-6, as there are elevated levels in RA patients, averaging about 100 pg/mL.

It was found that within a day of infliximab therapy, serum IL-6 levels reverted to the normal range (50). This was not unexpected, as it was already known that CRP, believed to be controlled chiefly by IL-6, returned to normal levels within a few days of treatment. However, the IL-6 result is important, as it is a formal proof that TNF-a regulates other proinflammatory cytokines. The speed and magnitude of the effect makes it likely to be a direct consequence of TNF blockade on the cytokine network, rather than due to reduction in numbers of cells producing IL-6 (for example, due to indirect effects on leukocyte trafficking, or by killing of TNF-a–producing cells).

There is abundant other evidence for a downregulation of the cytokine “cascade.” Our own group has documented a reduction in various cytokines and chemokines including IL-8, MCP-1, and vascular endothelial growth factor (VEGF) (51), and the group of Kalden (52) has reported downregulation of serum IL-1 (52).

Infliximab Diminishes Leukocyte Trafficking into Joints

As it was known that TNF-a regulates adhesion molecule expression on endothelial cells, the changes in adhesion molecule expression were monitored in the infliximab trials. Two approaches were used. The most quantitative was to measure serum concentrations of all three adhesion molecules, intercellular adhesion molecule (ICAM)-1, E-selectin, and VCAM-1, among which E-selectin, an endothelium-specific molecule, most probably reflects the adhesive properties of blood vessels. It was found that there were significant reductions in serum E selectin and ICAM-1 (53). Less quantitative, but more relevant to the joint disease, was semiquantitative analysis of synovial biopsies. This had demonstrated, with blinded observers, that the expression of adhesion molecules in the joint was diminished after anti–TNF-a (54).

Already discussed is the observation that serum levels of many chemokines are reduced after infliximab. Together with the adhesion molecule data, it strongly suggests that leukocyte trafficking will be reduced, and it was possible to verify this directly by using ^{111}In-labeled granulocytes, reinfused into the patient before and 2 weeks after infliximab treatment (55).

Whereas these radiolabeled cell-uptake results strictly apply only to granulocytes, it is very likely that other leukocytes also enter joints more slowly after infliximab. Posttreatment synovial biopsies are much less cellular, with numbers of T cells and macrophages reduced. Because T lymphocytes and macrophages also use the same spectrum of adhesion molecules as neutrophils and the relevant chemokines are downregulated, it is likely that there is reduced trafficking of all leukocyte

subsets. Increased apoptosis noted in T lymphocytes also may contribute to reduced cellularity (P. Taylor, unpublished data).

Infliximab Reduces Vascular Endothelial Growth Factor and Angiogenesis in Inflamed Joints

Angiogenesis is a prominent feature of chronic rheumatoid joints, and so it was pertinent to investigate whether infliximab therapy was associated with reduced angiogenesis. Initial studies focused on measurement of VEGF, a potent and endothelium-specific growth factor that promotes angiogenesis. Based on previous work of Fava et al. (56) and Koch et al. (57), who had demonstrated high VEGF levels in synovium, we assayed longitudinal blood samples from patients in the infliximab trials on the assumption that increased serum levels might reflect enhanced synovial synthesis. Pretreatment serum levels were indeed elevated and significantly reduced after infliximab therapy in two separate trials (51).

The partial reduction in serum VEGF levels led us to explore the possibility that angiogenesis was reduced. Computerized image analysis of endothelium, for multiple markers of endothelium, has shown a reduced vascularity after infliximab therapy (58,59).

Infliximab Restores Hematologic Abnormalities in Rheumatoid Arthritis

A tendency to low hemoglobin and a normocytic normochromic anemia is common in RA patients. In view of the profound effects of cytokines on hemopoiesis, it was of interest to investigate the effects of infliximab in this system.

In the phase II trial, with an end point at 4 weeks, hemoglobin levels decreased over a 4-week period in the placebo-treated group, possibly because of blood loss for experimental analyses. At the 1-mg/kg infliximab treatment, it stayed level, but at 10 mg/kg, it was significantly elevated over baseline. This result suggests that the anemia of RA, and by inference probably the anemia of other chronic inflammatory diseases is cytokine dependent. Whether the anemia is an effect of TNF-a or IL-6 or both is not clear, because both are reported to diminish red cell production experimentally (60).

Elevated platelet counts are a potentially dangerous consequence of RA, as in excess they may promote atherosclerotic and thrombogenic complications. Infliximab reduced the elevated levels to the normal range (61). However, there is as yet no evidence to support the hypothesis that infliximab is protective against thrombosis. The tendency of RA patients to exhibit a moderate neutrophilia was normalized.

ANTI–TUMOR NECROSIS FACTOR-a THERAPY IN OTHER CHRONIC INFLAMMATORY DISEASES

Crohn Disease

Crohn disease is a chronic inflammatory disease that affects any portion of the alimentary tract. The granulomatous inflammatory lesions can extend right through the full thickness of the gut, and can extend beyond it, causing fistulas.

CD was the first disease indication for which anti–TNF-a therapy was approved, for severe CD with or without fistula. This rapid approval was due to the capacity of infliximab to close more than 50% of the fistulas within 4 weeks of a single infusion (and all the fistulas in 30% to 40% of infliximab-treated patients). Because no other effective therapy is available for this distressing condition, this was a most impressive result (62).

CD trials began after it became evident that infliximab was effective in clinical trials of RA, and the results have been closely analogous (63). Patient populations treated were those doing badly on existing therapy, as judged by the CD activity index (CDAI). Single doses of infliximab were sufficient to put ~50% of the patients receiving 5, 10, or 20 mg/kg infliximab into remission for the 12-week duration of the trial. Retreatment was possible and led to further benefit. Endoscopy also was used to demonstrate the benefit of infliximab in CD (64). A maintenance of remission study was conducted as a follow-up, and four more doses given, with follow-up period of 44 weeks. This showed that remission was maintained in 60% at the 10-mg/kg dose, compared with improvements in 35% receiving placebo treatment. At the 1-mg/kg dose, remission was maintained in 51% of patients compared with 21% receiving placebo treatment (65).

Other anti-TNF reagents also have been used in CD. CDP571 also was efficacious, but the duration of benefit was shorter (66). There are no published data on etanercept in CD. Trials are in progress. A detailed review of anti–TNF-a treatment in CD has been recently published (67).

Sepsis

Anti–TNF-a therapy with a number of antibodies and fusion proteins has been in clinical trials with more than 4,000 patients treated, with no significant success. The reasons for lack of success in patients, in stark contrast to many studies in experimental animals, are not yet clear. There is no consensus for the discrepancy, but possibilities include that to be successful, anti–TNF-a therapy must be very early, as it is in experimental models. In most human patients, sepsis supervenes on grave underlying diseases, and the diagnosis is often delayed. These factors may obviate a positive result. In anti-TNF antibody trials there have been trends toward benefit, noticeable in subset analyses, but no conclusive results. The negative result may reflect on the complex role of TNF-a *in vivo*, with some protective, as well as potentially pathogenic, effects (68,69).

Trials with etanercept, which also blocks LT-a, yielded different results in a sepsis study, as there was a dose-dependent increase in mortality (69). The trial was not repeated, and at present it is not clear what mechanisms were operating. It is possible that LT-a blockade was important; alternatively, it is possible that TNF-a binding to etanercept was unstable, and its release by “ligand passing” may have been detrimental.

Congestive Heart Failure

TNF-a is produced in the heart, and has been found in the failing myocardium. A small trial of etanercept in CCF has been performed, and the results were very encouraging, with multiple parameters of cardiac function statistically significantly improved. The mechanism may be due to the effects of TNF-a on myocyte contractility, and/or in cardiac remodeling (70). Larger studies have recently been reported to be negative.

SAFETY OF ANTI–TUMOR NECROSIS FACTOR THERAPY

During clinical trials, safety is closely monitored. As the populations used in the trials are late severe RA patients, it is anticipated that complications would occur in the trials.

However, the overall safety profile has been good. There were initial scares about a possibly increased incidence of lymphoma. However, this or other cancer risks have not been established in subsequent studies, which have revealed the numbers expected by comparison with populations of this age.

There appears to be a minimal risk of drug-induced lupus, the mechanism of which may be different from that in other drug-induced lupus, as anti–TNF-a appears to be able to make some lupus models (e.g., NZB/W) worse (71). Increases in anti–double-stranded DNA antibodies occur in ~14% of patients given anti-TNF antibody or fusion proteins, but only about 0.2% develop symptoms of systemic lupus erythematosus (SLE), which responded well to discontinuation of the antibody treatment. This tells us that SLE is at a different end of the spectrum of cytokine-dependent disease from RA, and the risk of induced SLE by anti-TNF is not a clinical problem.

There is a concern that infections may be increased in anti-TNF–treated patients. Thus far there are no statistically augmented risks of serious infection during the trials, although increased antibiotic use suggests that there may be a difference. What will happen on a longer time scale of treatment is not clear, but as etanercept has been on the market for more than a year, the infectious risk does not appear to be a major issue. Whether different anti–TNF-a agents have a different propensity to infection is not known. Safety is discussed in more detail in other reviews (3,4). A recent review of TNF therapy has been published (76).

OTHER ANTICYTOKINE THERAPY

Much less has been reported concerning other anticytokine therapy. There have been attempts to block IL-1 and IL-6, with anti–IL-8 only just beginning.

Interleukin-1 Receptor antagonist

This is a receptor antagonist that binds to the signaling membrane type I IL-1R, but does not signal, and it prevents the binding of either IL-1a or IL-1b, and thus acts as

a competitive antagonist. This entity has been used in clinical trials of RA, only one of which is published in any detail.

In this study, 440 patients with active RA of varying duration were repeatedly injected with three different doses of IL-1Ra subcutaneously (30, 75, and 150 mg) daily for 24 weeks (72).

There was a moderate antiinflammatory effect at the higher doses, although not comparable with the effect of TNF-a blockers. The authors have highlighted the results in radiographic progression, which was statistically significant at some but not all doses. These results are puzzling, as there was not a clear dose/response curve or maximal benefit at the highest dose, which would have been expected from its known mechanism of action. Further studies are needed to know exactly how it compares with TNF blockers, and whether there is an additive or synergistic effect with the latter. This possibility has been shown in experimental models of arthritis (73). In this context, it is worth pointing out that IL-1Ra has a very short half-life, and so the results with this agent do not necessarily reflect on the relative roles of IL-1 and TNF in RA.

Anti IL-6 Therapy

Two studies are known. First a murine anti–IL-6 antibody was used, with transient benefit in active RA patients. The immunogenicity of this antibody precluded its long-term use (74).

A humanized antibody to the IL-6 receptor also was reported by Kishimoto et al. (75). This had a good clinical effect, apparently matching that of anti–TNF-a in preliminary trials, although the kinetics of onset was much slower, over 4 weeks rather than a few days. Whether this difference will be consistent in larger trials is not known.

Anti–Interleukin-8

A trial has been reported in psoriasis with a humanized antibody made by Abgenix with benefit.

CONCLUSION

Anticytokine therapy has arrived in clinical medicine, and the omens are that this field will grow very rapidly in future years. This is because the indications for the undoubted success of anti–TNF-a will expand, and many more cytokine inhibitors will be assessed. As cytokines are molecules produced in small quantities in time of stress, they are rate-limiting steps and are thus likely to be good therapeutic targets.

90 The Use of Intravenous Immunoglobulin

C. Garren Hester, B.Sc., and Michael M. Frank, M.D.

Intravenous immunoglobulin (IVIG) is used in the treatment of a wide variety of immunologic diseases. There are now five Food and Drug Administration (FDA)-approved clinical indications for IVIG therapy and numerous others currently under investigation. In some cases, the effect on disease progression is very dramatic, but the mechanisms of action and the indications for IVIG therapy remain unclear.

HISTORICAL OVERVIEW

The cold ethanol fractionation method developed in the 1940s by E. J. Cohn and J. L. Oncley (1,2) to separate plasma proteins into stable and biologically active fractions initiated the modern use of immunoglobulin preparations. Cohn fraction II was found to contain more than 95% gamma globulin as well as high antimeasles activity, and the intramuscular administration of small amounts of this plasma protein fraction was found to have prophylactic activity against measles, tetanus, and diphtheria (3,4). As a result, a 16% solution of Cohn-Oncley fraction II (immune serum globulin, ISG) became the first commercially available gamma globulin preparation. ISG proved to be effective in the prevention and attenuation of measles and infectious hepatitis (hepatitis A), and later became indicated for prophylaxis of tetanus and rabies (5,6 and 7). However, there were disadvantages associated with intramuscular administration, including slow and incomplete absorption into the circulation, pain at injection site, and limits in the volume that could be administered (8). Attempts were made to administer larger amounts of ISG intravenously for the treatment of children with severe symptoms of measles, but the children experienced serious reactions (e.g., fever, convulsions, restlessness, chills, and vasomotor collapse) (4,5). Further attempts at intravenous use were discouraged until Bruton's discovery of agammaglobulinemia in 1952 and the emergence of antibody-replacement therapy (9). Again, intravenous injections proved unsuccessful, and Barandun (10) reported that the intravenous administration of gamma globulin induced adverse reactions in 93% of agammaglobulinemic children with severe acute infections compared with 13% of normal children. Intramuscular injections of ISG could be used as prophylaxis in children with agammaglobulinemia, but clinically acceptable doses gradually lost the ability to increase serum immunoglobulin levels effectively and to reduce the occurrence of infection as the patients became older (11). The subsequent discoveries of other primary and secondary antibody-deficiency syndromes during the 1960s solidified the need of a safe high-dose gamma globulin preparation and escalated many efforts to produce immunoglobulin concentrates with intravenous application and few adverse side effects.

Initial experiments were aimed at lowering the immunoglobulin aggregates in intravenous preparations that were believed to activate complement and induce anaphylaxis-like reactions. Enzymatic and filtration techniques were used to prevent immunoglobulin aggregation during concentration yet retain the ability of immunoglobulin to bind antigen. An early intravenous preparation consisted of $F(ab')_2$ fragments of IgG, prepared by pepsin digestion (12). Although this preparation was well tolerated and did not activate complement, it proved to be ineffective without Fc activity and was rapidly eliminated from the circulation by urinary excretion (13). Other modifications included the use of b-propriolactone, reduction and alkylation, reduction and sulfonation, and trypsin (14). These procedures also affected the integrity and the activity of the immunoglobulin (Ig)G molecule. Milder treatments aimed at eliminating impurities and unwanted activities were silica gel adsorption, polyethylene glycol (PEG) precipitation, and diethylaminoethyl (DEAE) Sephadex chromatography. All final preparations were initially at a neutral pH until ISG preparations at pH 4 in the presence of trace amounts of pepsin were found to contain decreased anticomplement activity but to retain normal functional activity (10). Imbach et al. (15) used this IVIG preparation to treat patients with hypogammaglobulinemia and thrombocytopenia and observed that patient platelet counts increased significantly 1 to 2 days after infusion. This important finding led to the successful treatment of children with idiopathic thrombocytopenic purpura (ITP) with IVIGs, and led to attempts to treat a diverse spectrum of inflammatory and autoimmune diseases (16). In 1983 Tenold (17) demonstrated that Cohn-Oncley fractions II and III are stabilized at an acid pH, eliminating the need for further chemical modification or enzymatic treatment. Consequently, several relatively nontoxic preparations of immunoglobulin concentrates have been produced for intravenous use (IVIG) in the United States and are now available for general clinical therapy.

CHARACTERISTICS OF INTRAVENOUS IMMUNOGLOBULIN PREPARATIONS

There are currently nine IVIG preparations available in the United States (Table 90.1) (3,18). Standard IVIG preparations are derived from large donor pools of human plasma, typically consisting of more than 10,000 individual donations. Manufacturers use the Cohn-Oncley fractions of gamma globulin or a modification by Kistler and Nitschmann as the starting material for batches of IVIG. The gamma globulin fraction is further modified by using various combinations of enzymatic treatment (plasmin, pepsin) incubation at low pH with or without low concentrations of porcine pepsin, PEG precipitation, ultrafiltration and diafiltration, and ion-exchange chromatography. Final preparations may be at low pH or a neutral pH, liquid or lyophilized, and all contain one or more of the following stabilizers: maltose, glucose, sucrose, mannitol, albumin, and PEG. The final product is more than 95% IgG with intact Fc effector functions. IVIG preparations contain low but variable amounts of IgA (0.005% to 1.5%) and negligible amounts of IgM, IgD, and IgE. The distribution of IgG subclasses tends to vary according to the characteristics and subclass distributions of the donor pools, but each batch usually contains normal subclass ratios. IVIG preparations also have a broad range of antibody activity for various antigens, again reflecting the population and exposure of the donor pool. In 1981, in an attempt to standardize partially preparations of IVIG, the World Health Organization (WHO) established a list of criteria for production of IVIG (19).

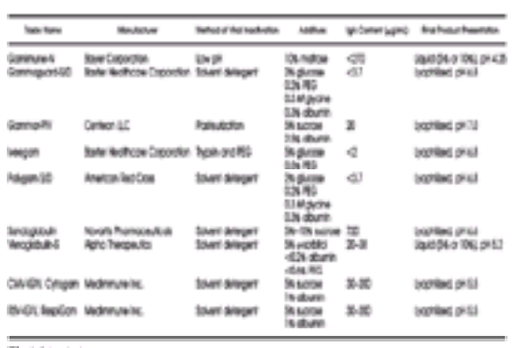

TABLE 90.1. Intravenous Immunoglobulin Products Licensed in the United States

IVIG preparations should

Be derived from human plasma of at least 1,000 donors;

Be free of prekallikrein activator, kinins, plasmin, preservatives, and essentially free of aggregates;

Contain at least 90% intact IgG, with a normal distribution of IgG subclasses;

Maintain biologic activity (e.g., complement fixation and opsonic activity);

Contain a wide spectrum of antibodies to various antigens, including tetanus and measles; and

Be free of infectious agents.

Two hyperimmune immunoglobulin preparations are currently available for intravenous application. Respiratory syncytial virus immune globulin intravenous (RSV-IGIV) contains a high titer of anti-RSV antibodies and is used to induce prophylaxis in pediatric patients susceptible to RSV infections. Cytomegalovirus immune globulin intravenous (CMV-IGIV) is indicated for prophylaxis of CMV associated with patients receiving organ transplants. Presently, only unmodified, intact IVIG preparations are available in the United States. Other preparations outside the United States include several modified preparations as well as one preparation enriched with significant amounts of IgM and IgA (Pentaglobin, Biotest Pharma, GmbH). This combination of the three major classes of immunoglobulins is used in the treatment of bacterial infections and reported to be highly opsonic and more potent in immunomodulatory activity when compared with standard IgG preparations (20,21).

The Safety of Intravenous Immunoglobulin Preparations

Viral Safety

Transmission of viral infection has been a major concern in all preparations of plasma proteins prepared by plasmapheresis of multiple donors. In 1993 and 1994, there was an outbreak of hepatitis C (HCV) from batches of IVIG predominantly but not exclusively prepared by ion-exchange DEAE Sephadex chromatography (22). HCV was transmitted to an estimated 450 patients worldwide. Approximately 115 cases were reported in the United States, leading to the establishment of stringent donor exclusion criteria and a reevaluation of production methods. Traces of HCV particles were detected in the immunoglobulin fraction after the Cohn-Oncley fractionation process, and HCV has been found in lyophilized IVIG products (23,24). The exclusion of donors with anti-HCV antibodies from the donor pool may affect neutralization or precipitation of HCV particles and how they partition during primary fractionation (25). In addition to screening all individual donations and plasma pools for evidence of infection by HBV, HCV, human immunodeficiency virus (HIV)-1, and HIV-2, manufacturers of IVIG now use various viral inactivation and elimination methods. These include the use of solvent detergents, low pH, pasteurization, and trypsin, pepsin, or PEG addition. Risk of viral transmission is now extremely low, and there has not been another reported case of HCV transmission. The cold-ethanol fractionation process has been shown to inactivate HIV, and although HIV-infected plasma had been used in the early 1980s, there have been no reports of HIV transmission by IVIG (26). The overall safety record of IVIG preparations is exceptionally good, but there is no 100% safe product. Some considerations concerning the viral safety of IVIG are listed in Table 90.2.

- HIV-1, HIV-2, HBV, and HCV screening of individual donors, plasma pools, and final preparations
- Donor exclusion criteria
- Viral partitioning during cold ethanol fractionation
- Viral inactivation treatment of Cohn fraction II
- Neutralizing antibodies present during fractionation/purification procedures
- Segregation and containment after viral inactivating procedures
- Surveillance of patients receiving IVIG: follow-up of adverse reactions

HIV, human immunodeficiency virus; HBV, hepatitis B virus; IVIG, intravenous immunoglobulin.

TABLE 90.2. Viral Safety Considerations

There is no evidence that the rare neurologic disorder, Creutzfeldt-Jakob disease (CJD), or other prion-related diseases are transmitted via blood products, although transmission has occurred from tissue transplantation (27). If a plasma donor is later diagnosed with CJD, manufacturers are required to recall the corresponding production lots from the market. A shortage of IVIG has occurred in the United States in parallel with a 10% per year increase in demand, as manufacturing techniques have been made more stringent to avoid viral contamination. Physicians are now reevaluating the necessary and effective conditions for IVIG therapy to conserve IVIG supplies and to meet the rising costs of IVIG therapy.

ADVERSE EFFECTS OF INTRAVENOUS IMMUNOGLOBULIN THERAPY

IVIG is one of the safest biologic products on the market. Severe adverse reactions have been documented, but they occur seldom and may be the result of a preexisting immunologic condition unknown at the time of infusion. Reports of such conditions are crucial to the overall safety of IVIG administration.

Mild and moderate adverse reactions during and after infusion occur in approximately 10% of patients receiving IVIG therapy (28,29). Signs and symptoms usually occur within the first hour of infusion. The most common side effect is headache; other symptoms include chills, facial flushing, dyspnea, back pains, and myalgia. Slight changes in blood pressure and tachycardia also may be detectable. Postinfusion reactions such as headache, nausea, vomiting, diarrhea, fever, and malaise develop within 24 hours and may last from several hours to several days. Suggested mechanisms are possible aggregates and dimers in IVIG preparations (30). Aggregates in IVIG preparations and acute antibody/antibody complex formation in some patients may induce complement activation and the production of the complement anaphylatoxins C3a and C5a. They also may interact with Fc receptors and directly or indirectly stimulate mast cells and polymorphonuclear granulocytes to release their contents, including histamine, prostaglandins, platelet-activating factor (PAF), and other granular mediators (11). Proinflammatory cytokine release also has been suggested, but other studies show that IVIG is able to downregulate proinflammatory cytokine release (31,32). Certain stabilizers in IVIG preparations also may be sources of rare adverse reactions, and preparations may contain low-molecular-weight peptides or compounds that may activate the fibrinolytic system (29). Most of these adverse effects subside with an interruption in therapy followed by a slower rate of infusion. If symptoms disappear, the regular infusion rate may be resumed. Other forms of management include the use of analgesics, antihistamines, or hydrocortisone, which may prevent or reduce the risk of known adverse effects of IVIG in certain disease states. Patient histories are vital to risk management, and initial treatments should be carefully monitored and documented. IVIG therapy should not be administered for the first time in a home-care environment.

Anaphylactic Reactions

True anaphylactic reactions are very rare and almost exclusively occur in patients with low or absent levels of serum IgA. Most of the reported reactions have occurred in patients with common variable immunodeficiency (33). Some of these patients have anti-IgA antibodies, which may react with the variable amounts of IgA in IVIG preparations. These complexes may consist of IgG, IgE, and IgM anti-IgA antibodies and may lead to anaphylaxis within seconds to minutes after beginning an infusion. Symptoms include facial swelling, shortness of breath, and hypotension. Determination of patient serum IgA concentrations before starting IVIG therapy and use of IVIG preparations containing the lowest possible concentration of IgA to treat patients with selective IgA deficiency markedly reduce the risk of anaphylaxis.

Acute Renal Failure

Approximately 40 cases of acute renal failure have been reported in association with IVIG therapy (34). In approximately half of these patients, there has been preexisting kidney disease. It was noted that sucrose, a stabilizing agent in some IVIG preparations, was responsible for renal tubular injuries in affected patients (35). Unlike glucose and maltose, sucrose given intravenously must be enzymatically hydrolyzed to glucose and fructose before filtration occurs at the glomerulus. The resulting increased sucrose exposure of the renal tubules potentially leads to acute renal failure. There are rare reports of fatalities, thus emphasizing the need to

assess renal function before the advent of IVIG therapy and, although it is not an exclusive indicator of renal damage, to monitor serum creatinine levels after administration.

Thrombotic Events

Serum viscosity is increased in IVIG patients up to 0.5 cp above the normal range, and patients with preexisting elevated viscosity levels are prone to potential thrombotic reactions (36). Such conditions as ITP, cryoglobulinemia, hypercholesterolemia, or hypergammaglobulinemias, especially in the elderly, increase the risk of stroke, myocardial infarction, and pulmonary embolism after IVIG treatment. Older patients with vascular disorders such as hypertension or cerebrovascular or cardiac disease are at risk for IVIG-induced thrombotic events, especially myocardial infarction (37). Careful consideration should be given to justify the use of IVIG therapy in such patients. More important, slow infusion rates will reduce the risk of impaired blood flow. It has been reported that pediatric HIV patients with high serum immunoglobulin levels also may be at risk of hyperviscosity syndrome and neurologic complications (38). Recently the FDA ruled that prophylaxis with RSV-IGIV is contraindicated in pediatric patients with cyanotic congenital heart disease (39).

Neurologic Complications

Some patients with a history of migraine are susceptible to migraines after IVIG administration (40). This can be prevented with the use of propranolol. These patients appear to have a risk for recurrent aseptic meningitis as well, but this reaction has not correlated with the IVIG product, the infusion rate, or the daily dose (28). One study reported that six of 54 patients with neuromuscular disorders experienced severe adverse effects including migraine, fever, lethargy, photophobia, painful eye movements, nausea, and vomiting (41). These symptoms continued for 3 to 5 days, and seemed to mimic bacterial meningitis. Cerebrospinal fluid contained increased protein levels and polymorphonuclear pleocytosis, but no bacterial growth was observed. The mechanism of aseptic meningitis is still unclear, and its association with IVIG therapy is equally perplexing. Although the number of reported cases is very low, reduced dosages and extended infusion times (1 g/kg over 24 hours) for patients with a history of migraine are recommended.

Hemolytic Anemia

IVIG is often used for treatment of autoimmune hemolytic anemia; however, there are some conflicting reports of efficacy (42). Paradoxically, it also has been reported that *in vivo* hemolysis and, in rare cases, the onset of hemolytic anemia can follow IVIG treatment (43). IVIG as well as enriched-IgM preparations have been shown to contain antibodies to major and minor blood group antigens and to Rh factors that cross-link red cells and increase the tendency to rouleux formation (29,44). “Immune complex–like moieties” in IVIG preparations also have been reported to activate complement, bind to erythrocyte CR1, and enhance erythrocyte sequestration and opsonization (45,46). Hemolysis has been described in both patients and healthy volunteers, and some patients show a positive Coombs test after infusion.

Dermatologic Effects

IVIG-treated patients have experienced allergic reactions to IVIG, the most common being a transient rash, either urticarial or maculopapular (47,48). One case involving an elderly patient with Sjögren syndrome developed lichenoid dermatitis after IVIG therapy with cutaneous eruptions on the trunk and upper extremities (49). Immunofluorescence of skin biopsies showed nonspecific fibrinogen deposition and significant lymphocyte infiltration, suggesting a type IV cell-mediated allergic reaction. Other dermatologic adverse reactions associated with IVIG treatment include eczema, erythema multiforme, purpuric erythema, and alopecia. The mechanisms for these effects are not well understood.

One case of arthritis has been reported after IVIG administration, and symptoms of severe joint pains have been documented to be transient, lasting approximately 10 days (50). The formation of immune complex aggregates at the site of inflammation may be responsible for these effects. IVIG-induced neutropenia has been reported in several pediatric patients with ITP and appears to be transient as well (51,52).

Vaccine and Serologic Interactions

IVIG preparations can interfere with live viral vaccinations for up to 6 months after IVIG therapy and 9 months after RSV-IGIV prophylaxis (53). This is not a contraindication for IVIG treatment for patients who have been recently vaccinated against measles, mumps, and rubella, but physicians should be aware of this interaction. An increase in serologic titers to viruses also may be seen in some patients receiving IVIG infusions, the result of passive infusion of antiviral and antibacterial antibodies present in preparations.

MECHANISMS OF ACTION

The immunologic effects of IVIG have been studied in many *in vitro* and *in vivo* models. Many of these are outlined later. The positive effects of IVIG in these models are striking, but no simple model integrates these diverse observations.

Fcg Receptor Modulation and Blockade

The rapid increase in platelet counts observed in ITP patients administered IVIG suggests a direct interference with the phagocytic destruction and reticuloendothelial clearance of antibody-coated platelets associated with the disease (54,55). Immunoglobulins interact with Fcg receptors (FcgRs; CD16, CD32, CD64) on phagocytes, lymphocytes, and natural killer (NK) cells and may subsequently influence Fc-mediated functions and the immune response (56,57). Monomers or dimers in IVIG preparations or immune complexes formed after IVIG infusion may interact with FcgRs with varying affinity, potentially saturating receptor sites or altering receptor affinity for disease-related immune complexes (30,32). The most convincing evidence for an IVIG-induced FcgR blockade occurs in patients with ITP. It has been reported that IVIG administration causes a decrease in the rate of clearance of anti-Rh (D)-coated autologous erythrocytes followed by an increase in the number of circulating platelets in adult patients with ITP (58). It was later shown that rosette formation between peripheral blood mononuclear cells (PBMCs) of IVIG-treated patients and IgG-coated erythrocytes is significantly inhibited and that the administration of anti-FcgRIII (CD16) antibodies are able to increase platelet counts in patients with refractory ITP (59,60). Infusions of Fcg fragments also have been demonstrated to induce platelet increases in children with acute ITP, and it was suggested that IVIG may exert its immunomodulatory effects by increasing the level of soluble FcgR in the circulation that is free to bind antibody-coated cells and prevent phagocytic destruction (61). FcgR modulation by IVIG also may play a role in the treatment of certain autoimmune-related neuromuscular disorders [Guillain-Barré syndrome (GBS), chronic inflammatory demyelinating polyneuropathy (CIDP), inflammatory myopathies], affecting macrophage-mediated phagocytosis and demyelination (28).

Effects on Lymphocyte Function and Proliferation

Many reports demonstrate a regulatory role of IVIG on lymphocyte function and proliferation. *In vitro* experiments using various models of cellular immune function show suppressive effects by IVIG and both Fc and $F(ab')_2$ fragments of IgG. Intact IgG has been shown to inhibit in a dose-dependent manner the mitogenic responses of human PBMCs to phytohemagglutinin A (PHA), concanavalin A (Con A), and pokeweed mitogen (PWM) (57,62,63 and 64). This suppressive effect is inhibited by the addition of antibodies to the FcgRIII or the Fcg fragment and is reversed if IVIG is removed. IVIG inhibition of IgM production by Epstein-Barr virus (EBV)-transformed B lymphoblastoid cells also has been reported to be dependent on the Fcg fragment. It was suggested that IVIG is able to suppress Ca^{++}-dependent signal transduction via Fcg receptors on the surface of B lymphocytes and interfere with cell differentiation and antibody synthesis (65). Another study shows that $F(ab')_2$ fragments of IgG inhibit IgG and IgM production of spleen cells stimulated with the polyclonal B-cell activators lipopolysaccharide (LPS) from *Escherichia coli* and PWM, whereas no inhibition was observed with Fc fragments (66). This result may reflect the ability of the $F(ab')_2$ fragment of the IgG molecule, perhaps via antiidiotype interactions, to bind B- and T-cell surface receptors (TCRs) and other molecules [CD4, CD5, and human leukocyte antigen (HLA) class I molecules] that influence lymphocyte proliferation and antibody production (57,66). IVIG inhibition of IgE synthesis also has been reported in patients with severe asthma receiving long-term steroids (67).

IVIG induced a 35% decrease in $CD4^+/CD8^+$ lymphocyte ratio and a 50% increase in circulating $CD8^+$ T lymphocytes in hypogammaglobulinemic patients (68). However, there was no increase detected in levels of soluble CD8 antigen in the circulation associated with $CD8^+$ lymphocyte activation. High plasma levels of neopterin strongly correlated with *in vitro* inhibition of PMA- or ConA-stimulated lymphocyte proliferation, indicating a possible IVIG-induced release of monokines that downregulate lymphocyte function and proliferation. Other reports demonstrate that IVIG inhibits cytokine-dependent T-cell proliferation and the generation of cytotoxic T lymphocytes *in vitro*, and a posttranscriptional interference with cytokine production has been suggested (69,70). IVIG supplementation also was shown to affect NK cell cytotoxicity. Women at high risk for recurrent spontaneous abortion (RSA), a condition associated with high NK cytotoxic activity, show significant decreases in NK activity as well as decreased interleukin (IL)-12 and increased IL-10 expression on peripheral lymphocytes in response to IVIG treatment (71). Because these effects are not observed in healthy pregnant women, the authors suggested that these results imply an IVIG-related shift from a cytotoxic T-helper (Th)1 immune response to a more protective Th2 immune response. Whether IVIG can downregulate an overactive immune system and restore balance between Th1 and Th2 immune responses needs further elucidation.

Modulation of Cytokine Production and Release

IVIG therapy may selectively regulate cellular cytokine production and release, and, as a result, numerous proinflammatory and antiinflammatory cytokines may be affected. The ability of IVIG administration to modulate IL-1 production is an important observation because excessive IL-1 production is thought to be detrimental in certain immune-mediated disorders and to contribute to tissue damage in various organs (72,73). For example, IL-1 release decreases to normal levels in children with acute Kawasaki disease treated with IVIG, although patients with chronic symptoms do not respond (74). Other studies demonstrate that IVIG induces monocytic release of IL-1 receptor antagonist (IL-1ra), which may subsequently block IL-1 binding to receptors of various cell types (32,75,76). PBMCs and plasma from IVIG-treated hypogammaglobulinemic patients show increases in IL-1ra production and levels of soluble IL-1 receptor type II correlated with moderate decreases in production of IL-1a, IL-1b, and levels of soluble IL-1 receptor type I (77). This blockade in turn affects the ability of IL-1 to stimulate PBMC production and release of tumor necrosis factor (TNF)-a and other pro-inflammatory cytokines. In patients with GBS, IVIG therapy decreased the circulatory levels of IL-1b and TNF-a, whereas antiinflammatory cytokines were unaffected (78). Clinical improvement was then correlated with a reduction in unbound TNF-a during the acute phase of the disease. Increased TNF-a production also is associated with HIV-1 infection in children, and one bolus injection of IVIG has been shown to decrease TNF-a levels and increase levels of TNF receptors in plasma and LPS-stimulated PBMCs (79). This suppression of TNF-a activity also correlated with a significant increase in circulating CD4 T lymphocytes.

Evidence against an antiinflammatory role of IVIG was observed in patients with common variable immunodeficiency (CVID) (80). IVIG administration induced an increase in IL-2 expression in CD4+ lymphocytes and TNF-a expression in CD8+ lymphocytes without an influence on interferon (IFN)-g expression. These effects were not observed in patients with X-linked agammaglobulinemia (XLA). An IVIG-induced elevation of TNF-a production also has been shown in rheumatoid arthritis patients, but the dose of IVIG was much higher than the dose used in CVID and XLA (81).

Another important *in vivo* study shows that IVIG downregulates transforming growth factor-b1 (TGF-b1) mRNA expression in patients with dermatomyositis (82). TGF-b1 expression is normally high in these patients and may play a pleiotropic role in chronic inflammation and tissue fibrosis. An IVIG-induced decrease in TGF-b1 expression strongly correlated with clinical improvement and repair of the intramuscular cytoarchitecture, but this effect was not observed in patients with inclusion body myositis (IBM).

In vitro reports have shown that IVIG is capable of inducing a wide range of effects on cytokine activity produced by normal and patient PBMCs, depending on the system used. Anti-CD3 activation of normal PBMCs in the presence of IVIG is associated with a decrease in IL-2, IL-10, TNF-b, IFN-g, and TNF-a production, as well as a decrease in IL-2 receptor expression (83). A significant increase in IL-8 production also is observed. PMA/ionomycin-stimulated cells, however, show a reduction of IL-2, IL-3, IL-4, IL-5, IL-10, TNF-b and granulocyte-macrophage colony-stimulating factor (GM-CSF) production in the presence of IVIG, whereas IFN-g and TNF-a are not affected (84). With the bacterial superantigen streptococcal pyrogenic exotoxin-A (SPE-A), IVIG can dramatically inhibit toxin-induced synthesis of IFN-g and TNF-a, even if added 24 hours after the incubation has begun (85). In this model, monokine production (IL-1a, IL-1b, IL-1ra, IL-6, IL-8) is either unaffected or increased. If staphylococcal enterotoxin-B (SEB) is the superantigen, cytokine IL-4 is selectively inhibited, but IFN-g and TNF-a production remain unchanged (86). With an LPS-activated system, IL-6 synthesis is selectively downregulated by IVIG in a dose-dependent response (87). Because IL-6 is required for IgG secretion by B lymphocytes, this negative-feedback mechanism appears consistent with the IVIG-mediated effects on lymphocyte responses that regulate antibody synthesis. It is clear that IVIG can affect numerous cytokine functions, depending on which experimental model is used. However, one important study suggests that the ability of IVIG to modulate cytokine production and lymphocyte function is highly dependent on the accessory cells present in the system studied (88). Stabilizing agents in IVIG preparations also must be considered and have been shown to interfere with mononuclear cell proliferation and contribute to the immunomodulatory effects of IVIG (89).

Inhibition of Complement-mediated Immune damage

IVIG has been shown to inhibit the deposition of activated complement fragments on target cells and tissues *in vitro* and *in vivo*. This effect is thought to be important clinically, interfering with complement-mediated tissue damage associated with disease. Initial studies were performed in two *in vivo* models in the guinea pig. A decrease in the rate of clearance of IgM-coated erythrocytes from the circulation and the prevention of Forssman shock demonstrated the inhibitory effects of IVIG on complement-dependent immune injury (90,91). Several mechanisms have been postulated for the IVIG effect, and in almost all systems studied, IVIG exerts its effects by inhibiting the classic pathway of complement activation (92,93 and 94). It has been proposed that IgG and IgM molecules act as preferred acceptors or “scavengers” for fluid-phase complement components C3b and C4b, thereby inhibiting complement deposition on target membranes (95,96 and 97). No evidence has been presented thus far showing an IVIG effect on the alternative pathway of complement, although C3 is a major component of this pathway (98). A recent report found no influence of IVIG on antibody-independent complement attack on oligodendrocytes, but IVIG did interfere with antibody-mediated complement deposition (99). The authors concluded that IVIG exerts its effects via antibody binding and does not directly interfere with complement activation.

IVIG administration given to nonhuman primates during xenotransplantation has been shown to inhibit complement deposition in porcine cardiac xenografts and to prevent complement-mediated hyperacute rejection (100). One group reported that IgG natural antibodies specific for Gala1-3Gal directly interfere with complement activation mediated by host IgM antibodies bound to the foreign xenograft; however, IVIG preparations contain very low levels of this natural antibody, indicating the importance of other mechanisms (101). Several groups have used a guinea pig-to-rat cardiac transplantation model, each demonstrating that IVIG can successfully delay hyperacute xenograft rejection. Both Fc and $F(ab')_2$ fragments of IVIG have been shown to mediate this effect (102,103 and 104).

In patients with dermatomyositis, IVIG has been shown to inhibit complement deposition and membrane attack complex (MAC) formation on endomysial capillaries *in situ* and to prevent complement-dependent microangiopathy (105). Again, IVIG is hypothesized to form complexes with activated C3, thus reducing the amount of C3 available to bind to target tissues and affecting subsequent C5 convertase assembly and MAC formation. This IVIG-induced effect may extend to other immune disorders, such as GBS and myasthenia gravis, which involve complement-mediated immune damage (106).

Inhibition of Endothelial Cell Proliferation

In vitro activation of healthy umbilical cord endothelial cells was significantly and reversibly inhibited by the presence of IVIG in a dose-dependent manner (107). This effect also was observed with either $F(ab')_2$ fragments or Fc fragments of the IgG molecule. IVIG also downregulated mRNA expression of various adhesion molecules, chemokines, and proinflammatory cytokines induced by TNF-a and IL-1b. This suggests a profound effect of IVIG that may control endothelial cell activation and the generation of microvessels characteristic of inflammation and neoplasia. IVIG has been shown to be beneficial in such vascular disorders as Kawasaki disease, Wegener granulomatosis, or vasculitides in which the endothelium plays a major role in disease pathogenesis (108).

Enhanced Immunoglobulin G Autoantibody Catabolism

Under normal conditions, IgG binds to a protective receptor, FcRn, in recirculating endocytotic vesicles to avoid uptake in phagocytic endosomes and intracellular degradation, thus enabling the intact IgG to return to the circulation. This receptor is located in many tissues, including skin, muscle, and intestinal epithelium, and is highly expressed in vascular endothelial cells, thought to be the predominant site of IgG catabolism (109). It is hypothesized that IVIG administration may lead to a saturation of FcRn receptors on the endothelium and an increase in catabolism of endogenous pathogenic IgG autoantibodies (110,111). This depleting effect may participate in the overall clinical efficacy of IVIG in patients with antibody-mediated immune disorders.

Fas-mediated Apoptosis

In the severe adverse drug reaction, toxic epidermal necrolysis (TEN, Lyell syndrome), keratinocytes undergo Fas (CD95/APO-1)-mediated apoptosis via the lytically active Fas ligand (FasL). IVIG was shown to inhibit keratinocyte death *in vitro*, possibly interfering with Fas/FasL interactions and preventing apoptosis (112). However, another study demonstrated *in vitro* an IVIG induction of apoptosis in human lymphoid cell lines due to anti-Fas antibodies in IVIG triggering the Fas apoptotic pathway (113).

Antiidiotype Modulation

IVIG is prepared from large plasma pools with a wide spectrum of low-titer antibodies that react with various human protein antigens or antigenic sequences on the variable regions of immunoglobulins, or idiotypes. Idiotypic determinants are thought to play a role in autoantibody pathogenesis and thus are potential sites of immunoregulation and autoreactivity control by antiidiotypic antibodies (56,114,115 and 116). Antiidiotypic antibodies have been found during remission in autoimmune diseases associated with pathogenic autoantibodies [GBS, systemic lupus erythematosus (SLE), anti–factor VIII, myasthenia gravis, and anti-fibrinogen autoimmune disease], supporting their role in antibody-mediated immunomodulation (114). IVIG therapy is thought to transfer passively to patients these immune-modulating antiidiotypic antibodies that can react with idiotypic regions of disease-related autoantibodies. The formation of idiotype/antiidiotype complexes may interfere with autoantibody binding to antigen and facilitate Fc-mediated clearance of the autoantibody. These complexes also may bind Fcg receptors on B cells and downregulate

autoantibody synthesis.

IVIG preparations contain a large percentage (up to 40%) of dimeric pairs or idiotypic/antiidiotypic antibody complexes, depending on the number of donors in the plasma pool (28,30,117). Increasing the number of donors increases the percentage of dimeric pairs and the probability of an antiidiotypic antibody in an IVIG preparation specific for the idiotype of a pathogenic autoantibody, although a large donor pool may dilute the activity of a specific antiidiotypic antibody. IVIG has been shown to inhibit the activity of autoantibodies to factor VIII, thyroglobulin, DNA, intrinsic factor, peripheral nerve, neutrophil cytoplasmic antigen (ANCA), platelet glycoprotein IIb/IIIa, and retinal autoantigens in a dose-dependent manner (118,119). The $F(ab')_2$ fragments of IVIG were demonstrated to have high affinity for the variable regions of these autoantibodies, but no antibodies have been found against the allotypic regions of the IgG molecule. Investigators also have found antibodies to the Fc fragment of IgM, cytokines (IL-1a, IFN-a2a, GM-CSF), cytokine receptors, determinants on ab TCR, CD4 and CD5, major histocompatibility complex (MHC) class 1 molecules, and adhesion molecules in IVIG preparations (57,116,120). All of these findings suggest that there are many direct and indirect mechanisms of IVIG immunomodulation that can influence both antibody-mediated and cell-mediated functions, and as a result, may induce a transient or long-term suppression of pathogenic autoantibody production.

One general hypothesis to explain the diverse actions of IVIG is an effect on the immune network regulation of autoreactivity (114,116). It is suggested that autoreactivity is a physiologically normal but highly regulated immune function, and a normal immunoglobulin repertoire downregulates autoimmune reactivity to avoid the occurrence of a pathologic autoimmune disease. Because IVIG antibodies are thought to neutralize some circulating pathogenic autoantibodies in autoimmune patients, it is suggested that this may downregulate lymphocyte production of pathogenic autoantibody clones and induce lymphocyte production of immunoglobulins representative of the immunoglobulin repertoire in an IVIG preparation. IVIG may exert selective pressures that stimulate and restore normal repertoires of circulating immunoglobulin in IVIG patients and an immune network capable of preventing potential pathologic autoimmune conditions.

Clinical Uses of IVIG Therapy

There are numerous suggested indications for IVIG use, including primary and secondary antibody deficiencies, treatment of specific infections, and numerous autoimmune and inflammatory conditions. Few are FDA approved, and most remain at the experimental level. Clearly, more controlled trials are needed to clarify a role for IVIG therapy in many of these disease states. Discussion of individual disease indications is beyond the scope of this chapter; however, a list of FDA-approved indications, generally accepted indications, and those that come from small clinical trials or anecdotal reports is provided in Table 90.3.

91 MONOCLONAL ANTIBODY THERAPY

David W. Thomas, Ph.D., and James W. Larrick, M.D., Ph.D.

HISTORICAL PERSPECTIVE

During the past 100 years, antibodies have evolved into a remarkable platform technology for generating therapeutic molecules to benefit human and animal health. In 1998 more than 700 antibodies were in clinical and preclinical development with more than 250 companies worldwide exploring monoclonal antibodies (mAbs) for human therapeutic and diagnostic uses. The recognized potential of antibody therapy was evident early this century when Von Behring and Kitasato received the first Nobel Prize for their demonstration that passive administration of immune sera could prevent or treat certain infectious diseases (264). Based on this pioneering work, passive “serum immunotherapy” using rabbit or horse immune sera was developed and widely used for the treatment of pneumococcal pneumonia, meningococcal meningitis, diphtheria, scarlet fever, measles, tuberculosis, and so on (35,36 and 37). Although serum therapy was remarkably effective for certain conditions, a number of problems (see Table 91.1), primarily serum sickness, limited the extent of its use. With the advent of antibiotics in the 1930s (sulfonamides, 1935) and 1940s (penicillin, 1942), the use of immune serum was largely abandoned. However, toxin-mediated diseases such as tetanus, botulism, diphtheria, and snakebites (271), as well as digitalis drug toxicity (243) still continue to be treated with antibody preparations (278). Despite the recognized potential and usefulness of antibodies, the modern renaissance in antibody therapy awaited the development of mAbs and recombinant DNA technology.

Serum sickness
Immediate and delayed allergic reactions
Lot to lot variation in potency
Need for parenteral administration
High expense

DEVELOPMENT OF MONOCLONAL ANTIBODY TECHNOLOGY

Development of Monoclonal Antibodies Rests on a Firm Understanding of Clonal Selection and the Molecular Basis of Antibody Structure and Diversity

Two major scientific advances led to the development of mAb technology. The first was the firm establishment of the Clonal Selection Theory proposed by Talmage (249) and Burnet (29) in the late 1950s, in which it was shown that each B cell produced an antibody of only a single specificity. The second was an understanding of the genetic formation of antibodies and creation of binding diversity from an assembly of discontinuous gene segments by Tonegawa et al. (254), which provided the basis for genetic manipulation of antibodies. Thus the stage was set for the generation of mAbs through the immortalization of B cells, producing an antibody of single antigen-binding specificity. In the first demonstration, Kohler and Milstein (135) created hybridomas by fusing the spleen cells of mice immunized with sheep erythrocytes (SRBCs) with an immortal murine plasmacytoma cell line that grew continuously in culture. A fraction of the immortalized cells were single-cell cloned and shown to produce only monoclonal anti-SRBC antibody. This basic hybridoma technology has since been used to generate mAbs to a vast number of antigens and has led to wide application in discovery and characterization of antigens, diagnostics, and to a new family of therapeutic drugs. Within a few years of the Kohler-Milstein *Nature* article, enthusiasm created by this technology supported the foundation of many antibody-based companies. However, 20 years later, the clinical potential of mAbs is just being realized. Over the past decade, there has been a major renaissance in antibody-based drugs, as evidenced by the recent registration of several important therapeutic antibodies and the large number of mAbs in clinical development.

Recombinant Monoclonal Antibodies

Although murine mAbs provided powerful new tools for antigen characterization, discovery, and diagnostics, their use in humans as therapeutic drugs was limited by several problems (148,149). For example, murine antibodies injected into humans had a relatively short circulating half-life of only about a day as compared with up to 3 weeks for human antibodies. Second, murine antibodies were highly immunogenic, and patients rapidly produced antibody responses against the murine antibody that neutralized its binding activity and caused rapid clearance (143,235). The immune response elicited by the human antimurine antibody antibodies (HAMAs) also was potentially dangerous because, as with heterologous antisera, subsequent injection could lead to severe allergic reactions. For these reasons, molecular engineering of mAbs to manipulate their properties became important for creating antibody drugs better suited for use in humans (24,25).

Ideally, a mAb drug should be nonimmunogenic, have a long-lived *in vivo* retention, and in some cases, retain effector functions for the elimination of the antigenic target (e.g., cancer cells or pathogenic organisms). In this respect, a human-derived antibody would be expected to be superior to a rodent antibody (145). However, generation of human mAbs from immortalized human antibody-producing B cells proved much more difficult than that with rodent cells, and the resultant mAbs were usually of the lower-affinity immunoglobulin (Ig)M isotype. In addition, with B cells derived from normal or immune human donors, the repertoire of antibody-binding specificities was limited, and it was difficult to generate therapeutic antibodies recognizing human targets. Recently the production of fully human antibodies has been achieved by using recombinant DNA technologies and transgenic mice.

The Polymerase Chain Reaction Greatly Facilitates Antibody Engineering

With the elucidation of the genetic organization of antibodies came the use of recombinant DNA technology both to capture rare antibodies and to manipulate the structure of mAbs. Application of recombinant DNA technology has been an important advance in the evolution of mAb drugs for several reasons. First, it was no longer necessary to immortalize the antibody-producing cell, because isolation of an individual antigen-binding B cell was sufficient to isolate the relevant antibody-binding variable (V) region through use of polymerase chain reaction (PCR) (71,189) by using oligonucleotide primers to amplify antibody V regions (130,150,151,195). Second, the V region of mAb-producing B-cell hybridomas could easily be isolated and genetically fused to different immunoglobulin constant regions to produce the desired antibody isotype and subclass. Finally, this method provided the means to capture the entire antibody repertoire in the form of recombinant antibody libraries (281).

Chimeric Mouse/Human Antibodies: Molecular Engineering Reduces Immunogenicity

The creation of chimeric mAbs with an antigen-binding V region from the original murine mAb and a human constant region was the first major advancement in recombinant mAb drugs (186). Human/mouse chimeric mAbs (Fig. 91.1) in part solved some of the problems inherent in fully murine antibodies. They had a longer circulating half-life and reduced immunogenicity because of the human constant regions. Many of the initial chimeric antibodies used the human IgG1 constant region, which also preserved the effector functions of complement fixation and Fc receptor binding. These effector functions were important because many of the initial therapeutic uses of chimeric mAbs were to bind and eliminate tumor cells. However, where therapeutic applications use a chimeric antibody that binds to human cells, these effector functions are potentially destructive. For those uses, chimeric mAbs were generated with a human IgG4 constant region, which has greatly reduced complement activation and Fc receptor binding compared with human IgG1.

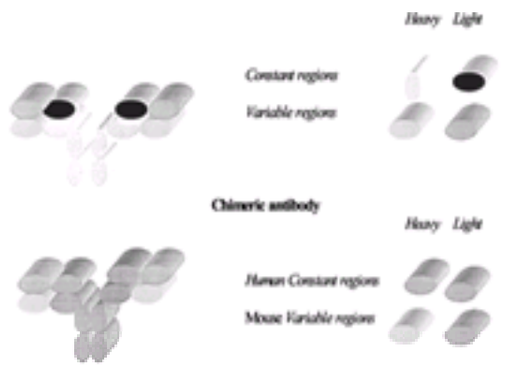

Figure 91.1. Chimeric murine/human antibody created by linking murine antigen-binding variable regions to human heavy- and light-chain constant regions. (See Color Figure 91.1.)

Despite the improved features of chimeric antibodies, immunogenicity generated by repeated administration to patients remained a problem for many antibodies because of the murine V region. In particular, antibody responses were generated against both murine framework determinants and idiotypic determinants contained within the complementarity-determining regions (CDRs) that form the antigen-binding site. The immunogenicity of chimeric antibodies, however, is still determined empirically. For example, IgG1 chimeric anti-IgE antibodies injected into patients with allergic diseases did not generate antibody responses in most patients (53), a situation similarly observed with IgG1 chimeric anti-human immunodeficiency virus (HIV) envelope antibodies (236). A chimeric anti–tumor necrosis factor (TNF-a) antibody (Remicade) has shown dramatic therapeutic benefit and is marketed for treatment of Crohn disease and rheumatoid arthritis (RA) (5,164,188). Antibody responses against this chimeric antibody have occurred in only 6% of the treated patients and have not prevented readministration of chimeric antibody (226). These results demonstrate that chimeric antibodies can be successful drugs and have reduced the problems with immunogenicity of fully murine antibodies. Nevertheless, the relative immunogenicity of chimeric antibodies cannot be unequivocally determined before injection into humans, because all of the rules governing immunogenicity of antibodies remain to be established.

Complementarity-determining Region Grafting Demonstrates That Antigen-binding Activity Can Be Transferred between Antibodies

To reduce further the potential for immunogenicity of chimeric antibodies, Winter (261,281) developed a new technology in which the murine CDRs were genetically grafted onto human V-region framework sequences. Initially, human V-region frameworks were identified that most closely resembled the original murine V region to maximize the chance that the grafted CDRs would be positioned in the proper orientation to retain the original binding specificity. Although this worked well for some CDR-grafted antibodies, in most, the binding activity was substantially reduced. To resolve this problem, key V-region framework amino acids were identified through analysis of antibody crystallographic structures to define additional framework amino acids that were important for orienting the CDRs properly to retain binding (49,124,197). Thus in most CDR-grafted mAbs generated today, several murine framework amino acid residues are retained, and in many cases, the recombinant antibodies exhibit approximately the same binding specificity and properties as the original murine antibody. Antibodies generated by this process are commonly referred to as “humanized” antibodies because the resultant antibody is mostly of human origin and retains only murine CDRs and a few murine framework residues (Fig. 91.2). Because humanized antibodies have murine CDRs, there remains a potential problem with immunogenicity and generation of antiidiotype responses in treated patients. In fact, 60% of RA patients treated with a humanized antibody designated CAMPATH-1 generated a neutralizing antiidiotype antibody response precluding further treatment (272). By contrast, a large number of patients with allergic diseases treated with humanized anti-IgE E25 antibody failed to produce any detectable antibody response (120), and only about 0.1% of patients treated with the humanized anti-HER2 antibody, Herceptin, developed antibody responses (Product insert, Physicians' Desk Reference). Thus, as is the case with chimeric antibodies, the relative immunogenicity of humanized antibodies remains empiric, and predictions about potential immunogenicity in humans cannot yet be made.

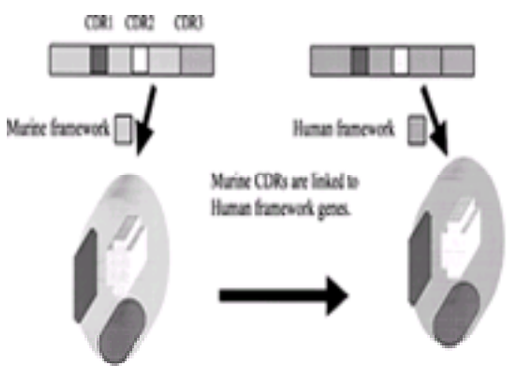

Figure 91.2. Humanization of antibodies using complementarity-determining region (CDR) grafting. CDR loops transfer antigen binding to variable region constructed with human framework regions. (See Color Figure 91.2.)

In part, the problem of potential immunogenicity may be based on the nature of the antigen bound by the administered antibody. Using a transgenic mouse model, Waldman (85) showed that CAMPATH-1 was much more immunogenic when the antigen to which it bound was expressed on the surface of cells. If the CAMPATH antigen was expressed in soluble form, then the immunogenicity of the CAMPATH antibody was greatly reduced. Results from a number of humanized mAbs recognizing a diverse set of targets, which are currently in clinical testing, should yield important information to help define the variables that contribute to the immunogenicity of antibody drugs.

TECHNOLOGIES TO PRODUCE FULLY HUMAN ANTIBODIES

Most mAbs are isolated products of normal antibody responses after immunization of mice with antigen. The repertoire of antibody specificities is determined in part by the strain of mouse immunized and by the type of antigen and adjuvant used. On repeated boosting, the mice produce high-affinity antibodies with improved antigen-binding properties through the process of affinity maturation. For therapeutic antibodies directed against human targets, this has worked well, because mice

recognize many human antigens as foreign, and high-affinity antibodies can be generated. As mentioned before, the use of human B cells for mAb production was limited mainly to those antigens to which the donor was immune, and it was difficult to generate high-affinity antibodies (150,151). It was therefore very challenging if not impossible to produce therapeutic human antibodies against a large number of targets, particularly if the target was a human antigen. Two technologies were developed to overcome these limitations and to generate fully human mAbs: transgenic mice and phage-displayed antibody libraries.

Transgenic Mice Producing Human Antibodies

Genetically engineered mice have been generated to produce human antibodies instead of murine antibodies (Fig. 91.3) (28,76,89,118,159,176). Major sections of the chromosome encoding the human antibody genes have been introduced into the germline of mice by using yeast artificial chromosomes (192). In addition, the endogenous mouse loci have been knocked out by using site-specific recombination and embryonic stem cell technology. These mice can be immunized and their human antibody-producing spleen cells immortalized by conventional hybridoma methods. Thus far, these mice have generated antibody responses against most antigens with which they have been immunized, including human antigens, such as CD4. Apparently the human antibody responses are regulated in a near-normal manner as affinity maturation takes place, generating high-affinity antibodies equivalent to those produced in unmodified mice (76,90). The clinical testing of the human antibodies from engineered mice is just beginning and includes an anti-CD4 antibody for treatment of RA (Medarex.com) and an anti–interleukin (IL)-8 antibody for treatment of psoriasis (Abgenix.com). Initial reports indicate that these human antibodies have not elicited an antiantibody response in the treated patients.

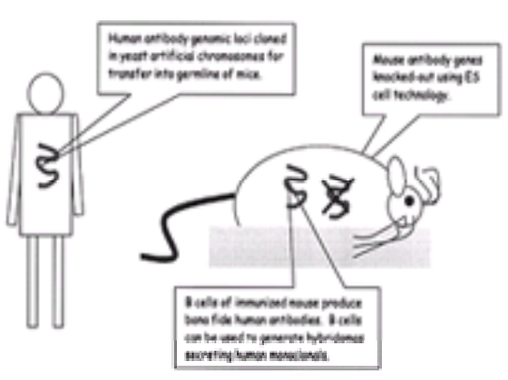

Figure 91.3. Human antibodies generated from transgenic mice.

Human Antibody Libraries Expressed on Filamentous Phages

Another approach to generation of human antibodies has taken advantage of a technology called phage display (Fig. 91.4), in which single-chain antibodies or F(ab) fragments are expressed on the surface of bacteriophages, which can be propagated by infection of host bacteria (12,13,109,167,171,172,281). To generate a library of human single-chain antibodies, the antibody V regions from B cells isolated from normal human donors are cloned into the bacteriophage. In this way, each phage expresses a single antibody-binding specificity and essentially replaces the B cell as the source of the monoclonal specificity. Instead of immunization to generate antigen-binding antibodies, the library of single-chain antibody–expressing phages is selected based on antigen binding (91,201). Those phages binding to the antigen are isolated and propagated in bacteria. Several rounds of antigen selection followed by propagation of binding phages yields human single-chain antibodies specific for the selecting antigen. The single-chain antibody V regions can then be genetically engineered into a complete human antibody. However, unlike immunization with antigen, the phage-expressed antibodies do not undergo affinity maturation and often exhibit lower binding affinities. To remedy this, mutational approaches have been taken to substitute amino acid residues in the CDRs to select for those mutations that lead to better antigen binding (206). This approach has been successful, and the antibody affinities improved as much as 1,000-fold over the starting antibody (15,286). Another way to generate the antigen-binding repertoire by using phage display is to prepare a library of antibodies in which the CDRs have been mutated before antigen selection. This is a “semisynthetic” approach to generate novel binding specificities of higher affinity through creation of new CDRs that may never occur naturally (14).

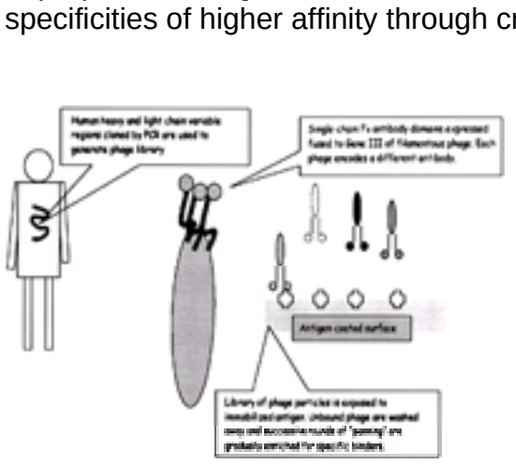

Figure 91.4. Human antibodies generated by using phage display technology.

Despite the potential to reduce the immunogenicity of antibodies by making them fully human, theoretically it is still possible that they could elicit neutralizing antiidiotype antibody responses. The reason for this is that the newly created human antibody contains novel joining regions that can be immunogenic because they are essentially “foreign.” More extensive testing of human antibodies in clinical trials will determine the extent to which fully human mAbs have solved the problem of immunogenicity.

Deimmunization: Understanding of Antigen Presentation Can Reduce Immunogenicity

The immunogenicity of therapeutic antibodies is controlled by helper T lymphocytes. In the absence of helper T cells that recognize peptides derived from the therapeutic antibody, those B cells whose surface Ig antigen receptors recognize the therapeutic antibody epitopes are not sufficiently activated to generate an antibody response. Thus to reduce the immunogenicity of therapeutic antibodies most effectively, the helper T-cell epitopes should be removed. This can be accomplished through several approaches that rely on knowledge of antigen processing by antigen-presenting cells (APCs) (98,122). Helper T cells recognize only antigens presented on the surface of the APC in association with a type of major histocompatibility antigens, termed class II human leukocyte antigens (HLAs). Class II HLA molecules consist of heterodimers of two transmembrane glycoproteins that form a groove at the top of the extracellular structure that binds a peptide containing the antigenic epitope recognized by the T-cell receptor. The loading of HLA molecules with peptides takes place inside the APC within endosomes that contain proteolytic fragments of the ingested antigen. In the case of a therapeutic antibody, the antibody is internalized by the APC, proteolytically cleaved to generate a series of derivative peptides, some of which contain the appropriate amino acid motifs to be bound in the HLA groove. The peptide-loaded HLA molecules are then transported to the APC surface to be recognized by a T cell bearing the receptor specific for that HLA/peptide complex. To render a therapeutic antibody nonimmunogenic for T cells, it can be engineered to change (a) those amino acids that are bound by the HLA proteins, (b) those amino acids serving as contact residues for the T-cell receptor, or (c) those amino acids that serve as the cleavage sites for the proteases creating the immunogenic peptides. The databases on which these strategies are based are still being compiled, particularly for determination of the structure of peptides recognized by T cells and bound to different HLA alleles. A Scottish company, Biovation Ltd., has used this information to reduce the T-cell epitopes of therapeutic antibodies based on the composition of known T-cell antigenic peptides and their HLA-binding motifs. Their strategy is to first remove B-cell epitopes through a process of “veneering,” as described by Padlán (198), in which potential B-cell epitopes are identified from structural information, and such regions are modified to eliminate the epitope. The antibody H and L variable-region sequences are then “threaded” through numerous HLA alleles, and the potential HLA-binding peptides are identified. Site-directed mutagenesis is then used to change residues responsible for HLA binding. This and related procedures (169) represent a rational design to eliminate immunogenicity of proteins. Although animal studies of such deimmunized antibodies are promising, these reengineered antibodies have yet to enter clinical trials.

MONOCLONAL ANTIBODIES: A FLEXIBLE DRUG PLATFORM

MAbs are an exceptionally flexible platform (Table 91.2) allowing a great deal of novelty in creating new drugs. As a result, mAbs have become an exciting new drug

modality for treatment of cardiovascular and infectious diseases, cancer, and allergic and autoimmune diseases, in addition to prevention of rejection of transplanted organs. The features that make mAbs such attractive drugs are their exquisite specificity in target binding and their limited inherent toxicity. In addition, mAbs can have a half-life of up to several weeks in circulation, requiring only infrequent treatment, and yet have good penetration into many body tissues.

Half-life (minutes to weeks)
Biodistribution (intravascular vs. extravascular)
Effector functions (via cells, complement, clotting, etc.)
Valency (monovalent vs. bivalent vs. multivalent)
Binding properties (affinity)
Carriers of toxins and radionuclides
Diverse structure (antibody fragments, fusion proteins, bispecificity, etc.)

TABLE 91.2. Flexible Properties of Antibodies

Genetic manipulation of mAbs can generate a variety of forms ranging from small monovalent fragments (22) to unique proteins that use the antibody constant region fused to other receptors, ligands, or other antibody fragments. MAb drugs either can be inhibitory through neutralization of the biologic activity of the target antigen, or can be agonists that cause cellular activation, acting as growth and differentiation factors. These extraordinarily diverse features allow creation of new antibody-based drugs to treat diseases in quite novel ways unmatched by small organic compounds.

THERAPEUTIC ANTIBODIES: DIVERSE TARGETS

Too many antibodies are in preclinical and clinical development to be covered in detail here. What follows is a sampling of the major classes of antibody therapeutics.

Anti–infectious Disease Antibodies

Many acute infectious diseases are successfully prevented by vaccination that generates protective antibodies and are therefore good targets for passive antibody therapy. Antibodies can directly neutralize pathogens through their high-affinity variable regions, or activate and coordinate other host defense mechanisms such as enhanced phagocytosis and complement activation through their constant regions. As long ago as the 1930s, convalescent human sera were shown to prevent mumps and measles virus infections in children (156). Recently, preparations of human polyclonal antibodies specific for rabies (146), hepatitis B (e.g., H-BIG, NABI), varicella-zoster, respiratory syncytial virus (RSV; e.g., RespiGam, MedImmune, Gaithersburg, MD) and cytomegalovirus (CMV; e.g., CytoGam, MedImmune) have been developed for treatment and postexposure prophylaxis. Pooled intravenous immunoglobulin preparations (IVIG) often contain protective titers of antiviral and antibacterial antibodies, which are effective for passive immunotherapy (e.g., Gamimune, Bayer) (23,66,275). For example, chronic red cell aplasia caused by persistent infection with parvovirus B19 has been successfully treated with IVIG (187), and human serum globulin is given to travelers to prevent hepatitis infection (240). Because highly specific antibodies can be generated rapidly, they are the preferred therapeutic modality for new, exotic, and emerging diseases. For example, a high-titer Ebola virus–neutralizing polyclonal horse serum was reported that could have therapeutic potential (117).

One recent success of mAbs to prevent RSV infection has been the clinical application of a humanized anti-RSV mAb (246) marketed as Synagis. Additional mAbs are in phase II studies for protection against infections with hepatitis B virus (PDL.com), cytomegalovirus (9), and varicella-zoster (116). Several clinical trials have been performed with mAbs directed against the envelope of HIV (39,236,289). However, the rapid mutation of the HIV envelope and the inability of these antibodies to react with all HIV clades limited the success of this approach. This result illustrates one problem in using mAbs directed against pathogens; it is easy for the epitope to modulate/mutate such that the mAb no longer binds. This is why polyclonal antibodies have an advantage in preventing infectious diseases. In the future, many infectious diseases will likely be treated with a mixture or “cocktail” of mAbs. Such “oligoclonal” drugs, comprising mAbs recognizing several different antigens, will be more effective at preventing infection and more likely to limit the emergence of resistant organisms. A recent example of this concept used anti-HIV monoclonals (10).

As noted, before antibiotics, several toxin-mediated bacterial diseases, such as tetanus and diphtheria, were successfully treated with immune sera (47,104,129). Recently, toxin-mediated diseases such as botulism and diarrhea caused by overgrowth of *Clostridium difficile* in hospitalized patients treated with antimicrobial agents have been targeted with mAbs (84). In the 1980s, numerous attempts were made to attenuate the deleterious effects of endotoxin released by gram-negative bacteria contributing to the sepsis syndrome. At least three companies developed and carried out phase III clinical trials of antiendotoxin/lipopolysaccharide mAbs in the early 1990s (270). The outcome of these trials was disappointing because of a failure to appreciate the complexity of the sepsis syndrome (40). Nevertheless, using mAbs to treat toxin-mediated diseases will likely remain an important bastion for antibody therapy because of its high specificity and ability to neutralize toxins rapidly that is unmatched by most other drugs.

In the area of infectious diseases, antibodies are expected to continue to provide potent therapeutics to neutralize pathogens. The development of low-cost production systems (i.e., transgenic plants or animals) combined with an improved understanding of microbial pathogenesis and genomics to provide novel targets will promote the application of mAb technology for prophylactic and therapeutic uses.

Antibodies for Cancer: Magic Bullets?

Unlike the application of mAb therapy to infectious diseases, in which the history of vaccination and passive immunotherapy provides reason to expect success, application of mAb technology in oncology rests on a less secure foundation. Based on the perceived promise of an mAb-based magic bullet that would specifically identify and eliminate cancer cells, an enormous amount of work has been devoted to generation and characterization of anticancer antibodies over the past 25 years (74,274). Indeed, as of this writing, anticancer antibodies are the largest group of therapeutic mAbs under development.

Antitumor antibodies have been generated to a number of targets, most of which reside on the cancer cell surface. In theory, this should be an excellent therapeutic approach based on the capacity of autoreactive antibodies to bind self-tissue antigens and mediate tissue damage through antibody-dependent cellular cytotoxicity (ADCC), complement, or natural killer (NK) cell activation. Autoimmune diseases would in this light predict that the “firepower” of the humoral immune system might successfully destroy tumor cells. However, positive clinical results have been limited by antigenic variation in tumors (174,217), lack of identification of suitable tumor-specific antigens, and poor penetration into solid tumors (191). Despite these limitations, there have been some major recent successes in treatment of cancer with mAbs, two of which were recently approved for clinical use, Rituxan and Herceptin (Table 91.3).

Name	Molecular Target	Clinical Target	MAb Form	Company
Orthoclone®, OKT3	CD3	Organ transplantation	Murine	Ortho Biotech
ReoPro®	GP IIb/IIIa	Percutaneous coronary intervention; chronic unstable angina	Fab fragments of Murine Mab	Centocor/Lilly
Synagis®/Palivizumab	65-kD F protein	Respiratory syncytial virus	gp24 humanized Mab	MedImmune
Zenapax®/Daclizumab	IL-2 receptor, CD25	Organ transplantation	gp24 humanized Mab	Protein Design/Roche/Hoffmann-La
Rituxan®/Rituximab	CD20	Non-Hodgkin's lymphoma	gp24 Chimeric Mab	IDEC/Genentech/Roche

TABLE 91.3. Therapeutic Monoclonal Antibodies: A Major Class of FDA Approved Products

Growth factors and their receptors are promising targets for antitumor antibodies (27). The anti–breast cancer Herceptin mAb binding the erb-b2 (HER2/neu) growth-factor receptor is one such example. Treatment of patients with advanced breast cancer with Herceptin leads to objective responses in a modest fraction of patients with overexpression of the HER2/neu oncoprotein (approximately 30% of breast cancer patients are HER2/neu positive). As first-line therapy combined with anthracyclines/cyclophosphamide, Herceptin increased 1-year survival of breast cancer patients from 68% to 79% (87). Other examples of this approach include antibodies blocking epidermal growth factor (EGF) and its receptor (285) and anti–gastrin-releasing peptide (GRP) antibodies that inhibit this autocrine growth factor for small-cell lung cancer cells (128). Positive phase II studies have been reported for antibodies neutralizing each of these targets.

Another approach to treatment of solid tumors targets angiogenesis, the formation of new blood vessels. Because angiogenesis plays an important role in the metastasis and growth of tumors, a number of antiangiogenic approaches are currently being tested with both small-molecule drugs and mAbs. One such antibody in phase II clinical development is directed against vascular endothelial cell growth factor (VEGF), which plays a major role in tumor neovascularization (212).

Efficacy has been seen in clinical trials using antibodies that target tumor cell surface antigens such as B-cell idiotypes, CD20 on malignant B cells, and CD33 on leukemic blasts (4,153). Rituxan, an unconjugated anti-CD20 antibody, induced partial and complete responses in up to 50% of patients with advanced, indolent non-Hodgkin lymphoma. When such antibodies are conjugated to radionuclides, overall response rates increase, and two different radionuclide-conjugated (one with ^{131}iodine and ^{90}yttrium) anti-CD20 antibodies are currently in phase III clinical testing (123). Conjugates composed of anti-CD33 antibodies and the potent chemotherapy agent, calicheamicin, have shown promising activity in patients with relapsed or refractory acute myelogenous leukemia (6). In Europe an anti-EPCAM antibody, Panorex, has been approved for adjuvant therapy for colon cancer, and phase III trials of this antibody are under way in the United States (210,276).

These exciting results in mAb treatment of cancer provide a basis for further refinement of the existing approaches to develop new antibody-based cancer therapy strategies (125,131,207). Results from the Human Genome Project combined with gene-chip profiling of cancer cells will improve future target selection. A multitude of other mAbs have been generated for use in flow cytometry, histopathology, and diagnostics, and these have greatly contributed to our understanding of cancer cell biology and pathogenesis. Based on past performance, mAbs will increasingly become an important therapeutic modality in oncology.

Immunomodulatory Monoclonal Antibodies

In addition to using mAbs for the specific treatment of infections and cancer, many antibodies are being developed to modify immune responses. Indeed, the first mAb approved for clinical use, Orthoclone (OKT3), is an antibody directed against T-lymphocyte antigen CD3 that abrogates immune rejection of tissue grafts (44,112,279). OKT3 may inhibit T-cell responses by cellular depletion as well as by suppression of T-cell activation (242). Sometimes OKT3 stimulates T cells to release cytokines, causing what is called the “cytokine release syndrome” (265). Several humanized versions of anti-CD3 antibodies that show reduced toxicity are in clinical development for transplantation and autoimmune disorders (52,82). Several other antibodies inhibiting T-cell activity are in clinical development, including a humanized anti-CD2 antibody to prevent transplant rejection (214) and anti-CD4 antibodies to treat autoimmune diseases (287). Clinical testing of some anti-CD4 antibodies was problematic because of lack of efficacy and depletion of CD4-positive T cells (34,136,182,183,221,259,260). Despite this setback, a fully human anti-CD4 antibody is currently in phase I/II trials for RA (Medarex.com).

Whereas all of the antibodies described earlier directly prevent T-cell activation, several other antibodies are directed against cell-surface antigens to prevent cellular migration or to block cellular interactions. Antibodies directed against adhesion structures reduce the emigration of cells out of circulation into the tissues and thereby inhibit inflammatory responses. Examples of this class of antibody include humanized antibodies in phase II clinical trials directed against CD11a for treatment of psoriasis (Genentech/Xoma), anti-CD18 antibodies to prevent reperfusion injury (Leukosite), anti-VLA4 antibodies to treat multiple sclerosis (Athena/Elan), and anti-intercellular adhesion molecule (ICAM) antibodies to prevent graft rejection (228). CD40/CD40 ligand-mediated cellular interactions provide a key immunoregulatory pathway that is essential for production of IgG, IgA, and IgE antibodies and for regulation of cellular immune responses (31,62,69,144). Several humanized antibodies directed against CD40 ligand are in phase II clinical trials for treatment of autoimmune diseases, including systemic lupus erythematosus, and to prevent transplant rejection (Biogen, IDEC), and an inhibitory anti-CD40 antibody has recently entered a clinical trial for treatment of Crohn disease (v).

Soluble protein cytokines or their receptors represent yet another group of promising therapeutic targets for antibody therapeutics. Several cytokine-specific antibodies have already been approved for clinical use including the chimeric anti–tumor necrosis factor-a antibody, Remicade, for treatment of severe Crohn disease and RA (11,163,164,229,258). Zenapax, a humanized mAb directed against the IL-2 receptor, has been approved for prevention of transplantation rejection (18,262,267) and is in early clinical trials for treatment of uveitis and psoriasis (67). Other cytokine- or chemokine-directed antibodies in clinical testing include a humanized anti–IL-5 antibody for treatment of asthma (Schering Plough/CellTech), which blocks the activation and influx of eosinophils into the lungs, and a fully human anti–IL-8 antibody for treatment of psoriasis (Abgenix.com).

One exciting new mAb drug for treatment of allergic asthma and rhinitis is the humanized mAb called E25 directed against human IgE (61,120). The concept behind this novel therapeutic strategy is to prevent IgE from binding to the high-affinity IgE receptors expressed on the surface of mast cells and basophils. This therapeutic strategy has been successful in preventing the symptoms of allergic rhinitis in patients with seasonal allergies (38), as well as in decreasing the disease symptoms of patients with chronic moderate to severe allergic asthma (26,73,178).

Ironically, products of the immune system, mAbs, are emerging as a major class of drugs to regulate or modify immune responses for therapeutic benefit. A large number of antibody-based products are in development to attenuate immune responses to treat diseases caused by inappropriate or unwanted immune responses, as well as to stimulate the immune system to protect against infection and cancer (106,107,248). We anticipate that immunomodulation will be an increasingly important niche for antibody drugs in the future. Difficulties in discovering small-molecule drugs that inhibit protein/protein interactions involved in cellular recognition or cytokine/receptor binding that are key components of immune responses support development of antibody-based drugs.

Antibody Treatment of Cardiovascular Diseases

In contrast to the use of antibodies to treat infectious diseases, many mAbs are being used in “innovative” roles that are very different from their traditional protective function. This is perhaps best illustrated by the success of mAb therapy to treat cardiovascular diseases. The most widely used and commercially successful antibody on the market today is ReoPro, a monovalent chimeric mAb fragment (Fab) that prevents platelet aggregation and clotting. ReoPro can successfully prevent complications after angioplasty, acute myocardial infarctions, and unstable angina (33,168,170,180,251,255). Several other humanized antibodies are in clinical trials to prevent ischemia/reperfusion myocardial damage and stroke by interfering with the immigration of inflammatory cells into the site of tissue damage (e.g., anti-CD18, anti-ICAM, anti-CD11a antibodies). Because activation of the complement system may be one of the early triggers of cardiovascular tissue damage, another approach to treating ischemia/reperfusion injury and complications after surgery involving cardiopulmonary bypass is to block the production of proinflammatory peptides released by complement activation. A humanized single-chain antibody directed against complement component C5 has shown promise in phase II clinical trials for treatment of complications after cardiopulmonary bypass and is in early clinical trials for treatment of acute myocardial infarction as well as inflammation associated with RA and lupus (77,253,257,258). In summary, there is a plethora of clinical applications of mAbs. A subset of these is summarized in Table 91.4.

TABLE 91.4. Representative Antibodies in Preclinical and Clinical Development

NOVEL COMPOSITIONS OF ANTIBODY-BASED DRUGS

Bispecific Antibodies

Totally new binding moieties exhibiting two or more distinct antigen-binding specificities can be created with recombinant DNA technology (230). Two different mAbs or their Fab fragments can be chemically coupled, or two single-chain antibodies can be genetically linked to form a so-called diabody. Theoretically these bispecific constructs can create novel biologic functions. Many bispecific antibodies are being developed to treat a wide range of cancers (59,108,134,181,233,237,241). A bispecific construct being developed by Medarex has one binding specificity directed against the Fcg receptor I (CD64) expressed on the surface of macrophages and monocytes. Binding of antibody to CD64 results in cellular activation for ADCCs and other properties that help destroy cancer cells (45). To target this activity specifically against the tumor cells, the humanized anti-CD64 Fab is coupled to the Fab of a second antibody directed against either the EGF receptor (EGF-R, MDX-447) or HER2/neu (MDX-210), which are overexpressed by some tumor cells. Targeting the tumor cells expressing EGF-R or HER2/neu thus focuses the anti-CD64 to bind and activate macrophages for cancer cell destruction (56,211,215,222). Early clinical studies of MDX-447 in cancer patients showed tumor stabilization in a fourth of those treated. A phase II clinical trial in renal cell carcinoma with MDX-447 showed antitumor effects in about 40% of the treated patients, with some patients showing a 50% reduction in tumor volume. In a phase II trial of patients with breast, ovarian, colorectal, or prostate cancer, MDX-210 also showed antitumor activity.

A number of additional bispecific constructs have been created to specifically activate T cells at the tumor site (32,140). In most of these constructs, an anti-CD3 antibody known to trigger T cells is linked to an antibody directed against antigens overexpressed by the cancer cells. One construct using anti-CD3 linked to an anti–erb-B2 (HER2/neu) antibody stimulated Th1 cells and showed antitumor activity against human breast cancer cells implanted into mice (194). Anti-CD3 also has been coupled with anti-CD19, a B-cell antigen, for treatment of malignant lymphomas (132) and to anti-CD30 for therapy of Hodgkin lymphoma (100). In one study, immunodeficient mice were implanted with Hodgkin lymphoma cells and human T cells. When these mice were treated with bispecific constructs of anti-CD3 and anti-CD28 antibodies coupled to anti-CD30 antibodies, human cytotoxic T lymphocytes were generated, and these cells specifically infiltrated the sites of the tumors (16). In a related approach, NK cells were targeted by using a bispecific construct comprising anti-CD16 and anti-CD30 antibodies. Treatment of mice implanted with Hodgkin lymphoma cells with the anti-CD16/anti-CD30 diabody caused tumor regression (8). A phase I/II clinical trial used a murine bispecific anti-CD16/anti-CD30 construct, and antitumor activity was observed in some patients with Hodgkin lymphoma; however, the HAMA response precluded further treatment (220).

An alternative to using bispecific antibodies to focus cellular anticancer activity on the cancer cells is to use these agents to target radiotherapy to the tumor cells (113,266). In a phase I/II clinical trial, patients with small-cell lung carcinoma (SCLC) who had experienced a relapse from chemotherapy were initially treated with intravenous injection with a bispecific antibody comprising an anti–carcinoembryonic antigen (CEA) antibody coupled to an antihapten (diethylenetriaminepentaacetic acid, DTPA) antibody. Because CEA is overexpressed by many SCLC cells, the anti-CEA antibody localized on the SCLC cells. After several days to allow the unbound bispecific antibody to be cleared, leaving mainly SCLC-bound antibody, the patients were injected with radioiodinated DTPA that bound to the SCLC cell surface through the anti-DTPA. Initial results of this study were reported to be encouraging (266).

Although the primary clinical application of bispecific antibodies to date has been cancer, this type of drug offers a wide range of exciting possibilities for treatment of other diseases. Not only can bispecific antibodies mediate cellular interactions that would not normally occur, but they can also be used to modify cellular activities. As the biology of interacting receptors on the cell surface becomes better established, unique opportunities will arise to use bispecific antibodies to alter cell biology by creating novel receptor interactions. This is an exciting application of antibody technology to create new biology to treat diseases.

Immunoglobulin Fusion Proteins

Fusion of the antibody constant region to ligands or receptors can create multivalent binding molecules with improved *in vivo* bioavailability and biologic activity (17,41,101,105,110,119,158,204,288). One of the earliest antibody fusion proteins tested clinically was a construct comprising a human IgG1 constant region fused with the extracellular domain of CD4, which retained binding activity for HIV (42,83). The rationale for this therapeutic was to provide a multivalent form of soluble CD4 that would act as a decoy receptor to bind HIV virions to prevent viral spread. More recently, Progenics Inc. has tested a similar construct in HIV-infected patients in a phase I clinical trial reporting a dose-dependent reduction in HIV load (Progenics.com).

An immunoglobulin fusion protein designed to inhibit T-cell responses contains the immunoglobulin constant region of IgG1 fused to CTLA4 called CTLA4Ig. Both CD28, which provides a major T-cell costimulatory signal, and CTLA4 bind to B7.1 and B7.2 on APC. The soluble CTLA4Ig fusion protein binds to the APC B7 molecules to prevent CD28-mediated T-cell activation. A large number of preclinical models using CTLA4Ig have shown it to be very effective in blocking antibody- and cell-mediated immune responses, including those causing autoimmune diseases (55,115,205,232). CTLA4Ig also has been widely used in murine and primate organ transplantation studies, in which it has been shown to delay organ rejection, which was even more effective when combined with an anti-CD40 ligand mAb (69,133,152,154,202). T-cell anergy was apparently achieved in a clinical trial to prevent graft-versus-host disease (GVHD) in bone marrow transplantation (96). In this study, donor bone marrow was cultured *ex vivo* with recipient leukocytes in the presence of CTLA4Ig. CTLA4Ig blocked the second costimulatory signal given during recognition of the recipient antigens on the APC, resulting in anergy of the T cells in the donor bone marrow. The “anergized” bone marrow was then transfused into the recipients, who showed a dramatic long-lived reduction or elimination of GVHD. Recently, in a phase I clinical trial in patients with severe psoriasis, CTLA4Ig caused a dramatic reduction in skin lesions (1).

Another T cell–directed immunoglobulin fusion protein contains the human IgG1 constant region fused to the extracellular region of leukocyte function–associated antigen (LFA)-3 that binds CD2 expressed by T cells (175). Because CD2 can be costimulatory for T-cell activation, the LFA-3Ig was thought to block T-cell activation through interference with the CD2 activation signal (126,179). However, further studies showed that the mechanism by which the LFA-3Ig construct inhibits T-cell responses is through depletion of T cells through ADCCs (48,165). A completed phase II clinical study of LFA-3Ig in psoriatic patients demonstrated a dramatic reduction in psoriatic skin lesions (Biogen.com).

TNF-a is a major inflammatory cytokine that binds to either of two specific receptors expressed by numerous cell types. Immunex has created Enbrel, an Ig fusion protein containing the extracellular domain of the low-molecular-weight TNF-a receptor. Enbrel inhibits TNF-a–mediated inflammation and has been approved for the treatment of RA. Treatment of RA patients with twice-weekly subcutaneous injections of Enbrel caused a dramatic reduction in disease symptoms that was sustained for up to 6 months (86,121,184,185,273). Enbrel is in clinical trials for a number of additional clinical indications, including Crohn disease (65).

The clinical successes described demonstrate the therapeutic power of antibody-based drugs using properties of the flexible antibody drug platform: valency and improved bioretention. In addition, Ig fusion proteins with receptors and ligands are providing an important laboratory reagent for investigating biologic pathways. Some of these new antibody-based fusion proteins will have tremendous therapeutic value as novel clinical applications emerge.

Immunotoxins: Antibody-directed Warheads

Nature has provided a number of potentially lethal cellular toxins, such as the plant toxins ricin and gelonin, and bacterial toxins *Pseudomonas* exotoxin and diphtheria toxin. The question is how to target these proteins specifically to cancer or virally infected cells. To accomplish this goal, most of these toxins have been modified to destroy their ability to bind independently to cells, and then chemically coupled or genetically fused to mAbs to provide specific cellular delivery. Although a large number of laboratory and animal models have shown promising results with this approach (7,19,20,60,78,79 and 80,158,199,216,227,247,252,256), successful treatment of cancer in humans has thus far been limited (2,43,70,75,142,196,234). In one recent clinical trial, patients with refractory hairy cell leukemia were treated with an anti–IL2 receptor–binding fragment (Fv) fused with a modified form of *Pseudomonas* exotoxin (137,138). Of the four treated patients, one showed complete remission, and the others had a dramatic reduction in the numbers of circulating leukemia cells. Encouraging results also were found in a phase II trial in which patients with B-cell non-Hodgkin lymphoma were treated with a conjugate of a B cell–specific antibody, anti-B4, and a modified ricin toxin (94,190). However, this same immunotoxin conjugate was less successful in treatment of patients with multiple myeloma (95).

Toxic side effects remain a major problem with immunotoxin therapy, and problems exist with the maximally tolerated dose that will selectively eliminate the malignant cells (244). Although mAb delivery of toxins can be highly specific, often the cellular antigen is expressed by cells other than those targeted for destruction. For example, treatment of cancer patients with a fusion product between the Fv of an anti–erb-B2 antibody and modified *Pseudomonas* exotoxin showed unexpected liver toxicity. Subsequently, erb-B2 was found to be expressed at low levels on hepatocytes (200).

In addition to difficulty in finding an acceptable therapeutic window for immunotoxins with tolerable side effects, immunogenicity remains a major problem (70,137,263). Because these toxins are of plant or bacterial origin, they are highly immunogenic in humans, and treated patients often generate antitoxin antibody responses that preclude further treatment. Even if further treatment is possible, another problem is the emergence of resistant cancer cells no longer expressing the target of the immunotoxin. These problems present difficult hurdles for the broad therapeutic application of immunotoxins. Nevertheless, there are some clinical indications for which immunotoxins will be effective drugs, particularly when used locally rather than systemically. One such application is in the prevention of secondary cataracts in the eye (50). This therapeutic application consists of a modified ricin toxin conjugated to an epithelial cell–specific mAb to kill the epithelial cells that overgrow the lens to form the cataract, resulting in a loss of vision. A phase I/II trial in which the immunotoxin was applied to the eye at the conclusion of cataract surgery showed a significant reduction in the recurrence of cataracts. Based on these results, this promising immunotoxin has now entered phase III clinical testing.

Gene Therapy Using Antibody Genes and Fusion Products

In the future some mAbs may be delivered through antibody gene administration (203,213). Indeed, this may be an attractive way to reconstitute protective antibody responses where the immune system has been damaged or cannot produce the appropriate protective antibodies. Most experience with gene-delivered antibodies to date has been with the intracellular expression of single-chain antibody fragments, called intrabodies (46,166,282). The major advantage of this technology is that the intrabody can bind and neutralize a large number of intracellular antigens inaccessible to extracellular antibodies. Intrabodies can be localized to different subcellular compartments by using specific peptide tags engineered into the molecules. This strategy has been used successfully in cell-culture studies to prevent HIV infection with intrabodies directed against several different HIV antigens (155,177). In other laboratory studies, intrabodies neutralizing proteins that regulate cell growth were delivered to cancer cells to interfere with cell growth as an approach to creating intracellular "knockouts" (51,127,223). For example, an anti–erbB-2 intracellular scFv localized to the endoplasmic reticulum of cancer cells overexpressing erbB-2, causing the cells to undergo apoptosis and die (63,64,92,93,245,284). This anti–erb-B2 intrabody was successful in preclinical animal models of ovarian, breast, and prostate cancers, and a phase I clinical trial was performed in patients with ovarian and extraovarian cancer (3). Delivery of intrabodies by gene therapy is anticipated to permit specific targeting of a large number of intracellular targets involved in cellular activities, such as cell division and cytokine production and infectious agents such as HIV and human papilloma virus (269). However, for intrabodies to reach their potential, highly efficient and targeted cell delivery will be required, a goal that has not yet been achieved for any form of gene therapy.

PRACTICAL CONSIDERATIONS FOR DEVELOPMENT OF ANTIBODY DRUGS

Delivery

Most therapeutic mAbs are now delivered either by intravenous infusion or subcutaneous injection. However, other routes of administration, such as oral or intranasal, that have been successfully used with some polyclonal antibodies for treatment of bacterial or viral infection (54,57,58,81,87,160,173,277), have not been extensively tested with mAbs. Intranasally administered anti–respiratory syncytial virus (RSV) antibodies are able to reduce pulmonary infection (88,277). A polymer device impregnated with an anti–herpes simplex virus (HSV) mAb placed in the vagina of mice allowed slow release of the antibody, resulting in reduced HSV infection (238). In a clinical trial to prevent oral *Streptococcus mutans* colonization, a monoclonal secretory IgA antibody produced in plants was applied to the teeth and prevented bacterial recolonization for at least 4 months (161). Aerosolized monoclonal anti-IgE antibody E25 was tested in one clinical trial in allergic asthma patients (72). Although the aerosolized E25 retained activity, the mAb concentrations in the tissues were too low to achieve clinical improvement. As novel delivery technologies improve the delivery of larger proteins, mAbs will increasingly be delivered topically, by inhalation, and possibly even orally (141,219).

Production Expense

Cost of production remains a critical issue in the commercialization of therapeutic antibodies. Currently, intact mAbs are manufactured in mammalian cells (218), whereas antibody fragments can be made in insect cells and yeast (21,30,68,111,114,139,208,224,225,239,283). To create manufacturing cell lines, murine myeloma cells or Chinese hamster ovary (CHO) cells are transfected with the antibody heavy- and light-chain genes (218). The transfected cells are grown in serum-free media in large stainless steel fermenters or hollow-fiber devices, and the mAbs purified from the culture supernatant fluid. This is an involved and costly process that results in a relatively high expense for antibody drugs. To reduce the cost of antibody manufacture, novel "bioreactors" are being explored. Both transgenic animals and plants are being tested for the production of antibodies (147,162,209). Transgenic mammals have been generated by fusing the antibody heavy- and light-chain genes to mammary gland–specific promoters to facilitate expression and secretion of large amounts of the antibodies in milk, from which the mAb is purified (157,209). Antibody genes also have been expressed in plants (103,162,250) and "Plantibodies" produced at agricultural scale are expected to be available at a fraction of the cost of currently available fermenter-produced antibodies.

THE FUTURE OF MONOCLONAL ANTIBODY–BASED THERAPEUTICS

According to a 1998 survey by the Pharmaceutical Research and Manufacturers of America, antibodies account for the largest group of investigational new drugs (INDs) filed among the different classes of biotechnologic drugs including cytokines, growth factors, enzymes, antisense, and gene therapy, and currently mAbs represent more than 20% of all biotechnology drugs in clinical development. An increasing amount of information about antibodies and related topics is readily available on the worldwide web (Table 91.5). Many problems encountered in the early history of murine mAbs have been solved, and human mAb-based drugs are fast becoming a major new therapeutic drug class. In addition, antibodies have proved important to identify and validate therapeutic concepts. In some cases, the antibodies themselves have been developed as the therapeutic agents. In other cases, the antibodies have been replaced by peptides or small organic drugs.

TABLE 91.5. Antibodies on the World Wide Web

Within a year, the entire sequence of the human genome will be completed. Characterization of each of the more than 100,000 gene products will require at least one and probably multiple mAbs. These reagents will find use in protein characterization and in biologic experiments. Some will be used directly or in modified form (i.e., as a fusion protein, bispecific, intrabody) as recombinant therapeutic antibody-based drugs. In addition, we predict that a significant subset of these mAbs will provide leads for drug development by demonstrating therapeutic concepts. Already mAbs are being used to model receptor/ligand binding, and mimics of antibody loops (231,280) may provide a rapid novel means to generate pharmaceutical leads. Novel display technologies (99,102) will speed the discovery process. Recently, so-called "psi-bodies," binding molecules having hypervariable loops similar in function to the antibody CDRs, have been selected to bind target antigens (193). These "designer proteins" may eventually represent a novel subgroup of antibody-like binding molecules. In the future, it is likely that only the imagination of antibody engineers will limit the application of these exquisitely designed and useful molecules!

92 DRUGS THAT MODULATE THE IMMUNE RESPONSE

Edwin S. L. Chan, M.B., Ch.B., and Bruce N. Cronstein, M.D.

Both the innate and adaptive immune systems evolved to prevent or eradicate invasion by microorganisms and to eliminate dead or injured tissue. These functions are essential for the maintenance of homeostasis, but overactive immune or inflammatory responses characterize the pathogenesis of a number of acute and chronic illnesses such as rheumatoid arthritis, inflammatory bowel disease, and systemic lupus erythematosus (SLE), the “autoimmune” diseases in which an exaggerated or inappropriate immune or inflammatory response leads to significant disability. Although there are no cures for autoimmune diseases, great strides have been made in the last half century in the development of increasingly safe and effective therapies for these illnesses. Many of the drugs introduced were originally developed for other uses, and their mechanisms of action in the therapy of autoimmune diseases were not understood. In this chapter, the mechanisms of action and uses of common antiinflammatory and immunomodulatory drugs (Fig. 92.1) are discussed.

Figure 92.1. Drugs that affect the immune response.

CORTICOSTEROIDS

The doyen of immune-modulating drug therapy for half a century, corticosteroids have long been regarded as a mainstay in the treatment of inflammatory diseases. Hench's (1,2) benchmark and Nobel prize-winning discovery that corticosteroids have a profound antiinflammatory effect against rheumatoid arthritis brought attention to what was to become one of the most widely used and potent naturally occurring drugs in rheumatic and other inflammatory disease states. These four-ringed, 21-carbon steroid hormones are of adrenal medullary origin (cortisol/hydrocortisone) and are produced in response to stimulation by adrenocorticotropic hormone. Corticosteroids have received many pharmaceutical modifications and disguises over the years, which result in varying durations of action and relative glucocorticoid-to-mineralocorticoid potencies. Their widespread clinical use has been hampered by the recognition of their many side effects and toxicities, not least in relation to the suppression of the hypothalamic/pituitary/adrenal axis. Other major side effects involve multiple organ systems, as listed in Table 92.1.

Endocrine	Suppression of hypothalamus pituitary adrenal axis Diabetes
Skin	Hirsutism Skin thinning Striae Acne Purpura Alopecia
Gastrointestinal	Peptic ulcer disease Gastritis Pancreatitis
Eye	Glaucoma Posterior subcapsular cataract
Musculoskeletal	Osteoporosis Avascular necrosis Myopathy
Cardiovascular	Hypertension Dyslipidemia Dysrhythmia Premature coronary artery disease
Neuropsychiatric	Euphoria Depression Psychosis Insomnia Pseudotumor cerebri
Infectious disease	Increased risk of usual infections Opportunistic infections

TABLE 92.1. Major Adverse Effects of Corticosteroids

Antiinflammatory Effects

EFFECTS ON CELLS INVOLVED IN THE INFLAMMATORY RESPONSE

Neutrophils and Endothelial Cells

The short-lasting increase in the circulating pool of neutrophils, often persisting for less than 24 hours, is one of the best known of clinical effects after corticosteroid administration (3). A number of factors contribute to its occurrence, including an increase in the circulatory half-life of the neutrophils, perhaps due in part to a decrease in apoptosis of neutrophils; an increase in neutrophilic demargination from the vascular endothelium; the premature release of neutrophils from the bone marrow, partly in response to released granulocyte colony-stimulating factor; and a decrease in the egress of neutrophils into sites of inflammation (4,5,6,7,8,9,10,11,12 and 13). The exact mechanisms by which these phenomena occur are ill defined, but observations suggest various factors that might contribute to these effects. The change in electrophoretic mobility, reflecting cell-surface charge, was altered in neutrophils stimulated with *N*-formyl-methionyl-leucyl-phenylalanine (*f*MLP) after corticosteroid administration (14). Neutrophil chemotaxis in response to *f*MLP and interleukin (IL)-8 is reduced by treatment with dexamethasone (15). The change in expression of adhesion molecules on both polymorphonuclear leukocytes and endothelial cells is another mechanism by which neutrophil attachment to blood vessels and subsequent recruitment to inflamed sites may be altered (16,17 and 18). Dexamethasone decreased L-selectin expression and b_2-integrin ligand-binding avidity on the surface of resting neutrophils, an effect mediated by the glucocorticoid receptor (19,20). Endothelial cell permeability and expression of major histocompatibility complex molecules may also be affected; and more importantly for inflammation, corticosteroids decrease endothelial expression of the adhesive molecules E-selectin and intercellular adhesion molecule (ICAM)-1 (21,22,23,24,25 and 26). Reduction in neutrophil binding to tumor cells may be responsible for the inhibition of neutrophil-mediated tumor cell cytostasis seen with corticosteroids (19). Neutrophil production of inflammatory mediators such as cytokines, prostaglandins,

leukotrienes, and reactive oxygen species may also be modulated by corticosteroids (15,27,28,29,30,31 and 32).

Monocytes and Macrophages

Corticosteroids affect the numbers, differentiation, and phenotypes of cells of the monocyte/macrophage lineage (23,33,34). Interaction between macrophages and other inflammatory cell types may also be modulated. The expression of adhesion molecules such as ICAM-1 may be suppressed by corticosteroids, an effect dependent on the preparation used and cell type studied (35,36,37 and 38). Through the production of cytokines, macrophages have a profound influence on the inflammatory behavior of multiple cell types, and corticosteroids have documented effects on the generation of cytokines such as IL-1 and tumor necrosis factor-a (TNF-a), contributing to the suppression of inflammation (39,40 and 41). As antigen-presenting cells, macrophages influence the production of T-helper (Th)2 cytokines by lymphocytes. This capacity is enhanced by treatment of macrophages with corticosteroids (42). Effective antigen presentation requires the participation of human leukocyte antigen (HLA)-DR antigens on the cell surface, and their expression may also be decreased by corticosteroid treatment, thus blunting any further macrophage-induced amplification of the inflammatory response. However, the evidence for this latter effect is contradictory, and inhibition of antigen presentation may occur regardless of the effect of corticosteroids on MHC expression (36,43,44).

Eosinophils

Corticosteroids reduce the survival of eosinophils, an effect that may be overcome by the influence of cytokines such as interferon (IFN)-g or tumor necrosis factor-a (TNF-a), thus leading to a decrease in circulating cell numbers (45,46 and 47). This may occur in part by induction of apoptosis in this cell population (7,48,49). Corticosteroids also induce the migration of peripheral blood eosinophils to several lymphoid organs, such as the spleen, lymph nodes, and thymus (50). Eosinophil chemotaxis, adherence, and degranulation may also be inhibited (23,51,52 and 53).

Lymphocytes

The circulating numbers of lymphocytes are reduced by corticosteroids (54). Redistribution to lymphoid tissues and the bone marrow may contribute to this decrease (55,56). The induction of apoptosis by corticosteroids seen in other cell types is also operative in lymphocytes, particularly thymocytes and immature lymphocytes (57,58 and 59). Lymphocyte proliferation, particularly that of the T-cell population, is also inhibited by corticosteroids (60,61). Corticosteroids also influence the expression of cytokines by T-cell subsets, generally shifting the balance in favor of a Th2-predominant profile (62,63). Downregulation of IL-2 production by T lymphocytes further attenuates an important stimulating signal for the proliferation and amplification of the lymphocyte population (64).

Phlogistic Effects

The powerful antiinflammatory actions of corticosteroids are manifested in their influence on almost every class of inflammatory mediators. An important effect is the stimulation of the production of lipocortins, which inhibit the activity of phospholipase A_2, which, in turn, attenuates arachidonic acid metabolism and eicosanoid production (65). Cyclooxygenase activity is reduced, and nitric oxide synthase expression is inhibited as well (66,67). The production of many inflammatory cytokines is suppressed, including IL-1, IL-2, IFN-g, and TNF-a; and the production of destructive enzymes such as collagenase and stromelysin is also downregulated (68,69).

Intracellular Signal Transduction

Glucocorticoids are potent regulators of the expression of a large number of gene products. On ligation of the glucocorticoid receptor, which normally resides in the cytosol complexed to heat shock protein (hsp)90 and immunophilin p56, homodimers of glucocorticoid receptors are formed and may enter the nucleus and positively affect gene transcription by binding to glucocorticoid response elements. Such regulatory processes contribute to some of the antiinflammatory properties of corticosteroids, particularly in relation to the effects of glucocorticoids on phlogiston production. However, since many corticosteroid-sensitive immunoregulatory genes do not have a recognizable glucocorticoid response element in their promotor regions, and corticosteroids inhibit the upregulation of many gene products stimulated by proinflammatory stimuli, alternative mechanisms must exist to explain how corticosteroids produce their antiinflammatory effects. The ligand-activated glucocorticoid receptor also possesses the ability to inhibit AP-1 and NF-kB–mediated transcription (70,71). Protein/protein interactions between NF-kB and glucocorticoid receptors may result in the repression of transcriptional activity (72). More strikingly, corticosteroids induce the production of an inhibitory protein, IkBa, which, by complexing with the heterodimeric NF-kB complex in the cytoplasm, effectively blocks the translocation of NF-kB into the nucleus, thus attenuating downstream transcriptional activity (see Chapter XX) (70). Glucocorticoids also promote the reassociation of free NF-kB with IkBa (73). Examples of NF-kB–regulated genes important in the inflammatory response that are repressed by corticosteroids include IL-2, IL2-Ra, IL-3, IL-6, IL-8, TNF-a, granulocyte-macrophage colony-stimulating hormone (GM-CSF), inducible nitric oxide synthase (iNOS), and adhesion molecules ICAM-1 and E-selectin (21,70,73,74). Interference with AP-1, the major enhancer for the collagenase promotor, may account for the downregulation of collagenase by corticosteroids, and a direct protein/protein interaction is known to exist between the glucocorticoid receptor and AP-1 (75). Whereas the glucocorticoid receptor is a potent inhibitor of AP-1 activity, c-Jun and c-Fos are potent repressors of glucocorticoid-receptor activity (76). The direct interaction between CREB-binding proteins and the ligand-binding domains of nuclear factors such as AP-1 may be responsible for the mediation of this activity without necessarily affecting the binding of AP-1 to DNA response elements (77).

METHOTREXATE

A disease-modifying drug that is now accepted as the gold standard for the treatment of rheumatoid arthritis, methotrexate was developed as one of the first chemotherapeutic agents for the treatment of malignant diseases. Methotrexate was developed as a folic acid analog that diminishes the cellular proliferation of malignancies by inhibiting the synthesis of purines and pyrimidines required to support cell growth (78). It was generally assumed that inhibition of the proliferation of cells involved in the immune and inflammatory response was responsible for the antiinflammatory action of methotrexate, as applied to inflammatory diseases such as rheumatoid arthritis. However, the doses of methotrexate used in the treatment of inflammatory diseases are from ten- to 1,000-fold lower than those used for its antimalignant effect. Furthermore, the addition of folic or folinic acid to the treatment regimen, a strategy that would nullify the antifolate action of methotrexate used for malignancies, has been widely adopted as an adjunct to counteract toxic side effects of methotrexate therapy, such as stomatitis and bone marrow suppression, processes that depend on cellular proliferation. In contrast to its effects on methotrexate-induced toxicity, folic acid supplementation does not result in any loss of antiinflammatory efficacy (79). It would therefore appear that the antiinflammatory actions of methotrexate must depend on mechanisms other than inhibition of dihydrofolate reductase.

The Pharmacologic Fate of Methotrexate

Methotrexate, whether administered orally or intramuscularly in inflammatory diseases, has a very short plasma half-life. Although a wide variation in interindividual levels exists, peak serum levels may be achieved in as little as 2 hours after oral administration (80). Methotrexate is hydroxylated to form 7-hydroxymethotrexate, which possesses many of the biologic properties of the parent compound (81). Both methotrexate and 7-hydroxymethotrexate are in turn polyglutamated, and as such remain intracellularly for extended periods while remaining biologically at least as active as methotrexate itself (82). Much of the excretion occurs through the renal route (83).

Molecular Actions

The molecular mechanisms by which methotrexate exerts its antiinflammatory actions have been well studied. There are currently three major hypotheses regarding the mechanisms of action of methotrexate, which may be complementary in explaining the molecular effects of the administered drug. The dihydrofolate reductase–inhibiting properties of methotrexate have long been known, and it has been suggested that low-dose methotrexate decreases purine and pyrimidine synthesis *in vivo* and thus diminishes lymphocyte proliferation. A single dose of methotrexate transiently decreases serum purine and pyrimidine levels (24 to 48 hours) (84). This decrease is associated with a transient reduction in antigen-stimulated proliferation of lymphocytes *ex vivo*. Methotrexate also induces apoptosis of activated peripheral T lymphocytes from patients with rheumatoid arthritis (85). Although these changes are quite consistent with the hypothesis, their transient nature does not correlate with the long duration of antiinflammatory action of a single dose of the drug.

The second proposed mechanism of methotrexate action posits that the immune pathways responsible for inflammatory diseases such as rheumatoid arthritis may be blunted by blocking transmethylation reactions intracellularly, an action accomplished by methotrexate. This hypothesis rests on the ability of methotrexate to inhibit the production of potentially toxic compounds such as the polyamines, spermine, and spermidine. Figure 92.2 illustrates the formation of *S*-adenosylmethionine, a methyl donor for transmethylation reactions within the cellular environment. The acquisition by homocysteine of a methyl group donated by tetrahydrofolate results in the formation of methionine, which is then converted to *S*-adenosylmethionine. The resultant *S*-adenosylmethionine is the primary methyl donor in intracellular reactions including the methylation of DNA and lipids, as well as the posttranslational modification of proteins, all essential for cellular survival. After the donation of the methyl group, *S*-adenosylhomocysteine is converted by *S*-adenosylhomocysteine hydrolase to adenosine and homocysteine, which can reenter the cycle. Blockage of cellular transmethylation reactions occurs with the accumulation of high concentrations of *S*-adenosylhomocysteine and consequent inhibition of the formation of *S*-adenosylmethionine, which occurs in the red cells and lymphocytes of children with inherited adenosine deaminase deficiency, a form of severe combined immunodeficiency syndrome, suggesting a critical role for transmethylation reactions in normal immune function (86,87,88 and 89). The inhibition of monocyte and

lymphocyte function that occurs with the blockade of transmethylation reactions lends further support to this hypothesis. Moreover, *S*-adenosylmethionine is required for the synthesis of polyamines such as spermine and spermidine, which may accumulate in the synovium of rheumatoid arthritis patients. Monocytes produce toxic metabolites from polyamines such as NH_3 and H_2O_2, which have been shown to inhibit lymphocytic IL-2 production (90,91,92 and 93). Polyamine formation also is associated with increased production of rheumatoid factor and altered monocyte function. Methotrexate, by inhibiting the formation of *S*-adenosylmethionine, can reverse these immunologic effects *in vitro* (Fig. 92.2). There are many other sources of toxic oxygen metabolites in the inflamed rheumatoid synovium, and the inhibition of polyamine formation alone is unlikely to account for the antiinflammatory effects of methotrexate. Moreover, the lack of clinical efficacy of 3-deaza-adenosine, an *S*-adenosylhomocysteine hydrolase inhibitor that diminishes transmethylation reactions and *S*-adenosylmethionine production, in the treatment of rheumatoid arthritis, suggests that inhibition of transmethylation pathways alone cannot account for the antiinflammatory actions of methotrexate (94,95,96 and 97; M. Weinblatt, personal communication).

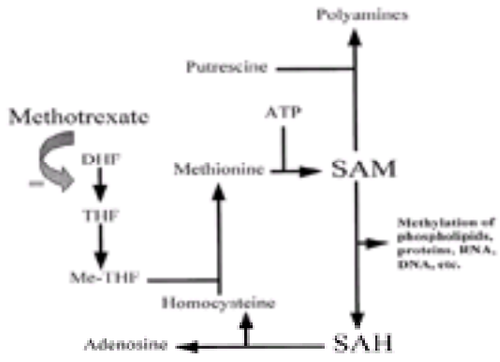

Figure 92.2. Methotrexate inhibits transmethylation reactions and polyamine formation. *DHF*, dihydrofolate; *THF*, tetrahydrofolate; *Me-THF,* methyl-tetrahydrofolate; *ATP*, adenosine triphosphate; *SAM, S*-adenosyl-methionine; *SAH, S*-adenosyl-homocysteine

Methotrexate polyglutamates are potent inhibitors of various intracellular folate-dependent enzymes, and one of those most effectively inhibited is 5-aminoimidazole-4-carboxamide ribonucleotide (AICAR) transformylase, which catalyzes the conversion of AICAR into formyl-AICAR (Fig. 92.3). Inhibition of AICAR transformylase by methotrexate polyglutamates results in the accumulation of AICAR, and cancer patients treated with methotrexate have previously been shown to excrete increased amounts of aminoimidazole carboxamide in their urine (98). The accumulated AICAR has two important intracellular effects. First, AICAR is a direct inhibitor of the enzyme adenosine monophosphate (AMP) deaminase. The dephosphorylated metabolite of AICAR, AICARiboside, is an inhibitor of adenosine deaminase. AICAR accumulation can therefore lead to the release of adenosine, either directly through adenosine deaminase inhibition, or indirectly from AMP deaminase inhibition and hence the accumulation of AMP, which can be dephosphorylated to adenosine (99). In support of this hypothesis, Baggott et al. (100) recently observed an increase in urinary aminoimidazole carboxamide and adenosine in patients taking antiinflammatory doses of methotrexate.

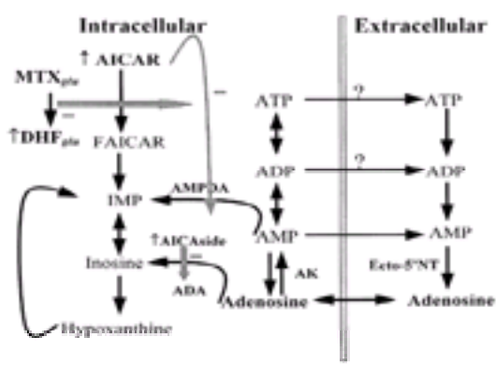

Figure 92.3. Pathways in adenosine formation. *AICAR*, 5-aminoimidazole-4-carboxamide ribonucleotide; *FAICAR*, formyl-AICAR; *IMP*, inosine monophosphate; *AMPDA*, adenosine monophosphate deaminase; *ADA*, adenosine deaminase; *AK,* adenosine kinase; *ecto-5'NT*, ecto-5'nucleotidase.

The released adenosine, acting through one of the four known types of adenosine receptors, A_1, A_{2A}, A_{2B}, and A_3, has a wide diversity of physiologic effects. Adenosine receptors are members of the seven-transmembrane-spanning receptor family related to adrenergic receptors (101). The A_1, A_{2A}, and A_{2B} receptors, unlike the A_3 receptor, are highly conserved during evolution. Many of the physiologic events mediated by adenosine are antiinflammatory in nature and involve a number of different cell types (102). With respect to the neutrophil, these include the diminution of their accumulation at the inflamed site, inhibition of stimulated neutrophil adhesion, and inhibition of the generation of toxic oxygen metabolites and neutrophil phagocytosis (103,104,105 and 106). Lymphocyte proliferation also is inhibited, and adenosine induces suppressor function and phenotype among lymphocytes (107,108 and 109). Secretion of cytokines by monocytes/macrophages also is modulated by adenosine, which enhances the production of antiinflammatory cytokines (e.g., IL-10) and suppresses the production of inflammatory cytokines (e.g., IL-6, IL-8, TNF-a), an effect mediated through adenosine A_{2A} and A_3 receptors (110,111,112,113 and 114). Ligation of adenosine A_1 receptors may decrease the production of collagenase, but not stromelysin or tissue inhibitor of metalloprotease by synoviocytes (115).

By releasing adenosine, methotrexate can therefore exert a variety of antiinflammatory effects (116). That adenosine mediates the antiinflammatory action of methotrexate is supported by the *in vivo* demonstration that adenosine-receptor antagonism can reverse or eliminate the antiinflammatory effects of administered methotrexate (117).

Aside from the desired effects that adenosine produces, it also may be responsible for some adverse effects encountered during methotrexate therapy. The mild, reversible renal dysfunction caused by methotrexate, thought to be vascular in origin, may be a function of the vasoconstrictive properties of adenosine acting through A_1 receptors in the kidney (118,119). The methotrexate-induced release of adenosine from macrophages promotes the formation of multinucleated giant cells, an effect again mediated through the adenosine A_1 receptor, and may account for the occurrence of subcutaneous nodulosis seen in patients with rheumatoid arthritis treated with methotrexate (120). Other adverse effects include gastrointestinal upset, cirrhosis, stomatitis, alopecia, interstitial lung disease, neurotoxicity, congenital abnormalities and abortion, lymphoproliferative malignancies, bone marrow suppression, and increased susceptibility to infections.

SULFASALAZINE

A compound originally introduced for the treatment of rheumatoid arthritis, sulfasalazine has gained clinical application in a wide range of inflammatory diseases, most notably in inflammatory bowel disease and the seronegative spondyloarthropathies. Composed of sulfapyridine and 5-aminosalicylic acid moieties, it possesses both antiinflammatory and antimicrobial properties. The active part of the drug may vary in different disease states, and whereas 5-aminosalicylate may mediate the therapeutic effects in inflammatory bowel disease, sulfapyridine is probably the responsible agent in the inflammatory arthritides (121,122 and 123).

Less than 20% of ingested sulfasalazine is absorbed intact, although some reenters the colon via biliary recirculation (124). The remaining sulfasalazine is metabolized by intestinal bacteria to sulfapyridine, which is well absorbed, and 5-aminosalicylate, which is only minimally absorbed, after which it is acetylated and excreted in the urine.

Sulfasalazine suppresses T-cell and B-cell proliferation *in vitro* and diminishes total immunoglobulin and rheumatoid factor levels *in vivo* (125,126,127 and 128). It may decrease the biologic effects of TNF-a by reducing its production and by inhibiting the binding of TNF to its receptor (125,129,130). Much as does methotrexate, sulfasalazine (but not sulfapyridine) inhibits AICAR transformylase, and the resultant AICAR accumulation inside the cell is associated with adenosine release, which in turn produces its salutary antiinflammatory effects, most likely mediated by adenosine A_2 receptors, because the sulfasalazine-induced inhibition of leukocyte accumulation in a murine air-pouch model of inflammation was reversed by an antagonist to the adenosine A_2 receptor (131,132 and 133). Inhibition of NF-kB may be the mechanism responsible for some of the physiologic actions of sulfasalazine, although the concentration of sulfasalazine required to inhibit translocation of NF-kB is

probably ten-fold higher than that achieved in patients (134,135).

Adverse effects of sulfasalazine therapy include gastrointestinal upset, urticaria and photosensitivity, Stevens-Johnson syndrome, aplastic anemia, interstitial nephritis, and oligospermia.

LEFLUNOMIDE

Leflunomide is an isoxazole derivative that is converted into the malononitrilamide compound A77 1726 (2-cyano-3-hydroxy-*N*-[4-trifluoromethylphenyl]-butenamide) before it becomes active. Because A77 1726 is highly protein bound in the plasma, it has a long half-life of more than 2 weeks. Excretion occurs through both feces and urine. It has been used in the prevention of solid organ transplant rejection and is approved for use in the treatment of rheumatoid arthritis, in which its clinical effects are evident when it is used either alone or in combination with methotrexate.

Leflunomide has been shown to be effective in diminishing lymphocyte proliferation (136,137). Humoral responses are also affected because B lymphocyte proliferation is suppressed during the progression through the S phase of the cell cycle with diminution of a cyclin-dependent kinase, Cdk2 protein (138). The antiproliferative action of leflunomide is believed to occur by inhibition of the *de novo* synthesis of pyrimidines in the G_1 phase of the cell cycle (139). The availability of pyrimidine nucleotides must be high enough to support the proliferation of cells such as activated lymphocytes, and salvage pathways alone do not fulfill the demands imposed by inhibition of *de novo* synthetic pathways (140). This notion is supported by the observation that administration of uridine reverses the antiproliferative effects of leflunomide *in vitro* (141,142). A77 1726 is an inhibitor of the enzyme dihydroorotate dehydrogenase, the activity of which is required for the *de novo* synthesis of uridine monophosphate from adenosine triphosphate (ATP) and glutamine, and this action may be important in the antiinflammatory effects of leflunomide in rheumatoid arthritis (143,144). The antiproliferative actions of very high concentrations of A77 1726 are, however, not reversed by the addition of uridine, suggesting that at these concentrations, leflunomide may exert its antiproliferative actions through a different mechanism, perhaps by inhibition of protein tyrosine kinases, as IL-2–induced tyrosine phosphorylation of Jak1 and Jak3, the protein tyrosine kinases initiating signaling by IL-2R, are inhibited by A77 1726 in high concentrations, and that tyrosine phosphorylation of the b chain of IL-2R, which is required for IL-2–driven proliferation, is also inhibited by A77 1726 (145). Leflunomide decreases stimulated NF-kB activation and also inhibits the adhesive process of peripheral blood and synovial fluid mononuclear cells (146,147).

Adverse effects of leflunomide therapy include gastrointestinal upset, respiratory and urinary tract infections, hypertension, peripheral edema, headache, alopecia and skin rash, hypokalemia, diabetes, dyslipidemia, anemia, leukopenia and thrombocytopenia, musculoskeletal pain, and elevated liver enzymes.

MYCOPHENOLATE MOFETIL

Mycophenolate mofetil is another immunomodulant used in the prevention of renal transplant rejection that is under study in clinical trials for the treatment of rheumatoid arthritis and SLE. It is well absorbed when administered orally and hydrolyzed to the active compound, mycophenolic acid. Mycophenolic acid is highly protein bound, and its metabolism takes place mainly by glucuronidation. Most of the excretion occurs through urine.

Mycophenolic acid is a potent inhibitor of the enzyme inosine monophosphate dehydrogenase and as such inhibits the *de novo* synthesis of purines (148). Lymphocytes are inherently dependent on the *de novo* rather than the hypoxanthine-guanine phosphoribosyl transferase salvage pathway for purine synthesis, and this imparts a relative selectivity for mycophenolic acid on cells involved in the immune response. The resultant decrease in the concentration of guanine nucleotides impairs DNA synthesis in lymphocytes and hence inhibits their proliferation. Mycophenolic acid suppresses antibody production by B cells and inhibits cytotoxic T-cell and NK-cell activity (149,150). It has also been shown to inhibit the production of cytokines by stimulated mononuclear cells after 48 hours of incubation, including IL-1a, IL-1b, IL-2, IL-3, IL-4, IL-5, IL-6, IL-10, IFN-g, TNF-a, TNF-b, and GM-CSF; and reduced the IFN-dependent induction of MHC in an *in vivo* model (151,152). In a murine model of SLE, mycophenolate mofetil suppressed the production of anti-DNA antibodies and reduced the number of $CD4^+$ T lymphocytes expressing very late antigen-4 and ICAM-1 without any effect on total immunoglobulins, CD4-, CD8-, or IgM-positive splenocytes. Survival of the treated mice was significantly greater than that of the control group after 60 days (100% vs. 10%) (153). Because mycophenolic acid reduces the guanine nucleotide pool in lymphocytes and monocytes, the synthesis of fucose- and mannose-containing saccharide components of membrane surface glycoproteins that are recognized by selectins is also inhibited. Thus mycophenolic acid may also limit neutrophil, lymphocyte, and monocyte recruitment (154). Side effects of mycophenolate therapy include fever; headache; abdominal, chest, and back pain; infection; hypertension; skin rash; gastrointestinal upset; insomnia; tremor; anemia; thrombocytopenia; leukopenia or leukocytosis; dyslipidemia; hyperglycemia; and electrolyte imbalance.

ANTIMALARIALS

The observation that patients with SLE improved while taking antimalarials led to the use of these agents in inflammatory diseases including rheumatoid arthritis. The variably absorbed drugs, chloroquine and hydroxychloroquine, which are both relatively weak antiinflammatory agents, have a predilection for pigmented tissues such as melanocytes and retinal cells. Excretion occurs via the urinary tract, but tissue deposition is associated with a prolonged half-life of more than 45 days (155). Retinal deposition of the drug causes retinopathy and blindness, although with the adoption of lower doses of hydroxychloroquine now commonly used in inflammatory diseases (6 to 7 mg/kg/day), retinal complications are rare (156). As they can easily traverse the plasma membrane, they gain ready access to acidic cytoplasmic vacuoles, where the acquisition of protons by these diprotic bases renders them acidic and unable to diffuse out of the vacuoles again. The concentrations of these antimalarial drugs are therefore higher within cytoplasmic vacuoles (157).

Antimalarials have varied antiinflammatory effects including inhibition of the production of multiple cytokines (TNF-a, IL-1 and IFN-g), phospholipases A and C activity, DNA and RNA polymerase reactions, and stimulated superoxide anion production by neutrophils (158,159,160,161,162 and 163). Their ability to buffer the acidic lysosomal pH has important ramifications in processes involved in the generation of the inflammatory response, most notably the interference of antigen presentation by macrophages (164). Side effects include skin rash and hyperpigmentation, gastrointestinal upset, headache, neuromyopathy, retinopathy, and corneal deposits.

CYTOTOXIC DRUGS

Various chemotherapeutic agents designed for the treatment of malignancies, including alkylating agents and antimetabolites, have been applied to the therapy of inflammatory diseases with the rationale that they target the most rapidly dividing cells, which in the case of inflammatory diseases are also the cells involved in the immune response. These drugs share many common features and toxicities including cytopenias, susceptibility to infection, gastrointestinal upset, and alopecia. We examine two examples of these agents used in the treatment of inflammatory diseases such as rheumatoid arthritis and SLE, azathioprine and cyclophosphamide.

Azathioprine

Azathioprine is an imidazolyl derivative of 6-mercaptopurine, which is a purine antimetabolite originally developed for the treatment of malignant diseases. It has been widely used in the management of solid organ transplants and in inflammatory diseases such as rheumatoid arthritis and SLE.

The ingested azathioprine is well absorbed and metabolized in the liver by xanthine oxidase to the active compound, 6-mercaptopurine. The subsequent conversion to 6-mercaptopurine nucleotides results in the inhibition of *de novo* purine synthesis. Alternatively, the conversion to thio-inosine monophosphate (thio-IMP) may interfere with the salvage pathway of purine synthesis, and the thio-IMP suppresses the conversion of IMP to AMP and guanine monophosphate, important in nucleic acid generation. The metabolism of thio-IMP yields thio-guanine monophosphate, which may be faultily interpolated into the DNA backbone.

Azathioprine induces the loss of NK-cell function without apparent change in cell numbers (165,166 and 167). It has the capacity to reduce antibody production and humoral response to challenges (168,169). Antibody-dependent cellular cytotoxicity is similarly suppressed (166). The circulating population of $CD8^+$ T lymphocytes also is reduced, with a resultant increase in the CD4/CD8 ratio (167). Production of cytokines such as IL-6 may also be diminished, and azathioprine reduces the expression of cytokine-induced neutrophil chemoattractant in an animal model (170,171). Chemotactic responses of neutrophils, monocytes, and lymphocytes are all reduced by azathioprine (172).

Cyclophosphamide

Cyclophosphamide is a prodrug that can be administered orally and intravenously. Absorption is complete when given orally. On metabolism by hepatic microsomal enzymes, aldophosphoramide is produced, which is cleaved into the phosphoramide mustard responsible for the alkylating action of cyclophosphamide, and acrolein, which is toxic to the bladder. Excretion occurs through the renal route.

The alkylation of guanine residues of DNA by cyclophosphamide renders the macromolecules cross-linkable and therefore interferes with DNA replication, transcription, and translation, overwhelming innate cellular DNA repair mechanisms (173). Cyclophosphamide has been shown to be markedly antiproliferative in mitogen-induced blastogenesis (174). B-lymphocyte function is altered, with suppression of immunoglobulin synthesis, although an increase in

immunoglobulin-secreting cells has been observed after cyclophosphamide therapy (175,176 and 177). Over time, cyclophosphamide decreases the number of circulating $CD4^+$ T cells with a lesser effect on $CD8^+$ T cells, thus reducing the CD4/CD8 ratio. T-cell proliferative responses were similarly suppressed with no apparent effect on NK cells or antibody-dependent cellular cytotoxicity (178).

CYCLOSPORINE

A powerful immunosuppressant used in organ transplantation and autoimmune diseases, cyclosporine is notable for targeting signal-transduction processes in immunocompetent cells, particularly T lymphocytes, and as such, shares many similarities with its more recently developed counterpart tacrolimus (FK506). This highly lipophilic compound has a high volume of distribution after oral or intravenous administration, particularly in cells high in cyclophilin content, such as leukocytes and erythrocytes. The many side chains arising from its complicated ring structure are subject to metabolism by the cytochrome P-450 system, and the principal route of elimination for these metabolites is through biliary excretion, although a small percentage undergoes urinary excretion. Adverse effects of therapy include nephrotoxicity and electrolyte imbalance, hypertension, tremor, hirsutism and acne, gastrointestinal upset, pancreatitis, hepatotoxicity, and infection.

The heterodimer formed from cyclosporine and cyclophilin is capable of inhibiting a calcium-dependent serine/threonine phosphatase activity by virtue of its ability to bind to and inactivate calcineurin (179,180). Thus regulatory proteins that include a subunit of the nuclear factor of activated T cells (NF-AT) in the cytoplasm, which require dephosphorylation before translocation into the nucleus, fail to be activated under the influence of cyclosporine. Because nuclear transcription of many inflammatory proteins requires the participation of these regulatory proteins in their activated form in the formation of transcription factors, the inhibitory process initiated by cyclosporine effectively attenuates the transduction signals that would otherwise result in the transcription of genes yielding products that amplify the inflammatory process. These products include cytokines, cytokine receptors, as well as protooncogenes. One such example is IL-2, important in mediating the mitogenesis of stimulated T lymphocytes (181). An alternative mechanism by which cyclosporine inhibits T-cell proliferation is the induction of a cell-cycle inhibitor, p21 (182). Stimulated gene transcription for IL-2 receptor is inhibited, and the synthesis of a number of other cytokines may also be affected, including IL-3, IL-4, IL-6, transforming growth factor-b, and IFN-g (183,184). NK-cell activity as well as B-cell function are also subject to inhibition by cyclosporine; and transcription of immunoglobulin genes may be inhibited (184,185 and 186). Production of cytokines by monocytes/macrophages such as IL-6 may be diminished by cyclosporine, and this diminution may occur at the posttranscriptional level because IL-6 synthesis but not IL-6 mRNA was inhibited by cyclosporine in a cell-culture model, and similar findings have been described in relation to the inhibition of TNF-a production. Thus cyclosporine may exert its antiinflammatory actions by mechanisms other than by regulating signal transduction via immunophilin binding, as described earlier (187,188).

CONCLUSION

The treatment of inflammatory diseases has enjoyed remarkable progress during the last half century after the introduction of immunomodulatory agents into clinical practice. It is worth noting that all the medications covered exert their antiinflammatory effects by influencing many different arms of the inflammatory network; and it would appear that such an approach is necessary to produce adequate and observable changes in outcome. Our understanding of the mechanisms of action of the commonly used immunomodulants complements the growing insights into the pathways of the immune network, and this knowledge will certainly find application in the design of more efficacious immunomodulants in the future.

93 New Approaches to Vaccine Development

Gary J. Nabel, M.D., Ph.D.

The difficulties in generating effective vaccines for several highly prevalent infectious diseases, including acquired immunodeficiency syndrome (AIDS), malaria, and tuberculosis, have underscored the need to advance vaccine development with modern technologies. Typically, characterization of naturally occurring, protective immune responses have guided such efforts, but significant challenges are posed when the immune system does not confer protective immunity, for example, as in human immunodeficiency virus (HIV) infection. In such cases, several approaches may facilitate the development of highly effective vaccines. The identification of immunogens that elicit broadly neutralizing antibodies, an understanding of the molecular and cellular basis for immune responses to components of the infectious agent, identification of relevant forms of viral proteins for antigen presentation, stimulation of relevant T-cell types, and enhancement of antigen-presenting, dendritic cell function, may be required. A high priority for effective vaccine development is the quantitation of immune responses in animals and in humans, identification of surrogate markers of immune protection, streamlined vaccine production, and rapid evaluation of candidate vaccines for testing in clinical trials. Finally, the technologic advancements in genomics offer great potential to develop predictive algorithms that may facilitate vaccine design and allow identification of genetic determinants of immunogenicity for vaccine-induced responses.

Vaccines are among the most successful medical interventions for human disease. The smallpox vaccine served as the prototypic example, leading to the eventual eradication of one of the most devastating infectious diseases in history. This vaccine was developed more than 200 years ago and built on the observation that immunity to disease can be acquired naturally. For Edward Jenner, the knowledge that some persons became resistant to infection, specifically, milkmaids who had previously contracted cowpox, provided the critical lead that enabled the isolation of the virus that conferred immunity to disease. Nearly all successful vaccines since have built on examples of natural immunity to the offending pathogen. The definition of mechanisms of acquired immunity has formed the scientific basis for vaccine development. Immunologic protection can be mediated through antibodies that bind and neutralize virus infectivity. The role of cytotoxic T lymphocytes (CTLs) in the recognition of proteins processed by antigen-presenting cells (APCs) has also been established from the work of Zinkernagel, Doherty, and others (1), as has their importance in the elimination of cells infected with virus.

Modern immunology has provided important insights into disease pathogenesis and the identification of surrogate markers that may guide the development of vaccines. Some successful vaccines have been identified in this way; however, some medically important pathogens do not provide compelling examples of immunity to infection in nature. Such infections as HIV disease, malaria, and tuberculosis are of high medical impact but have thus far proven recalcitrant to immunization. In AIDS, for example, natural immunity to infection is rare: HIV-exposed seronegative sex workers have demonstrated a higher degree of resistance to infection, but they are not completely immune to viral infection (2). Although CTLs can be found in HIV-exposed persons who remain healthy after exposure to HIV-contaminated fluids (3), the role of these cells in protective immunity is not known. Except for these rare examples, the absence of known prototypic immunity for HIV and other infections requires that novel strategies be applied to these challenging problems. For malaria and tuberculosis, evidence indicates that immunization can contain or reduce the severity of disease, but complete resistance to infection is uncommon.

Historically, investigators have exploited different methods for vaccine delivery. These approaches include the use of live-attenuated or nonpathogenic viruses that can generate persistent viral gene expression, which can elicit cellular and humoral immune responses and can perhaps also interfere with virus replication. Second, inactivated viruses have been used to induce immunity as, for example, with the Salk polio or hepatitis A vaccines. Third, recombinant proteins can present viral antigens in the absence of infectious virions and have shown remarkable efficacy for viruses such as hepatitis B. Finally, inactive toxin or toxoids have been used to develop neutralizing antibodies for diseases such as diphtheria. The latter two approaches have often relied on adjuvants to enhance their effects.

GENE-BASED VECTORS

Live-attenuated viruses have provided compelling examples of protection against infection, perhaps best seen with the Sabin polio vaccine. The advantages of live-attenuated viruses are their sustained gene expression, their ability to induce protective immunity, and possible viral interference. The disadvantages are the potential for pathogenic infection, the possibility of enhanced replication during immune suppression, and the consequences of persistent immune stimulation and integration that may occur as a result of sustained viral replication. These vaccines stimulate cytolytic T cells to recognize multiple linear epitopes of viral gene products in infected cells and eliminate virus producer cells, possibly reducing the magnitude of the reservoir of infected cells. Conversely, it is not yet known that CTLs can persist for a sufficiently long period to provide long-lasting protection against infection. There may also be mechanisms to evade immune detection, including the inability to recognize virus in the absence of major histocompatibility complex (MHC) or specific viral mechanisms that reduce MHC expression, as the Nef protein of HIV or E3 gene products of adenovirus. Central to long-lasting protection against many viral infections is the ability to develop broadly neutralizing antibodies, which has proven critical to numerous successful vaccine efforts. Such antibodies are able to neutralize virus, to prevent new infection of cells, and to activate the inflammatory system, findings suggesting that they will be required for highly effective vaccines. Gene-based vaccines offer the potential to stimulate both types of immune responses.

Viral Vectors

Historically, viruses have been used to elicit immune responses that protect against infection. In many instances, these viruses are attenuated from the pathogenic agent, as in the case of the Sabin poliovirus or chickenpox. In other cases, viruses related to the pathogen may cross-react immunologically but do not cause disease, as was the case with modified poxvirus vectors that have built on the success of Jenner. The advantages of such vectors are the extensive experience and established safety in diverse populations. As new vaccines are needed, however, it is more challenging to adapt them to new pathogens because their widespread use may result in the development of antibodies to the vector in large segments of the population, as is the case for vaccinia virus vectors (4).

Over the past several years, new viral vectors have been defined, both from vaccine and gene therapy efforts, that may prove useful in vaccine development. These include additional poxvirus vectors, such as canarypox, fowlpox, and modified vaccinia Ankara (4,5 and 6). The use of uncommon strains of highly immunogenic viruses, such as adenovirus, may also prove useful, particularly when strains are identified that are not reactive with common antibodies (7), which could otherwise neutralize the virus and render it ineffective. Other vectors are also advancing in preclinical development, for example, the Sindbis (8,9) and Venezuela equine encephalitis virus alphaviruses (10,11). Replication-defective vectors derived from these viruses can synthesize high levels of recombinant gene products and, in some cases, can target delivery to dendritic cells. Finally, there is considerable interest in the identification of vectors that may allow for persistent transgene expression to provide continuous T-cell stimulation. Advances in lentiviral vectors have suggested that they, too, can be modified to address numerous safety concerns (12,13 and 14). In addition, adenoassociated virus has been useful for long-term gene expression and is the subject of investigation (15,16). Advances in molecular virology and vector development should allow rapid adaptation of newly discovered viruses for vaccine development.

Nonviral Vectors

Injection of plasmid DNA into muscle was shown to direct the synthesis of recombinant proteins (17), a finding suggesting that this gene transfer method would be useful for vaccination. Genetic immunization has been demonstrated in several model systems (18,19 and 20). More important, it has been shown to confer protective immunity to different infectious diseases in rodents, including influenza virus (21), malaria (22,23,24 and 25), tuberculosis (26), Ebola virus (27), rabies (28), lymphocytic choriomeningitis virus (29,30), and herpes simplex virus (31). It has also been applied to therapeutic immunization strategies for autoimmune and allergic diseases. This technology is now being refined in many ways.

Traditional vaccines composed of protein, peptides, or virus particles have been used to raise a specific immune response against the immunogen. DNA vaccines represent a more recent class of vectors that express protein immunogens *in vivo* (32,33). These plasmids allow eukaryotic cell gene expression and typically contain a prokaryotic origin of replication, a drug resistance marker for selection of the plasmid in bacteria, a strong eukaryotic promoter to drive expression of the immunogen gene, and a eukaryotic signal for polyadenylation following the immunogen gene. On injection, cells internalize the plasmid and transport the DNA to the nucleus, but they do not appear to integrate substantially into cellular chromosomes. The cellular transcription machinery transcribes the plasmid DNA in the nucleus to produce

mRNA encoding the immunogen, and different eukaryotic promoters, as well as autostimulatory polymerase regulatory elements, which are used to optimize the magnitude and duration of gene expression of the immunogen.

DNA vaccines have several potential advantages compared with traditional vaccines. In contrast to peptide vaccines, the entire protein is expressed from the DNA vaccine vector, and this allows processing and presentation of more epitopes to produce a better immune response in individuals with different MHC alleles. Compared with recombinant protein vaccines produced in bacteria or yeast cells, the proteins expressed from a DNA vaccine vector are more likely to fold into a native conformation. In addition, immunogens expressed from the DNA vectors undergo posttranslational modification. Appropriate posttranslational modification such as glycosylation or phosphorylation produces an immunogen more relevant to native protein for which immune protection is sought. Myocytes that express the DNA vaccine protein function poorly as APCs because they lack MHC class II antigens necessary to generate helper T cells (34). Although myocytes express low amounts of class I MHC, they lack other costimulatory molecules necessary to stimulate cellular immunity (33,35). Several studies, using bone marrow chimeras and reconstituted SCID (severe combined immunodeficiency) mice, have established that bone marrow–derived cells are required for antigen presentation after DNA injection into muscle (36,37), and peptide transporters are required in the APCs for cross priming *in vivo* (38). It appears that such APCs are recruited to the transfected myocytes through local inflammation (39), and these APCs present the antigens encoded by the DNA vectors (40). DNA vaccines can be delivered to the epidermis by either needle or gene gun delivery (18,41). Unlike intramuscular injection, intradermal injection causes little inflammation that would recruit APCs; however, professional APCs are abundant in the skin as tissue macrophages, Langerhans cells, and dendritic cells. Dendritic cells may be particularly important because of their ability to activate T cells (42,43). To generate mucosal immunity by DNA vaccination, it may be necessary to deliver the DNA at a mucosal surface using liposomes, microspheres, or other carriers.

Previous experiments suggested that a palindromic hexamer (AACGTT) found twice in the ampicillin resistance gene of many plasmid DNAs is an immune stimulatory sequence that favors a T-helper 1 (Th1)-type response (44). The coinjection of either cytokines or vectors expressing costimulatory molecules can also shift the type of immune response. The administration of granulocyte-macrophage colony-stimulating factor (45), B7 expression vectors (46,47), or other cytokine genes (48), together with a DNA vaccine vector, can increase antibody production. Thus, the dose of DNA vectors given, the route of injection, and the coinjection of immune system modulators can all have an effect on the type of immune response that is generated. Finally, the inclusion of inert carriers, such as liposomes (49), sustained release formulations, or *in vivo* electroporation (50), likely enhances the efficacy of this vaccine gene delivery strategy.

PROSPECTS FOR IMPROVED VACCINES AND CLINICAL TRIALS

Critical to the development of new vaccines is the ability to analyze vaccine candidates in humans. The ability of DNA vaccines to elicit potent cellular immune responses safely makes them strong candidates as a component of vaccines in humans; however, these responses have not been so strong that, on their own, they can be expected to be highly effective in clinical settings. In the absence of clear examples of natural immunity to an infectious agent, it is important to test the efficacy of different vaccine strategies and to compare candidates. The necessary safety studies are best done with rigorous immunologic analyses. Selected candidates can then be tested in relevant clinical populations. Phase III trials thus become the ultimate test of efficacy and form the basis of hypothesis-driven clinical research: the trial tests the hypotheses that a specific immune response elicited by a vaccine candidate can be successful in preventing infection in humans. The relatively complex nature of this effort requires multidisciplinary teams that cover a range of basic science and clinical disciplines.

New Technology and the Identification of Immunogens

To develop effective immunogens that elicit broadly neutralizing antibody responses, structural biology will increasingly contribute to rational approaches to this problem. In the case of HIV, x-ray crystallographic studies from the laboratories of Sodroski and Hendrickson (51) have yielded important structural data on gp160/gp120. The interactions of CD4 with gp120 and the recessed nature of the CD4 binding site provide better understanding required for the generation of broadly neutralizing antibodies. The molecular definition of the helical coiled-coil region (52) has defined highly conserved epitopes of the viral envelope critical to its function that are attractive targets for neutralizing antibodies. These considerations apply to challenging vaccine targets from other infectious agents. Other rational approaches to the identification of immunogens include rational mutagenesis using molecular genetic modification of target genes. With advances in recombinational polymerase chain reaction (53,54 and 55), it is also possible to generate large libraries of immunogens that may be screened for mutant versions of normal viral proteins that display enhanced immunogenicity.

Genomics, Informatics, and Vaccine Development

The use of genomics and bioinformatics can provide unprecedented opportunities for the clinical studies of vaccines. Genetic information within individual gene products determines alternative immune responses. Such is the case, for example, with gp160 and Nef. Identical immunization protocols for these two alternative gene products induce distinct immune responses for each, predominantly CTLs for env and antibodies for Nef. The control of this response is determined by the amino acid sequence of these proteins, and it should therefore be possible to define immune responses based on genetic sequence of the immunogen. By delineating such relationships, vaccine technology will be advanced.

Genomic analysis of the infectious agent has considerable potential to assist in vaccine design. The emerging genomic sequences of such pathogens as malaria (56) or *Haemophilus influenzae* (57,58) has allowed a focused analysis of target genes and provides a foundation that will allow greater understanding of their expression and role in disease pathogenesis. This information may assist in the identification of immunogens and the systematic analysis of combination gene vaccines that may prove helpful in vaccination.

Opportunities for the judicious use of genotyping in human trials will also facilitate the identification of genes that determine antigen responsiveness in human populations. This information must be collected in a way that maintains patient confidentiality, but it will provide opportunities to make vaccines more effective in specific persons and can be applied to larger populations. It will also provide insight into the genetic control of the immune response in humans.

Analysis of Human Immune Responses

Critical to the interpretation of human clinical studies is the analysis of human immune responses. Progress has been made in the development of assays that allow reproducible measurement of immune responses within and among persons. These evaluations are required for identification of vaccine candidates that induce strong immune responses that could potentially confer protection. Although CTL assays have been used for this purpose, this assay is relatively cumbersome, costly, and time-consuming. These analyses cannot be readily performed in large patient populations, thus making it impractical, particularly for phase III vaccine trials. Two assays have shown promise in their ability to quantify human immune responses. These approaches include the cytokine enzyme-linked immunosorbent assay, which provides a broad, sensitive, and consistent measure of immune function. More recently, another excellent analytic tool has become evident: analysis of intracellular cytokine induction by flow cytometry provides insight into the expression of immunologically activated genes and also into the analysis of T-cell subsets that are stimulated by different immunogens (59). It is likely that further refinements of immune assays will continue, although it may take time to understand their significance and relationship with conventional assays.

In performing large-scale clinical efficacy trials, it is important to anticipate the implications of such studies. Although sterilizing immunity, the ability to prevent infection entirely, may be observed, partial immunologic protection may nonetheless be useful. Partial protection could have several consequences. For example, complete protection may occur in a fixed percentage of vaccinees. Conversely, reduced disease pathogenicity or transmission could be seen with the same frequency as in unvaccinated control subjects. Yet another possibility is that vaccination could alter the disease course. For example, the infection could be converted from an aggressive to a more asymptomatic form, or the set point of viral load could be reduced. It will be critical to define these possible alteratives in the natural history of the disease that may be caused by vaccination. Animal models may serve this purpose well. For example, if a benign disease course is not accompanied by a reduction in transmissibility, a serious problem may ensue. Informed decisions about the appropriateness of vaccine candidates in large patient populations will be needed. Despite the urgent need to evaluate specific vaccines in humans, rigorous safety studies will be required.

Certain critical hurdles remain to be addressed in vaccine development. The field has progressed significantly and is poised to make significant advances. Immunogens have been identified that induce CTL responses, and it will become easier to assess their efficacy in human studies. Crystallographic structures have provided insight relevant to the development of broadly neutralizing antibodies. Immunologic methods to understand correlates of protection in humans and nonhuman primates have improved. Rigorous human trials, the need to prepare clinical-grade vaccine, and the need to improve methods to assess immune responses in humans will remain. The involvement of the biotechnology and pharmaceutical industries in vaccine production will be essential to these efforts, because it will be extremely difficult to develop, market, and distribute effective vaccines without their specialized infrastructure and expertise. The collective efforts of academia, industry, and government provide important synergy that will be needed to advance the field. This work on vaccines for infectious diseases has implications that extend beyond specific pathogens. This research not only will apply to other emerging viruses, parasites, and bacteria that threaten human populations, but also it has important potential for treatment and prevention of cancer, neurologic diseases, cardiovascular diseases, allergies, and autoimmunity. Expanded vaccine efforts may help to prevent outbreaks of infectious diseases and to set the stage for future treatments for a range of human diseases.

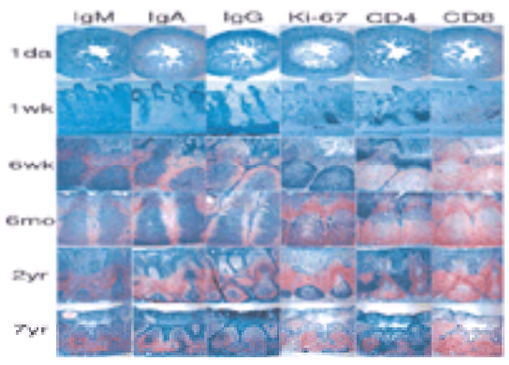
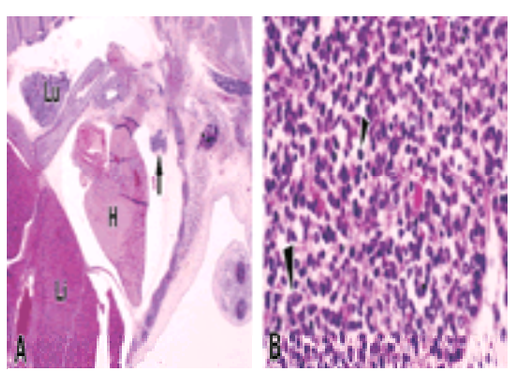
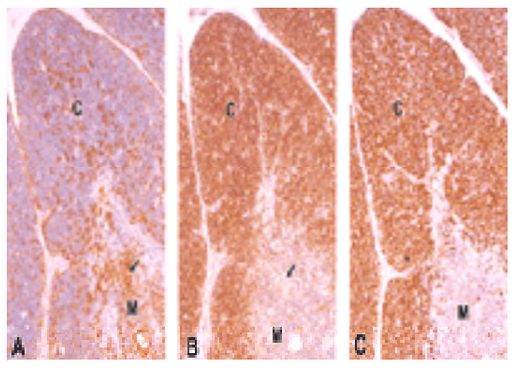
Volume 1 Color Figures



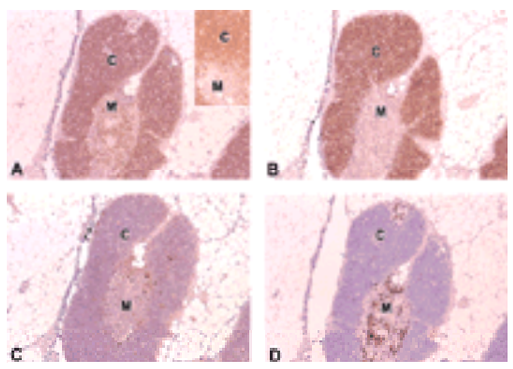
Color Figure 2.3. The rabbit appendix at various times after birth. The basic structure of the appendix is similar to that of the bursa of Fabricius (Fig. 2.2), with numerous ovoid or trapezoidal follicles containing B lymphocytes (B) in apposition to a supporting follicular epithelium. The development of follicular structure begins after birth and depends on the presence of a gut flora. With time, the follicles enlarge, reaching a maximum in young adult animals and then regressing with advancing age. The appendix contains well-described perifollicular T-cell zones, and $CD4^+$T lymphocytes (T) are scattered about in secondary follicles or germinal centers (GC). These germinal centers contain light and dark zones (LZ, DZ) (original magnification ×100). (From Dasso JF, Obiakor H, Bach H, et al. A morphological and immunohistochemical study of the human and rabbit appendix for comparison with the avian bursa. *Dev Comp Immunol* 2000;24:797–814, with permission.) (This figure is printed in black and white as Figure 2.3.).



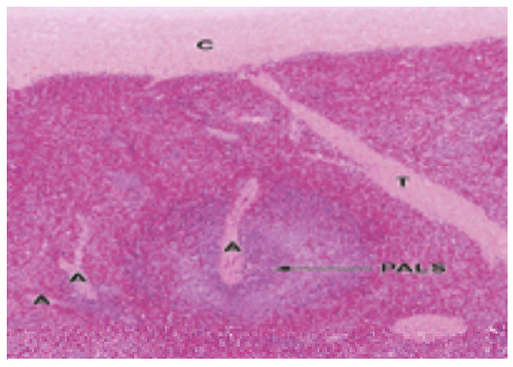
Color Figure 2.4. Human thymus at 8 weeks, gestation. **A:** The developing thymus is located in the anterior mediastinum overlying the heart (H). The position of the lung (Lu) and liver (Li) are also shown. **B:** At this stage of development, both lymphocyte precursors *(small arrowhead)* and epithelial cells *(large arrowhead)* are present; however, a distinction between cortex and medulla will not become apparent until week 14 of gestation (hematoxylin and eosin stain; original magnification ×3 in **A** and ×132 in **B**). (This figure is printed in black and white as Figure 2.4.).



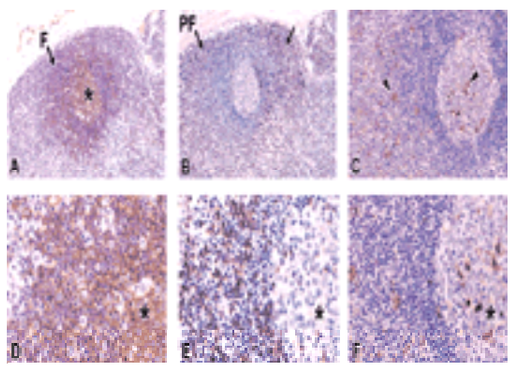
Color Figure 2.5. Architecture of the pediatric human thymus. Immunoperoxidase staining highlights cell types present in thymic cortex (C) and medulla (M). *Arrows* point to Hassall bodies. Cytokeratin antibodies highlight the meshwork of thymic epithelium **(A),** which is more attenuated in the cortex as compared with the medulla. The immature thymocytes present in the cortex can be uniquely identified as those cells reactive with antibodies specific for CD1a **(B)** and for the Ki-67 nuclear proliferation antigen **(C).** *Brown* indicates positive reaction (original magnification ×33). (This figure is printed in black and white as Figure 2.5.).



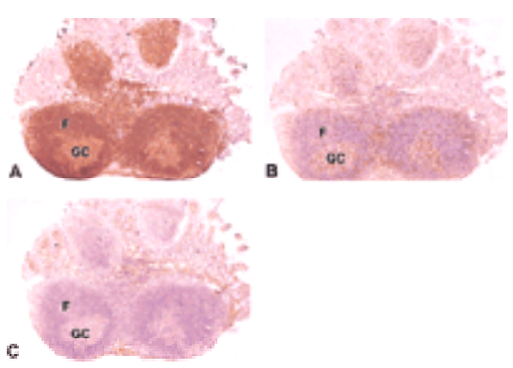
Color Figure 2.6. Architecture of the adult human thymus. Age-related thymic atrophy results in an increase in adipose tissue within the perivascular space (seen on the **left** and the **right** of each panel) concomitant with a decrease in the thymic epithelial space that is involved in production of new thymocytes. The architecture of the remaining cortex (C) and medulla (M) is relatively unaltered. Immunoperoxidase staining identifies the phenotype of cells present in the cortex and medulla. **A:** CD3 stain (T cells); the **inset** shows $CD8^+$ cells (immature cortical and a subset of medullary thymocytes). **B:** CD1a (immature cortical thymocytes and medullary dendritic cells).**C:** CD68 (macrophages). **D:** CD20 (B cells). *Brown* indicates positive reaction (original magnification ×16; ×40 for the **inset**). (This figure is printed in black and white as Figure 2.6.).



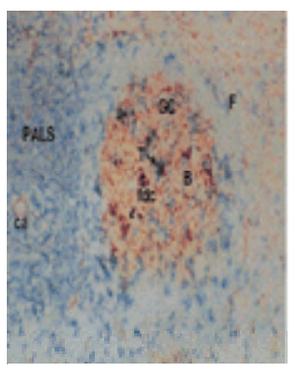
Color Figure 2.7. Architecture of the human spleen. The spleen is surrounded by a fibrous capsule (C) that invaginates to form trabeculae (T). The white pulp is arranged concentrically around arterioles (A) to form the periarteriolar lymphoid sheath (PALS) (hematoxylin and eosin stain; original magnification ×16). (This figure is printed in black and white as Figure 2.7.).



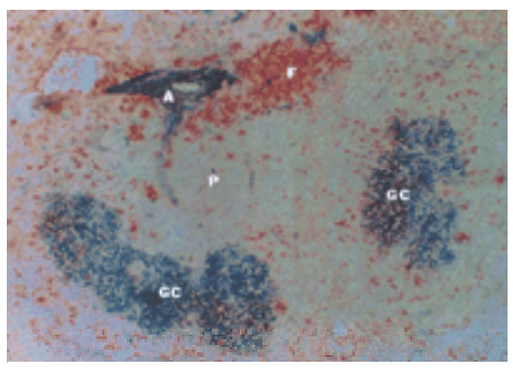
Color Figure 2.8. A–F: Architecture of the human lymph node. Lymphocytes within lymph nodes are organized into B-cell–rich follicles (F in **A**) and T-cell–rich perifollicular zones (PF in **B**). *Arrowheads* point out representative macrophages in **C.** Germinal centers are denoted by an *asterisk* in **A** and **D–F.** Immunoperoxidase stains identify specific cell types present in various lymph node regions. **A, D:** CD20 (B cells); **B, E:** CD3 (T cells); **C, F:** CD68 (macrophages). *Brown* indicates a positive reaction (original magnification ×33 for **A–B,** ×66 for **C,** and ×132 for **D–F.**) (This figure is printed in black and white as Figure 2.8.).



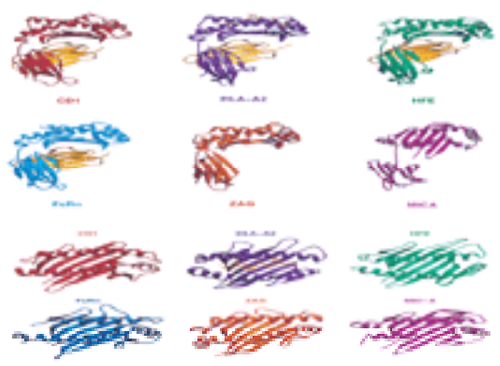
Color Figure 2.9. A–C: Architecture of Peyer patch. Peyer patches consist of organized aggregates of B-cell follicles (F) with germinal centers (GC) and intrafollicular zones of T cells that are present within the lamina propria of small bowel. Immunoperoxidase stains identify the locations of B cells (**A,** CD45RAB/B220 stain), helper-T cells (**B,** CD4/GK1.5 stain), and macrophages (**C,** F4/80 stain) (original magnification ×16). (This figure is printed in black and white as Figure 2.9.).



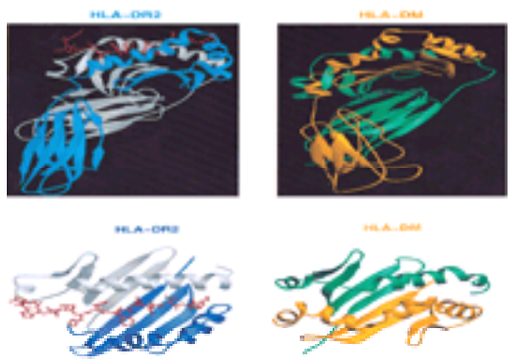
Color Figure 2.10. Germinal center reaction in murine spleen. Immunization with most thymus-dependent antigens initiates the germinal center (GC) reaction. GCs form within the B-cell follicle (F) by the expansion of antigen-specific T- and B-cell immigrants (T, B) from the periarteriolar lymphoid sheath (PALS). Both lymphocyte types proliferate in the reticulum of follicular dendritic cells (fdc) forming a distinct histologic structure containing light and dark zones (LZ, DZ). Original magnification ×200. Thus, the primary humoral immune response begins with antigen-dependent activation of lymphocytes [C, C']. Activated T- and B-lymphocytes then meet along the border of the PALS and follicle [D] where cognate interactions drive proliferation in both lymphocyte compartments. Some daughter B-lymphocytes remain adjacent to the T-cell area and differentiate into foci of antibody-secreting plasmacytes [E]. Other, clonally related, B-cells migrate along with specific T-cells back into the follicle and lodge in the processes of fdc where the GC reaction begins. Modified from ref. 71. (This figure is printed in black and white as Figure 2.10.).



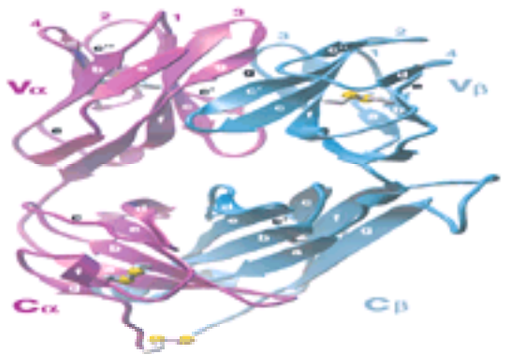
Color Figure 2.11. Plasmacytic foci and germinal centers in murine spleen. Following a period of proliferation near the periphery of the splenic T-cell zone, the periarteriolar lymphoid sheath (P), antigen-specific B lymphocytes differentiate into plasmacytes (F) and remain in close approximation to the T-cell zone. These large foci of AFC produce the earliest serum antibody and the plasmacytes within them may undergo IgM®IgG class switching but do not support V(D)J hypermutation. Original magnification ×200. From ref. 119. (This figure is printed in black and white as Figure 2.11.).



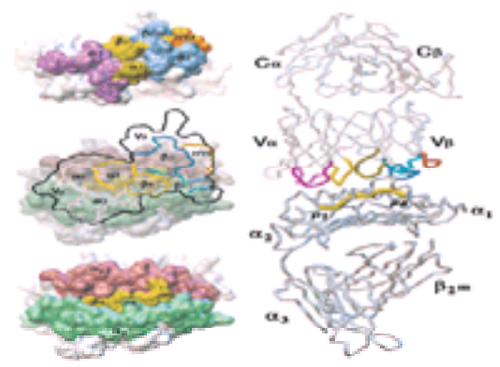
Color Figure 3.2. A: Structure of major histocompatibility complex (MHC) class I products and related structures. The HLA-A2 structure is representative of the so-called classic class I products, involved in presentation of peptide to T-cell receptors. The CD1 molecule presents lipid antigens. The HFE product interacts with and modifies internalization of the transferrin receptor. The neonatal Fc receptor (FcRn) is involved in transepithelial transport of immunoglobulins in the gut of the newborn. The ZAG protein is a zinc-binding serum protein. The MIC-A product is encoded by a gene linked to the MHC (Fig. 3.1) and is probably involved in antitumor immunity and eradication of cells subjected to stress. Note the presence of the common light chain, b_2-microglobulin, in CD1, HLA-A2, HFE, and FcRn. **B**: As in **A,** but structures viewed from above. Note the presence of the peptide in the cleft of the HLA-A2 molecule. (This figure is printed in black and white as Figure 3.2.).



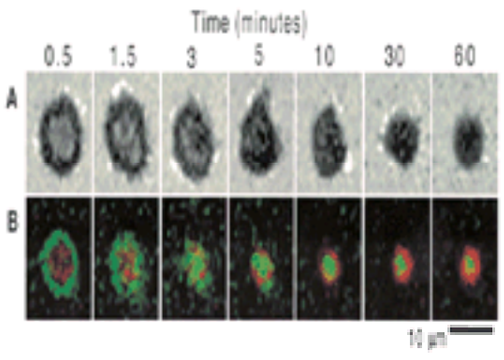
Color Figure 3.3. A: Comparison of the structure of the class II molecule HLA-DR2 and of the DM molecule, a catalyst involved in the peptide loading of major histocompatibility complex (MHC) class II molecules. **B**: As in **A,** viewed from above. (This figure is printed in black and white as Figure 3.3.).



Color Figure 4.2. T-cell receptor (TCR) structure. Ribbon diagram of the structure of an ab TCR heterodimer (extracellular portion). b Strands are indicated in *letters*, and complementarity-determining region (CDR) loops in *numbers*. The *yellow spheres* depict disulfide bonds within the V and C domains and joining the a and b chains. (From Garcia KC, Decagon M, Stanfield RL, et al. An ab T-cell receptor at 2.5Å and its orientation in the TCR-MHC complex. *Science* 1996;274:209–219, with permission). (This figure is printed in black and white as Figure 4.2.).

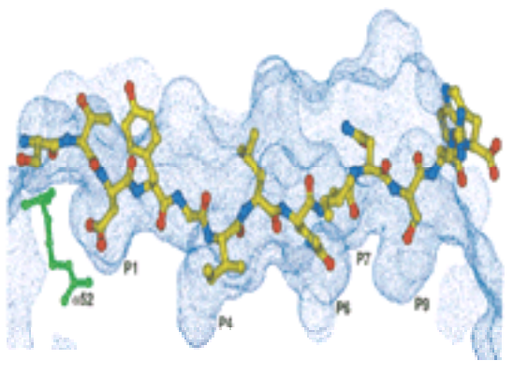


Color Figure 4.4. T-cell receptor (TCR)/peptide/major histocompatibility complex (MHC). The structure of an ab TCR binding to peptide/MHC. (From Garcia KC, Decagon M, Stanfield RL, et al. An ab T-cell receptor at 2.5Å and its orientation in the TCR-MHC complex. *Science* 1996;274:209–219, with permission.) (This figure is printed in black and white as Figure 4.4.).

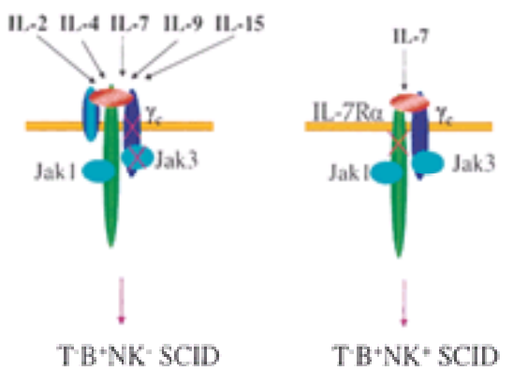


Color Figure 4.5. Formation of an immunologic synapse. An antigen-specific T cell **(A)** contacts an artificial lipid bilayer containing labeled major histocompatibility complex (MHC; *green*) and intercellular adhesion molecule (ICAM-1; *red*). Within minutes, it has recognized the antigen contained within the MHC and gathered the MHC and ICAM-1 into the distinctive “bulls-eye” pattern. (From Grakoui A, Bromley SK, Sumen C, et al. The immunological synapse: a molecular machine controlling

T-cell activation. *Science* 1999;285:221–227, with permission.) (This figure is printed in black and white as Figure 4.5.).



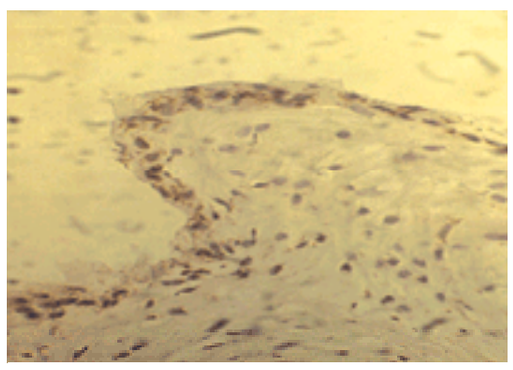
Color Figure 6.1. Peptide 52-61 of hen egg white lysozyme binds to I-A^k. **A:** Side view of the peptide. **B:** Ribbon diagram of the peptide as it is found on the I-A^k protein. The sequence of 52-61 is DYGILQINSR. The Asp52 residue is responsible for the selection of the peptide from HEL as well as in the binding affinity. Asp52 forms a salt-bridge with Arga52 situated at the base of the P1 pocket. Mutation of Asp52 to Ala52 reduces binding affinity severalfold. (Fremont DH, Monnaie D, Nelson CA, et al. Crystal structure of I-A^k in complex with a dominant epitope of lysozyme. *Immunity* 1998;8:305–317, with permission.) (This figure is printed in black and white as Figure 6.1.).



Color Figure 28.5. Cartoon showing on the left side that Janus kinase 3 (Jak3) is the major signal transducer for the common gamma chain (g_c) shared by multiple cytokine receptors. Mutations in the gene encoding g_c cause SCID-X1 and in the gene encoding Jak3 cause a form of autosomal recessive SCID that mimics SCID-X1 phenotypically. On the right side, it is seen that mutations in the gene encoding the IL-7 receptor a chain also result in another form of autosomal recessive SCID. The latter suggests that the reason for the severe T-cell defect in SCID-X1, and Jak3-deficient SCID is failure to signal through the IL-7 receptor. (Courtesy of Dr. Warren Leonard.) (This figure is printed in black and white as Figure 28.5.).

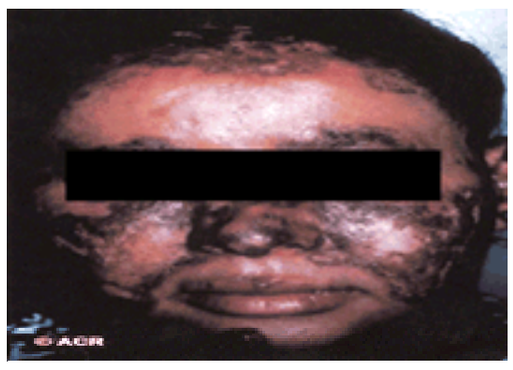
Color Figure 36.1. Urticaria pigmentosa in an adult patient with indolent disease. (This figure is printed in black and white as Figure 36.1.).

Volume 2 Color Figures

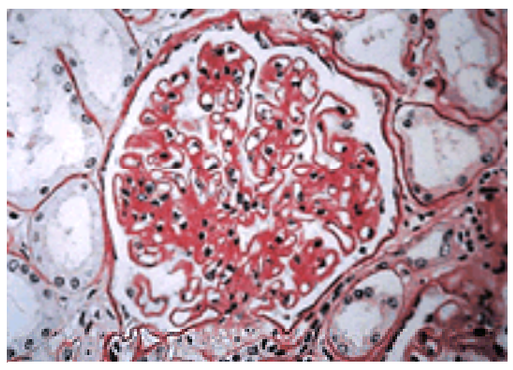


Color Figure 37.5. Noninflammatory osteoarthritis synovial membrane showing two or three layers of lining cells stained for stromal cell–derived factor-1 (SDF-1). (This figure is printed in black and white as Figure 37.5.).

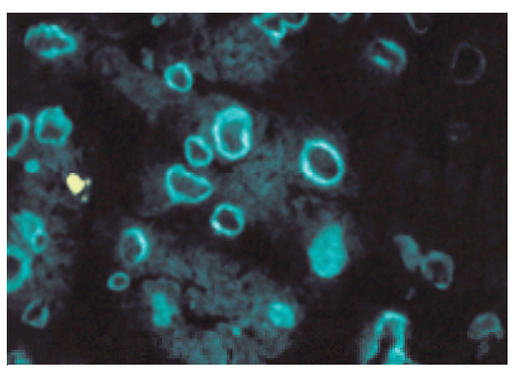
Color Figure 39.1. Malar rash. An erythematous facial eruption on the malar and chin areas. (Reprinted from the Clinical Slide Collection on the Rheumatic Diseases, American College of Rheumatology, with permission.) (This figure is printed in black and white as Figure 39.1.).



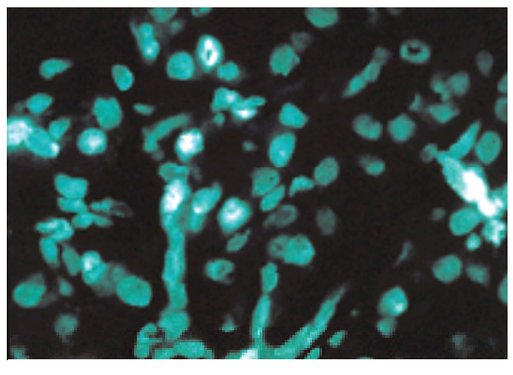
Color Figure 39.2. Discoid lupus. An erythematous and hyperpigmented rash on the face with central scarring and epidermal atrophy. Follicular plugging is also seen. (Reprinted from the Clinical Slide Collection on the Rheumatic Diseases, American College of Rheumatology, with permission.) (This figure is printed in black and white as Figure 39.2.).



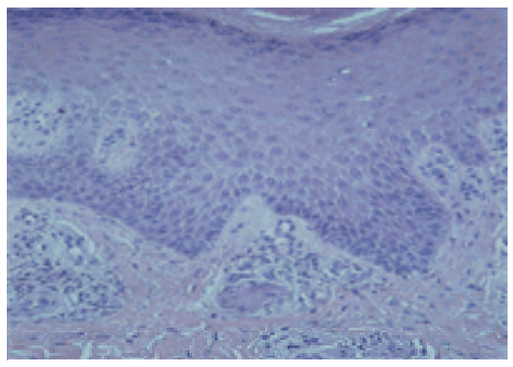
Color Figure 39.6. Membranous glomerulonephritis. Widespread, uniform thickening of capillary basement membranes of the glomerulus is seen on periodic acid-Schiff staining. (Reprinted from the Clinical Slide Collection on the Rheumatic Diseases, American College of Rheumatology, with permission.) (This figure is printed in black and white as Figure 39.6.).



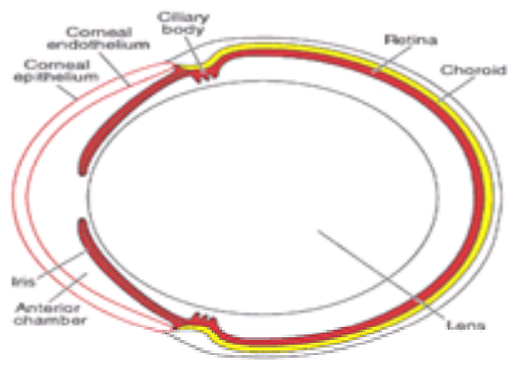
Color Figure 39.7. Antinuclear antibody: Rim (peripheral) pattern. (Reprinted from the Clinical Slide Collection on the Rheumatic Diseases, American College of Rheumatology, with permission.) (This figure is printed in black and white as Figure 39.7.).



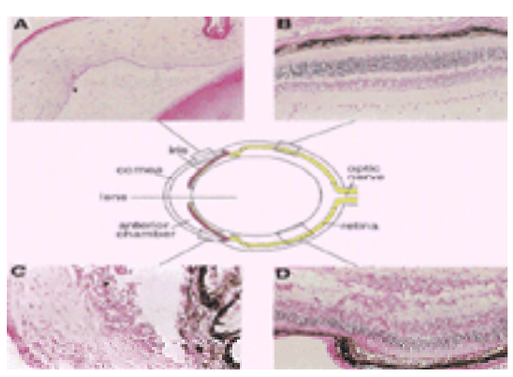
Color Figure 39.8. Antinuclear antibody: Homogeneous (diffuse) pattern. (Reprinted from the Clinical Slide Collection on the Rheumatic Diseases, American College of Rheumatology, with permission.) (This figure is printed in black and white as Figure 39.8.).



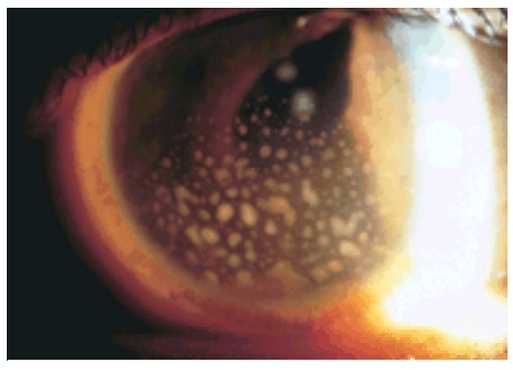
Color Figure 46.2. Cutaneous small vessel thrombosis in the antiphospholipid syndrome. Skin biopsy from the painful skin nodules of a 33-year-old woman with anticardiolipin, lupus anticoagulant, anti–b_2-glycoprotein I, deep venous thrombosis, and miscarriage. The hematoxylin and eosin–stained section of a skin biopsy shows a small dermal vessel in the center of the lower third of the frame that contains bland fibrin thrombus without inflammation. (Courtesy of Dr. K. Georgeous.) (This figure is printed in black and white as Figure 46.2.).



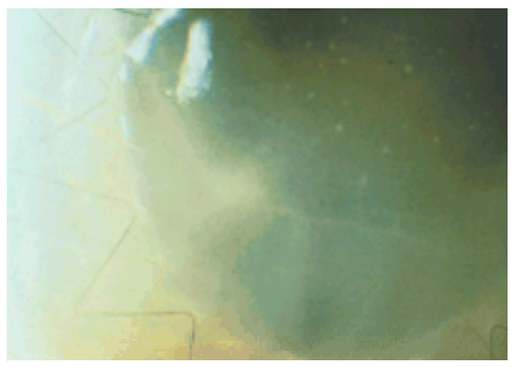
Color Figure 53.1. Fas ligand (FasL) expression. Schematic drawing of a mouse eye showing localization of FasL (FasL tissues in red). FasL is expressed on the corneal endothelium and epithelium, iris, ciliary body, and throughout the retina, forming a protective barrier (From Griffith TS, Brunner T, Fletcher SM, et al. Fas ligand-induced apoptosis as a mechanism of immune privilege. *Science* 1995;270:1189–1192, with permission.) (This figure is printed in black and white as Figure 53.1.).



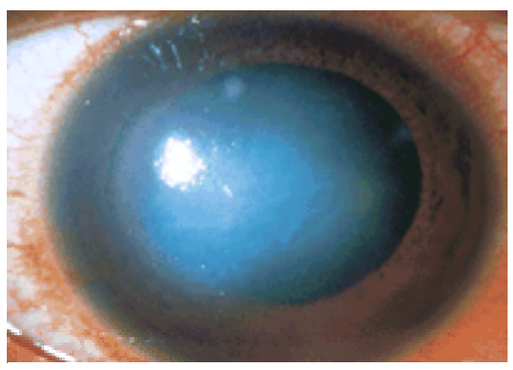
Color Figure 53.2. The consequences of not expressing functional FasL in the eye. B6 (**A, B**), B6-*gld* (**C, D**) mice were injected in the anterior chamber of the eye with 2.5×10^4 herpes simplex virus (HSV)-1 (KOS) as described (From Griffith TS, Brunner T, Fletcher SM, et al. Fas ligand-induced apoptosis as a mechanism of immune privilege. *Science* 1995;270:1189–1192, with permission.) Eyes were removed 10 days after infection, processed for paraffin sections, and stained with hematoxylin and eosin (H&E). *Boxes* on the schematic drawing of the eye (**center**) denote the area of detail for the H&E stain (× 200). (This figure is printed in black and white as Figure 53.2.).



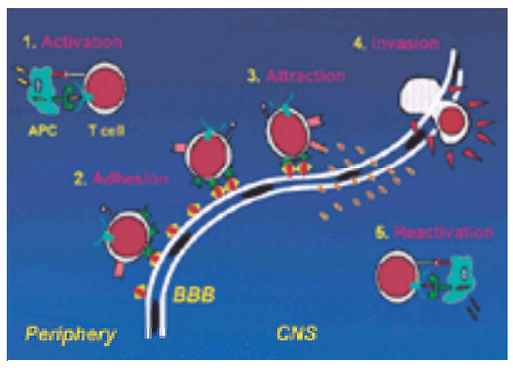
Color Figure 53.3. Typical appearance of granulomatous anterior uveitis on the cornea of a 46-year-old African-American woman with sarcoidosis. The corneal endothelium is covered in dense keratic precipitates, composed of epithelioid cells in small noncaseating granulomas. (This figure is printed in black and white as Figure 53.3.).



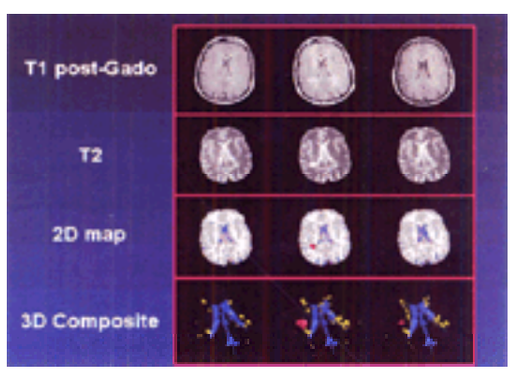
Color Figure 53.4. Allotypic corneal graft rejection. The *white line* in the graft represents an infiltrate of host lymphocytes. Very subtle rejection can be readily seen because of the transparency of the cornea. Despite routine use of non–human leukocyte antigen (HLA) matched donors and minimal immunosuppressive medication, corneal allografts are rejected in fewer than 10% of cases. (This figure is printed in black and white as Figure 53.4.).



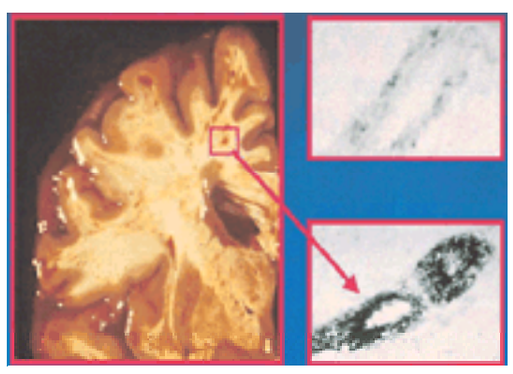
Color Figure 53.5. Herpetic stromal keratitis. After corneal infection with herpes simplex type 1 (HSV-1), a subset of patients subsequently develops a chronic, autoimmune keratitis. Herpesvirus is not recovered from these lesions. Murine models of this condition suggest that molecular mimicry between a corneal antigen and an HSV-1 coat protein causes the autoimmune keratitis. HSV-1 mutants lacking this antigen cannot trigger stromal keratitis, and mice made tolerant to this antigen are likewise protected from this disease. (This figure is printed in black and white as Figure 53.5.).



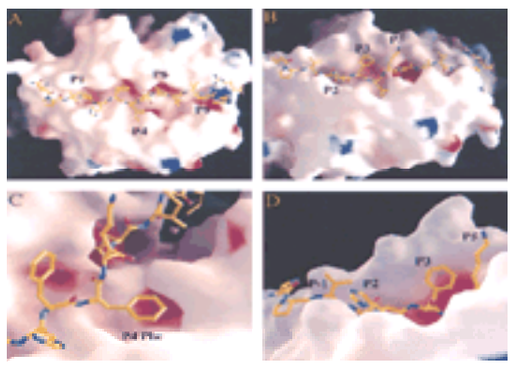
Color Figure 56.1. A model of multiple sclerosis (MS) immunopathogenesis. Myelin autoreactive T cells are found in an enhanced state of activation in the circulation of patients with MS. Upregulation of adhesion molecules *(1)*, chemoattraction *(2),* and elaboration of matrix proteinases *(3)* results in invasion of activated autoreactive T cells across the blood–brain barrier *(4)* (BBB). Inside the central nervous system (CNS), reactivation of T cells by local or infiltrating antigen-presenting cells (APCs) results in release of proinflammatory and cytotoxic mediators and leads to tissue injury. (This figure is printed in black and white as Figure 56.1.).



Color Figure 56.3. Serial magnetic resonance imaging (MRI) studies in multiple sclerosis (MS) highlight the dynamic disease pathophysiology. Serial brain MRI studies of a single patient with MS were taken at three different times **(left column:** study performed day 0; **middle column:** day 266; **right column:** day 362). **Top row:** Axial T1-weighted sequences obtained after gadolinium-contrast administration. Corresponding anatomic levels are compared at the three time points. A ring-enhancing lesion, absent in the first scan, is present on day 266 and disappears again by day 362. **Second row:** T2-weighted images at the same anatomic level demonstrate the appearance and subsequent shrinkage of this lesion, which remains visible on T2, but no longer enhances, at day 362. **Third row:** Computed algorithms enable the construction of accurate two-dimensional (2D) maps that distinguish and quantify white matter *(white),* gray matter *(gray),* ventricles *(blue),* and lesions *(yellow).* The ring-enhancing lesion is red. **Bottom row:** Three-dimensional (3D) composite model of the whole brain. The gray matter and white matter are stripped away to reveal the dynamic changes in lesional activity and burden over time (see text for further discussion). (From Weiner HL, Guttmann CR, Khoury SJ, et al. Serial magnetic resonance imaging in multiple sclerosis: correlation with attacks, disability, and disease stage. *J Neuroimmunol* 2000;104:164–173, with permission from Elsevier Science.) (This figure is printed in black and white as Figure 56.3.).

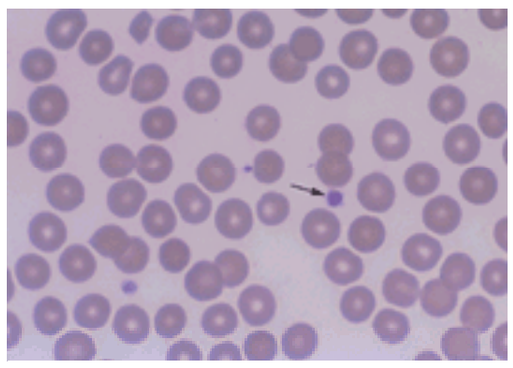


Color Figure 56.4. The pathology of multiple sclerosis (MS). **Left**: Coronal section of a cerebral hemisphere of a patient with MS. Multiple areas of discoloration, such as the one outlined in the **box,** are seen in the periventricular and subcortical regions and represent the classic MS plaques. **Lower right:** Microscopic view of a cryostat section from outlined subcortical plaque, stained with anti-CD4 antibody (magnification ×98). The hallmark perivascular inflammatory infiltrate is demonstrated. **Upper right:** Antikeratin control stain. See the text for a discussion of the pathologic heterogeneity of MS lesions. (From Windhagen A, Newcombe J, Dangond F, et al. Expression of costimulatory molecules B7-1 (CD80), B7-2 (CD86), and interleukin 12 cytokine in multiple sclerosis lesions. *J Exp Med* 1995;182:1985–1996, with permission of the Rockefeller University Press.) (This figure is printed in black and white as Figure 56.4.).

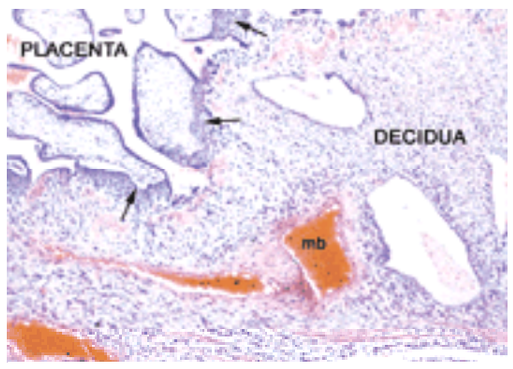


Color Figure 56.5. Structure of the HLA-DR2–myelin basic protein (MBP) peptide complex. **A** and **B**: Top and side views of the complex; 14 residues are included for the MBP peptide. P1 and P4 are hydrophobic pockets in the DR molecule and are occupied by the P1 Val and the P4 Phe of the MBP peptide, respectively. These interactions anchor the peptide in the groove. Peptide atoms are shown as ball-and-stick structures. **C**: Close-up view of the P4 pocket. The Gln b70 of the DR2 molecule (not labeled) is positioned over the P4 Phe of the MBP peptide. **D**: The T-cell receptor contact residues of the MBP peptide. P2 His, P3 Phe, and P5 Lys (previously shown to be important for T-cell recognition of the MBP peptide) are prominent, solvent exposed residues. (From Smith KJ, Pyrdol J, Gauthier L, et al. Crystal structure of HLA-DR2 (DRA*0101, DRB1*1501) complexed with a peptide from human myelin basic protein. *J Exp Med* 1998;188:1511–1520, with permission of the Rockefeller University Press.) (This figure is printed in black and white as Figure 56.5.).

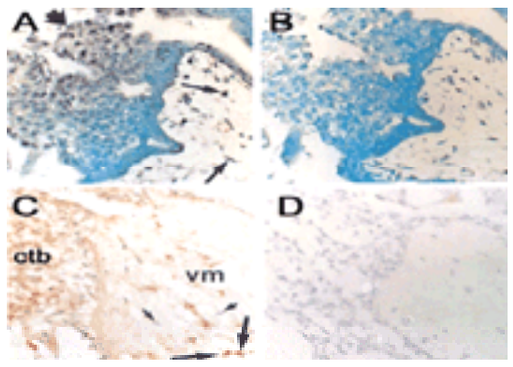
Color Figure 58.1. Large bruises (purpura) on the trunk and extremities in a young child with immune thrombocytopenia. (This figure is printed in black and white as Figure 58.1.).



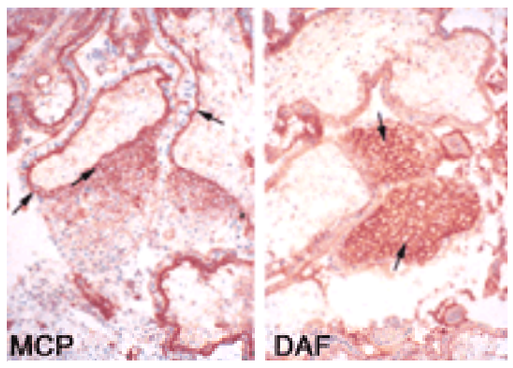
Color Figure 58.2. Peripheral blood smear of a patient with immune thrombocytopenia. Few platelets are present, but those that are newly released into the circulation (*arrow*) are larger than the normal diameter of 1 to 2 µ. (This figure is printed in black and white as Figure 58.2.).



Color Figure 60.5. Histologic section of a gestation week 8 human placenta showing attachment and invasion of the decidua by extravillous trophoblast cells emerging from villi (*arrows*). Modified maternal arteries surrounded by fibrinoid maternal and containing pools of maternal blood (mb) mark the implantation site in the decidua. Stained with hematoxylin and eosin. Original magnification, ×100. (From the Boyd Collection, Department of Anatomy, Cambridge University, courtesy of G. Burton.) (This figure is printed in black and white as Figure 60.5.).



Color Figure 60.9. *In situ* hybridization and immunohistochemical staining demonstrate that human leukocyte antigen-G (HLA-G) mRNA and protein are present in discrete populations of cells in first-trimester placentas. **A**: HLA-G mRNA is evident in migrating trophoblast cells (*large arrow*) as well as macrophage-like villous stromal cells (*smaller arrows*). **B**: A sense version of the HLA-G probe does not hybridize to placental tissues. **C**: HLA-G protein is identified using the mouse monoclonal antibody, 87G, specific for HLA-G1. Signal is present in migrating cytotrophoblast cells (ctb) and in some villous mesenchymal cells (vm). **D**: The immunostaining control is negative. Paraformaldehyde-fixed tissue was used for (A,B), and flash frozen, acetone-fixed tissue was used for (C,D). Original magnifications: ×250. (This figure is printed in black and white as Figure 60.9.).



Color Figure 60.12. Immunohistochemical staining of human first-trimester placentas for membrane cofactor protein (MCP, CD46) and decay accelerating factor (DAF, CD55). Note that both these complement regulatory proteins are expressed but are differentially located, with MCP being prominent on villous cytotrophoblast (left panel, *arrows*) and DAF being prominent on migrating cytotrophoblast cells (right panel, *arrows*). Original magnifications: ×250. (This figure is printed in black and white as Figure 60.12.).

Appendix A METHODS

Thomas A. Fleisher, M.D.

Interest in evaluating the immune response began with the need to assess the efficacy of vaccines. This early technology opened the way for experimental models and studies that dramatically extended our understanding of immune responses and the immune system. These data have evolved and allow a clearer understanding of the immunopathologic mechanisms underlying many human diseases. This understanding, in turn, has increased the need for more sophisticated and specific means to assess the immune response. Applications of immunologic studies in clinical medicine include evaluation of patients for primary or secondary immune deficiency, as well as the investigation of diseases involving autoimmune, allergic, infectious, and malignant processes. The human immunodeficiency virus (HIV) pandemic has further increased the clinical application of immunologic testing because these results provide prognostic information that is directly linked to the development of new therapies. The future is likely to herald an increasing emphasis on assays of not only general but also specific immune function.

This discussion is directed at general concepts and standard applications of current laboratory methods used to characterize and quantitate immunoglobulins (Igs), assay-specific antibody levels, immunophenotype lymphocytes, evaluate lymphocyte function, study neutrophil function, test monocyte function, assess complement, and examine immediate hypersensitivity. In view of space limitations, the presentation focuses on an overview of the various topics; more complete discussions of these various subjects are available in texts devoted to laboratory immunology (1,2).

CHARACTERIZATION AND QUANTITATION OF IMMUNOGLOBULINS

Igs are glycoproteins secreted by terminally differentiated B lymphocytes or plasma cells after encounter with specific antigen. Serum Igs are polyclonal because their production involves multiple B-cell clones, each synthesizing a unique antibody molecule that binds with varying strength to the stimulating antigen. The interaction between antibody and antigen is influenced by the strength of the reversible attraction between antigen and antibody (affinity), as well as by the stability of the complex formed between antigen and antibody in solution (avidity). Antibody production after initial antigen exposure is referred to as the *primary response,* whereas subsequent exposure induces a *secondary, or anamnestic, antibody response.* The latter occurs more rapidly and generates primarily IgG as well as higher specific antibody levels than a primary response.

There are five different classes (isotypes) of Ig produced by human B cells. The basic molecular structure of each of these classes consists of two identical polypeptides, referred to as heavy chains (a, d, e, g, or μ), that bind two identical light chains (k or l) forming a Y-shaped monomeric protein. Each monomer (two identical heavy and two identical light chains) contains two antigen combining sites referred to as the *Fab portion* (antigen binding fragment). The sites of other biologic functions are found in the constant region of this molecule, referred to as the *Fc part* (crystallizable fragment). In some isotypes such as IgM, multiple monomers are bound together to form a polymeric structure. The various classes differ with regard to isoelectric point, molecular weight, carbohydrate content, and susceptibility to enzyme digestion. In addition, each class has certain significant functional differences (Chapter 13). This chapter reviews selected qualitative and quantitative assays applied for assessment of Igs that include techniques based on electrophoresis, immunoprecipitation, and nephelometry.

Zone Electrophoresis

The principle that charged particles migrate at different rates in an electrical field forms the underlying principle of *zone electrophoresis.* The application of this technique in the evaluation of serum proteins was first described by Tiselius in 1937 (3). In this report, serum proteins subjected to an electrical field were demonstrated to be resolved into five zones (bands), identified as albumen and a-1, a-2, b, and g globulin fractions (Fig. A.1). Igs fall primarily in the g globulin band, although IgA and IgM also migrate into the b and a-2 globulin regions (4). In this semiquantitative method, the solution of interest is applied to a support medium (e.g., agarose, methyl

cellulose) that is saturated with buffer; an electric potential is then introduced to separate the proteins; the final step requires the addition of a stain to visualize the separated protein bands. The rate of migration depends on the charge of the different proteins, the strength of the electrical field, and the resistance of the matrix. The relative quantity of each separated band is based on the total protein level and can be evaluated with a densitometer. This approach is useful in assessing overall plasma protein status and also can be used to screen for monoclonality, although low-level monoclonal and oligoclonal proteins may be missed (5). The initial description of a patient with hypogammaglobulinemia was based on the observation that the g globulin band, as determined by zone electrophoresis, was absent in a boy with recurrent infections (6). Zone electrophoresis can be applied to other fluids including cerebrospinal fluid (CSF) and urine. This test, however, is only a semiquantitative method, and quantitative methods (e.g., radial immunodiffusion, nephelometry) should be used to determine the actual concentration of Igs.

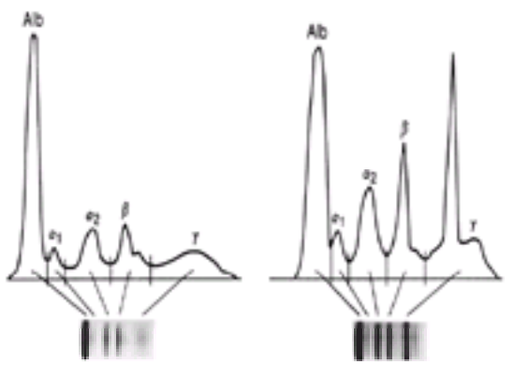

Figure A.1. Zone electrophoresis. The electrophoretic pattern and densitometric tracing demonstrate the five major bands (albumen plus a-1, a-2, b, and g globulins) from a normal **(left side)** and from a patient with a clonal immunoglobulin.

Immunoelectrophoresis

The combination of zone electrophoresis (described earlier) and immunodiffusion underlies the technique of *immunoelectrophoresis* (7,8). This two-step method applies electrophoretic separation of proteins in a gel, followed by the addition of specific antisera into troughs cut parallel to the direction of the electrophoretic migration. The antisera diffuse through the support medium at right angles to the separated proteins. Interaction between antibody and the separated, specific proteins (antigens) produces antigen-antibody complexes in the gel. These complexes immunoprecipitate in the region where the antigen-antibody concentrations are at or near equivalence (Fig. A.2). The degree of precipitation decreases in areas of antibody excess (prozone) and antigen excess (prezone or postzone) because of the increasing solubility of the immune complexes. The site and pattern of the resulting precipitin arcs depend on the specificity of the antiserum used; in standard immunoelectrophoresis, the antibodies typically are directed against each of the three major heavy-chain (a, g, and µ) proteins and both light-chain (k or l) proteins. Abnormal (clonal) proteins alter the appearance of the precipitin and often produce a spur or thickening of the arc (Fig. A.3).

Figure A.2. Immune complex immunoprecipitation curve. The insolubility of complexes when antigen and antibody concentrations are near equivalence is demonstrated. The concentration dependence of immune complex precipitation is central to immunoprecipitation assays.

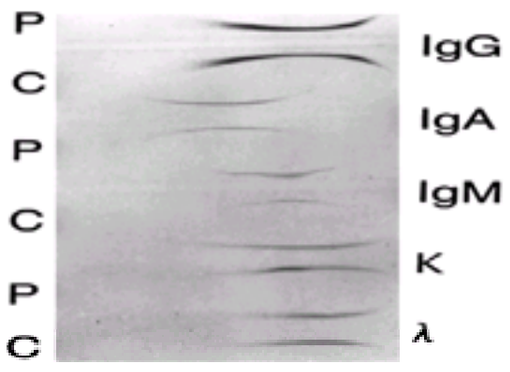

Figure A.3. Immunoelectrophoresis. Gel demonstrates a normal pattern with the control (C) serum and µ heavy-chain and k light-chain spurs with the patient (P) compatible with immunoglobulin M-k monoclonal gammopathy.

Immunoelectrophoresis is commonly used for identification of monoclonal Igs, particularly myeloma and Bence Jones proteins, because it is relatively insensitive to antigen excess (8). It also is the preferred method for identifying protein components with similar electrophoretic mobility present in complex mixtures (8). This is a nonquantitative technique and should not be used as a primary means of evaluation for presence or absence of Igs. In addition, the interpretation of the varied immunoelectrophoretic patterns requires considerable experience to master (9).

Immunofixation Electrophoresis

This technique is similar to immunoelectrophoresis in that it combines zone electrophoresis with the unique specificity of an antigen-antibody reaction (8,10). Proteins are electrophoretically separated in a support medium, and then monospecific antibodies are overlaid directly onto the surface of the gel, in contrast to the diffusion from troughs used in immunoelectrophoresis. The overlaying of specific antisera results in immune complex formation and immunoprecipitation in the region of antigen-antibody equivalence. The gel can be stained for visualization, and normal serum (polyclonal) Igs demonstrate a diffuse band after staining (Fig. A.4). This pattern contrasts with the intense, narrow band formed by a monoclonal Ig or the multiple intense bands resulting from oligoclonal Igs. Automated immunofixation assay systems are now available that provide consistent results for clinical laboratories. This approach is used as the primary technique for identifying clonal Igs by many clinical laboratories, whereas some still use either immunoelectrophoresis or a combination of these two techniques.

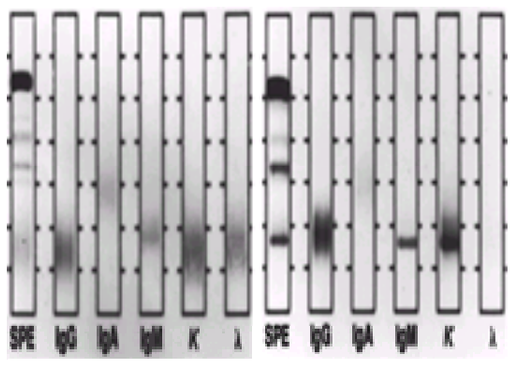

Figure A.4. Immunofixation electrophoresis. The **left panel** lanes demonstrate a normal pattern, whereas the **right panel** shows an immunoglobulin M (IgM)-k monoclonal gammopathy. The clonal protein is also seen on the serum protein electrophoresis (SPE) in the **left lane of the right panel.** The location of this clonal immunoglobulin is consistent in all three positive lanes (SPE, IgM, k), the *darker staining* in the IgG lane is an application artifact.

The advantages of this method over immunoelectrophoresis include more rapid diffusion, easier interpretation, direct comparison with zone electrophoresis results, and higher sensitivity for clonal Igs (8). The last point makes this technique particularly useful in identifying oligoclonal Igs in serum, CSF, and other body fluids. Immunofixation yields more specimens with low-level monoclonal and oligoclonal Igs. The impact of identifying monoclonal gammopathy in otherwise asymptomatic patients has been evaluated in longitudinal studies, and it appears that as many as one-fourth of patients with this finding ultimately develop a malignant B-cell process (11). These observations have led to the term *monoclonal gammopathy of unknown significance,* rather than benign monoclonal gammopathy, when describing this finding (11). The disadvantages of immunofixation electrophoresis include its detection insensitivity in the presence of antigen excess and the difficulty in resolving monoclonal proteins with similar electrophoretic mobility.

Single Radial Immunodiffusion

Single radial immunodiffusion is technically a noncomplex method that allows quantitative assessment of a protein in solution (8). The approach consists of adding a sample (serum or other biologic fluid) to a well that is cut into agarose containing specific antiserum. The sample proteins (including the antigen of interest) diffuse into the agarose radially, and the specific antigen forms immune complexes on interaction with antibody contained in the support medium. An immunoprecipitate forms in the region of antigen-antibody equivalence; thus, the diameter of the immunoprecipitin ring varies according to the concentration of the diffusing protein, because the antibody level in the agarose is fixed (Fig. A.5). Controls, with known antigen concentrations, can be used to generate a standard curve from which the protein level in an unknown sample can be determined. Two different testing approaches are used for radial immunodiffusion: one involves reading the immunoprecipitin ring once it has reached the end point, often referred to as the Mancini method (12). The other technique evaluates the immunoprecipitate at a fixed time, before end-point equivalence has been reached, and is referred to as the Fahey and McKelvey method (13). A linear relationship is found between the antigen concentration and the square of the ring diameter when using the end-point method and between the log of the antigen concentration and the ring diameter in the fixed-time diffusion approach. Radial immunodiffusion is a simple and reliable method to quantify Igs, IgG subclasses, complement components (e.g., C3, C4, factor B, C1 inhibitor), and other proteins. Low-level kits are commercially available that extend the lower limits of detection to approximately 0.03 mg/L; these can be used in the determination of CSF IgG levels. However, this technique is cumbersome for high-volume protein quantitation as well as requiring 1 to 3 days before the immunoprecipitin rings can be read and results generated.

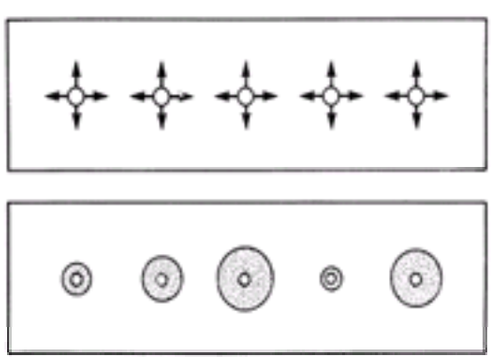

Figure A.5. Radial immunodiffusion. The size of the immunoprecipitate ring correlates with the concentration of the protein being measured because the concentration of the antibody (in the gel) is constant. The three rings on the **left** are controls, the fourth ring represents a patient with decreased levels of the protein being measured, whereas the fifth represents a person with a normal result.

At least three situations may result in erroneous results using conventional radial immunodiffusion testing. The presence of monomeric (low molecular weight) IgM, which is seen in Waldenström macroglobulinemia and ataxia telangiectasia, may result in the reporting of incorrectly high IgM levels. This is caused by the low-molecular-weight IgMs diffusing more rapidly than the pentameric IgM standards. Second, the presence of IgG rheumatoid factor in high concentrations can result in rheumatoid factor-IgG complexes that diffuse more slowly than the IgG standard, thus causing a spurious decrease in the total IgG level to be reported. Finally, antibovid species antibodies are found in certain patients with IgA deficiency. These can bind to Bovidae (e.g., goat) produced antisera used in the support medium and can produce a precipitin ring despite a deficiency of IgA.

One-Dimensional Electroimmunodiffusion

One-dimensional electroimmunodiffusion, also known as rocket electrophoresis, is an active immunodiffusion technique developed by Laurell (14). This technique is a variation of radial immunodiffusion in which multiple dilutions of a sample are placed in a series of wells cut in an agarose gel containing specific antibody. The sample is introduced into the well and then is subjected to an electrical field that causes the protein to migrate into the antibody-containing agarose. Antigen-antibody complexes are produced as the antigen moves into the antibody-containing support medium, and an immunoprecipitate is produced in the region of antigen-antibody equivalence. The immunoprecipitate forms in the shape of a spur or “rocket,” and the antigen concentration is directly proportional to the length of the “rocket.” Controls of known concentration are run to generate a standard curve from which the protein level of unknown samples can be generated. This method has a sensitivity similar to that of radial immunodiffusion but requires less time for completion, because the electrical field–induced immunodiffusion step is complete in hours rather than days. However, it is used relatively infrequently in most clinical laboratories even though commercial systems for assaying Igs and complement components are available.

Nephelometry

The basic principle underlying *nephelometry* is based on measuring the amount of incident light scattered by immune complexes in solution (15). The soluble immune complexes are generated by the addition of specific antibody to the protein (antigen) of interest, by allowing time for the immune complexes to form, and then by measuring the amount of scattered light. Nephelometry is performed in the antibody excess region of the precipitin curve where the complexes remain in solution, in contrast to precipitin reactions that require antigen-antibody equivalence to produce an immunoprecipitate. The concentration of the antibody added to each sample is constant, so changes in light scatter reflect differences in the antigen concentration. Because the method is designed to operate in dilute solutions, polyethylene glycol is often added to enhance the formation of immune complexes under the operational conditions. Currently, two different technical approaches are used: rate nephelometry, which measures light scatter associated with the peak rate of immune complex formation; and fixed time nephelometry, which evaluates light scatter at the same time point for all reaction mixtures. Both methods enable accurate measurement of IgG, IgA, IgM, C3, C4, factor B, C-reactive protein, IgG subclasses and certain other serum proteins (16). In addition, they are adaptable for the determination of proteins found in extremely low levels, including CSF IgG and albumen. Nephelometry is currently the standard method used in most busy clinical laboratories to quantify protein analytes because of the high throughput capabilities, together with the excellent precision provided by the commercially available automated nephelometers.

DETECTION AND QUANTITATION OF SPECIFIC ANTIBODIES

The *detection of specific autoantibodies* has become a standard approach used in the diagnostic evaluation of a variety of autoimmune diseases. In addition, testing for microorganism-specific antibodies provides serologic evidence for present or past infection. Substantiating the diagnosis of primary infection may be done by evaluating for the presence of organism-specific IgM, such as IgM antiviral capsid antibody in Epstein-Barr virus (EBV) infection. This approach is based on the finding that IgM is generated initially during the primary antibody response, whereas IgG appears slightly later and persists during the convalescent phase. This approach is most reliable if acute and convalescent samples are obtained to assay for both IgG and IgM antibody determinations (preferably tested in the same assay). Additional evidence of an acute or semiacute infection is a rising titer of antibody specific for the organism.

The evaluation of specific antibodies can be performed semiquantitatively using various methods including immunodiffusion, immunodiffusion combined with electrophoresis, agglutination, indirect immunofluorescence, and Western blotting. Quantitative assessment for specific antibodies is performed most commonly using an immunoassay such as radioimmunoassay or enzyme-linked immunosorbent assay (ELISA).

Double-Gel Immunodiffusion

Two-dimensional, double-gel (Ouchterlony) immunodiffusion is a test that facilitates the qualitative identification and characterization of specific antibodies (or antigens) in solution (7,17). In this method, a reference material (control antigen) and an unknown sample are placed in separate wells, and a characterized antibody is put into a central well (Fig. A.6). The antigens diffuse radially from their site of application into the support medium, where they encounter the antibody preparation diffusing radially from the central well. Immune complexes are formed when specific antibody interacts with the antigen to form an immunoprecipitate at the point of antibody and antigen equivalence. The test is designed to compare the reference material with the neighboring unknown samples based on three qualitative reaction descriptions: identity, nonidentity, or partial identity. This evaluation is derived from the pattern formed at the intersection of the reference antigen-antibody immunoprecipitate and the unknown sample-antibody immunoprecipitate (Fig. A.6). Fusion of the two different immunoprecipitin bands at the point of intersection represents the reaction of identity, and crossing of both bands constitutes nonidentity, whereas crossing of only one band signifies partial identity. Serial dilutions of a sample can be used for a semiquantitative titer of a specific reactant. The reactants can be reversed by using characterized antigen in the central well to detect and compare for the presence of specific antibodies contained in samples placed into the surrounding peripheral wells. Clinical application of this method includes the evaluation of autoimmune disorders for the presence or absence of autoantibodies to extractable nuclear antigens, including Sm, RNP, SS-A, SS-B, as well as other antigens such as Scl-70 and Jo-1. It lacks the detection sensitivity of many quantitative methods and requires time for the immunodiffusion to occur. However, it is technically easy, can be performed with antigen preparations that are only partially purified, is highly specific, and serves as an excellent screening test for the presence of a specific antibody or antigen in solution.

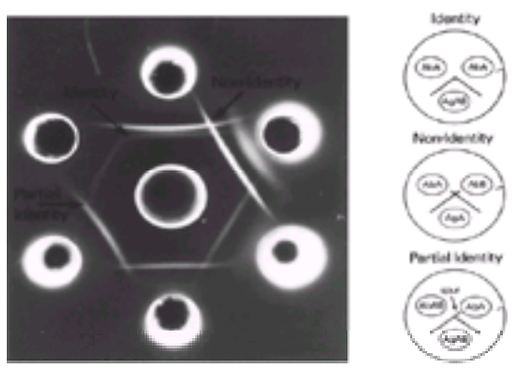

Figure A.6. Double-gel (Ouchterlony) immunodiffusion. Immunoprecipitation patterns at the intersection points demonstrate reactions of identity (fusion), nonidentity (both crossing), and partial identity (spur).

One-Dimensional Double Electroimmunodiffusion

This method, also known as *counter immunoelectrophoresis,* consists of placing an antigen-containing sample into a cathodal well and antibody into an anodal well within a specific type of gel (18). The reactants are then exposed to an electrical field, and antigen, with a relative negative charge, will move in the direction of the electrical current, whereas the relatively neutral antibody will move in the opposite direction as a result of endosmotic flow. Specific, high electroendosmosis grade agarose is required for this technique to ensure that Igs migrate cathodically. The reactants migrate toward each other and produce immune complexes that immunoprecipitate in the region of antigen-antibody equivalence. Because this represents active diffusion, the test can be performed far more rapidly than the passive method of double-gel immunodiffusion (Ouchterlony). This semiquantitative technique has been used primarily for identifying the presence of antigens or antibodies specific for certain infectious diseases in patient samples.

Agglutination Assays

Agglutination is a technique in which antibody reacts with antigen to produce multivalent binding (19). When antibodies combine with more than one particulate antigen, the result is the bridging of multiple antigens and antibodies with visible clumping. Direct agglutination assays use particles that naturally express the antigens of interest (e.g., red blood cells), whereas indirect agglutination assays use inert particles (e.g., latex spheres) that have been coated with the antigen of interest. This technique represents a simple and rapid method for determining the presence of specific antibody. Various serum dilutions are added to the antigen-coated (or antigen expressing) test particles, followed by incubation and observation for the presence of visible clumping. In agglutination assays, the evaluation of specific antibody that demonstrates wide variation in levels can result in a false-negative value when testing a single dilution as a result of the prozone effect (antibody excess with no immunoprecipitate). Avoiding this effect requires testing a range of sample dilutions rather then simply screening a single dilution of the sample.

Examples of agglutination tests that are routinely used clinically include red blood cell cross-matching (direct hemagglutination), rheumatoid factor (indirect, latex agglutination), and anticytomegalovirus antibody (indirect, latex agglutination). Agglutination assays are technically easy to perform, require no sophisticated instrumentation, and generate relatively quantitative results rapidly (20). They are less sensitive than immunoassays and have a bias in detecting IgM antibodies over IgG antibodies (21). Modification of the agglutination assay by the addition of an anti-Ig reagent, referred to as the Coombs test, improves detection of IgG antibodies.

Indirect Immunofluorescence Assays

The detection of an antibody to antigens that are expressed in some solid phase can be performed using *indirect immunofluorescence.* The clinical application of this technique typically uses cultured cells or a tissue section fixed on a microscope slide as the antigen substrate (22). The slide is overlaid with a sample (e.g., serum) that allows specific antibody, if present, to bind to the antigen of interest on the cells. After a wash step, fluorochrome-labeled antibody to human Ig is added, free antibody is washed away, and any bound antibody is detected by examination using fluorescence microscopy. Indirect immunofluorescence is used to test for antinuclear antibodies and specific antiviral antibodies (23). The availability of a cultured human cell substrate (such as Hep2 cells) for antinuclear antibody testing facilitates the identification of certain antibody specificities (e.g., anticentromere antibody and definition of cells in mitosis) (24). Other tissue substrates used for autoantibody testing include neutrophils (antineutrophil cytoplasmic antibody), stomach (anti–smooth muscle antibody), Purkinje cells (anti-Yo antibody), and hepatocytes and kidney tubules (antiliver kidney microsomal antibody). The substrate for antiviral antibody testing is usually infected cells or cell lines that express specific viral antigens (25). Indirect immunofluorescence tests can distinguish between IgG and IgM using fluorochrome-conjugated, class-specific antibodies. Although this sensitive test is relatively easy to perform, it requires technical knowledge and the availability of fluorescence microscopy.

Western Blot

The *Western blot* technique, a type of immunoblotting, is a semiquantitative method to identify specific antibodies (or antigens) in a solution (26). This technique combines the selectivity of gel electrophoresis with the specificity of an antibody-antigen interaction. The method involves electrophoretic separation (usually by sodium dodecyl sulfate-polyacrylamide gel electrophoresis) of a mixture of proteins (antigens), followed by transfer from the separation gel onto a synthetic membrane. Protein binding to nitrocellulose, the most commonly used synthetic membrane, is essentially irreversible over a wide range of protein concentrations. The actual detection phase of the test is initiated by overlaying the sample of interest onto the membrane containing the separated antigens. Specific antibody in the sample binds to its appropriate antigen, and after a wash step, labeled (enzyme, radionuclide) antihuman Ig is added to identify the presence of antigen-specific antibody (Fig. A.7). The general location and molecular weight of the separated protein antigens are known, and a control membrane is stained with either colloidal gold or amido black to confirm the presence and location of the specific proteins (antigens). Although this method is only semiquantitative, it is extremely sensitive, with a lower limit of detection in the range of 10 to 100 pg protein. It also has the added advantage of characterizing the pattern of antibody reactivity directed at certain distinct protein

antigens. This feature has enabled more specific assessment of the antibody response in HIV infection and Lyme disease as well as other infectious diseases. The availability of commercial Western blot test kits with prepared methylcellulose strips has significantly simplified the performance of this assay and has allowed the widespread use of the Western blot as a confirmatory test in assessing HIV serologic status (27). This approach also may have utility in the characterization of autoantibody reactivity in certain autoimmune disorders. Western blotting has wide applicability in the research laboratory to characterize antibody responses to complex antigens.

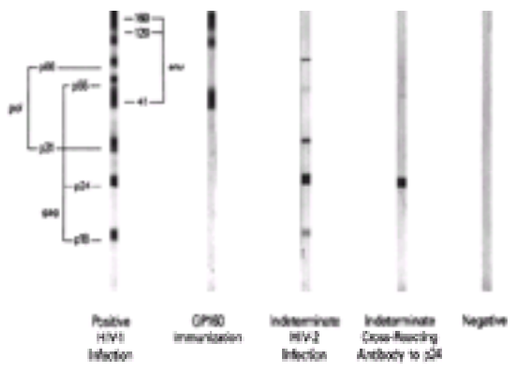

Figure A.7. Western blot. Various patterns of anti–human immunodeficiency virus antibody reactivity including a positive with antibody to all the major antigens, a postimmunization serum demonstrating the limited reactivity to the GP160 (envelope) proteins, and indeterminate and negative sera.

Radioimmunoassay

Until Yalow and Berson described a method to measure human insulin levels in the 1950s, the evaluation of circulating proteins present in relatively low concentrations had been a major technical obstacle (28). This initial report detailed the competitive binding immunoassay in which a constant amount of antigen-specific antibody is placed together with a small, predetermined amount of the antigen that has been previously radiolabeled. Next, standards, consisting of known quantities of unlabeled antigen, as well as unknown samples, are added to individual tubes containing the antibody and labeled antigen. After incubation, antigen-antibody immune complexes are precipitated, and their radioactivity is measured. Because the displacement of labeled antigen depends on the concentration of the antigen in the standard (or unknown sample), a concentration curve can be generated using the data from the standards. The radioactivity of the unknown samples then can be plotted on the standard curve to determine the concentration of the antigen in each sample tested.

This assay can be applied to determine specific antibody concentration by reversing the reagents, starting with a fixed concentration of purified antigen mixed with a small amount of labeled antibody. The second step involves the addition of either an antibody standard or an unknown sample that contains antibody. As noted earlier, displacement of the labeled protein (antibody) depends on the concentration of specific (unlabeled) protein (antibody) in each sample. The radioactivity observed in each of the precipitated immune complexes is inversely related to the antibody concentration.

A modification of the initial *radioimmunoassay* method uses a solid phase to immobilize one of the reactants (either antigen or antibody) (29). Binding of the unknown to the reagent attached on the solid phase can be detected with a second reagent that is radiolabeled or by using a sequence of antiantibody reagents with the final antibody being radiolabeled. The use of more than one reagent such as an antiantibody in the detection mode can increase the low-end sensitivity of the test, but it also can produce higher levels of nonspecific reactivity. The radioimmunoassay is a sensitive test for the quantitation of specific antigens or antibodies. The major disadvantages of this type of test are the requirements for expensive equipment to determine the level of radioactivity (i.e., g counters), radiolabeled reagents with short shelf lives, and special means for disposal of the radioactive waste.

Enzyme-Linked Immunosorbent Assay

A nonradioactive modification of the solid-phase immunoassay method, *ELISA,* was developed to address the disadvantages previously noted for the radioimmunoassay (30,31). This method depends on detection using an enzyme labeled reagent plus an appropriate, chromogenic substrate to produce a color. The intensity of the color generated is directly related to the concentration of the analyte tested. The indirect method has been used extensively for the detection of antibody, typically using polystyrene microtiter plates, tubes, or beads as a solid phase to which a purified antigen is bound. Serum (or other fluid) is added to the antigen-coated surface to enable any specific antibody to bind the immobilized antigen. The bound Ig then can be detected using an enzyme-labeled antihuman Ig followed by addition of the chromogenic substrate (Fig. A.8A). Washing is required between each individual step to remove unbound reactants. The optical density of the color reaction is measured and is proportional to the antibody concentration present in the sample. A simple modification of this method again involves an indirect detection method that uses a primary unlabeled antibody (antihuman Ig), followed by a second, labeled antibody that is reactive with the primary Ig. This may enable detection of lower concentrations of antibody, but it also may result in higher nonspecific reactivity.

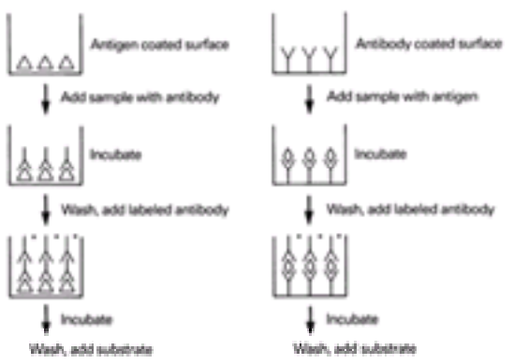

Figure A.8. Solid-phase immunoassay: indirect assay **(A),** sandwich assay **(B).** The label on the antibody can be an enzyme plus substrate (as shown), a radionuclide, or a fluorochrome.

An alternative approach for the detection of specific antigen is referred to as a *sandwich assay.* This method uses antigen-specific antibody bound to the solid phase that “captures” specific antigen. This is followed by the addition of a second, enzyme-labeled antibody specific for the antigen; after a wash step, substrate is added, and the color intensity is measured (Fig. A.8B). When only impure antigen is available, a specific antibody bound to the solid phase can be used to capture the antigen of interest from the heterologous mixture. The detection method also can use an indirect procedure with antigen-specific antibody and then antiantibody after the antigen capture step. The sandwich assay can be modified to detect antibody by initially binding specific antigen onto the solid phase and using enzyme-labeled antigen plus chromogen for the detection step. ELISA testing also can be set up in a competitive binding assay similar to the method discussed in the radioimmunoassay section. In each of these various approaches, control samples of predetermined concentration are used to construct a standard curve from which the specific levels of the various unknowns can be derived. Numerous test kits are available commercially for determining the levels of antibodies or other proteins. These usually include coated microtiter wells and standards as well as software to generate the concentrations of unknown samples. Laboratory-developed ELISA tests take advantage of the readily available reagents, automated ELISA readers, and various data reduction programs.

The sensitivity of current ELISA assays is comparable to that of radioimmunoassays. This method can be used for quantitating a host of specific antibodies or antigens, and it has several advantages, including performance simplicity, excellent reproducibility, and no requirement for isotopes. ELISA testing is currently the standard assay for various antiviral antibody tests, including the primary HIV antibody test. It is also a popular test method for detecting certain other immunologic proteins including IgG subclasses and IgE. The major disadvantage of ELISA is nonspecific binding to the solid-phase surface (microtiter plate, tube, or bead). This problem is common to all solid-phase assays, and it can be diminished by using specific blocking steps (saturate the nonspecific binding with unrelated protein) and washing thoroughly between steps.

The newer-generation immunoassays have incorporated certain changes, including improved solid phase (e.g., beads) to increase the amount of antigen available, the

use of recombinant or well-characterized proteins as targets, better reporter systems using either fluorescence or chemiluminescence, and automated platforms. These changes have resulted in assays with greater sensitivity and expanded dynamic range that are also less labor intensive with a lower test unit cost. As with all laboratory tests, immunoassays require careful test design, with appropriate controls to evaluate and monitor test performance, including the level of nonspecific reactivity.

FLOW CYTOMETRY

Flow cytometry is a method that uses an instrument to measure light emission generated by fluorochrome-labeled cells. The illumination source is typically a monochromatic beam generated by a laser and chosen to provide appropriate excitation energy for the fluorochrome reporters. Most instruments can provide data on at least five different measurements or parameters per cell. This approach has the distinct advantage over bulk techniques of retaining the collected data as discrete events specific to each cell are evaluated. It affords the opportunity to examine a variety of cell characteristics including surface antigen expression, intracellular protein production, and cell-cycle or viability status.

Testing for the presence of specific antigens (receptors) on the surface of lymphocytes allows for the identification of specific cell types or subtypes. This approach, referred to as *immunophenotyping,* can provide qualitative and quantitative data regarding cell lineage, stage of differentiation, functional potential, and state of activation. The clinical application of immunophenotyping has been shown to be important for assessing disease status in HIV infection as well as for characterizing leukemia and lymphoma cells. This technique also is being used as an adjunct in the evaluation of immune deficiencies and immune-mediated diseases, as well as in monitoring patients undergoing immunomodulatory therapy or organ transplantation. The most common method for analysis uses fluorochrome-conjugated monoclonal antibodies that are specific for lymphocyte-surface antigens.

Monoclonal Antibodies and Fluorochromes

The capacity to produce a *monoclonal antibody reactive with a specific antigen* was first described by Kohler and Milstein (32). The approach described in this seminal report consists of fusing an “immortal” murine myeloma cell line with normal murine plasma cells obtained from the spleens of mice that had been specifically immunized. The myeloma cell and the plasma cell are physically fused using polyethylene glycol to yield a hybridoma. This somatic hybrid combines the advantage of immortality with survival in selective medium. After a period in culture, the cell-free supernatants are examined for the presence of specific antibody. Cultured cells identified as producing specific antibody are cloned using a limiting dilution technique based on a Poisson distribution. The cells producing antibody are expanded to provide additional antibody for further characterization. Finally, specific antibody-producing clones can be expanded either by *in vitro* culturing techniques or by *in vivo* growth in the peritoneal cavity of a mouse. This antibody “factory” can produce a long-term supply of a specific antibody. The ever-increasing numbers of monoclonal antibodies to different lymphocyte cell-surface antigens that are available are categorized according to a CD (cluster of differentiation) numeric convention (Table A.1) (33). The CD assignments are made at international workshops that are held periodically to characterize and assign CD specificities to more recently developed monoclonal antibodies. This designation system is also used to describe monoclonal antibodies directed at surface antigens on other hematopoietic cells, including monocytes, platelets, and granulocytes, as well as other cells (e.g., endothelial cells).

TABLE A.1. Selected Lymphocyte-Surface Antigens

The availability of a large number of monoclonal reagents directed at lymphocyte-surface antigens has allowed for significant progress in the understanding of lymphocyte differentiation and maturation. In addition, other monoclonal antibodies have been produced that yield information about mechanisms of cell adhesion, activation, and function. The immunophenotyping of lymphocytes can provide information regarding the presence or absence of particular cells or specific cell characteristics, and the potential for certain functions. However, identification of cells using this technique is not the equivalent of evaluating actual cell function.

The detection of antibody binding to the cell surface requires a reporter, which typically is a fluorochrome, a compound that absorbs light (excitation) of a defined wavelength and converts this energy into light (emission) of a longer wavelength (lower energy). Cells are exposed to a monochromatic source of light designed to excite fluorochrome conjugated antibody bound to the cell surface. The light emitted by the fluorochrome is detectable with the human eye using fluorescence microscopy or with a flow cytometer.

The simplest technique for immunophenotyping consists of using monoclonal (or occasionally polyclonal) antibodies that have been directly conjugated with a fluorochrome. This approach is referred to as *direct staining* because the reaction is accomplished in one step. The alternative approach, referred to as *indirect staining,* uses a nonconjugated primary reagent (antibody) that is detected in a second step with a fluorochrome conjugated secondary reagent (e.g., fluorochrome labeled goat antimurine IgG).

The fluorochromes that are routinely used in clinical immunophenotyping include fluorescein isothiocyanate (FITC) and phycoerythrin (PE). Both these compounds are excited by blue light (488 nM), with FITC producing green light (525 nM) and PE emitting orange light (575 nM). A newer fluorochrome, peridinin chlorophyll protein (PerCP), is also excited by blue light generating a red signal (675 nM). An alternative for the third color uses two fluorochromes linked together, with one serving as the source of excitation energy for the second, a process referred to as *energy transfer.* The most common example of this approach is using blue light to excite phycoerythrin, which emits orange light that serves as the excitation light source for a cyanin dye such as Cy5. The combination of either PerCP or the energy transfer pair with FITC and PE enables direct staining with three different monoclonal antibodies using a single excitation (blue) beam to perform a three-color analysis (34). This would provide eight potential cell populations (i.e., positive or negative with each of the three reagents yielding 2^3 combinations). Other fluorochromes, including Texas red, rhodamine, and allophycocyanin, are used primarily in research settings, because alternative wavelength light (a second light source) is required to excite these compounds.

Research-based flow cytometers with multiple excitation sources enable workers to perform studies with up to six or seven different fluorochromes (“colors”) simultaneously; this situation could generate 64 (2^6) or 128 (2^7) phenotypically distinct cell subpopulations from one combination of 6 or 7 antibodies. Significant effort is being expended to develop additional fluorochromes to enable even greater numbers of reagent combinations. However, the identification of large numbers of cell subpopulations poses a significant challenge with regard to data management and interpretation.

Flow Cytometer

A *flow cytometer* consists of a light source, focusing optics, fluidics, photodetectors, and a computer system (Fig. A.9) (35). An air-cooled, argon laser is the standard source for the monochromatic blue light beam. A system of fluidics using hydrodynamic focusing regulates the flow and location of the cells passing through the focused beam of light. Photodetectors consisting of photomultiplier tubes and photodiodes detect and amplify the specific light signals derived from the cells, and the computer allows for data acquisition and analysis. This system is capable of collecting the multiple pieces of data (parameters) obtained from each individual cell at rates that range from 500 to 2,000 events per second or greater. Many specific software packages are available that allow a correlated analysis of these multiparameter data to identify qualitative and quantitative characteristics about various cell subpopulations. The quantitative, multiparameter analysis of large numbers of cells provides a significant advantage over conventional fluorescence microscopy, particularly when dealing with small populations or subpopulations of cells. In addition, the various reagents can be detected independently on each cell without the interference of the other bound reagents (fluorochromes).

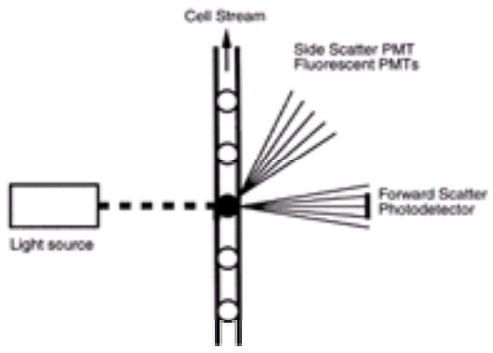

Figure A.9. Basic design of a flow cytometer. This instrument has a monochromatic light, an optical system to focus the light onto a specific area, fluidics to move the cells in suspension through the path of the light, and photodetectors to collect nonfluorescent and fluorescent light signals.

Most flow cytometers can evaluate two nonfluorescent parameters: forward-angle (low-angle) light scatter, measured in the plane of the excitation beam, and side (orthogonal, 90-degree) light scatter, measured at a right angle to the incident beam and the cell flow. The former is a reflection of cell size, whereas the latter depends on cell granularity and topography. A standard flow cytometer also can collect at least two (usually three or four) fluorescent parameters using photomultiplier tubes arranged in the same plane as the side scatter detector. Each detector is "tuned" to a specific wavelength ("color") through the use of optical filters that are chosen to match the emission characteristics of the fluorochromes used.

Lymphocyte Phenotyping

As noted earlier, fluorochrome-conjugated monoclonal antibodies directed at specific cell-surface antigens in combination with flow cytometry are used to differentiate *lymphocyte* subpopulations. The technical approach employed in many clinical laboratories is a whole-blood lysis method that consists of adding one or more directly (fluoro-chrome-) conjugated monoclonal antibodies to a small volume of whole blood (36). The mixture is incubated to allow the antibody to bind the appropriate cell-surface antigen; next the red blood cells are lysed, and the sample is then ready for evaluation with a flow cytometer. The major advantage of the whole-blood technique is decreased sample handling with diminished likelihood of selective cell depletion. An alternative approach to the whole-blood technique uses lymphocytes that have been separated by means of a density gradient. The staining procedure is similar, except lysis of red cells is not necessary. This technique provides relatively pure population of mononuclear cells (lymphocytes and monocytes), although the separation method may deplete certain cell subpopulations.

The computer software typically displays single-parameter immunophenotypic data graphically as a histogram (Fig. A.10). This is a distribution plot with cell frequency (number) on the Y-axis and fluorescent intensity on the X-axis. Integration of the area under a curve or part of a curve yields information regarding cell distribution. Two color studies are usually displayed by means of a contour (Fig. A.9), a dot, or an isometric plot. This system allows the simultaneous display of two parameters versus frequency, and it defines four separate populations: cells that express both antigens, cells that express neither antigen, and those that express exclusively one or the other antigen (37). Resolution of antigen coexpression is best appreciated with two-parameter displays. The graphic display of three-color studies requires sequential analysis examining two-color data on cells identified as positive or negative for the third marker.

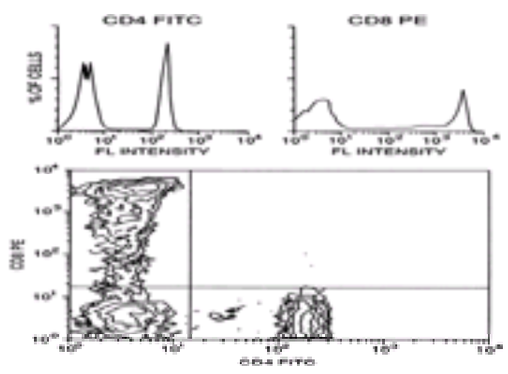

Figure A.10. Flow cytometry–derived histograms and contour plot. CD4 and CD8 histograms from a sample stained simultaneously with CD4-fluorescein isothiocyanate (FITC) and CD8-phycoerythrin (PE) showing the fluorescent ntensity (X-axis) versus cell frequency (number) on the Y-axis. The dual-parameter study is also displayed as a contour plot in which four basic populations can be distinguished: CD4-FITC positive **(lower right quadrant),** CD8-PE positive **(upper left quadrant),** CD4-FITC positive/CD8-PE positive (double positive, **upper right quadrant),** and CD4-FITC negative/CD8PE negative (double negative, **lower left quadrant).**

The proper characterization of lymphocytes requires differentiating the cells of interest from the other leukocytes (monocytes, granulocytes), nonleukocytes (red blood cells, platelets), and debris. A directed analysis confined specifically to lymphoid cells in a mixed cell population depends on a process referred to as *lymphocyte gating.* This is usually accomplished by evaluating the two nonfluorescent parameters, forward angle and side scatter (38). As previously noted, the former is a reflection of cell size, whereas the latter is a measure of cell granularity and topography. These two parameters enable the separation of leukocytes into three relatively distinct populations: granulocytes (greatest amount of side scatter), monocytes (greatest amount of forward scatter and intermediate side scatter), and lymphocytes (combination of low forward scatter and side scatter) (Fig. A.11). The inclusiveness of this three-part differential can be confirmed using monoclonal gating reagents consisting of the panleukocyte specific monoclonal antibody (CD45) with a monocyte-specific reagent (CD14) (39). This approach identifies lymphocytes (CD45 brightly positive, $CD14^-$), monocytes ($CD45^+$ and $CD14^+$), and granulocytes (CD45 dimly positive, $CD14^-$) as well as nonleukocyte contaminants ($CD45^-$ and $CD14^-$). The confirmation of the lymphocyte gate using the combination of CD45 and CD14 is especially critical when one uses the whole blood lysis method, because nonlymphocytes represent the majority of leukocytes in the peripheral blood of adults. Proper gating ensures that the percentages obtained for the various lymphocyte immunophenotypes are correct. Thus, exclusion of nonlymphocytes and inclusion of most lymphocytes by the primary gating technique are the first steps in providing valid immunophenotypic data. Incorrect gating, resulting from either including significant numbers of nonlymphocytes in the lymphocyte gate or excluding significant numbers of lymphocytes from the lymphocyte gate, can invalidate a study.

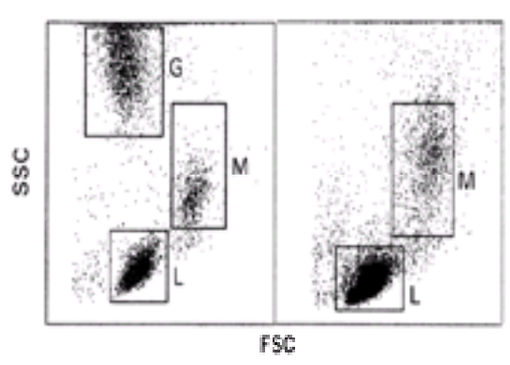

Figure A.11. Lymphocyte gating. The nonfluorescent parameters, forward scatter (FSC) and side scatter (SSC), identify three populations in lysed whole blood: lymphocytes (L), monocytes (M), and granulocytes (G). These parameters reveal the presence of lymphocytes (L) and monocytes (M) after density gradient separation (same sample). Most granulocytes have been depleted by this method of cell preparation.

Normal immunophenotypes vary with age, race, and sex; thus, patient data must be interpreted in the context of appropriate control values (40). Representative immunophenotyping data for immunologically normal adults derived in our laboratory are presented in Table A.2. Complete immunophenotypic data must include both the percentage and the absolute number (based on the total lymphocyte number) of the various subpopulations studied.

Surface Antigen	95% Confidence Interval	
	Percentage (%)	Cell Number (per mm³)
T cell		
CD2	74–89	990–2080
CD5	60–82	830–1990
CD3	61–84	830–2030
CD4	32.5–60	480–1340
CD8	18–46.5	350–910
B cell		
CD19	5.5–16	95–380
CD20	5–16	90–330
NK cell		
CD3-/CD16 and CD56	6.5–29.5	120–490

NK, natural killer.

TABLE A.2. Normal Adult Immunophenotype Data

Within a specific study, certain internal relationships can be used to validate the results. T cells + B cells + natural killer (NK) cells should equal 100% (plus or minus 5%) in any phenotyping study that reports all three major lymphocyte subpopulations. At least three different situations could alter the sum of the parts: improper lymphocyte gating with the inclusion of nonlymphocytes, the presence of an abnormal lymphoid population that is not stained by the reagents chosen, and technical problems. Additional internal controls include the finding that in immunologically normal adults, approximately 75% of circulating lymphocytes are T cells; most T cells express either CD4 or CD8, usually in a ratio of 2:1; the remaining non-T lymphocytes are generally equally divided between B cells and NK cells. There also should be internal consistency when specific reagents are used more than once as well as consistency between two different reagents that identify essentially the same population or subpopulation (e.g., CD19 and CD20 on B cells).

The most commonly requested flow cytometry test is a CD4 count because it is used as a diagnostic criteria for the acquired immunodeficiency syndrome, to develop prognostic data regarding HIV infection, and to make decisions regarding therapy. The evaluation of clonal excess, cell lineage, and state of differentiation by flow cytometry has become a standard approach in the assessment of leukemia and lymphoma cells. Additional applications of this method include evaluation for increases or decreases in specific cell subpopulations, as well as the status of activation markers in a variety of diseases. Generally, flow cytometry provides data used to support a diagnosis, as well as prognostic information. In many other settings, it is currently used for investigative types of studies.

Intracellular Flow Cytometry

The evaluation of *intracellular characteristics using flow cytometry* has been applied in different settings. In these applications, the common methodologic approach is to open the interior of the cell to probes using membrane fixation and permeabilization. An example of this approach is the evaluation for the presence of intracytoplasmic cytokines after mitogen or antigen stimulation (41). This has proven to be a useful tool in exploring the T-helper cell Th1 and Th2 paradigm (Chapter 10 and Chapter 11), and it has been applied in the setting of studies of allergic and autoimmune disease as well as investigation of allergen immunotherapy. An additional application of intracellular testing is the evaluation of phosphorylated proteins after cytokine activation (42). A flow cytometer also can be used to study cell cycle by evaluating total cellular DNA or RNA with certain specific fluorescent probes including those that intercalate into DNA or RNA (43). These studies can be combined with the evaluation of specific cell-surface antigens. This combination approach is used to evaluate cell-cycle or ploidy status of tumor cells. It also can be applied to a cell mixture containing malignant cells by using a tumor-specific monoclonal antibody to identify the malignant cells for cell-cycle assessment.

Finally, flow cytometry can be used to assess other intracellular characteristics associated with cell activation. These include evaluation of intracellular parameters with fluorescent probes that are sensitive to changes in calcium, pH, or transmembrane potential (44). An additional activation directed assessment is to evaluate oxidative burst in granulocytes and other leukocytes. This method is diagnostic for patients with chronic granulomatous disease, as well as the X-linked carriers of this disorder (45). It depends on loading granulocytes with a specific dye, dihydrorhodamine-123 (DHR), activating the cells, and then evaluating cell fluorescence using flow cytometry. The activation step induces hydrogen peroxide production through reduced nicotinamide-adenine dinucleotide phosphate (NADPH) oxidase pathway converting DHR to an active fluorochrome that can be detected by the flow cytometer. Patients with chronic granulomatous disease have a defect in this enzyme pathway, and their granulocytes show only background fluorescence, whereas normal cells show bright fluorescence and cells from X-linked carriers demonstrate two cell populations, normal and abnormal.

Tetramer Technology

A more recent application of flow cytometry allows for the enumeration of antigen-specific T cells (46). The reporter in this assay is a soluble *tetrameric antigenic peptide-major histocompatibility complex (MHC) complex* that serves as a ligand for T cells specific for the antigenic peptide and MHC. Flow cytometric detection is achieved by binding an avidin-linked fluorochrome to streptavidin contained within the tetrameric complex. Application of this technology requires that the composition of the antigenic peptide and its human leukocyte antigen (HLA) restriction are known. To date, most applications have focused on MHC class I–mediated (CD8) T-cell responses; however, detection of antigen-specific CD4 T cells with tetramers generated from soluble MHC class II and peptide has also been reported (47). These approaches should help to clarify the kinetics of primary and secondary T-cell responses. This method can also be combined with surface phenotype and intracellular functional markers. Tetramer-based flow cytometry is proving useful for the study of the immune response to infectious agents and vaccines. It is likely that this new technology will find many more applications.

EVALUATION OF B-CELL FUNCTION

Quantitative Immunoglobulin

Obtaining IgG, IgA, and IgM levels represents the initial screening test in evaluating B-cell function. These results must be interpreted with age-matched controls, because of significant changes with age, as well as more minor differences based on gender and race (48,49). Most normal ranges report a 95% confidence interval, meaning that 2.5% of normal values fall below and 2.5% fall above this range. The most common laboratory methods used to determine Ig levels are automated nephelometry or radial immunodiffusion.

IgG subclass levels are also available to investigate more subtle abnormalities in B-cell function. This approach is based on the findings of low normal total IgG accompanied by a selective depression of one or more IgG subclasses in certain patients with recurrent sinopulmonary infection (50). These results must be balanced with the observation that most persons with abnormal IgG subclass levels are clinically normal (51,52). Thus, the assessment of IgG subclass levels does not represent a screening test for immune deficiency. Furthermore, it is a moderately expensive test and should be reserved for evaluating patients with a history of recurrent bacterial infections in the setting of low normal to minimally depressed IgG levels. This test is most useful in the setting of IgA deficiency associated with recurrent sinopulmonary infections. Identifying an IgG subclass deficiency generally requires demonstration of a functional antibody abnormality *in vivo* to justify initiating replacement therapy.

Functional Antibody Testing

Assessment of specific antibody levels in vivo may be useful in screening for B-cell immune competence (53). This approach includes evaluating isohemagglutinins, as well as testing for antibody levels to documented prior immunizations or natural infections (e.g., tetanus toxoid, polio, rubella, rubeola). An important approach for evaluating B-cell immunity is the testing of *in vivo* antibody production in response to recall antigens. This consists of measuring preimmunization titers and 2- to 3-week postimmunization titers to both protein antigens (e.g., tetanus toxoid, diphtheria toxoid) and polysaccharide antigens (e.g., pneumococcal polysaccharides) (54,55). Evaluation of specific antibody levels is available at many medical centers, as well as from selected commercial laboratories and state department of health laboratories. There are also neoantigens, including bacteriophage fX174, that are studied under research protocols to evaluate the primary antibody response (56). No patient with suspected immune deficiency should receive an immunization with a live virus vaccine. Overall, this type of testing provides definitive evidence for the presence or absence of normal B-cell function. In the absence of a major depression in the Ig levels, information regarding *in vivo* antibody production is absolutely

essential before one considers intravenous Ig therapy.

In Vitro Antibody Production

Testing B cells for the capacity to undergo terminal differentiation and to secrete Igs after *in vitro* stimulation with either nonspecific polyclonal activators (mitogens) or specific antigens is used in many research laboratories (53,57). These studies generally involve culturing purified B cells in combination with T cells or T-cell products together with an activator for a prescribed time, followed by evaluation of the cell-free culture supernatant for secreted antibody or *in situ* using the ELISPOT immunofixation method (58). This can provide data regarding B-cell responsiveness as well as the function of regulatory T cells involved in the control of Ig production. The application of this testing may enable investigation into basic questions, including those directed at evaluating abnormalities in isotype switching and possible cytokine alteration in B-cell responsiveness or T-cell immunoregulation. This approach is generally reserved for more basic investigations directed at studying underlying mechanisms of disease or identifying disease variations and does not represent testing used for diagnostic purposes.

EVALUATION OF T-CELL FUNCTION

Delayed-Type Hypersensitivity Testing

Assessment of the capacity of T cells to respond to recall antigen *in vivo* is performed using the method of *delayed-type hypersensitivity skin testing.* Intradermal injection of a recall antigen induces an inflammatory process that requires the proliferation of antigen-specific memory T cells, cytokine release, and infiltration of monocytes (59). This process produces maximal local inflammation 48 hours after antigen exposure, as evidenced by erythema and induration at the injection site. The test site should be examined at 24, 48, and 72 hours, with the early assessment time used to rule out the alternative inflammatory response mediated by IgG (Arthus response), which peaks at 12 to 24 hours. Failure to mount a delayed-type hypersensitivity response can result from either immune dysfunction or lack of prior exposure to the test antigen. To minimize the latter possibility, a panel of antigens is useful based on the observation that virtually all immunologically normal persons respond to at least one antigen when they are tested with a combination of tetanus toxoid, *Candida,* and mumps antigens (60). The absence of reactivity to a panel of recall antigens strongly suggests cutaneous anergy with an underlying T-cell deficiency. Establishing that normally functioning T cells were present in the past is provided by obtaining a history of contact sensitivity including common responses to *Rhus* (poison ivy) or nickel. An absolute lymphocyte count should be obtained when initiating an *in vivo* evaluation of cell-mediated immunity, because T cells normally comprise approximately 75% of the circulating peripheral lymphocytes. A significant decrease in T cells would likely result in a decrease in the overall lymphocyte count, and as such, the count represents a simple screening test for the presence of circulating T lymphocytes.

Proliferation Assays

The *in vitro* correlate of delayed-type hypersensitivity testing is *T-cell proliferation* in response to a recall antigen. This test evaluates a complex process involving ligand-receptor interaction, signal transduction, generation of specific receptors, production of cytokines, and, ultimately, cell proliferation. In addition to recall antigens, alloantigens (mixed lymphocyte culture) mitogens (e.g., phytohemagglutinin, concanavalin A, pokeweed mitogen), and specific monoclonal antibodies (e.g., OKT3) can also be used to induce T-cell proliferation (53,61,62 and 63). The conventional approach is to evaluate cell proliferation by separating mononuclear cells from the peripheral blood on a density gradient and then culturing the cells in the presence or absence of an activator. At the end of the culture period, tritiated thymidine is added for a predetermined interval, to allow cellular incorporation of this radioactive DNA precursor to measure DNA synthesis. Tritiated thymidine incorporation is quantitated using a scintillation counter, and the results are expressed either as counts per minute (cpm) or disintegrations per minute (dpm). In addition, a stimulation index for each culture condition can be generated using the following equation:

$$\text{Stimulation Index} = \frac{\text{cpm of simulated cells}}{\text{cpm of unstimulated cells}}$$

Mitogen stimulation activates a significant proportion of normal T cells and is generally assessed after 3 days of culture. Antigen or alloantigen stimulation initially activates only those T cells with the appropriate antigen receptor, followed by recruitment and activation of additional cells such that a longer culture period of 6 to 7 days is generally used. Assessment of proliferation to recall antigens should include more than one antigen because, as with delayed-type hypersensitivity testing, the response to a recall antigen is predicated on previous exposure. In evaluating possible immune deficiencies, it may be useful to evaluate multiple doses of each activator and to examine more than one culture interval.

Longitudinal investigation in patients with HIV infection has demonstrated that unresponsiveness to recall antigen can be present early in the course of the infection, a finding suggesting the presence of a relatively subtle T-cell disorder already at this stage in the infection (64). As the disease progresses and the degree of T-cell deficiency increases, the T-cell response to alloantigens becomes depressed. Finally, in the later stages of disease, as the immune deficiency becomes more extensive, there is loss of the response to the mitogen, phytohemagglutinin. Thus, the degree of T-cell deficiency appears to be reflected by a progression in the level of the *in vitro* proliferative defect. These data suggest that the *in vitro* response to recall antigen is the most sensitive test for T-cell abnormalities, whereas mitogen (phytohemagglutinin) unresponsiveness is associated with profound T-cell deficiency.

Alternative techniques to evaluate T-cell activation involve flow cytometry. One such method is directed at quantitation of receptors that are upregulated after activation. Included among these is evaluation of CD69 expression that occurs within hours of the activation signal (65). Alternatively, the transferrin receptor (CD71) and the high-affinity interleukin-2 (IL-2) receptor (CD25) can be quantitated later after activation. This approach does not represent a standard method for evaluating T-cell activation, although some laboratories use it for screening. The expression of these activation antigens is not the equivalent of cell proliferation and thus may not fully reflect the findings with culture studies outlined earlier. A flow cytometric alternative for evaluating lymphocyte proliferation depends on evaluation of cell cycle after lymphocyte stimulation. This can be performed using DNA intercalating dyes to determine the distribution of cells in each phase of the cell cycle. Dividing cells can also be identified flow cytometrically by evaluating the incorporation of bromodexosyuridine into newly synthesized DNA using a labeled antibody directed at this substance. Finally, fluorescence intracellular, tracking dyes have been used with flow cytometry to evaluate cell proliferation based on the 50% decrease in total cell fluorescence associated with each round of cell division (66).

Cytotoxicity

The critical role of MHC (HLA) restriction, together with antigen specificity in T-cell recognition, was first established using an *in vitro* test for *T-cell–mediated cytotoxicity* (67). The assay described T-cell killing of virally modified self-targets, which is now known to involve $CD8^+$ T cells recognizing endogenously processed viral antigen in the context of class I MHC molecules (HLA-A and B molecules) (68). It has also been established that $CD4^+$ T cells can act as cytotoxic T cells, and these effectors recognize antigens, after endosomal digestion of the antigen, in the context of class II MHC molecules. Class I and class II MHC-restricted cytotoxicity is mediated by T cells with T-cell antigen receptors that express the ab chains. The underlying requirement for cytolytic activity is that the effector T cell has been previously sensitized (exposed) to the target antigen. Alternatively, some non–MHC-restricted cytotoxic T-cell activity does not require prior sensitization for cytolytic activity. These cells constitute a small percentage of the circulating T cells, most of which have T-cell receptors that express the gd chains.

In a conventional T-cell cytotoxicity assay, the target cells are labeled with a radioactive intracellular marker (chromium-51 [^{51}Cr]), and T-cell lysis of the target cell is assayed by measuring radioactivity released into the cell-free supernatant (69). Standard target cells include virally infected (modified) cells, allogeneic cells, mitogen-stimulated blasts, and tumor cell lines. In MHC-restricted assays of virally modified cell killing, previously sensitized T cells are initially cultured for 4 to 5 days, with the cells expressing the specific viral antigen to generate active cytotoxic cells. ^{51}Cr-labeled target cells are then cocultured with the activated effector cell preparation at a variety of prescribed effector cell–to–target cell ratios; the cell-free supernatants then are collected and are assayed for released ^{51}Cr. The degree of lysis is compared between normal and patient effector cells, with results expressed as the percentage of cytotoxicity, calculated as follows:

$$\%\ \text{cytotoxicity} = \frac{\text{experimental cpm} - \text{spontaneous cpm}}{\text{maximal cpm} - \text{spontaneous cpm}}$$

Maximal cpm (lysis) is determined by assaying the supernatant from detergent lysed target cells, whereas spontaneous cpm (lysis) is the amount of radioactivity in the supernatant obtained from target cells incubated without effector cells. Additionally, the results can be expressed as lytic units, where one lytic unit is defined as the number of control cells required to lyse a designated percentage of the target cells. An alternative method using cell tracking dyes and flow cytometry to evaluate the level of target cell lysis has also been described.

Analysis of T-cell–mediated cytotoxicity is not routinely available in most laboratories because the assays are difficult to set up, and the clinical utility of the results remains to be clearly defined. T-cell–mediated cytotoxicity directed at virally infected cells probably is a major protective mechanism in controlling or eradicating certain viral and other intracellular microbial infections as well as playing a role in tumor immunity (70). This theory has resulted in studies that monitored the evolution of

HIV-specific cytotoxic T cells and the production of specific antibody levels after immunization with experimental HIV vaccines.

Cytokines

Lymphocyte production of *cytokines* as a result of cell activation can be assessed by evaluating the supernatant obtained from cells cultured in the presence of mitogen, antigen, or other activator (Chapter 10 and Chapter 11) (71). Assay methods for quantitating these proteins include commercially available immunoassays most commonly based on an ELISA assay. Functional assays, technically more complicated, test for specific cytokine activity using appropriate *in vitro* culture systems. The evaluation of cytokine levels *in vivo* is complicated by the short half-life of most cytokines, together with the high-affinity binding of these proteins to their respective cell-surface receptors. At this time, testing for *in vivo* cytokine levels has provided useful information regarding immunologic mechanisms underlying certain chronic inflammatory conditions, particularly at the local level. Additional approaches include the evaluation of local cytokine production, the identification of cytokine antagonists, and the assessment of cytokine-specific receptors on cells or in a soluble form.

EVALUATION OF NATURAL IMMUNITY

Natural Killer Cell Function

NK cells are a population of circulating lymphocytes distinct from T cells and B cells that are characterized morphologically as large granular lymphocytes. Phenotypically, most of these cells are $CD16^+$ and $CD56^+$, but $CD3^-$ (72). In addition, approximately two-thirds to three-fourths of NK cells are $CD2^+$, whereas one-third to one-half are dimly positive for CD8. NK cell–mediated cytotoxicity does not require prior sensitization for the effector cell to lyse a susceptible target cell (69). *In vitro* assays typically use a cultured cell line (e.g., the K562 erythroleukemia cell line) as a target. The target cells are radiolabeled with ^{51}Cr and then are cocultured with density gradient, separated peripheral blood mononuclear cells, or a preparation of enriched NK cells. There is no requirement for a sensitization step, and cytolytic activity is tested immediately after cell processing. The assay method is similar to the assay described for T-cell cytotoxicity using various ratios of effector cells to target cells. The results are expressed either as a percentage of cytotoxicity or in lytic units.

Proliferation and cytokine production can also be assessed in NK cells using nonlabeled target cells as stimulants. The clinical utility of this approach has not been established.

The NK cell appears to be important in dealing with specific viral infections, allograft rejection, and tumor rejection. Absence of NK cell activity appears to be rare, with patients reported to have undetectable NK cell function in association with recurrent herpes infection (73). In addition, diminished NK cell function has been noted in certain situations, including in patients with advanced cancer.

Antibody-Dependent Cellular Cytotoxicity

The NK cell is one of several different cell types that mediate *antibody-dependent cellular cytotoxicity* (ADCC) (69). In this type of cytotoxicity assay, the cytotoxic effector cells attach by their IgG Fc receptors to IgG bound to the target cells. The actual role of ADCC in host defenses is still unknown, although it is theorized to play a part in the eradication of IgG-coated tumor or infected cells. ADCC is tested with a standard cytotoxicity assay system using ^{51}Cr-radiolabeled target cells that have been preincubated with anti–target cell antibody (IgG). Various effector cell–to–target cell ratios are used, release of the radioactive label into the supernatant is measured as a reflection of target cell lysis, and the results are expressed either as a percentage of cytotoxicity or in lytic units. The clinical application of ADCC testing is primarily of research interest at this time.

Cytokine-Enhanced Cytotoxicity

Preincubation of NK cells with specific cytokines, including interferons and IL-2, has been noted to *enhance in vitro* cytotoxicity. Interferon addition directly to the *in vitro* cytotoxicity assay enhances the level of target cell lysis (74). Alternatively, preincubation of the effector cells with IL-2 for 24 hours or longer increases not only the level of cytotoxicity, but also the range of susceptible target cells (75). Thus, *in vitro* preincubation of effector cells with IL-2 results in the lysis of target cells that would not be killed in a standard NK cell assay (e.g., autologous tumor cells). These IL-2–stimulated cytotoxic cells have the phenotypic characteristics of NK cells and are referred to as lymphokine-activated killer (LAK) cells. The observation that IL-2 enhances the effectiveness of cytotoxic cell lysis of tumor cells has led to cellular immunotherapy protocols for selected cancers. In these studies, mononuclear cells are obtained from patients, are cultured *in vitro* with IL-2 to generate LAK cells, and then are infused into the patient for possible cellular antitumor effect.

EVALUATION OF NEUTROPHIL FUNCTION

The *evaluation of neutrophils* can be separated into specific features of normal cell function that include chemotaxis, phagocytosis, generation of the respiratory burst, and microbial killing (Chapter 20) (76,77). In addition to evaluating each of these processes, assessment for the presence of the specific leukocyte adhesion molecules, CD11/CD18, also may be indicated in selected patients who have a history of recurrent bacterial infections with a predilection for the skin, periodontal tissue, and lungs. More than 15 congenital disorders affect neutrophil function, including congenital neutropenia as well as disorders of motility, adhesion, chemotaxis, granular unction, and oxidative metabolism. In addition, there are age-related changes in neutrophil function, as well as a various acquired phagocytic defects secondary to disease, pharmacologic agents, and other influences.

Neutrophil Chemotaxis

Directed cell migration can be studied using isolated peripheral blood neutrophils in an apparatus called a Boyden chamber (78,79). This device is designed with a millipore filter membrane that allows separation of the cells from a solution containing a chemoattractant (e.g., C5a, formyl-methionyl-leucyl-phenylalanine [FMLF]) or control material. The neutrophils are incubated in the chamber for a predetermined period to allow for directed cell movement in response to the chemoattractant. The filter is removed and stained to allow enumeration of neutrophils that migrated toward the chemoattractant. These results are compared with migration in response to a control stimulus as well as the response of normal neutrophil in the same assay system. An alternative approach involves evaluating chemotaxis under agarose in response to standard chemoattractants (79,80). Neutrophils are placed in a central well cut in the agarose; chemoattractant and control solution are placed in two different wells, equidistant from the site of the cells. The agarose plate is incubated for 1 hour, to allow directed and random cell migration. The cells are fixed, and the migration pattern is visualized under a microscope. The distance from the origin to the leading edge of cells in response to the chemoattractant is measured and is compared with the random movement of cells in the direction of the control well. Chemotaxis assays must be set up with normal controls, and results also must be compared with age-matched data. In addition, *in vivo* chemotaxis can be studied with the Rebuck skin window method by making a superficial skin abrasion and covering it with a sterile coverslip. The numbers of cells that migrate onto the coverslip are counted periodically over 1 day.

Abnormalities of chemotaxis have been found in the leukocyte adhesion deficiency, the Chédiak-Higashi syndrome, the Pelger-Huët anomaly, juvenile periodontitis, and some patients with the hyper-IgE syndrome. Certain drugs may interfere with chemotaxis, and monocytes can secrete substances that inhibit chemotaxis. Demonstration of a significant decrease in neutrophil response to chemoattractants *in vitro* is usually associated with a diminished inflammatory response *in vivo.*

Oxidative Burst

The oxidative response that follows neutrophil activation and phagocytosis increases hexose monophosphate shunt activity, oxygen consumption, hydrogen peroxide production, and superoxide radical formation. Functional screening of this process can be performed using qualitative assays such as the nitroblue tetrazolium (NBT) test or using a flow cytometric assay (45,81,82 and 83). In the NBT assay, stimulation of neutrophils with a potent activating agent such as phorbol myristate acetate (PMA) induces *oxidative burst* (81). This reduces the NBT dye within the cell and generates blue insoluble crystals of formazan, which can easily be detected by microscopic examination. Absence of NBT dye reduction is a classic finding in patients with chronic granulomatous disease. Similar information can be obtained using a flow cytometric method in which the neutrophils are loaded with DHR (discussed in the section on intracellular flow cytometry); after PMA activation, the increase in intracellular hydrogen peroxide produces a marked increase in fluorescence (45). This method has proven to be an extremely reliable approach to the diagnosis of chronic granulomatous disease and X-linked carriers of this disorder (83).

Quantitative assessment of the oxidative burst can be performed with the chemiluminescence assay or the ferricytochrome C reduction test (79). The chemiluminescence assay measures oxidative burst–dependent generation of light (energy) by activated neutrophils. Addition of ingestible particles (e.g., zymosan) or a soluble stimulator (e.g., PMA), activates neutrophils and induces phagocytosis; this results in the release of light (energy) which, in the presence of luminol, can be measured with a scintillation counter. Alternatively, the reduction of ferricytochrome C, manifested by increased light absorbance at 550 nM, is an accurate measure of superoxide release. A patient response in either the chemiluminescence or cytochrome C reduction assays should be compared with normal responses, and the results usually parallel the findings with the NBT or the flow cytometry tests.

Microbial Killing

Assessment of the capacity of neutrophils to kill microorganisms involves mixing neutrophils with opsonins and bacteria *in vitro* (79). The cell-free supernatant and the lysed leukocyte pellet are cultured for residual bacterial growth at prescribed time intervals. Patients' cells are compared with normal cells for both the uptake of organisms from the culture supernatant and the effectiveness of intracellular killing. Different types of microorganisms may yield varied results in this type of neutrophil assay; for example, cells from patients with chronic granulomatous disease demonstrate markedly diminished killing of *Staphylococcus aureus* but relatively normal killing of *Escherichia coli.* Accuracy of this assay requires establishing optimal bacteria-neutrophil ratios and well-defined normal controls.

Adhesion Molecule Testing

The evaluation of three related *adhesion molecules,* leukocyte factor antigen-1, Mac-1, p150,95, has evolved from the description of patients with a defect in the expression of these cell-surface receptors (77,84). These patients were noted to have recurrent infections with minimal inflammatory response, delayed wound healing, and persistent neutrophilia. All three of these molecules are heterodimers, each consisting of a unique a-chain protein (CD11a, CD11b, CD11c) linked to a common b-chain protein (CD18). They can be identified flow cytometrically with monoclonal antibodies to the a chains as well as to the common b chain. Patients with leukocyte adhesion deficiency type 1 have depressed or absent expression of these surface antigens in both resting and activated neutrophils related to a defect in the b-chain gene. Additional features in this disorder include decreased cell adherence, chemotaxis, and phagocytosis. This abnormality in expression of b integrin expression is found on other leukocytes and results in abnormalities in selected *in vitro* lymphocyte assays.

EVALUATION OF MONOCYTE-MACROPHAGE FUNCTION

The *evaluation of monocyte function* can be directed at the assessment of antigen presentation for T-cell proliferation, ADCC, tumor cell cytotoxicity, chemotaxis, microbial killing, and cytokine receptor expression. The availability of these tests has been limited primarily to research settings because the clinical indications for testing monocyte function are not well defined (85,86).

Antigen Presentation

Antigen presentation can be evaluated by adding soluble antigen to a preparation of monocyte-enriched cells. These cells can be obtained from peripheral blood mononuclear cells either by harvesting plastic adherent cells or by using a discontinuous density gradient (Percoll) centrifugation. After an incubation period, remaining soluble antigen is removed by washing, and the monocytes are then cocultured with autologous (or allogeneic MHC class II–matched) T cells. Memory CD4 T cells with the appropriate antigen receptor are activated through interaction with the processed antigen displayed on the monocytes' class II MHC antigens (86). The T cells are then cultured for a defined time, and cell proliferation is assayed using standard methods. This evaluates the capacity of monocytes to process and present antigen to T cells. However, an abnormal result would require additional studies because this can be the result of either a monocyte defect in antigen processing and presentation or a deficiency in T-cell function.

Monocyte-Mediated Killing

Evaluation of monocyte-mediated ADCC uses a standard assay system. The choice of ^{51}Cr-labeled target cell determines the primary effector cell being assayed: IgG-coated chicken red blood cells reflect predominantly monocyte-mediated killing, whereas IgG-coated Chang cells (a cultured tumor cell) are primarily NK cell targets. Assays of monocyte-mediated tumor cell killing are also available. Assessments of monocyte chemotaxis and microbial killing represent specialized testing performed infrequently. Testing requires using monocyte-enriched cells and assays analogous to those described in the section of this chapter on neutrophils.

Interferon Receptor Deficiency

Patients with recurrent *Mycobacterium avium-intracellulare* infections were identified who had a deficiency in the expression of the *interferon-g receptor* (87). This appears to define a subgroup of patients with more limited recurrent opportunistic infections, and the defect can be detected using flow cytometry, to evaluate for expression of the interferon-g receptor on monocytes. The method requires identification of monocytes based on standard gating procedures and comparing the binding of a labeled anti–interferon-g antibody between normal cells and patients' cells. The receptor defect has been associated with abnormalities in the genes coding for either of the protein chains in the interferon-g receptor (87,88).

ASSESSMENT OF COMPLEMENT

The *complement system* is made up of multiple protein components, some with subcomponents, which can be activated in a cascadelike fashion (89,90). In addition, plasma proteins and membrane proteins act to regulate the complement cascade. Activation of complement has a significant role in host defenses through its opsonic and lytic activity, as well as by providing inflammatory mediators, promoting the catabolism of circulating immune complexes, and playing a role in regulation of the immune response. The three pathways of complement activation are the classical, lectin, and alternative pathways (Chapter 26). The first is initiated by immune complexes formed from the interaction of IgG (IgG1, IgG2, IgG3) or IgM with specific antigen; the second is formed by the interaction of protein lectins such as mannan-binding lectin to surfaces rich in the appropriate sugar, and the third can be activated by the presence of repeating polysaccharides (e.g., lipopolysaccharide) and certain other polymeric structures. The alternative pathway is greatly accelerated by bound antibody of any class, and it also amplifies classical pathway activation. The complement proteins are labile, and complement activity is lost if the serum sample is not handled properly. To prevent loss of complement activity, samples must be stored at –70°C as well as diluted in special buffers and placed on ice during test procedures.

Complement Activity

Activity of the classical pathway of complement can be evaluated using the total hemolytic complement (CH50) assay (91). In this test, sheep red blood cells are sensitized by preincubating the cells with an anti–red cell antibody (hemolysin). Addition of various dilutions of patient or control sera serves as the source of complement for an aliquot of sensitized sheep red blood cells. The tubes are incubated at 37°C, and the degree of red cell lysis is measured by assaying the supernatant spectrophotometrically for hemoglobin released from lysed sheep red cells. Standard lysis curves are generated, and the CH50 result is reported as the inverse of the serum dilution that produces 50% lysis of the sensitized red cells. Currently, modifications of the traditional CH50 tube test use microtiter plates to simplify the procedure. There is also a commercial hemolytic complement test (CH100) in which test serum is added to wells cut in agar containing sensitized sheep red blood cells; after incubation, the diameter of red cell hemolysis around each well is determined and plotted on a standard curve. The lability of complement components means that improper sample handling or storage can result in diminished or absent total hemolytic complement activity with otherwise normal samples.

The most common abnormality of the CH50 assay is increased complement activity resulting from an acute-phase response (91,92). This results from a generalized increase in protein synthesis, including the complement components, and can be seen in a variety of inflammatory diseases. The opposite situation, depression in CH50 activity, can result from either hyposynthesis or hypercatabolism of the complement components. An extreme case of the former is seen with congenital deficiency of a component, in which the CH50 is zero because of the absence of any individual classical pathway component (93). This test has proven to be an effective means for identifying congenital component deficiency, and it is particularly useful in diagnosing late component defects that are observed in certain patients with recurrent *Neisseria* infections. The alternative explanation for depressed complement activity, hypercatabolism of complement components, is most frequently associated with complement activation resulting from immune complex generation. This would be expected in a systemic autoimmune disease, such as systemic lupus erythematosus, in which the generation of immune complexes is significant. The CH50 assay has been found to be abnormal at some period in most patients with systemic lupus erythematosus, but the clinical utility of this finding remains controversial (94). In most patients, alterations in CH50 activity has not proven to be a reliable predictor of impending disease flare or a satisfactory monitor of therapeutic efficacy.

Assessment of the alternative complement pathway is performed only in research laboratories, because these data are required in few clinical situations. The assay, referred to as the APH50 test, consists of adding various dilutions of test serum to (nonsensitized) rabbit red blood cells and assaying for hemolysis. The rabbit red cell expresses surface molecules that spontaneously activate the alternative complement pathway in the absence of specific antibody. The data generated in this test are handled in the same fashion as those from a CH50 test, with the results expressed as the inverse of the serum dilution producing 50% red blood cell lysis. The presence of serum antibody reactive with rabbit red blood cells would increase the hemolytic activity in the APH50.

Component Testing

Evaluation of specific complement components may be included in the laboratory evaluation of suspected congenital deficiency of a component, as well as immune-mediated inflammatory diseases. Component testing has limitations similar to those of the CH50 assay when used as a monitor of inflammatory disease. Immunoassays for complement components are technically the simplest means of assessing for component concentration, and they usually involve either radial

immunodiffusion or nephelometric testing. Most clinical laboratories use one of these methods to quantitate selected complement components, including C3, C4, factor B, and C1 inhibitor. The immunologic assessment of these proteins is satisfactory, except in the unusual situation of a functionally deficient component that is antigenically indistinguishable from its normal counterpart. An example of this is observed in some patients with hereditary angioedema, a condition that results from a deficiency of the complement regulatory protein, C1 inhibitor. This disease is associated with recurrent, nonpruritic swelling of the skin, respiratory tract, and gastrointestinal tract. A few patients with hereditary angioedema have normal levels of C1 inhibitor by immunoassay because of a functionally abnormal protein that is antigenically indistinguishable from normal C1 inhibitor. Thus, in these uncommon patients, only a functional assay (but not the immunoassay) for C1 inhibitor will establish the diagnosis.

Functional assays evaluate the actual activity of a specific complement component. The indicator system is usually a CH50 assay constructed to contain all components except the one tested. The unknown sample is added to provide this missing component and is compared for degree of red cell hemolysis with the results generated using a normal serum sample. These assays are labor intensive and generally are performed only in specialized laboratories that focus on complement testing. The main clinical application for component testing is in a patient with clinical findings suggesting a complement defect with laboratory findings of depressed or absent CH50 activity. Additionally, functional testing may be indicated in disorders of the various complement regulatory proteins, particularly in the clinical setting suggestive of C1 inhibitor deficiency (see earlier).

Assessment for evidence of complement activation as a result of immunologically mediated disease theoretically could predict flares or therapeutic efficacy of interventional therapy and could be useful in individual patients with systemic lupus erythematosus (95). However, the overall prognostic or predictive utility with either CH50 or component assays remains limited (96). The reason may be that the level of any component reflects the net balance of production and consumption. Studies suggest that assaying complement cleavage products could be a more reliable indicator of complement activation despite their short half-life and the high binding affinity of their specific receptors (97,98). These reports have used tests directed at one or more of the following cleavage products: C4d, C3a, iC3b, Bb, SC5b-9 (99). The ultimate clinical utility of this approach for the assessment of complement activation in clinical settings awaits additional studies.

Immune Complex Assays

Assessment of circulating immune complexes can be performed using various different techniques (100,101). Standard approaches currently used include solid-phase immunoassays to detect immune complexes through the binding of a complement component attached to the antigen-antibody complex. Included are three methods: the anti-C3 assay using antibodies to immune complex–bound C3 products (iC3b, C3d, C3dg); the C1q binding test that uses immobilized C1q to bind immune complexes containing IgG and IgM; and the conglutinin assay, which uses an immobilized bovine protein (conglutinin) that attaches to immune complex fixed iC3b. The immune complex detection step in all these systems involves addition of a labeled antibody that binds human Ig. The results are expressed as micrograms of immune complex based on a standard that is derived from a heat-aggregated IgG. Additional methods include the Raji cell assay, which uses an EBV cell line expressing receptors for C3b, iC3b, and C3d to capture immune complexes and the radiolabeled C1q precipitation assay. The clinical utility of testing for circulating immune complexes has not been clearly established, and detection remains primarily of research interest.

IN VITRO ALLERGY TESTING

Immunoglobulin E Quantitation

IgE is present in concentrations that are four to five orders of magnitude less than concentration of IgG, IgA, and IgM. This means that the determination of IgE concentrations requires alternative testing techniques. The most common method for IgE detection involves a sandwich immunoassay in which an nti-IgE antibody is immobilized on a solid phase (102,103 and 104). The sample is added to the antibody-coated solid phase (tube, microtiter plate, beads), which allows the binding of IgE. This is followed by a washing step and the addition of a labeled (radioactive, enzyme) second antibody to IgE. The amount of labeled antibody attached correlates directly with the quantity of IgE in the sample. A World Health Organization standard for IgE was developed to allow laboratories to standardize test results (103).

The measurement of total IgE is not a useful screen for allergy because of significant overlap between allergic and nonallergic subjects (103,104). It does appear that infants with elevated IgE levels have increased risk of allergies, and adults with extremely low IgE levels (less than 50 ng/mL) are relatively unlikely to have allergies. Marked elevation in IgE levels is seen commonly in patients diagnosed with the Wiskott-Aldrich syndrome and hyper-IgE syndrome, as well as with systemic parasitism. Serial IgE levels are useful in assessing the effectiveness of corticosteroids in the treatment of patients with allergic bronchopulmonary aspergillosis.

Allergen-Specific Immunoglobulin E

Testing for allergen-specific IgE is usually performed with epicutaneous skin tests. *In vitro* testing for allergen-specific IgE is usually reserved for situations that include extraordinary sensitivity to allergen, abnormal skin conditions, and required medication that interferes with skin test results (104,105). The *standard in vitro* test uses specific allergen attached to a solid-phase support (allergosorbent) as the test substrate. Serum is added to the allergosorbent to allow any specific antibody to bind, unbound antibody is washed away, labeled anti-IgE is added, and the amount of bound label is measured as a reflection of the allergen-specific IgE concentration. This test is called a *radioallergosorbent test* when the anti-IgE antibody is labeled with a radionuclide. It is also possible to use alternative reporters, including enzyme- or fluorochrome-labeled anti-IgE, in the allergosorbent test and to measure color change or fluorescence. The most recent assays use a World Health Organization IgE reference standard and express the results as the level of allergen-specific IgE per unit volume rather than using a numeric grading system. Studies using this new allergosorbent system suggest that the level of allergen-specific IgE may predict a systemic reaction in children with certain food allergies (106). The major obstacle in interpreting these data relates to the difference in results generated with assays from different manufacturers. In light of this situation, standardization of the various reagents and assays represents a desirable goal for *in vitro* allergen-specific testing.

The basophil histamine release assay is an alternative *in vitro* approach for assessing allergen-specific IgE that theoretically is more representative of an allergic reaction (107,108). The indicator system involves the addition of an allergen preparation to the patient's whole blood or separated leukocytes as a source of basophils. The allergen cross-links specific IgE bound to the basophil surface, which induces mediator (e.g., histamine) release similar to an *in vivo* allergic response. Histamine is measured in the supernatant and is compared with the total basophil histamine content. This test also can be used to examine the effect of drugs and other substances on the allergic response. It generally offers no advantage over skin testing and is primarily a research assay.

Mast Cell Products

Levels of plasma tryptase, plasma histamine, and urinary metabolites of histamine can be assayed as a measure of systemic *mast cell degranulation* (109,110 and 111). Testing for tryptase and histamine is performed by immunoassay, whereas evaluating histamine metabolites is done by high-performance liquid chromatography. An example of a recognized use of these techniques is the evaluation of plasma tryptase levels after a systemic shocklike reaction and for patients with systemic mastocytosis (111).

TEST ASSESSMENT

Sensitivity, specificity, and predictive value are used in evaluating the effectiveness of individual tests applied to specific clinical situations. With increasing concerns over health care costs, it will become even more important to choose the most appropriate laboratory test based on these criteria.

Sensitivity

Sensitivity is the frequency of positive test results in patients with a specific disease.

$$\text{Sensitivity (\%)} = \frac{\text{Number of true positives}}{\text{number of true positives + false negatives}} \times 100$$

Specificity

Specificity is the frequency of negative test results in persons without a specific disease.

$$\text{Specificity (\%)} = \frac{\text{Number of true negatives}}{\text{number of true negatives + false positives}} \times 100$$

Predictive Value

Predictive value is calculated both for positive and for negative test results and is influenced by disease prevalence in the population tested.

Predictive value of a positive test =

$$\text{Predictive value of a positive test} = \frac{\text{Number of true positives}}{\text{number of true positives} + \text{false positives}} \times 100$$

Predictive value of a negative test =

$$\text{Predictive value of a negative test} = \frac{\text{Number of true negatives}}{\text{number of true negatives} + \text{false negatives}} \times 100$$

Appendix B GLOSSARY

Accommodation Xenograft resistance to acute vascular rejection.

Adaptive immunity The ability to recognize a foreign antigen and develop a specific immune response to antigens.

Adjuvant Substance able to potentiate an immune response.

Adoptive transfer Transfer of the immune state from one subject to another via lymphoid cells or antibody (the latter condition is called passive immunity).

Affinity chromatography Technique by which a material with a selective affinity for a substance is coupled to an inert matrix. The substance to be purified interacts with over the material-matrix complex and adheres to it.

Agammaglobulinemia Absence of immunoglobulin in plasma. Properly speaking, this term is a misnomer because people and animals, even if immunodeficient, always have *some* immunoglobulins. *See also Hypogammaglobulinemia.*

Agglutination Reaction in which particles of antigen or particles coated with antigen are clumped by specific antibody.

Allele One of a pair of genes at a particular locus.

Allelic exclusion Expression of just one gene in a cell containing two allelic genes at that locus.

Allergen Antigenic substance capable of inducing sensitization by virtue of its ability to stimulate production of IgE.

Allergy Altered state of immunologic reactivity that can be cellular or humoral.

Allogeneic Immunologic relation between genetically different members of one species.

Allograft Graft of a tissue or organ placed in a genetically dissimilar recipient (previously *Homograft*).

Allotype Structurally different set of proteins present in one species.

Alpha-fetoprotein (AFP) A specific b-globulin, similar to albumin, that is present in serum and prominent during fetal life.

Alternative complement pathway System of complement proteins, that can be activated without antigen-antibody complexes, including properdin and factors D, B, C3b, finally activating C3 through C9.

Amyloidosis Disorder of protein folding in which normally soluble proteins misfold and aggregate as insoluble amyloid fibrils, with cross-b structure, and these accumulate in the tissues causing disease.

Anamnesis Positive immunologic memory: a second or later exposure to specific antigen causes a heightened immunologic response.

Anaphylactoid reaction Clinical picture similar to that of anaphylaxis.

Anaphylatoxins Group of complement protein derived peptides (C3a and C5a) that cause mast cell activation and histamine release.

Anaphylaxis Clinical syndrome caused by specific antigen reacting with IgE bound to mast cells and basophils, leading to one or more of the following: rhinitis, wheezing, angioedema, urticaria, cardiac dysrhythmia, hypotension, and rarely death.

Anchor residues Positions accommodating only specific amino acids in MHC peptide binding clefts.

Anergy Clinically, the inability to express delayed-type hypersensitivity via skin test challenge. Also, a state of unresponsiveness to antigen induced in T or B cells. *See also Tolerance.*

Angiocentric Growing around and into blood vessels.

Angiogenesis The formation of new blood vessels.

Antibody (Ab) Immunoglobulin produced by B cells that is capable of specifically combining with antigen.

Antibody combining site Cavity formed by the variable segments of the heavy (H) and light (L) chains of an antibody molecule, into which the specific antigenic epitope fits.

Antibody-dependent cell-mediated cytotoxicity (ADCC) Form of cytotoxicity in which an antibody-coated target cell is killed by an effector cell interacting with the Fc portion of the bound antibody.

Anticardiolipin (aCL) antibodies Autoantibodies detected in a cardiolipin ELISA; in the antiphospholipid syndrome the actual antigen detected is b_2-glycoprotein I, which itself binds the cardiolipin.

Antigen Substance capable of inducing a specific immunologic response.

Antigenic competition Interference of the immune response to an antigen produced by immunization with another, unrelated antigen.

Antigenic determinant Portion of an antigen that determines the specificity of the immune response. *See also Epitope.*

Antigenicity The ability of a molecule to be recognized by the product of a preexisting immune response.

Antigenic modulation The covering or alteration of a cell surface antigen following its interaction with specific antibody.

Antigen presentation Antigen processing and display of resultant MHC-peptide combination at cell surface.

Antigen-presenting cells (APC) Cells capable of presenting antigen to T and B cells. They include monocytes and macrophages, B cells, dendritic cells, and endothelial cells.

Antigen processing Conversion of an intact protein into an entity that can be recognized by T cells.

Antiglobulin (Coombs) test Method of detecting antibody bound to cells (direct test) or antibody in serum capable of binding to cells, usually red blood cells (indirect test).

Antilymphocyte serum Serum (usually heterologous) raised by immunization with lymphocytes and designed for immune suppression.

Antinuclear antibodies (ANA) Antibodies directed against nuclear antigens, such as DNA or histones, and associated with a number of autoimmune syndromes.

Antitoxins Antibodies capable of combining with and inactivating toxins, particularly those made by bacteria.

Apheresis Process of selectively removing blood elements or plasma. *See also Plasmapheresis.*

Apoptosis Programmed cell death through fragmentation of a cell into membrane-bound particles that are then eliminated by phagocytosis.

Arthus reaction Local inflammatory reaction, usually mediated by antibodies, one form occurs when antigen is introduced into a previously immunized subject.

Association constant (K value) Mathematic representation of the binding affinity between two molecules, usually an antibody and an antigen.

Atopy States of immediate hypersensitivity mediated by IgE, genetically influenced and including one or more of the following: allergic rhinitis, allergic asthma, urticaria, eczema (atopic dermatitis).

Autoantibody Antibody directed to self antigens.

Autoantigen Self antigen.

Autograft Tissue or organ graft transferred from one place to another in the same recipient.

Autoimmunity Immunologic reactivity to self antigens.

Autoradiography Method to detect radioisotopically labeled materials in tissue sections or cell suspensions by overlaying x-ray or photographic film.

Bacille Calmette-Guérin (BCG) Attenuated strain of *Mycobacterium bovis* used for immunization against M. *tuberculosis.*

Backcross Mating of a parental animal to a related hybrid.

B cells (B lymphocytes) Lymphocytes derived from bone marrow or yolk sac (or bursa of Fabricius in birds) capable of making antibodies, or in the developmental line of such cells.

Bence-Jones proteins Monoclonal light chains present in the urine of some patients with paraproteinemias.

Blast cell Large immature lymphoid or other cell with a large nucleus and active biosynthesis.

Blocking antibody Immunoglobulins capable of blocking cell-mediated lympholysis or promoting growth of tumors. Also, IgG antibodies capable of binding antigen and preventing IgE mediated mast cell degranulation.

Bradykinin Proinflammatory nonapeptide derived enzymatically from a serum b_2-globulin precursor.

Bursa of Fabricius Lymphoid organ near the cloaca of birds that controls the development of B cells.

Cadherins Calcium-dependent adhesion molecules.

Carcinoembryonic antigen (CEA) Antigen expressed on fetal endodermal cells and on some gastrointestinal malignant cells, particularly carcinoma of the colon.

Cardiolipin Material primarily composed of phospholipids; derived from beef heart; used as a substrate in antitreponemal serologic tests.

Carrier Immunogenic material which, when coupled to a hapten, renders the hapten immunogenic.

C3b receptor (CRI) Molecular complex on cells able to bind the C3b fragment of complement.

CD (cluster of differentiation) Denotes a molecule recognized by a monoclonal antibody. Usually the molecule is a cell-surface marker.

Cell-mediated cytotoxicity The strategy used by effector T cells to destroy, by direct contact, cells expressing the peptide/MHC complex to which their antigen receptors are directed.

Cell-mediated immunity (CMI) Immunity mediated by T cells without a requirement for B cells or antibody.

Cell-mediated lympholysis (CML) Specific destruction of lymphoid, tumor, or other target cells by specific T cells, usually of the CD8 class.

Centimorgan Unit of distance on a chromosome, equal to a 1 percent frequency of recombination between nearby genes.

Central lymphoid organs Organs essential for the ontogeny of lymphocytes, including the thymus and bone marrow (and in birds the bursa of Fabricius).

Chemokines Chemoattractant molecules that direct movement of hematopoietic cells.

Chemotaxis Process by which mobile cells are attracted to a source of cytokines.

CH_{502} unit Measure of lytic ability of serum in a standard hemolytic complement test.

Classical complement pathway Cascade of enzyme-substrate and protein-protein interactions of serum proteins beginning with C1 and ending with C9.

Class I MHC antigens Histocompatibility antigens encoded by A, B, and C MHC loci in humans and by other loci in animals.

Class II MHC antigens Histocompatibility antigens encoded by HLA-DR, HLA-DP, and HLA-DQ antigens in humans and by other antigens in other species.

Class III MHC antigens C2, C4, and complement factor B encoded by genes within the MHC.

Clonal anergy Antigen-induced unresponsiveness in a clone of B cells.

Clonal deletion Removal of clones of lymphocytes, primarily during ontogeny-a mechanism thought to be largely responsible for the absence of self-reactive lymphocytes.

Clonal selection theory Concept developed independently by Burnet and Talmage in which clones of lymphocytes with different antigen receptors develop randomly prior to antigen exposure, and where self-reactive clones are generally deleted.

c-*myc* gene Oncogene.

Cognate recognition MHC restricted interaction with a specific antigen.

Cohn fractionation Method of separating serum globulins on a large scale. Cohn fraction II contains most of the serum immunoglobulins.

Cold agglutinins Antibodies that agglutinate bacteria or cells more efficiently in the cold than at 37°C.

Colony-stimulating factors (CSFs) Group of hematopoietic cytokines able to promote the growth of hematopoietic stem cells.

Complement Complex series of serum proteins activated by antigen-antibody complexes and other substances; responsible for modulation and amplification of immunologic and inflammatory reactions.

Complement fixation Standard serologic method to detect the combination of antigen and antibody by depletion of complement via the antigen-antibody complex.

Concanavalin A (Con A) Glycoprotein plant lectin derived from the jackbean; used for polyclonal stimulation of T cells *in vitro.*

Congenic Denotes a strain of animal (usually mice) in which a portion of the genome, usually part of the histocompatibility complex, has been substituted from a different strain by appropriate backcrossing. (Previously *Congenic resistant.*)

Constant region Carboxy-terminal region of H or L chains that is identical in amino acid sequence with other cognate regions in molecules of the same class, subclass, or allotype.

Contact pathway (intrinsic pathway of coagulation) The portion of the coagulation pathway activated by the plasma being in contact with an activating surface such as collagen in vivo or glass *in vitro.*

Contact sensitivity Form of delayed hypersensitivity to antigens expressed on the skin or mucous membranes.

Contrasuppression Inhibition of suppressor activity.

Copolymer Polymer, either random or ordered, of at least two chemical substances.

Coproantibody Antibody present in the feces.

Counterimmunoelectrophoresis (CIE) Form of immunodiffusion in agar in which antigen and antibody diffuse toward each other in an electrical field.

C-reactive protein (CRP) The classical acute phase protein, a member of the pentraxin family, that increases in concentration in the plasma in response to most forms of tissue injury, infection, and inflammation. It binds to sugar moieties on microbes.

CREST Acronym for five manifestations of a rare limited form of scleroderma: *c*alcinosis, *R*aynaud's phenomenon, *e*sophageal dysmotility, *s*clerodactyly, *t*elangiectasis.

Cross-priming Presentation of cellular antigens from a nonpresenting cell by antigen-presenting cells.

Cross reaction Reaction of an antibody to an antigen structurally similar to the antigen that induced the antibody.

Cryofibrinogenemia Presence of reversibly cold-precipitable fibrinogen in blood.

Cryoglobulins Gamma globulins that precipitate in the cold.

Cryopathies Cold-related clinical syndromes that arise secondary to cold agglutinins or cryoglobulins.

Crypts Invaginations in the epithelium of lymphoid tissue in Waldeyer's ring.

Cytokine Substance, usually of low molecular weight and not antigen-specific, that is secreted by one cell (a monocyte or lymphocyte) and acts on another cell.

Cytophilic antibodies Immunoglobulins that bind to cells by their Fab or Fc regions.

Delayed hypersensitivity Prototype inflammatory reaction initiated by specific antigen and the cognate T cells leading to a cellular infiltrate within 24 to 48 hours.

Dendritic cells (DCs) Nonlymphoid bone marrow-derived cells that are efficient in antigen presentation.

Dermographism Urticarial lines appearing on skin along the course of a stroke with a sharp object.

Desmoplakins Intracellular plaque proteins of desmosomes.

D gene region Diversity segment of the genome that encodes part of the hypervariable region of the immunoglobulin heavy chain.

Direct agglutination Clumping of erythrocytes, bacteria, or other antigenic particles by antibody.

Direct immunofluorescence Detection of antigens by antibody labeled with a fluorescent dye.

Domains Segments of heavy or light chains showing homologous structure; stabilized by disulfide bonds.

Dutcher bodies Intracytoplasmic inclusions due to cytoplasmic Ig.

Dysgammaglobulinemia Condition in which one or several (but not all) immunoglobulin classes are over-or underproduced.

EA or EAC rosette Cluster of *e*rythrocytes coated with *a*ntibody and/or *c*omplement adhering to cells with receptors for immunoglobulin Fc or complement.

EBER Small nonpolyadenylated RNAs expressed in EBV-infected lymphoblasts.

EBV p62 nuclear antigen (EBNA) Epstein-Barr virus nuclear antigen. A set of molecules encoded by the herpes virus Epstein-Barr virus found in the nucleus of infected cells.

ECF-A (eosinophil chemotactic factor of anaphylaxis) Peptide, derived mainly from basophils and mast cells, that is chemotactic for eosinophils.

Electroimmunodiffusion Precipitation method in semisoft medium in which antigen precipitates with antibody during electrophoresis. Also called “rocket electrophoresis.”

Electrophoresis Separation of molecules, according to their net charge, in an electrical field.

Endocytosis Carriage of external substances into a cell by pinocytosis, phagocytosis, or both.

Endogenous pyrogens Substances produced by macrophages and other cells that cause fever by acting on the thermoregulatory center in the hypothalamus. Includes IL-1 and IL-6.

Endotoxins Lipopolysaccharides derived from cell walls of gram-negative bacteria.

Enhancement Increased survival of tumors or allografts in animals immunized by those materials, presumably working via antibody.

Enzyme-linked immunosorbent assay (ELISA) A more convenient development of the (radioactive) solid phase radioimmunoassay, whereby the presence of bound antibody is detected by a second antibody that binds to the first and is linked to an enzyme; this enzyme acts on a substrate to generate a color change.

Episome Extrachromosomal covalently closed circles of DNA.

Epitopes Antigenic determinants.

Epstein-Barr virus (EBV) A member of the herpes virus family; associated with a number of human malignancies.

Equilibrium dialysis Method of measuring the affinity by which a small molecule binds to a larger one.

Equivalence Ratio of antigen and antibody concentration that produces maximal precipitation.

E rosette Cluster (rosette) of erythrocytes adhering to a T cell.

Exon Coding strip of DNA.

Experimental allergic encephalomyelitis (EAE) Autoimmune disease produced by immunizing an animal with brain tissue or substances derived from brain tissue together with adjuvant.

Extravasation The process by which white blood cells cross the endothelium to leave blood vessels and enter tissues.

Fab Antigen-*b*inding fragment of an immunoglobulin molecule containing the NH_2-terminal ends of the H and L chains.

F(ab)'$_2$ Fragment of an immunoglobulin molecule containing the NH_2-terminal portions of two H-L chains.

Fc fragment Crystallizable portion of an immunoglobulin molecule containing the C-terminal portions of the H chains.

Fc receptor Receptor present on various cells for the Fc (C-terminal) portion of immunoglobulin molecules.

a-Fetoprotein (AFP) b-Globulin, similar to albumin, that is present in one species.

F_1 generation First generation of offspring after a designated mating.

F_2 generation Second generation of offspring, usually from the mating of two F_1 individuals.

Fibronectin Protein with adhesive properties that is important in the extracellular matrix of connective tissue.

Fluorescence Emission of light of one wavelength after irradiation by light of a different wavelength.

Fractional turnover (or catabolic) rate Percentage of the pool of a substance catabolized in unit time.

Freund's complete adjuvant Emulsion produced by mixing oil, an aqueous phase, and an emulsifier with killed mycobacteria. When mixed with antigen, it amplifies the immune response.

Freund's incomplete adjuvant Emulsion similar to Freund's complete adjuvant but without the mycobacteria.

Gell and Coombs classification A method for classifying mechanisms of immunopathologic damage: Type I, IgE-mediated hypersensitivity; Type II, antibody directed to cell-associated antigens; Type III, immune complex-mediated injury; Type IV, delayed hypersensitivity or cell-mediated immunity.

Germinal center Collection of macrophages and lymphocytes in lymph nodes and other organized peripheral lymphoid tissues.

b_2-Glycoprotein I (b_2-GPI) A phospholipid-binding plasma protein of unknown function that is the antigen for so-called “anticardiolipin” antibodies and some lupus anticoagulants.

Gm marker Genetically determined polymorphic marker on the heavy chain of human IgG.

Graft-*versus*-host disease (GVHD) Cell-mediated reaction mounted by donor T cells against histocompatibility antigens of the host (recipient).

Granulocyte colony-stimulating factor (G-CSF) Cytokine promoting the production of granulocytes from their precursors.

Granulocyte-macrophage colony-stimulating factor (GM-CSF) Cytokine promoting the production of granulocytes and macrophages from their precursors.

Haplotype Set of alleles on a single chromosome that are inherited as a closely linked set, generally considered in terms of MHC genes.

Hapten Antigenic determinant of low molecular weight that can act as an immunogen when coupled to an immunogenic carrier molecule.

Hassall's corpuscles Collections of thymic epithelial cells that may function in the *in situ* death of thymic lymphocytes.

Heavy chain diseases Heterogeneous group of paraproteinemias in which an aberrant clone of B cells makes monoclonal, but often incomplete, heavy chains without light chains.

Heavy chain (H chain) One of two identical polypeptide chains in an immunoglobulin molecule. It contains a V (variable region) at the NH_2 terminus and a C (constant region) at the carboxy terminus.

Helper T cells (Th) Subset of T cells, usually bearing CD4, which functions by cooperating with B cells or other T cells.

Hemagglutination inhibition Sensitive test for antigen in which the agglutination of antigen-coated particles by specific antibody is inhibited by specific antigen.

Hemolysin Antibody or other substance able to lyse erythrocytes.

Heterodimer Molecule composed of two different components.

High-dose tolerance Specific immunologic unresponsiveness induced by large amounts of specific antigen.

High endothelial venules (HEVs) Specialized vessels in the lymphoid system that permit passage of lymphocytes from the vasculature into the tissues.

Hinge region Segment between the first and second constant region domains in an H chain.

Histamine Potent bioactive amine produced by mast cells and basophils; important in IgE-mediated hypersensitivity and other reactions.

Histamine-releasing factors Heterogeneous collection of molecules able to promote histamine release by mast cells and basophils.

H-2 locus Main genetic (MHC) locus in the mouse controlling transplantation reactions and genetic control of the immune response.

Homocytotropic antibody Antibody that binds to cells of the same species.

Homopolymer Molecule composed of repeating units of the same chemical fragment.

Homozygous typing cells (HTCs) Cells from an individual who is homozygous at the class II MHC locus. These cells are used for mixed lymphocyte reaction (MLR) typing.

Horror autotoxicus Concept proposed by Ehrlich indicating that an individual cannot usually mount an immune reaction against his own tissues.

Human leukocyte antigen (HLA) Human MHC region and its products.

Humoral Term applied to soluble substances in body fluids. In immunology, it generally refers to immunoglobulins or complement components (or both).

Hybridoma Transformed cell in which somatic fusion of two parental cells results in a cell with genetic material from both parents.

Hyperacute rejection Accelerated form of graft rejection mediated by antibodies to donor (graft) MHC antigens.

Hypervariable regions Genetically determined areas of amino acid sequence variability in the V regions of H and L chains that determine the unique binding sites for antigen.

Hypogammaglobulinemia Quantitative deficiency of all immunoglobulin classes; often misnamed agammaglobulinemia.

Hyposensitization (desensitization) Production of allergen-specific immunologic hyporesponsiveness in sensitive individuals by repeated exposures.

Ia antigens (I region-associated antigens) Antigens produced by genes in the Ir region.

Iatrogenic Effects induced in patients as a consequence of treatment.

Idiotope Unique configuration on the antigen-combining site of an immunoglobulin or T cell receptor considered as an antigen (epitope).

Immediate hypersensitivity Rapidly developing immune reactions caused by antigen combining with IgE or another class of mast cell–sensitizing antibody. (Type I hypersensitivity of Gell and Coombs.)

Immune adherence Agglutination of particles (including microbes or cells) facilitated by antibody or complement (or both).

Immune complexes Protein complexes composed of antigen and antibody, with or without complement.

Immune elimination (clearance) Enhanced removal of antigen from the circulation by combining with its antibody; it leads to rapid clearance of antigen-antibody complexes by cells of the reticuloendothelial system.

Immune privilege The phenomenon whereby there are sites in the body that appear to preclude cell-mediated immune responses. In transplantation, the prolonged survival of allogeneic or xenogeneic tissue grafts in certain anatomic places.

Immune response (Ir) genes Genes in the MHC that control responses to specific antigens.

Immune surveillance Hypothesis stating that an important function of the immune system is to detect and destroy tumor cells bearing distinct antigens.

Immunization Induction of an immune response by natural exposure or deliberate stimulation of the immune system.

Immunocytoadherence Method for identifying antigen or antibody by the adherence of cells or particles coated with those reagents.

Immunoelectrophoresis Method of detecting antigen-antibody reactions that involves electrophoretic separation of antigens and subsequent immunodiffusion against antibodies.

Immunofixation electrophoresis Method of identifying proteins by electrophoretic separation and subsequent binding to specific antibodies.

Immunofluorescence Technique by which fluorescent molecules are coupled to immune reactants or cells to permit localization of antigens or antibodies.

Immunogen Substance capable of inducing an immune response.

Immunogenicity The ability of a substance to elicit an immune response.

Immunoglobulin Protein composed of H and L chains; it functions as an antibody.

Immunoglobulin class Division of immunoglobulin molecules that depend on unique structures in the constant region of the H chain. There are five immunoglobulin classes in humans: IgG, IgA, IgM, IgD, IgE.

Immunoglobulin isotype switching (class switch) Genetic process by which B cells change the heavy chain isotype of the antibody they produce during the continuation of the antibody-forming process.

Immunoglobulin subclass Further subdivision of immunoglobulin molecules within a class according to structural differences in the H chain. There are four IgG subclasses in humans: IgG1, IgG2, IgG3, and IgG4, and two IgA subclasses: IgA1 and IgA2.

Immunoglobulin supergene family Group of genes that code for a number of immunologically relevant and structurally related proteins, including immunoglobulins, T cell receptors, and class I and II MHC.

Immunosuppression State of diminished immune responsiveness produced by disease or by therapy.

Immunotherapy Treatment of disease by immunologic methods, including hyposensitization with antigen and passive administration of antibodies.

Immunotoxin Compound containing an antibody and an inactive toxin or radioactive isotope; the antibody “delivers” the material to a target cell containing the antigen (a tumor cell) so the toxin or isotope can specifically kill that cell.

Indirect immunofluorescence Three-component system in which antibody binds to the substrate antigen, and fluorescein-labeled anti-immunoglobulin is added to detect the complex.

Innate immunity The immune system that consists of effector cells and soluble mediators that respond rapidly to a variety of insults and that use constantly present germ line recognition mechanisms of broad specificity to accomplish self *versus* non-self discrimination.

Integrins A family of proteins that promote cell adherence.

Interferons (IFN) Diverse group of low-molecular-weight polypeptides having multiple antimicrobial and immune regulatory functions. The group includes IFN-b, IFN-b, and IFN-g.

Interleukins (IL) A heterogeneous group of low-molecular-weight substances having diverse activities in immunologic and inflammatory processes. At the time of writing, IL-1 through IL-12 have been identified and characterized.

Intrabodies Single-chain antibody fragments expressed intracellularly.

Intron Noncoding region of a DNA molecule. *See also Exon.*

Inv marker Genetically determined polymorphic marker on the light chain of human IgG.

Ir region Region of the MHC (usually class II) containing genes that control various immune responses.

Isoagglutinin Antibody able to agglutinate cells of individuals of the same species.

Isograft Tissue or organ graft placed in a genetically identical recipient.

Isohemagglutinins Anti-erythrocyte antibodies able to bind to erythrocytes of other individuals of the same species.

Isotype Characteristic of a class or subclass of immunoglobulins.

J chain Glycopeptide that is part of polymeric immunoglobulins of the IgM and secretory IgA classes.

J region genes Genes coding for the J segment of heavy chains.

Kappa (k) chains One of the two types of immunoglobulin light chains.

K cell Lymphocyte bearing Fc receptors and capable of carrying out antibody-dependent cellular cytotoxicity (ADCC).

Keratoconjunctivitis sicca A condition marked by hyperemia of the conjunctiva, lacrimal deficiency, thickening of the corneal epithelium, itching and burning of the eye.

Kinin system Humoral system linked to the coagulation pathway. The enzymatic activation of kallikrein results in the cleavage of bradykinin from kininogen.

Knock-out animals Animals in which a gene has been selectively eliminated.

Kveim test Diagnostic test for sarcoidosis in which extracts of sarcoid tissue are injected into the skin. A subsequent delayed hypersensitivity response is a positive test.

Lambda (l) chain One of the two types of immunoglobulin light chains.

Langerhans cell Dendritic bone marrow-derived cell in the epidermis that has antigen-presenting capabilities.

Late-phase reaction Inflammatory response occurring 4 to 8 hours after an immediate IgE-dependent allergic reaction.

Latex fixation test Passive agglutination reaction in which latex beads, coated with IgG or other antigens, are used to detect antibody.

LE cell test (or phenomenon) Phagocytosis of nuclear material by leukocytes *in vitro* (rarely *in vivo*) mediated by anti-DNA antibodies and seen in patients with systemic lupus erythematosus and other rheumatic diseases.

Lectin Substance, usually of plant origin that agglutinate cells, usually by binding to sugar moities, and which may have nonspecific mitogenic properties.

Leukotriene (LT) Product of the 5-lipoxygenase pathway of arachidonic acid metabolism.

Ligand Molecule capable of binding to another molecule.

Light chain disease Monoclonal gammopathy in which the B-cell clone produces only light chains.

Light chain (L chain) Polypeptide that is part of all immunoglobulin molecules. Two classes exist: kappa (k) and lambda (l).

Linkage disequilibrium Tendency of certain genes on a chromosome to be inherited as a group.

Lipopolysaccharide Group of molecules derived from gram-negative bacteria, which frequently are proinflammatory. *See also Endotoxins.*

Liposome Artificial particle surrounded by a lipid membrane.

5-Lipoxygenase pathway Enzymatic pathway of arachidonate metabolism leading to leukotrienes.

Local anaphylaxis IgE-mediated reaction that occurs in a specific target organ or tissue.

Low-dose (low-zone) tolerance Production of specific acquired unresponsiveness by small doses of antigen.

Lupus anticoagulant (LA) Autoantibodies that prolong the time to clot formation of *in vitro* coagulation assays; often found in the antiphospholipid syndrome and systemic lupus erythematosus (SLE).

Lymphocyte activation (stimulation, transformation, or blastogenesis) Process of activating resting small lymphocytes via an interaction with specific antigen, superantigen, antibody to surface molecules, or mitogen.

Lymphomas Neoplasms of lymphocytic cells of the immune system.

Lymphoreticular Term referring to tissue containing lymphocytes, mononuclear phagocytes, and stromal elements.

Lymphotropic An infectious agent that preferentially infects lymphocytes.

Lysosomes Cytoplasmic vesicles that contain proteolytic enzymes.

Lysozyme Naturally occurring low-molecular-weight enzyme in mucosal fluids that has antimicrobial activity. *See also Muramidase*

Macroglobulinemia The presence of elevated levels of monoclonal IgM in plasma.

Macrophages Tissue phagocytes derived from bone marrow promonocytes.

Major basic protein (MBP) Cationic protein found in eosinophil granules that, when released, is toxic to tissues.

Major histocompatibility complex (MHC) Cluster of genes responsible for most transplantation reactions and associated with many aspects of immune responsiveness and autoimmunity.

Mast cell Cell with secretory granules containing histamine, neutral proteases, and proteoglycans and having high-affinity Fc receptor for IgE on its surface.

Mastocytosis A relatively rare disease characterized by mast cell hyperplasia in organs such as bone marrow, skin, lymph nodes, liver, gastrointestinal tract, or spleen.

M cells Specialized epithelial cells overlying lymphoid aggregates in the small intestine that are involved in antigen passage and presentation.

Membrane attack complex (MAC) A complex formed of the late acting components of the complement activation cascade (C5-C9) responsible for damaging membranes, including the lysis of cells.

b_2-Microglobulin (b_2M) Small monomorphic protein; member of the immunoglobulin supergene family that is one of the two chains of class I MHC molecules.

Migration inhibition factor (MIF) Cytokine, perhaps related to interferon, that was detected in the first *in vitro* test for delayed hypersensitivity.

Mitogen Substance capable of activating a resting cell to undergo mitosis.

Mixed lymphocyte culture or reaction (MLC or MLR) *In vitro* technique in which non-T cells of one genotype stimulate resting T cells of another genotype to divide.

Molecular mimicry Cross-reactivity between an antigen and a tissue component, so that an immunologic reaction against the former leads to tissue damage; a mechanism for autoimmunity. Formation of a molecular structure, usually by a microorganism, that resembles a normal host component, thereby protecting the organism from host defense mechanisms or facilitating tissue invasion.

Monoclonal antibodies (mAb) Set of identical immunoglobulins produced by one B cell alone.

Monoclonal gammopathy Condition in which a hyperplastic or malignant clone of B cells overproduces a monoclonal immunoglobulin.

Monoclonal protein Homogeneous product of a single clone of cells.

Monokine Cytokine produced by mononuclear phagocytes.

Monomer Unit of a multimeric molecule.

Mononuclear phagocytic system Collection of promonocytes, monocytes, macrophages, and histiocytes – the main components of the reticuloendothelial system.

M protein Surface antigen of streptococci. *See also Monoclonal protein.*

Mucosal immune system Lymphoid tissues associated with the gastrointestinal and respiratory mucosa.

Multiple myeloma (MM) A malignant disease affecting the most mature cell of the B-cell lineage, the plasma cell.

Myelin basic protein (MBP) Component of myelin used as an antigen in experimental allergic encephalomyelitis (EAE).

Myeloperoxidase (MPO) Enzyme in granules of neutrophilic phagocytes.

Natural antibody Antibody produced without apparent antigenic stimulation.

NBT (nitroblue tetrazolium) test Test for the activity of the hexose monophosphate shunt, which is defective in individuals with chronic granulomatous disease.

Neoantigen Appearance of a new antigen. Also, modification of an existing (usually self) antigen by mutation or chemical means.

Neoplasia Tumors or their formation.

Nephelometry Technique to measure antigen–antibody reactions that cause turbidity or light scattering in solution.

Nephritic factor An immunoglobulin capable of reacting with and stabilizing components of the alternative complement pathway; found in the serum of some patients with glomerulonephritis and partial lipodystrophy.

Network hypothesis Jerne's theory of immune regulation involving idiotype-anti-idiotype reactions.

Neutralization Process by which the toxicity or infectivity of toxins or microbes is neutralized by antibody.

NK (natural killer) cells Cells able to kill certain target cells without previous immunization.

Nonresponder Subject who is unable to respond to an ordinarily immunogenic stimulus, usually for genetic reasons.

Northern blotting Process used to identify RNA fragments by electrophoresis and subsequent binding to labeled DNA or RNA oligonucleotides.

Nude (nu) mouse Strain of mouse lacking body hair, thymus, and almost all T cells.

Null cells Lymphocytes that do not bear the typical surface markers of T or B cells.

NZB (New Zealand black) or NZW (New Zealand white) Strains of mice used in studies of spontaneous autoimmunity.

Oligoclonal bands Immunoglobulins of restricted electrophoretic mobility seen in cerebrospinal fluid of patients with multiple sclerosis and other inflammatory diseases of the central nervous system.

Oncofetal antigens Antigens present on normal fetal cells (but not normal adult cells) and that reappear on malignant cells.

Oncogene Gene causing malignant transformation of normal cells.

Ontogeny Developmental history of a group of individuals.

Opportunistic organism Organism of limited virulence that can cause disease in an immunocompromised host.

Opsonin Protein able to enhance phagocytosis of a particle.

Oral tolerance Process by which orally administered antigen causes specific acquired unresponsiveness.

Osteoclast activating factor (OAF) Cytokine that enhances bone resorption.

Ouchterlony test or analysis Method of detecting precipitating antigen-antibody reactions in which both reactants diffuse in a gel-supporting medium.

Palindrome Length of DNA bases that displays an equivalent sequence, whether read from the 5' to the 3' end or vice versa.

Paracrine Effects of a hormone or cytokine on neighboring (rather than distant) target tissue.

Paraproteinemia Situation in which an abnormal monoclonal immunoglobulin or fragment is present in plasma or urine.

Passive agglutination Clumping of particles or erythrocytes coupled with antigens by specific antibody.

Passive cutaneous anaphylaxis Method for detecting biologically active IgE *in vivo.*

Passive immunity State in which a nonimmune recipient has been provided with specific immunity via the transfer of antibody or immunocompetent cells.

Peripheral lymphoid organs or tissues Lymphoid aggregates or tissues excluding the thymus, bursa of Fabricius (in birds), and bone marrow, the latter considered to be the source of lymphoid stem cells.

Peritoneal exudate cells Cells present in peritoneal fluid after injection of an inflammatory stimulus.

Peyer patches Specialized collections of lymphocytes and antigen-presenting cells in the submucosa of the small intestine.

Phagocytes Cells able to ingest particles, including microbes.

Phagolysosome Vesicle formed by fusion of a lysosome and a phagocytic vesicle (phagosome).

Phylogeny Evolutionary history of a group of organisms.

Phytohemagglutinin (PHA) Plant lectin capable of stimulating virtually all T cells.

Pinocytosis Process of cellular ingestion of soluble material.

Plaque-forming cells Individual antibody-forming cells seen in an assay for hemolytic antibody.

Plasma cell myeloma Monoclonal gammopathy characterized by paraproteinemia and often paraproteinuria and lytic bone lesions.

Plasma cells Mature B cells capable of intensive antibody production and secretion.

Plasmapheresis Removal of plasma from the vascular system, usually with the return of the formed elements.

Plasmin Proteolytic enzyme capable of cleaving fibrin and complement components.

Plasminogen activator Enzyme capable of converting plasminogen to plasmin.

Platelet-activating factor (PAF) A phospholipid mediator with proinflammatory properties.

Plectin Plaque protein of hemidesmosomes.,

Pokeweed mitogen (PWM) Plant lectin able to stimulate both T and B lymphocytes.

Polyclonal hypergammaglobulinemia Increase of various isotypes of immunoglobulins of different specificity; characteristic of chronic inflammatory states.

Polymerase chain reaction (PCR) Method of amplifying DNA or RNA segments.

Prausnitz-Küstner (PK) reaction A wheal-and-flare reaction produced by injection of serum containing specific IgE antibodies into the skin of a nonallergic person followed by local antigen injection.

Pre-B cells Precursors of mature B cells, having cytoplasmic but not surface IgM.

Precipitation reaction Formation of an insoluble lattice by the specific interaction of soluble antigen and soluble antibody.

Primary follicles Aggregates of lymphoid cells within lymph nodes or splenic white pulp.

Properdin system Proteins comprising the alternative complement pathway, including factors B, D, properdin, and C3.

Prostaglandins (PG) Naturally occurring aliphatic acids, mostly derived from arachidonic acid via the cyclooxygenase pathway.

Prothrombin Zymogen precursor of thrombin and the antigen for some lupus anticoagulants.

Prozone phenomenon Incomplete lattice formation in a precipitin reaction in the region of antibody excess.

Pyogenic microorganisms Microbes, often called high-grade pathogens, that elicit reactions rich in polymorphonuclear leukocytes.

Pyrogens Substances that cause a rise in body temperature, acting either directly or indirectly on the hypothalamus. *See also Endogenous pyrogens.*

Pyroglobulins Proteins, usually monoclonal, that precipitate when heated to 56°c.

Radial immunodiffusion Precipitation technique in which antigen diffuses radially from a well into semisolid medium containing antibody.

Radioallergosorbent test (RAST) Radioimmunoassay in which antigen is coupled to a solid phase; often used to detect IgE *in vitro.*

Radioimmunoassay One of a group of tests for detecting antigen or antibody where one of the reagents is labeled with a radioactive isotope.

Raji cell test Method of measuring immune complexes by their ability to bind to the Raji cell line.

RANTES Stands for Regulated on Activation Normal T Expressed and Secreted.

Raynaud's phenomenon Intermittent attacks of ischemia mainly of the fingers or toes that is marked by pallor and often is accompanied by paresthesias and pain.

Reagin Early name for skin-sensitizing (IgE) antibody. Also the name for the antibody detected in Wassermann and similar nonspecific serologic tests for syphilis.

Respiratory burst Process by which phagocytic cells generate oxygen radicals.

Retrovirus RNA virus that uses reverse transcriptase for replication and cellular integration.

Reverse transcriptase Enzyme in microorganisms that catalyzes the transcription of DNA from RNA.

Rheumatoid factor (RF) Immunoglobulin, usually IgM, directed against the Fc portion of IgG, often seen in patients with rheumatoid arthritis or other rheumatic diseases.

Schirmer's test Tear flow measurement by wetting of filter paper strip.

Schultz-Dale test In vitro method to demonstrate cytotropic antibody (e.g., IgE) by its ability to bind to smooth muscle tissue and cause contraction when bound to specific antigen.

Second set graft rejection Accelerated graft rejection that occurs after previous sensitization to the same alloantigens.

Secretory IgA Specialized form of IgA, found mainly in mucous secretions, composed of a dimer of IgA molecules together with a J chain and secretory piece.

Secretory immune system That part of the peripheral lymphoid system associated with the upper and lower respiratory, gastrointestinal, and genitourinary tracts in which the major immunoglobulin isotype is secretory IgA.

Secretory piece (component) Polypeptide (95 kd) produced by mucosal epithelial cells that facilitates transport of secretory IgA across the epithelium.

Sequestration The entry of pathogens into intracellular or extracellular compartments not accessible to all components of the immune response.

Serotonin (5-hydroxytryptamine) Catecholamine stored in granules of rodent (not human) mast cells and platelets; a neurotransmitter.

Serum amyloid P component (SAP) Normal plasma protein of the pentraxin family that binds to all types of amyloid fibrils and therefore accumulates specifically in amyloid deposits.

Serum sickness Clinical syndrome that includes fever, arthritis, urticaria, and lymphadenopathy; due to deposition of circulating antigen-antibody complexes.

Sicca symptoms Symptoms of dryness of eyes and mouth. *See Xerostomia* and *Keratoconjunctivitis sicca.*

Slow-reacting substances of anaphylaxis (SRS-A) Early term denoting nonhistamine substances released by an anaphylactic reaction and eliciting a smooth muscle contraction; now known to contain the cysteinyl leukotrienes.

Slow virus Virus that produces a protracted illness, usually after a long incubation period.

Solid phase radioimmunoassay Form of radioimmunoassay in which one of the reactants is adsorbed to a solid surface.

Southern blotting Technique for DNA analysis that includes digestion with restriction endonucleases, electrophoresis, and then probing with complementary oligonucleotide fragments.

SS-A (Sjögren's syndrome A; anti-Ro) Autoantibody directed to nuclear RNA, often found in Sjögren's syndrome. Also known as *anti-Ro.*

SS-B (Sjögren's syndrome B; anti-La) Autoantibody directed to nuclear RNA, often found in Sjögren's syndrome. Also known as *anti-La.*

Suppressor T cells Subset of T cells able to inhibit T cell or B cell reactivity. May be antigen-specific or antigen-nonspecific.

S value Svedberg unit. Sedimentation coefficient of a homogeneous protein as determined in an analytic ultracentrifuge.

Syndesmophyte A bony excrescence.

Syngeneic Genetically identical.

T-cell antigen receptor (TCR) Antigen-specific complex on a T cell, composed or b and b chains or d and g chains, that is able to recognize a specific antigenic peptide in the context of an MHC molecule.

T cells (T lymphocytes) Thymus-derived lymphocyte.

Tetramer Artificial association of four peptide MAC molecules on strep evidence for identification of specific antigen binding T cells.

Thermal amplitude The temperature range within which an antibody will react with target cells.

Thymus Central lymphoid organ in which bone marrow-derived stem cells mature into immunocompetent clones of T cells.

Thymus-dependent antigen Antigen that requires T cell “help” for its specific B cell to produce antibody.

Thymus-independent antigen Antigen that can directly stimulate B cells to produce antibody without “T cell help.”

Tissue factor pathway (extrinsic pathway of coagulation) The component of the coagulation pathway activated by the interaction of tissue factor with Factor VIIa.

Tolerance Unresponsiveness to antigenic stimulation. Tolerance can be genetic or it can be acquired by special methods of antigenic exposure.

Toxoid Toxin that has been chemically modified so it is immunogenic but not toxic.

Transcription Synthesis of RNA from a DNA template.

Transfection Transfer of an extra gene (or genes) to a cell or (via the embryo) to an individual.

Transfer factor Extract of leukocytes from an immune person capable of passively transferring delayed hypersensitivity to a nonimmune recipient.

Transgenic Situation in which a foreign gene (or genes) is present in an individual or cell.

Translation Synthesis of a polypeptide from an RNA template.

Transplantation antigens Antigens present on cell surfaces that produce rejection reactions when introduced into genetically dissimilar recipients.

Trophoblast Embryonic tissue containing the fetus and interfacing with maternal tissue in the uterus.

Tropism Preferred target cell for infection by a virus.

Tryptic peptides Peptide fragments of a polypeptide derived by tryptic digestion.

Tumor necrosis factor (TNF) Cytokine able to cause tumor cell lysis and other effects, including inflammation. TNF-b and TNF-b (lymphotoxin) exist.

Tumor-specific antigens Cellular antigens expressed on malignant but not on normal cells.

Urticaria (hives) Pruritic skin eruption with edematous wheals, often (but not always) with an allergic etiology.

Vaccination Immunization with microbial antigens to prevent infectious disease (originally, the production of immunity to smallpox by introduction of cowpox [vaccinia] material).

Variable (V) region Amino-terminus end of an H or L chain where the amino acid sequence differs from one antibody to another.

Variolation Immunization by inoculation with the live virus of smallpox (variola).

Vasculitis This term refers to clinical disorders characterized by inflammation of, and damage to, blood vessels.

V-beta (Vb) region Variable (polymorphic) section of the b-chain of the T cell receptor.

Virion A viral particle.

Waldeyer's ring A series of lymphoid tissues and organs surrounding the nasopharyngeal region, including the tonsils and the adenoids.

Western blotting (immunoblotting) Method to detect antigens in a complex mixture resolved for size of components (SDS-PAGE) followed by overlaying with antibody.

Xenogeneic Relation between different species.

Xenograft Graft of organs, free tissue, or isolated cells between members of different species.

Xenotransplantation The transplantation of organs, tissues, or cells between individuals of different species.

Xerostomia Dryness of the mouth from salivary gland dysfunction.

Zone electrophoresis Electrophoretic separation of molecules on a solid substrate according to the net electrical charge.
